Autism and Child Psychopathology Series

Series Editor

Johnny L. Matson, Department of Psychology
Louisiana State University
Baton Rouge, LA, USA

Brief Overview

The purpose of this series is to advance knowledge in the broad multidisciplinary fields of autism and various forms of psychopathology (e.g., anxiety and depression). Volumes synthesize research on a range of rapidly expanding topics on assessment, treatment, and etiology.

Description

The **Autism and Child Psychopathology Series** explores a wide range of research and professional methods, procedures, and theories used to enhance positive development and outcomes across the lifespan. Developments in education, medicine, psychology, and applied behavior analysis as well as child and adolescent development across home, school, hospital, and community settings are the focus of this series. Series volumes are both authored and edited, and they provide critical reviews of evidence-based methods. As such, these books serve as a critical reference source for researchers and professionals who deal with developmental disorders and disabilities, most notably autism, intellectual disabilities, challenging behaviors, anxiety, depression, ADHD, developmental coordination disorder, communication disorders, and other common childhood problems. The series addresses important mental health and development difficulties that children and youth, their caregivers, and the professionals who treat them must face. Each volume in the series provides an analysis of methods and procedures that may assist in effectively treating these developmental problems.

1 History of Applied Behavior Analysis

Megan M. Callahan, Jill C. Fodstad, and James W. Moore

Broadly, behavior analysis is the experimental evaluation of the behavior of living organisms. It is considered by many to overlap with the field of psychology; however, there are key distinctions, making behavior analysis a separate field of study. The underlying tenets of behavior analysis are evident in behaviorism, the experimental analysis of behavior (EAB), and applied behavior analysis (ABA). ABA relies on the principles of learning and behavior to increase or decrease socially significant behaviors in human beings. Over the course of several decades, the field of ABA continues to evolve. ABA has a rich history. Although impossible to discuss the history of ABA in one chapter, our goal is to provide an overview of some of the key turning points in the history of ABA.

Early Beginnings

The precise beginning of Applied Behavior Analysis (ABA) is an open topic of discussion. Although the first published account of ABA was made by Allyon and Michael (1959), the roots of the field run much deeper. In order to find clues to the precise background of ABA, it is helpful to realize that the discipline takes a *natural science approach* to the study of human behavior which is distinct from the social science approach of fields, such as psychology. This is unique given that social science is usually synonymous with behavioral science. In behavior analysis, however, emphasis is placed upon objective measurement that stems from a basic unit, the operant.

While Edward Thorndike is not considered a true behaviorist, his work set the stage and influenced behaviorism that was to come. At the time, mentalism, the belief that causes the mind account for behavior, was prevalent. In contrast to this, Thorndike believed mental life is also behavior, rather than the cause of behavior. He worked under William James at Harvard University studying how animals learn with behavioral applications in education (Malone, 2014).

Thorndike was critical of comparative psychologists at the time, as they often used small samples, anecdotal data, and only reported "marvelous" findings. To combat this, he systematically studied cats' behaviors in puzzle boxes as his doctoral dissertation, published in the same year in 1898. He used 15 different puzzle boxes and 13 cats. Thorndike described the behavior of the cats initially placed in the boxes as a series of random acts, such as clawing, biting, etc.

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_1

Eventually, the cats, by accident, land upon the correct behavior to be released from the box. In future trials, the successful behavior occurs earlier in the sequence, while the failed behaviors are eliminated until eventually the cat has learned to get out of the box in seconds. Thorndike methodically graphed these escapes, which showed a gradual decline in the escape time. From these studies, Thorndike developed the *Law of Effect*.

> Of several responses made by the same situation, those which are accompanied or closely followed by satisfaction to the animal will, other things being equal, be more firmly connected with the situation, so that, when it recurs, they will be more likely to recur; those which are accompanied or closely followed by discomfort to the animal will, other things being equal, have their connections with that situation weakened, so that, when it recurs, they will be less likely to recur. The greater the satisfaction or discomfort, the greater the strengthening or weaking of the bond. – Thorndike (1911/2000)

Thorndike later modified this, placing a greater emphasis on rewards being more effective than punishments in increasing learning (Goodwin, 2010, p. 53). Skinner wrote of this law, it was "[o]ne of the first serious attempts to study changes brought about by the consequences of behavior" (Skinner, 1953, p. 59).

Across the world, Russian physiologist Ivan P. Pavlov was studying conditioned reflexes in animals in a lab at the Military Medical Academy. He had graduated with a license to practice medicine and later received his degree of Doctor of Medicine following his dissertation completion in 1883 (Liddell, 1936). Starting in 1886, he conducted experiments under S. P. Botkin, results from which Botkin would interpret and apply. However, this position allowed Pavlov the freedom to independently conduct experiments, leading to his sham feeding experiments. In these experiments, the dog's esophagus is divided so the "mouth is cut off from all communication with the cavity of the stomach" (Pavlov, 1910 p. 50). As the dog eats, the food does not reach the stomach and as such, "pure gastric juice" is produced.

In 1891, the Prince of Oldenburg founded the Institute of Experimental Medicine, for which Pavlov directed the construction of a surgical ward for dogs, allowing him to perform surgeries and study the digestive system in healthy dogs. Liddell (1936) credits Pavlov in motivating "young psychologists to familiarize themselves with the structure of the body and with its simpler operations as a preparation for the arduous task of analyzing those highly complex functions which are traditionally regarded as physical."

In 1909, Robert M. Yerkes and Sergius Morgulis described Pavlov's conditioning method in "The method of Pavlov in animal psychology" (Windholz, 1983; Yerkes and Morgulis, 1909). Subsequently, Morgulis (1914) published another article in which he described Pavlov's view that the "seat" of the conditional reflexes are the cortical hemispheres. Further, in this article, Morgulis outlines that Pavlov viewed "consciousness as a purely physiological phenomenon," which sparked early behaviorists. Although he had great influence in early behaviorism, he was not a behaviorist, nor did he necessarily support psychology. Pavlov believed psychology lacked clear goals and methods and preferred physiology for both methodological and practical reasons as phenomena in physiology occur in both space and time, whereas psychology phenomena only occur in time and he disagreed with the anthropomorphizing of conditioning phenomena (Windholz, 1983).

Another precursor, and perhaps the catalyst, to behaviorism, was James B. Watson. In 1913, Watson gave a lecture at Columbia University, titled "Psychology as the Behaviorist Views it," which was published under the same title that year. In this lecture, known as the Behaviorist Manifesto, he coined the term "behaviorism" as a new discipline and applied it to behavior psychology. He outlined four foundational points, which were later expanded to 13. These points included (1) advocating for psychology as a natural science rather than a subset of mentalist or spiritual science, (2) using objective, observable data rather than introspective data, (3) moving away from discussing purposes and teleological goals and moving toward formulating deterministic laws, and (4) rejecting psychophysical dualism and mentalism to explain behavior (Watson, 1913).

The following year, Watson rejected Thorndike's *Law of Effect*, relying on the frequency and recency in the formation of connections, rather than the emphasis of rewards (O'Neil, 1995). In 1916, he adopted Pavlov's conditioned reflex, which made the S-R analysis more explicit in his work. Watson viewed learned behavior as conditioned reflexes in complex sets of stimuli, and as such, he considered reflex conditioning as the basis of learning.

In 1916, Watson suggested that Pavlov's conditioned secretion reflexes could also be used to investigate sensory characteristics and memory processes in animals (Windholz, 1983). Later, in 1926, Watson wrote: "Complex human behavior is the conditional response to (social) stimuli", thus, "securing the conditional reflex an integral position within the framework of early behaviorism" (Windholz, 1983).

Watson saw learned behavior as consisting of conditioned reflexes operating in complex sets of conditioned stimuli and considered reflex conditioning the basis of learning with contiguity of the unconditioned and conditioned stimuli and of the response (O'Neil, 1995). He formulated a theory of emotion, which posits that humans have three emotions: fear, rage, and love, which are first evoked by simple actions. These three simple emotions develop into the wide spectrum of emotions as adults through conditioned reflexes. This theory inspired the Little Albert experiment, which Moore (2017) notes "was more a 'proof of concept' demonstration than a formally designed experiment."

The Little Albert study was his last published work in academia, in which Watson sought to investigate if one could condition fear to an animal and if that fear would generalize. Little Albert was assessed between 8 and 12 months of age (Watson & Rayner, 1920) during the winter of 1919 to 1920. During baseline, he was introduced to a white laboratory rat, a rabbit, a dog, a monkey, masks, cotton, and burning newspaper. Two months later, they conducted the conditioning trials, which consisted of seven trials over two sessions of hitting a metal bar directly behind Little Albert's head as he reached for the white rat. To test generalization, after 5 days, he was presented with wooden blocks, the rat, a rabbit, a dog, a fur coat, the cotton, Watson's and his assistants' hair, and Santa mask. Watson and Rayner reported Little Albert reacted negatively to the rat, the rabbit, the dog, fur coat, cotton, Watson's hair, but not his assistants' hair or the Santa mask. After an additional 5 days, they presented the rabbit and dog alone, which induced a mildly negative reaction, and then hit the metal bar behind him. On the same day, they moved Little Albert into a different room and presented the rat, rabbit, and dog alone. Watson and Rayner concluded the fear generalized. One month later, Little Albert was tested again and reacted negatively to the Santa mask, the rat, the rabbit, and the dog, which Watson and Rayner cited as proof that conditioned emotional responses persist.

Since the original publication of the study, it has been cited and recounted hundreds of times. Watson and the study have also been subject to many controversies, starting with Watson's affair with Rayner, which led to him leaving academia for a career in advertising. Additionally, many of these retellings of the original study have been inaccurate, as Harris outlined (1979), including facts about Little Albert's age and name. Further, some publications incorrectly reported the initial conditioning was with a rabbit instead of the rat. Other inaccuracies change the methodology and the results of the original study, such as expanding the list of stimuli Little Albert's fear generalized to and including that Watson reconditioned Albert's fear. In a follow-up article, Harris (2011) notes that these myths convey the notion that psychologists can impose order and have social power with data supporting their claims.

Beck et al. (2009) investigated the true identity of Little Albert and concluded it was Douglas Merritte, who died at 6 years of age, due to hydrocephalus and convulsions (Fridlund et al., 2012). Fridlund et al. (2012) note that documents show Douglas contracted hydrocephalus in 1922; however, they hypothesize it could have been congenital. Fridlund et al. (2012) also raised concerns regarding Little Albert's functioning, as reported by Watson and as seen in a video recording of the experiments. They reference his general unresponsiveness, lack of social smiling, delayed speech, and lack of social referencing or eye contact, supporting the theory Little Albert was not the "healthy" child Watson and Rayner reported. However, this claim is disputed, as Powell et al. (2014) believed Little Albert to be William Albert Martin who might have been known as Albert Barger before his mother Pearl married.

Although Watson knew of Little Albert's impending departure, they did not decondition him. Rather, a follow-up study by Mary Cover Jones (1924) investigated deconditioning fear responses in three-year-old Peter. In the experiment, Jones attempted to decondition Peter with one animal (i.e., rabbit), to also investigate if the deconditioning would transfer to his other fears (e.g., a rat, fur coat, a feather). Every day, a rabbit was present during a play period with Peter and three other control children. Then, Jones proceeded to expose Peter through progressive "degrees of toleration". Peter was taken to the hospital for 2 months. Upon returning, Jones switch methods, beginning "direct conditioning," in which Peter was given preferred food and an experimenter brought the caged rabbit as close to Peter without disrupting his eating, which Jones reported was successful in reducing his fear and that this reduction in fear generalized to the cotton, fur coat, and feathers.

Skinner (1978) argued that the study of behavior should be conducted in the same manner and with the same rigor as biology, physics, chemistry, and other "hard" sciences. In behavior analysis, behavior is the subject of study. In social science approaches, behavior is viewed as an indicator of some other process, usually seen within the organism. Given this focus, it could be argued that the seeds of behavior analysis were planted in Ancient Greece as philosophers moved away from mysticism and focused on physical determinants that influence human behavior (see Bishop et al., 2020 for a more detailed discussion). Ultimately, the work of the American psychologist Burrhus Frederic Skinner laid the ultimate foundation upon which ABA was built. In order to appreciate the history of ABA, however, one must consider the scientific history and life experiences that influenced Skinner. Through an analysis of the life of B.F. Skinner, the history of ABA comes into clearer focus.

Skinner and His Influence on the Field of ABA

On March 20, 1904, Burrhus Frederic Skinner, known to most as Fred, was born in Susquehanna, Pennsylvania, to William and Grace Skinner. Both of his parents exuded a tremendous influence over Skinner, talking to him at an early age about the consequences of good and bad behavior (Skinner, 1967). On two occasions, his father exposed Skinner to the penal system, once visiting the county jail and then attending a lecture on life at Sing Sing Prison. Even as a boy, Skinner showed talent with inventing and building, including crafting a flotation system for separating ripe from green elderberries. Throughout his life, Skinner often manipulated his physical environment in order to make day to day activities more effective and efficient. Vaughn (1990) described the office of Skinner as "a labyrinth of switches, pulleys, extension cords, lights, magnifying glasses, cardboard boxes, and cubbyholes" (p. 101).

During his early schooling, Skinner showed a strong interest in language arts, leading to a major in English at Hamilton College. Despite this focus, he followed a course of study that he deemed "absurd" (Skinner, 1967, p. 391), including classes in public speaking, mathematics, Romance languages, biology, and embryology. Interestingly, Skinner did not take a single psychology course while at Hamilton. This eclectic course of study, though diverse, provided major influences on the young college student. He remarked later in life, "At some time or other I have used something from every course" (Skinner, 1983, p. 25). As part of these early educational experiences, Skinner was exposed to the work of Charles Darwin, which would later have a tremendous impact on the development of the philosophy of science that undergirds behavior analysis.

Thankfully for the field, Skinner was not successful in his first ambition after Hamilton College, which was aspirations of writing a great novel. After having continued difficulty when switching to short stories, Skinner considered many alternatives in order to make a living, including working as a landscaper. The field he would later establish was again fortunate that Skinner had an allergy to grass (Skinner, 1967). As he considered his failures as a writer, Skinner realized that his lack of success may have been attributed to the focus of his writing: investigating human behavior. Skinner determined that he could not write about this subject matter because he truly did not understand the behavior of humans. This brought the field of psychology into his view. In order to investigate psychology, Skinner first turned to philosophy, specifically Bertrand Russell's book, *Philosophy*. It was reading this work that introduced Skinner to the behaviorism of John Watson, leading Skinner to purchase Watson's book *Behaviorism*, which was originally published in 1913. Given his educational background, which was heavily littered with mathematics and natural science, Skinner immediately found Watson's empirical and scientific approach to human behavior appealing.

As fate would have it, Skinner soon happened upon an article by H. G. Wells that lauded the work of Ivan Pavlov, the Russian physiologist who serendipitously discovered respondent conditioning. Once again, encountering a scientific approach to human behavior solidified Skinner's decision to pursue graduate studies in psychology and he was accepted to Harvard University in the Fall of 1928. It was at this time that Skinner met the already committed behaviorist, Fred Keller. The two challenged and enriched each other's studies, which predominantly focused on abnormal psychology (with a distinct Freudian slant) and the "new" discoveries about respondent behavior. A contemporary, Jacob Robert Kantor, had just published his book *Principles of Psychology*, which would later become described as an approach known as interbehaviorism. Around the same time, the American psychologist Edward Thorndike built a bridge from the stimulus-response respondent conditioning of Pavlov into what Skinner would develop into operant conditioning and radical behaviorism. Similar to Pavlov, Thorndike studied the behavior of animals, such as placing food-deprived cats into puzzle boxes that required escape in order to obtain food.

These influences on Skinner established a strong belief; "control the environment and you will see order in behavior" (Skinner, 1967, p. 399). Although Skinner's dissertation studied reflexive behavior and respondent conditioning, the work of Thorndike shaped Skinner's subsequent work that examined the effect of consequences on behavior. His early work at the University of Minnesota focused on the behavior of rats in a device he invented and termed an operant chamber. Skinner found that depriving a rat of food could set the occasion to condition a lever press from a rat if that behavior produced food. Skinner also discovered that lever pressing could be shaped if that behavior terminated an aversive stimulus, such as an electric shock. Furthermore, Skinner learned that rats could learn to discriminate between behaviors in the presence of different stimuli, such as colored lights, if those lights consistently occasioned specific consequences. Skinner outlined his initial findings in his first published work, *The Behavior of Organisms*, which appeared in 1938.

Around the time *The Behavior of Organisms* appeared, there were many theories regarding human behavior, in particular motivation. Most of these theories focused on an internal state or condition that serves as a catalyst of behavior. Little attention was given to either behavior as the exact subject matter, or the impact of the environment on human behavior. In *The Behavior of Organisms*, Skinner devoted two chapters to the internal construct of "drive." Skinner suggested that an analysis of functional relationships between the environment and behavior would offer a more parsimonious and effective explanation of human behavior than internal causal variables (Sundberg & Michael, 2001). Skinner focused on the evocative effects of deprivation and the abative effects of satiation on behavior.

He proposed a basic unit in the study of behavior that he termed the *operant*. Skinner used the terms positive reinforcer and negative reinforcer to describe consequent events that would impact the future probability of behavior. Originally, he viewed these as the two main sources of operant conditioning, stating, "the cessation of a positive reinforcement acts as a negative, the cessation of a negative as a positive" (Skinner, 1938, pp. 65–66). This replaced the layman terms "reward" and "punishment" with "positive" and "negative" reinforcement (Michael, 1975). Although a major landmark in the study of behavior, this two-term contingency had some logical problems. As Michael (1975) pointed out, "'reinforce' is synonymous with 'strengthen' in a number of usages, and although 'negatively strengthen' as a synonym for 'weaken' is not logically unreasonable, it is somewhat confusing, as would be such a term as 'positively weaken.'" (p. 35).

Skinner's former graduate school colleague, Fred Keller, who had himself embarked on a career in research academia dedicated to this new emerging field Skinner termed the experimental analysis of behavior, helped push the conceptualization of operant conditioning forward. In 1950, along with his colleague William Schoenfeld, Keller published *Principles of Psychology*, which remains a highly influential text to this day. In this work, Keller and Schoenfeld created a synthesis of Thorndike's past work, Skinner's work, as presented in *The Behavior of Organisms*, and the work of Estes (1944), which was conducted as a follow-up to Skinner's text. From this analysis, Keller and Schoenfeld clarified Skinner's terminology:

> Certain stimuli (electric shocks, loud sounds, strong lights, etc.) serve to *decrease* the frequencies of responses in the wake of which they follow. Nowadays, we call them *negative reinforcers,* but they are not best defined in terms of their weakening function….Another, and probably better way of handling the matter is to define *positive* reinforcers as those stimuli which strengthen responses when *presented* (e.g., food strengthens bar-pressing or loop-pulling behavior), and *negative* reinforcers are those which strengthen when they are *removed* (Keller & Schoenfeld, 1950, p. 61).

Keller and Schoenfeld were also comfortable using the term "punishment" and introduced the concept of extinction, or the phenomenon in which the occurrence of a previously reinforced response without its reinforcement would ultimately describe or extinguish response frequency. Influenced by this text, Skinner published *Science and Human Behavior* in 1953 in which he revised his terminology. In this work, Skinner proposes *positive reinforcement* as the presentation or increase in some consequent stimulus event that serves to increase the future probability of a behavior. He offered *negative reinforcement* as the removal or lessening in some consequent stimulus event that also increases the future probability of behavior. He also offered the terms *positive punishment* and *negative punishment*, which both describe contingencies that decrease the future probability of behavior. Again, the term *positive* refers to the presentation or increase in a stimulus event, whereas *negative* refers to the removal or lessening of a consequent stimulus. Skinner's definition of negative reinforcement remained opposed to the one offered by Keller and Schoenfeld (1950). In 1961, Skinner published *The Analysis of Behavior* with J.G. Holland (Holland and Skinner, 1961), which meant to replace the Keller and Schoenfeld work as a basic text and further cemented the terms introduced by Skinner (1953).

Another major contribution of *Science and Human Behavior* was the establishment of behavior analysis as a natural science approach to behavior, led by what Skinner deemed six attitudes of science. Skinner (1953) defined sciences as living within the behavior of scientists, not the materials they used. According to Skinner, science is only known as such due to an overriding idea of the *scientific method*. These attitudes included determinism (the universe is an orderly and lawful place in which all phenomena occur as the result of other events), empiricism (practice of objective measurement of the behavior of interest), experimentation (a structured analysis of the effects of an independent variable on a dependent variable), replication (the repeating of experiments to determine the accuracy and usefulness of findings), parsimony (the idea that less complex, objective, logical explanations must be ruled out before more complex, abstract explanations are considered), and philosophical doubt (the constant questioning of the truthfulness and validity of all scientific theory and knowledge).

When considering other roots that fed the history of ABA, the influence of Charles Darwin on Skinner's perspective must be taken into account. At its core, Darwinian evolution and natural section occur at the phylogenic level, meaning that selection and variation occur within the species to support survival. In proposing the operant as the basic unit of measurement, and giving credence to the idea that variation and selection of behavior happen within the life of the organism, or at the ontogenic level, Skinner extended natural selection from a simple stimulus-response at the genetic level to the explanation of selection of behavior through consequences (see Skinner, 1981, for a more thorough discussion). According to Skinner (1953), the term operant "emphasizes the fact that behavior operates upon the environment to generate consequences" (p. 65). The notion of selection is paramount in behavior analysis, as it demonstrates the role of the environment on human behavior, particularly the consequences of behavior. In ontogenic selection, behavior is acquired, shaped, and maintained by *direct-acting* contingencies of reinforcement, meaning that a reinforcing consequence closely follows the behavior that is selected. Skinner noted that not all human behavior could be accounted for by phylogenic or ontogenic selection and offered a third type of selection, cultural selection, in which behaviors are passed from person to person across space and time via rules (see Catania, 2001 for a more detailed account). Through the influence of his own experiences, as well as the data collected in his lab, Skinner built the philosophy of the science that guides ABA: radical behaviorism (for a more detailed account of radical behaviorism, see Skinner, 1983, and Lundy et al., 2020).

This natural science approach led by the philosophy of radical behaviorism quickly took hold in the clinical world. Just 11 years after the publication of *Behavior of Organisms*, Fuller (1949) published the first demonstration of operant conditioning with an individual who was developmentally delayed. The first large-scale demonstration of the approach that would evolve into ABA came in 1959 from Ayllon and Michael in the study, *The Psychiatric Nurse as a Behavior Engineer.* Without a journal dedicated to the application of behavior analysis in applied settings, this seminal article appeared in the *Journal of the Experimental Analysis of Behavior.* Ayllon and Michael taught the nurses at a psychiatric hospital how to use a token economy to reduce psychotic speech in patients with schizophrenia.

Around the time that applied work began to emerge in the research literature, faculty at the University of Washington started using the principles of ABA to teach developmentally delayed children. These faculty, which included Donald Baer, Sidney Bijou, Bill Hopkins, Jay Birnbrauer, Todd Risely, and Montrose Wolf, also used behavior analytic principles in juvenile detention centers and even the workplace. In 1968, Baer, Bijou, Risley, Birnbrauer, and Wolfe left Washington to join the Department of Human Development and Family Life at the University of Kansas, which remains one of the top academic centers for behavior analysis to this day.

Quickly after joining the faculty at the University of Kansas, Baer, Wolf, and Risley launched the *Journal of Applied Behavior Analysis (JABA)*, with its first published study demonstrating the use of teacher attention to increase study behavior in general education classrooms (see Hall et al., 1968). The inaugural volume of *JABA* ended with a discussion about the characteristics, or dimensions of ABA by Baer et al. (1968). In this article, the authors established seven defining characteristics of ABA (i.e., applied, behavioral, analytical, technological, conceptually systematic, effective, generality) that still endure to this day.

The first of the characteristic defined by Baer et al. (1968) is that ABA is *applied*, meaning that ABA seeks to address problems deemed significant by society. The principles of behavior analysis have the ability to change any behavior, but within the field of ABA, efforts should be specific to behaviors that have social significance. Given that behavior is the subject matter of study within behavior analysis, methods within ABA should be *behavioral*, meaning that the focus of intervention is comprised of physical events that can be measured with as much precision as possible. The procedures, including assessment and intervention, should also be *analytical*, meaning that applied behavior analysts demonstrated functional relations between a behavior of interest and aspects of the environment that yield control over the behavior. Within this ideal, Baer et al. (1968) make a strong statement about the use of experimental designs in ABA work in order to show functional control. The authors specifically describe reversal and multiple baseline designs as effective ways to achieve the analytical dimension in applied work. Practitioners in ABA should also objectively and specifically identify and describe methodologies employed in order to meet the *technological* dimension of behavior analysis. In describing this aspect of ABA, Baer et al. state, "the best rule of thumb for evaluating a procedure description as technological is to ask whether a typically trained reader could replicate that procedure well enough to produce the same results" (p. 95). While procedures should be objectively defined and described, they also should show a *conceptually systematic* application of basic principles of behavior. By basing all procedures and describing outcomes in terms of the behavioral principles that undergird the field, "this can have the effect of making a body of technology into a discipline rather than a collection of tricks" (p. 96). Behavioral procedures should also demonstrate large enough change to show practical value, or in other words, they are *effective*. This ideal instills tremendous accountability for the clinician practicing ABA. Finally, and perhaps most importantly from a pragmatic standpoint, behavioral procedures should show *generality*, meaning "it proves durable over time," and are seen across environments, different people, and different situations (p. 96).

Within the years following the inaugural issue of JABA, the field of ABA experienced rapid growth. Throughout the 1960s and 1970s, a number of additional journals and books were published to disseminate behavior analytic research. Notably, in 1972, Willard Day created the journal "Behaviorism." In 1974, Azrin and Foxx published "Toilet Training in Less than a Day," demonstrating the effectiveness of a toilet training protocol, which had socially significant implications for the mainstream. This same year, the reach of behavior analysis started to extend beyond the United States when the "Mexican Journal of Behavior Analysis" began publication. These publications helped to create a means to disseminate research findings. Furthermore, the 1960s marked the beginning of research outside of the laboratory in applied settings such as the home, schools, or hospitals. With a rapidly growing interest in the science of behavior analysis, the first doctoral programs in behavior analysis were established in the 1960s and 1970s, allowing the field to further accelerate.

In 1974, the Midwestern Association for Behavior Analysis was founded as an interdisciplinary group of researchers, professionals, and students following a lack of representation of the science of behavior analysis at the existing psychology conferences (Peterson, 1978). The first elected president was Nathan Azrin (Peterson, 1978). This organization is known today as the Association for Behavior Analysis International (ABAI) and is one of the largest professional organizations dedicated to the dissemination of the "philosophy, science, application, and teaching of behavior analysis" (ABAI, n.d.).

ABA and Autism Spectrum Disorder

O. Ivar Lovaas was instrumental in establishing ABA as a prevalent intervention in children with autism. In 1961, Lovaas arrived at UCLA, as an assistant professor in the psychology department. In that following year, he primarily worked with one client, Beth, where he developed a system to score multiple behaviors and interventions with single-subject experimental designs (Smith & Eikeseth, 2011). He went on to publish a series of articles regarding the system to code behaviors, and a precursor to what is known as functional assessment, investigating the maintaining variables in antecedents and consequences.

His great impact is not without controversy, however. Lovaas promoted positive reinforcement, but would use aversive stimuli, such as low doses of electric shock and slaps on the thighs, to treat self-injury or aggression (Smith & Eikeseth, 2011). He reportedly ceased using these techniques during the late 1980s, when the interventions in the field had progressed so that aversive stimuli were not needed.

Early intensive behavioral intervention (EIBI) is widely researched and empirically supported to help children with autism make the greatest strides in learning skills and decreasing challenging behaviors (Eldevik et al., 2009). Much of this research owes thanks to Lovaas' work with the UCLA Young Autism Project (1987). The Young Autism Project was a home-based early intervention clinic. It was here that he produced research on "stimulus overselectivity," which is where children respond to only one detail of a stimulus and can prevent children with autism from learning and generalizing skills (Lovaas et al., 1971). Lovaas' intervention programs consisted of 30–40 hours of individual intervention per week, much higher than was common at the time (Smith & Eikeseth, 2011).

Lovaas published one of the first follow-up studies on ABA interventions and found that in a sample of 20 children with autism, the differences between children were due to environment, such that the institution group performed worse than children whose parents were trained to implement therapy at one-to-four-year follow-ups (Lovaas et al., 1973). He found that these differences could be temporarily mitigated by briefly resuming therapy. Lovaas later published a controversial follow-up study, in which he claimed almost half of the treatment group achieved "normal intellectual and educational functioning," compared to 2% of the control group (Lovaas, 1987).

Discrete Trial Training

The method Lovaas established is now referred to as discrete trial training (DTT). Discrete trial training consists of one-on-one learning events, typically at a table or in another structured, distraction-free environment. Smith (2001) outlines the five parts of each discrete trial: cue, prompt, response, consequence, and intertrial interval. A cue, also known as a discriminative stimulus, is the initial instruction or question. This is followed by a prompt, in which the teacher guides the child to the correct response. There are various types of prompts, such as verbal, gestural, and physical. This prompt will be faded out as the child becomes more independent in answering the cue. Following the prompt is the response, in which the child either answers correctly or incorrectly. The consequence of a correct response is reinforcement, which could consist of edibles, access to tangibles, or social reinforcers such as hugs, tickles, and praise. If the child answers incorrectly, the consequence is an error correction procedure. Last is an intertrial interval following the consequence, which is a brief moment before presenting the next cue, and thus repeating this cycle.

Discrete trial training can be used to teach a variety of skills and abilities to children with autism. A meta-analysis on EIBI in children with autism found it was effective in improving expressive and receptive language and adaptive behavior, in addition to IQ and nonverbal IQ (Peters-Scheffer et al., 2011). While DTT is an important aspect of ABA, it is not the only aspect of ABA (Smith, 2001).

Pivotal Response Treatment

Pivotal response treatment (PRT) is a technique to apply the principles of ABA, developed by Lynn and Robert Koegel (1987), also known as pivotal response training or pivotal response therapy. As opposed to Lovaas' technique, PRT is more naturalistic and child-directed. A core component of PRT is establishing motivation and rewarding attempted responses or behaviors (e.g., attempted speech) with preferred items. Compared to EIBI's 35–40 hours per week of intervention with qualified technicians, PRT requires a minimum of 25 hours per week. However, it also includes family members to employ PRT methods at home to help with generalization and better outcomes for the child.

PRT focuses on five core areas: motivation, responsiveness to multiple cues, self-management, self-initiation, and empathy (Koegel & Koegel, 2006). These areas are considered "pivotal" and are taught with the hopes that skills will then improve more "peripheral" areas, such as language and self-help skills. Bozkus-Genc and Yucesoy-Ozkan (2016) conducted a meta-analysis on 34 studies on PRT and found it to be an effective method in teaching children with ASD a variety of skills. They calculated the mean effect size using PND (76.10%), PNDC (78.03%), and PEM (89.34%) methods, which indicated the treatment was fairly to highly effective.

Functional Analysis

Another influential researcher is Brian Iwata, who is currently at the University of Florida. Iwata developed the functional analysis procedure used today. Functional analysis is a procedure used to empirically identify the conditions which maintain challenging behavior. Iwata and colleagues published "Toward a Functional Analysis of Self-Injurious Behavior" (1982/1994), which employed a multielement design to assess the function of self-injurious behavior (SIB) in nine children and adolescents with developmental disabilities. The design included four experimental conditions, with 15-minute sessions per condition: academic, alone, social disapproval, and play. The academic condition, also known as an "escape" or "demand" condition, represents the "negative reinforcement" function. In this condition, the experimenter and participant are made to sit at a desk together and the experimenter presents tasks. If the participant responded correctly, they received brief praise. If they did not respond correctly, the experimenter used a "three-step" prompt, such that they first repeated the task after 5 seconds, then they repeated the task and modeled the appropriate response after 5 seconds, finally they physically prompted the participant. If the participant engaged in SIB, the experiment removed task demands for 30 seconds and turned away from the participant. The alone condition represented automatic reinforcement, where the participant was in a room alone, without toys or any items. The social disapproval condition, also known as an "attention" condition, represented the positive reinforcement function. In this condition, the participant was told to play with toys, while the experimenter "worked" and ignored all behaviors. If the participant engaged in SIB, the experimenter would deliver attention to the participant (e.g., say "don't do that" and patting them on the shoulder). Lastly, the play condition served as a control condition, which allowed the participant to play with various toys and no demands were placed. Instances of SIB were ignored and if there were no instances of SIB for 30 seconds, the experimenter delivered brief social and physical attention.

This functional analysis was conducted until experimenters observed stability of SIB levels, the levels of SIB was unstable for 5 days, or sessions were conducted for longer than 11 days; the required number of sessions ranged between 24 and 53. The results from this study found that it successfully identified functions of behavior. In addition, this function was not correlated with the rate or severity of the SIB, indicating that function and topography were distinct and need to be assessed separately. Since its publication, the basic method of functional analysis has not changed much, although the behaviors the method has been applied to has expanded (Hanley, Iwata, and McCord, 2003). In addition, the original positive, negative, and automatic functions of behavior have expanded to escape, attention, tangible, and automatic (Dixon et al., 2012, p. 16).

Some concerns arose due to the perceived training needed and the time-consuming nature of functional analyses. However, Iwata et al. (2000) found that basic clinical skills for conducting functional analyses could be acquired in less than 14 sessions with individuals with Bachelor of Arts degrees. Of the baseline scores, 33 out of 51 sessions were below 80%. Of the post training scores, in comparison, 66 out of 99 were at 100%.

In addition, to address the time concern, individuals developed other means to identify functions of challenging behavior. One method is standardized tests, such as the Motivation Assessment Scale (MAS; Durand & Crimmins, 1988), the Functional Assessment Checklist (FACTS; March & Horner, 2002), and Questions About Behavior Function (QABF: Matson et al., 2012). These measures, and others, will be discussed in more length in a later chapter (see Standard Tests and Interviews for Functional Assessment). Another method, proposed by Hanley and colleagues (2014), is an open-ended interview paired with a 15-to-30-minute structured observation across two conditions, test and control, in order to establish functions of behavior.

Criticisms of ABA

Perhaps stemming from the availability of funding in the 1990s for ABA therapy for autistic individuals, contemporary ABA has erroneously become synonymous with "autism therapy." ABA has broader implications reaching beyond a therapy for individuals with autism spectrum disorder.

Since the inception of ABA, specifically in treating children with autism, it has received criticism and pushback, from both the academic and public spheres alike. From an academic standpoint, some argue the effects of ABA are inflated (Kirkham, 2017). Some researchers have criticized the low quality of research regarding ABA and the lack of randomized controlled trials (RCTs) (Kirkham, 2017; Gresham & MacMillan, 1998). Further, some have tried to replicate Lovaas' results, to no avail (Shea, 2005).

The public criticisms have come from mostly autistic individuals, many of whom received ABA in early childhood. With the growing body of the neurodiversity movement, the push for ABA as a treatment for autism has been contended. The first point of contention is the use of language regarding a person's diagnosis. Autistic self-advocates argue against person-first language (i.e., "person with autism"), as it suggests a person can be separate from their autism diagnosis. Rather, they consider autism an integral part of their identity and personhood (Kirkham, 2017). As such, in order to accurately and respectfully report the criticisms from this community, for the remainder of the chapter 'individuals with autism' will be referred to as 'autistic individuals.' This view goes hand-in-hand with individuals who reject the 'medical model,' and thus reject the notion of needing an intervention at all (Kirkham, 2017). As such, some individuals compare ABA with behavioral interventions once used to treat homosexuality, which is no longer considered an illness. Further, ABA maintains rooted primarily in behaviorism, whereas interventions for other conditions have adopted a cognitive and behavioral approach (Kirkham, 2017).

Further, autistic individuals have argued that ABA therapy is abusive. The argument goes back to Lovaas' days, when he would implement aversive stimuli, such as electric shocks. Beyond the use of aversives, autistic individuals argue ABA is psychologically abusive. Self-advocates note that behavior is communication, and by ABA teaching a child not to engage in a target behavior, they in essence take away an autistic individual's form of communication. ABA can also focus on decreasing repetitive behaviors, referred to as 'stimming', which often serve as methods to self-soothe. Overall, self-advocates argue against ABA on the basis that it aims to decrease 'autistic behavior,' which many view as, "authentic and harmless representations of their personality" (Kirkham, 2017). Ari Ne'eman, autistic self-advocate and president and co-founder of the Autistic Self Advocacy Network, states, "the emphasis on things like eye contact or sitting still or not stimming is orientated around trying to create the trappings of a typical child… It can be actively harmful when we teach people from a very early age that the way they act, the way they move is fundamentally wrong" (Child Mind Institute, n.d.). Opponents of ABA also cite the implementation of ABA as problematic, namely criticizing the repetitive nature and citing that some skills don't generalize. However, Dr. Lord has argued the programs should be more play-based and therapists are trained to make the treatment fun for the child (Child Mind Institute, n.d.).

Contemporary Applied Behavior Analysis

One of the most exciting advances in the field of ABA is the emergence of the field of clinical behavior analysis and specifically acceptance and commitment therapy (ACT). ACT is based on Relational Frame Theory (RFT), which has been described as a behavioral psychology of language and cognition. RFT shares overlap with Sidman's stimulus equivalence, which is an alternative view to Skinner's verbal behavior. Based on the theory of stimulus equivalence, following specific training, relations may emerge that had not been explicitly taught. This relationship between stimuli is the basis of RFT. There are multiple types of relationships. For example, there are causal relationships, relationships of coordination or rough equivalence, and hierarchical relationships. RFT also incorporates thoughts, emotions, physical sensations, and overt behaviors, which form the relationships. Relational responding in RFT is the discrimination of relationships between stimuli, which is important because it allows greater access to information than discriminating between the stimuli alone. Derived relational responding is the ability to relate stimuli in a variety of ways, when one stimulus has not been directly taught. This concept can be divided into two types: mutual entailment and combinatorial entailment. Mutual entailment can be explained by the fact that if stimulus A is related to stimulus B in a specific way, then stimulus B is related to stimulus A in a similar way. Blackledge (2003) provides the example of being taught that the cognition "I'm afraid" is the cause for the action of running away, then running away is an effect of thinking "I'm afraid". Combinatorial entailment involves at least three stimuli and refers to the reciprocal relationships between the two stimuli (A and C), which are not directly related to each other, based on how those stimuli are related to other, intermediate stimuli (B). For example, Blackledge (2003) states that "I/me" is related to "snake" by the fact they are both in a wooded area, and thus related to "wooded area". RFT presents an approach to language and cognition.

As mentioned previously, ACT branched from RFT. ACT uses six core processes in order to increase psychological flexibility (Hayes et al., 2006). These processes include acceptance, cognitive defusion, being present, self as context, values, and committed action. Acceptance is an active and aware recognition of internal events without trying to change the form or frequency of such events. This method is implemented in an attempt to increase values-based action (Hayes et al., 2006). Cognitive diffusion alters the function of internal events, rather than altering the form or frequency, such that it creates a context in which an individual can interact with thoughts and previous, maladaptive functions are decreased. Techniques to do this are used to weaken the quality of the internal event, and thus, decrease the credibility or attachment to said event. Being present refers to nonjudgmental interaction with internal and external events as they unfold. This method is implemented to encourage the individual to engage in more flexible behavior, and therefore, have their actions correspond with their values. Next, self as context involves "I" as a context for experience, from which an individual can objectively engage and evaluate thoughts and experiences. Values are activities or qualities which help guide an individual's choices, related to various domains such as family, career, or spirituality. Lastly, committed action is a pattern of behavior in which an individual acts in accordance with their values. While values can never be "accomplished," committed action includes concrete goals. This process can involve exposure, skill acquisition, shaping, and goal setting. Although they are introduced and conceptualized individually, the core processes are interrelated and thus, each supports the other. Therefore, most research has investigated ACT as a whole, rather than individual processes.

A meta-analysis by Powers et al. (2009) found that ACT is a successful intervention, with small to medium effect sizes, compared to placebo and control conditions. It has a small effect size (0.42) compared to control conditions, with an average improvement of 66%. Compared to waitlists and psychological placebos, ACT yielded a medium effect size of 0.68, and a small effect size (0.42) compared to treatment as usual. However, ACT was not more effective than established treatments (effect size = 0.18) or control conditions for distress problems (e.g., anxiety and depression, effect size = 0.03). A more recent meta-analysis by A-tjak et al. (2015) found similar results. Their analysis yielded medium to large effect sizes in primary outcomes in treating anxiety, depression, addiction, and somatic health problems compared to control (0.57), waitlist (0.82), psychological placebo (0.51), and treatment as usual (0.64). Additionally, they found small to medium effect sizes on secondary outcomes for life satisfaction and quality measures (0.30) and process measures (0.56) compared to controls. They also found no significant difference between ACT and established treatments (i.e., cognitive behavioral therapy). These studies indicate ACT is an effective treatment compared to controls, waitlist, and psychological placebos and may be as effective as currently implemented interventions.

Summary and Conclusions

Since its inception, the field of ABA has evolved considerably as our knowledge of the principles of behavior analysis has grown. Edward Thorndike and Ivan P. Pavlov contributed significantly in establishing research which resulted in the establishment of behaviorism. Thorndike is known for his work with puzzle boxes which developed the Law of Effect, which, in essence, states that behaviors which precede rewards are more likely to reoccur (Thorndike, 1911). Meanwhile, Pavlov's lab in Russia produced research on classical conditioning with dogs and salivation. Both served to create a basis for which behaviorism took root in. John B. Watson adopted Pavlov's conditioned reflex and applied it to learned behavior in humans. He is most well-known for his lecture referred to as a Behaviorist Manifesto and his work with Little Albert. B. F. Skinner expanded the field further, influenced by his predecessors, Thorndike, Watson, Pavlov, and Charles Darwin.

O. Ivar Lovaas furthered the field as he implemented ABA techniques as an intervention for autism. His method is referred to as DTT and he was instrumental in establishing EIBI as a widely researched and implemented therapy. However, his original methods, specifically his use of electric shock and other aversives, have received warranted pushback and criticisms. Brian Iwata had further influence as he developed functional analysis procedures to experimentally establish functions of challenging behaviors.

Although today ABA is synonymous with autism, it has been implemented with a variety of populations and communities. ABA has been researched in schools, such as within special education classrooms (Trump et al., 2018) and more widespread issues such as violence and discipline problems within a school (Anderson & Kincaid, 2005). Behavior analysis has also been used in foster care to reduce running away (Crosland & Dunlap, 2015). Further, the subfield of behavioral gerontology has developed which focuses on applying behaviorist strategies to aging populations (Burgio & Burgio, 1986). Behavior analysis has also found use in treating and studying a range of addictions, from cigarettes and illicit drugs (Silverman et al., 2008) to gambling (Weatherly & Dixon, 2007). Applied behavior analysis is ever expanding, by developing new techniques or finding applications in new populations or to treat various disorders and challenging behaviors.

Applied behavior analysis (ABA) has established itself as a well-regarded and scientifically grounded field of study and area of practice. Though it has grown steadily in both application and practitioner-base, recent years have seen a meteoric rise in those pursuing careers as professional behavior analysts and working within the discipline (BACB, 2021c). Ethical challenges and questions are in no way new to the field of behavior analysis. In many ways ethical challenges have helped guide the direction and course of professional behavior, the increase in those identifying themselves as behavioral analysts, representing the field to the public, and engaging in clinical and professional relationships. These trends not only solidify the significant need for comprehension of ethical behavior but also an understanding of what may be defined as unethical conduct.

As with most major respected human-service organizations and healthcare professions, identification and differentiation of ethical behavior must not be left solely to the interpretation of a field's individual representatives without proper consideration of the entirety of the field's membership. The establishment of a universal framework from which ethical practice can be determined and understood acts as the foundation for clinical and professional practice and is highly dependent on the goals and objectives set forth by the field itself, and the principles from which those who form the field establish as priorities.

The Development of Ethical Standards and Guidelines in ABA

Applied Behavior Analysis has had a complex relationship with the field of ethics. In 1987, the Florida Association of Behavior Analysis (FABA) was the first state to develop an ethical code. Shortly after, the Texas Association for Behavior Analysis (1990s) and the California Association for Behavior Analysis (1996) quickly followed. In 2002, the Association for Behavior Analysis International (ABAI) adopted the American Psychological Association's ethical code until the Behavior Analyst Certification Board (BACB) created an ABA-specific ethics code in 2004. While many of these organizations have taken it upon themselves to outline ethical behavior in the field, it's important for anyone learning about ABA to understand that the profession comprises a variety of independent professional and standard-setting organizations which exist to serve and support their stakeholders. Currently,

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_2

there are four independent types of professional organizations within ABA, some of which have been named above. The four types of organizations are (a) professional associations, (b) trade associations, (c) certifying bodies, and (d) accrediting bodies. Together, these organizations provide a variety of necessary functions for their respective constituents, including creating ethical codes, standards, and practice guidelines. Below, we provided a brief overview of each organization and the roles they play in ethics of behavior analysis services.

Certifying Body

Certification and licensure bodies exist to meet the professional licensure needs of the people who hold such a license or certificate. A certifying body verifies that individual professionals have the appropriate level of competence and expertise to effectively perform their roles. Additionally, certifying bodies are often at the forefront of industry research and training. They work with federal, state, government, and third-party entities to enhance recognition of their certified professionals. A hallmark of a credible credentialing program is that they hold accreditation by the National Commission for Certifying Agencies (NCCA) of the Institute for Credentialing Excellence (ICE) or the American National Standards Institute (ANSI).

The Behavior Analyst Certification Board (BACB) is the largest certifying body in behavior analysis and regulates any individual who has earned the Board Certified Behavior Analyst (BCBA©), Board Certified Assistant Behavior Analyst (BCaBA©), or Registered Behavior Technician (RBT©) certification. The BACB is also responsible for releasing the first Professional Disciplinary and Ethical Standards and Guidelines for Responsible Conduct for Behavior Analysts (2004) and the Professional and Ethical Compliance Code for Behavior Analysts (2014), now known as The Ethics Code (2020).

Professional Association

Professional associations come in many shapes and sizes. They are characterized typically by shared interest in a particular job or field. Professional associations place great effort on the development, training, and education of their constituents. Their aim is to improve their respective industry's capabilities and effectiveness.

A well-known hallmark of professional associations is the offering of conferences and training, designed to elevate the knowledge among a shared group. They also advocate for the right to practice via legislative efforts. These offerings can provide professional association members with continuing education units (CEUs) to meet the licensing and credentialing needs of certifying bodies, like those addressed above. Professional associations in ABA can be national or local. Regional professional associations, such as the state-specific Texas Association of Behavior Analysis (TxABA) and California Association of Behavior Analysis (CalABA), represent the interests and priorities of its constituents, which include behavior analysts practicing within the organization's locality, as well as those accessing behavior analytic services across the represented area. These regional associations often work in tandem, and with significant collaboration, from national organizations. Behavior analysts rely heavily on national organizations such as Association for Behavior Analysis International (ABAI) and Association for Professional Behavior Analysts (APBA) for guidance on practitioner ethical issues.

Trade Associations

A trade association engages in activities, such as advertising, education, publishing, and political donations, though its focus often hinges on collaboration between companies. These groups also work to influence public policy through lobbying and leveraging regulatory measures within their particular industry for the benefit of their members.

A trade association is founded and funded by the businesses it represents and often acts as a collective voice for companies. A large, common example is the WTO (World Trade Association) that oversees trade rules between countries. In the ABA industry, there are local trade association such as the Massachusetts Coalition for Behavior Analysis Providers (MassCAP) and Indiana Providers of Effective Autism Treatment (InPEAT), and national association such as Council of Autism Service Providers (CASP) and National Coalition for Access to Autism Services (NCAAS).

Accrediting Body

An accrediting body defines and measures quality in a particular field. These institutions represent objective, external groups that examine and evaluate a program or institution to ensure they meet a set of standards established by experts in the field. A hallmark of a credible accreditation program is that they hold accreditation by the American National Standards Institute (ANSI), which promotes transparency of how standards are developed and an opportunity for public commentary. To date, the only accrediting body in ABA is the Behavioral Health Center of Excellence (BHCOE), which administers a BHCOE Accreditation decision. The BHCOE is also responsible for releasing the first Code for Effective Behavioral Organizations (2015), now the BHCOE Standards of Excellence (Effective January 1, 2021).

The Foundation for Growth of ABA

While many of these professional and regulatory organizations which exist today aim to protect consumers of ABA services, up until the 2000s, most of these organizations did not exist. In 2016, Deochan and Fuqua released a paper that outlined the BACB certification trends between 1999 and 2014. Since the Behavior Analyst Certification Board was officially established in 1998, the number of individuals certified has grown exponentially, especially in the United States. As growth continued, a group of parents noticed that when their children were diagnosed with Autism Spectrum Disorder (ASD), many health insurance plans would deny coverage for ABA therapy. As a result, only those who could afford to pay out of pocket were able to afford paying for Applied Behavior Analysis. As a result, a group of parents and advocates in Indiana, including The Arc of Indiana (Kim Dodson), The Indiana Resource Center for Autism (Dr. Cathy Pratt), and a group of scientists and parents led by parent advocate, Michele Trivedi, asked the Indiana State General Assembly to pass the first comprehensive autism treatment coverage law.

In 2001, thanks to the hard work of Michele Trivedi and others, the first Autism Health Insurance Mandate law was passed in Indiana mandating coverage for ASD, requiring health insurers, health care subscription plans, and health maintenance organizations to cover the diagnosis and treatment of ASD in individuals within a specified age group. An immediate result of the Autism Mandate in 2001 passing led to parents and advocacy groups in other states to begin doing the same, with South Carolina passing in 2008. This legislative activity set the groundwork for the growth the field of ABA would experience over the next two decades.

While the increased coverage for individuals with autism has been monumental for those families who would otherwise not be able to afford treatment, the insurance coverage for Applied Behavior Analysis therapy had a direct impact on the growth curve of Board Certified Behavior Analysts in the United States, leading to an increased risk for ethical issues to arise. While the field continues to grow, a significant challenge has emerged as there are more individuals needing services than there are certified individuals across most of the United States (BACB, 2021c). Due to this growth, ethics has become an important topic to address both from the perspective of historical ethics concerns in the field and current issues related to individual ethical decisions and organization's ethical decisions (Sellers et al., 2020).

Learning from the Past to Shape the Future

The field of behavior analysis has evolved and developed from one that focuses on the application of learning principles to promote and change behavior within controlled environments, to one that supports the growth and development of socially significant behaviors across settings, populations, and areas of need (Baer et al., 1968). Yet, while this advancement has led to significant benefit through numerous arenas, the progression of behavior analysis has not been without substantial controversy, missteps, and wrong-doing (Bailey & Burch, 2016).

Though it may be possible to point toward those who associated themselves with the use and implementation of behavioral sciences as the primary culprits of these infractions rather than that of actions perpetrated by actual behavior analysts, it is the humble opinion of the authors that it would be irresponsible and potentially detrimental to the continued advancement of the field of behavior analysis to not acknowledge our role in committing and perpetuating the continued demonstration of the behaviors that may be considered beyond problematic. Recognizing how the field of behavior analysis may have facilitated, inspired, or benefited from these immoral actions allows the field not only to seize responsibility and regain potential lost trust but also to learn, develop, and improve.

Behavior analysts practicing today can maintain the dual position of promoting and furthering the advancement of the field, while at the same time acknowledging and validating the experiences of those who in the past (and perhaps presently) encountered the faults and failings during their involvement with behavior analysis. By listening to concerns, and including the populations with whom we wish to support the planning and direction of the field, behavior analysis has the opportunity not only to grow by preventing the repetition of past misgivings but also to create conditions that promote opportunities to engage in more clinically and ethically appropriate interactions and behaviors. In addition to promoting more clinically and ethically sound care, today, person-centered care is considered best practice across all patient populations. Codes of ethics assist in providing guidelines and framework from which to maintain ethical conduct; however, a code itself cannot prevent disreputable activities. Only through the continued identification of areas from which the field can improve and understanding of the rules the field sets for itself can behavior analysis and behavior analysts hope to continue to evolve in an honorable and ethical manner.

Ethics from the Individual Practitioner Perspective

While specific actions and responses may be considered to be more or less appropriate based on the context of the circumstance under which they occur, the basis for driving ethical behavior is established by maintaining and facilitating the guiding values that set the foundation for ethical standards in behavior analysis. The Behavior Analyst Certification Board (BACB, 2020) recognizes four core principles from which all who identify themselves as behavior analysts should endeavor to exemplify. Representing the field as a behavior analyst, interpreting appropriate and proper courses of action, and interacting with colleagues and the general public should all be conducted with these frameworks in mind.

First, behavior analysts strive to ensure that their involvement and interaction are to the benefit of those they mean to serve and any collateral parties that may be impacted by their participation. ***Benefiting others*** puts the individual or party identified as the primary client as the behavior analyst's central focus and priority. Any interaction and intervention must be conducted in a manner that keeps in mind both the short-term and long-term impact the behavior analyst may have toward the client and their circumstance. Contributions and changes are made to safeguard the rights and welfare of the client, keeping in mind any individual or contextual factors that might lead to potential challenges throughout the course of the behavior analyst's involvement and beyond. Finally, it is the behavior analyst's ultimate responsibility to "do no harm," no matter how subtle or unintentional, by placing the client's best interest at the forefront.

Behavior analysts' venture is to treat those with whom they serve with care, ***compassion, respect, and dignity***. Many recipients of behavior analytic services are considered to be members of particularly vulnerable populations who may not yet advocate for or represent themselves. Facilitating opportunities for individuation and self-determination and affording personal choices is imperative toward creating a more equitable environment. When involvement or intervention is employed to assist in developing autonomy, behavior analysts should do so in a manner that allows for appropriate fading of interaction or service and reduces the likelihood of reliance on such supports.

It is imperative that behavior analysts understand their responsibility not only to their own reputation, but also to that of the field of ABA. In their representation as a behavior analyst, those working within the field should conduct themselves with ***integrity***, in a manner that is professional, honest, and accountable. Doing so assists in establishing trust of the behavior analyst as an individual, as well as toward the field that is reflected by the practitioner. Providing clear and accurate expectations, identifying professional roles and boundaries, and utilizing behavior analytic strategies grounded in scientific research establish and maintain the integrity of the behavior analyst.

The final foundational principle guiding behavior analysts in facilitating and interpreting their interactions focuses on ensuring ***competence*** within and throughout their professional endeavors. As ABA expands across areas and populations, those working within the field must remain within their scope of practice, continue to maintain professional development, remain current of advances and changes, increase their knowledge and expertise, and understand their own boundaries and limitations (BACB, 2020).

While ethical principles assist in forming a framework and foundation for behavior analysts to embody, these ideals guide action rather than direct behavior. The Ethics Code for Behavior Analysts (BACB, 2020) establishes specified and defined rules of conduct that must be adhered to by all Board Certified Behavior Analysts ® (BCBAs ®), Board Certified Assistant Behavior Analysts ® (BCaBAs ®), Registered Behavior Technicians ® (RBTs ®), and BACB applicants (BACB, 2014).

Ethics codes are generally established within a field in order to guide and promote behavior that is considered to be more ethical or "right," as a response to behaviors conducted by individuals previously associated with the field that are more currently considered to be problematic or "wrong," and as a means of increasing public trust in the practitioners and the field as a whole (Brodhead et al., 2018). By establishing formalized rules of practice in the form of an ethics code, the field of behavior analysis is provided a framework from which to engage in more appropriate and beneficial decision-making. Codes and standards allow behavior analysts to be better equipped to evaluate and assess potentially detrimental choices, recognize more beneficial options, and identify when additional support, guidance, or disciplinary reporting is necessary (Sellers et al., 2020).

Though ethics codes are meant to be comprehensive and to provide substantial direction and guidance, personal interpretation, ambiguity, and misunderstanding of code elements continue. To an extent, ethics codes are written in a manner that should allow for situational understanding and application where appropriate. While in other circumstances, clear application is specifically implied for the identified benefit of all those involved. However, it is important to acknowledge that it is not only impossible but also not advised for all scenarios that may be encountered within professional practice to be integrated within even the most inclusive of ethics codes (Sush & Nadjowski, 2019). As a result, ethical practitioners and the field governing them must expect the rules of ethics to be applied and understood with consistency when specific interpretation is available and with informed and responsible decision-making across all other circumstances.

Simply developing an ethics code, even one where updates are consistently implemented to reflect changing times and expectations, does not preclude the possibility that ethical challenges or blatant ethical infractions will not continue to occur. The establishment of a well-reviewed and thorough ethics code does provide a foundation of ethical expectations, as well as a resource for identified behaviors that are considered consistent and inconsistent with a well-intentioned field. However, the code itself does not prevent unethical behavior from occurring. It would be inaccurate to presume that because an issue has been addressed and defined within an ethics code, it no longer has the potential to be displayed in clinical practice (Dawson, 2004).

Ethics from the Systems Perspective

While individuals engage in ethical decision-making when providing clinical services, the organizations who manage those individuals exercise great power. It has been argued that the behaviors of managing organizations ought to be governed by a more demanding set of standards than those that apply to private individuals (Drucker, 1981). The section on ethics, integrity, and professionalism in the Standards of Excellence (BHCOE, 2021) establishes specific rules of conduct that must be adhered to by all organizations who hold BHCOE Accreditation.

Similar to those at the individual practitioner level, organizational standards are typically established at the directorial level to guide and promote the behavior of an organization that is considered to be "right" and reduce the behaviors considered to be "wrong." By establishing a formalized standard for ethics of organizations, organization owners and operators can be better equipped to make decisions that can assist those who work with them to help improve the lives of those they serve.

Leveraging the Ethics Code in Clinical Practice

Ethics codes become useful tools in enhancing the clinical strength of a field when they are utilized not simply as a means of identifying missteps and justifying disciplinary actions in response or reaction to infractions, but rather when the purpose for inclusion of their elements is understood. Keeping in mind that the function of the ethics code above all else is to ensure that the practitioner is acting in the best interest of their client (Bailey & Burch, 2016) allows for a deeper grasp of the code itself and an increased likelihood of awareness of code elements prior to and when faced with ethically precarious circumstances.

Though much of a professional behavior analyst's knowledge both clinically, and in relation to ethical challenges, will be gained through practical experience, it is recognized that even with the most diverse of practicum environments and populations, or dedicated and attentive of supervisors, it is highly unlikely that those training in behavior analysis will have the opportunity to prepare for any potential ethical challenge that may be encountered (Sush & Nadjowski, 2019). Participation in coursework specifically focused on the ethical practice of ABA is required for practitioners who wish to sit for the BACB certification exam and earn their BCBA credential (BACB, 2021a). Additionally, maintenance of certification requires continuing education specifically focused on ethics in behavior analysis (BACB, 2021b). Doing so allows for exposure to a greater variety of learning opportunities and a more in-depth analysis of the components of potential challenge and contributing factors to ethical difficulties, as well as providing a supportive and sheltered environment within which to learn, question, and grow (Handelsman, 1986).

Factors Influencing Ethical Decision-Making

A behavior analyst's capacity to respond to and manage ethical challenges in an appropriate, adaptive, and reasonable manner is likely influenced by a number of different factors. As mentioned above, exposure to ethical issues through practical experiences under the watch of a knowledgeable and supportive supervisor may assist in developing a stronger capability for both preventing and reducing ethical risk. Additionally, participation in course sequences and educational opportunities related to the identification and study of ethical issues in behavior analysis may build clinical and ethical intuition and fill in areas not otherwise covered through direct involvement. Yet, even with the most substantive training and educational experience, the ethical practice of behavior analysis is likely most predominantly influenced by the individual behavior analysts themselves.

Ethical Competence

Responding in the most advantageous manner is often necessitated upon the behavior analyst's awareness not only of what the best course of action in relation to a challenging situation may be, but also their identification that they are in the midst of an ethical issue. However, perhaps most importantly, the behavior analyst's understanding of their own limitations in determining those risks and charting the necessary course of action may be the most crucial factor (Ghezzi & Rehfeldt, 1994).

Behavior analysts may best determine their proficiency to adequately manage an ethically precarious circumstance and situation based upon their direct training in similar areas, as well as their experiences when previously faced with comparable issues (Bailey & Burch, 2016). Though there is always the potential for an ethically difficult situation to occur or become evident, the majority of these issues will likely either resolve themselves through the general course of interaction and involvement without even the behavior analyst's knowledge that the challenge was present, or with minimal corrective action (LeBlanc et al., 2020). However, even the most innocuous of ethical difficulties has the potential to progress to more impactful and potentially detrimental levels (Sush & Nadjowski, 2019). The behavior analyst's identification of such circumstances and capability of addressing these issues prior to such problematic advancement are likely most highly related to the behavior analyst's own familiarity with the ethics code itself and knowledge and fluency with code elements that will allow them to more easily attribute difficult situations with related and established ethics codes, thus, increasing the likelihood that a behavior analyst may proactively engage with an ethically troubling event and prevent further escalation (Bailey & Burch, 2016).

Fortunately, a behavior analyst does not simply need to wait for an ethical challenge to occur to strengthen and build their experience as an ethical practitioner. Similarly, though formal ethical training may have been received in graduate coursework and reinforced through continuing education, behavior analysts may create learning opportunities to increase their expertise and comfortability in preventing and managing ethical challenges on a consistent basis, and without the additional stress or pressure of responding to legitimate, real-world confrontations (Sush & Nadjowski, 2019).

Behavior analysts who work with other professionals within a behavior analytic organization have the benefit of relying upon the different points of view, areas of expertise, and perspectives of their colleagues in discussing ethical issues and ideas. Behavior agencies and organizations can also be sure to make ethics a clear aspect of everyday practice through staff trainings, in-service meetings, journal clubs, discussion sessions, or team building exercises. Such practices can be held periodically, or in preparation of feasible challenges (Handelsman, 1986). It may also be beneficial for behavior organizations to establish a clear path for reporting ethical concerns or questions. Depending on availability or the structure of the agency, this may come in the form of peer mentors, clinical directors or supervisors, or a designated ethics coordinator that may be accessed should situations arise, or as a means of monitoring continued ethical behavior (Brodhead & Higbee, 2012).

Behavior analysts who work as independent practitioners may not have the opportunity to participate in group training activities similar to those who are employed within an agency. However, these professionals may benefit from creating a network of colleagues and mentors with whom they may contact regarding ethical challenges and best practices (Smith, 2003).

Benefit and Understanding of Potential Reinforcement

Responding to ethical challenges may also be influenced by the behavior analyst's ability to acknowledge, identify, and reconcile their own personal investment in the outcome or progression of the ethical issue. Whether clearly defined within the ethics code or not, charting a particular course in relation to a potential ethical concern may certainly assist those involved, but may be of particular benefit to the behavior analyst themselves. Separating motivation and decision-making to ensure that the best interests of the client are paramount requires significant insight on the part of the behavior analyst. The potential benefit to the behavior analyst, even when perceived to be of assistance to the client, may lead professionals toward choosing less ethical or more complicated paths (Sellers et al., 2016).

The contingencies governing ethical behaviors are the same as those which inspire and maintain all other behaviors and are in place regardless of whether the individual is aware of the opportunities for reinforcing consequences (Brodhead & Higbee, 2012). However, it can be assumed that a behavior analyst is much more likely to reflect on their ethical decision-making if they are aware that an opportunity for reflection is present. Just as a behavior analyst is able to more effectively and appropriately develop strategies to reduce a maladaptive behavior or increase a replacement skill if they have a more thorough understanding of the environmental conditions and circumstances in which those behaviors are acquired and will continue to occur, a behavior analyst is more likely to engage in accurate ethical analysis if they understand the context in which ethical behaviors, and similarly unethical behaviors, occur and may thus take steps toward facilitating appropriate action and, if necessary, intervention (Sush & Nadjowski, 2019).

Acknowledging Biases in Ethical Decision-Making

Knowledge of the ethics code itself, training in areas related to ethics in behavior analysis, the potential for reinforcement, and the context under which ethical challenges occur may all influence a practitioner's utilization of the ethics code, ethical decision-making, and overall ethical behavior. However, the behavior analyst's personal biases and interpretation may underlie all of these conditions. As ethical challenges often involve multiple circumstances or situations, environmental contexts, and individual parties, the most integral factor in identifying issues and responding appropriately is likely the behavioral analyst's own moral values and personal beliefs that influence the understanding of all these factors. While it is important to understand cultural context in determining how decisions may impact a behavior analyst's clients or the clinical relationship, the behavior analyst's background, history, and past experience of reinforcing and punitive consequences under similar conditions may impact their acknowledgement of challenging situations and determination for appropriate courses of action, as well as their overall comprehension of the ethics code itself. As a result, a behavior analyst's ethical decision-making ability may be dependent not only on their skills and clinical experience but also on their ability to identify when their own cultural foundations and beliefs may influence, supersede, hinder, or encourage the most advantageous course of action (Brodhead, 2019; Rosenberg & Schwartz, 2018).

Ethical Delivery of ABA Services

While ethics has been a timeless topic discussed at length by philosophers such as Kant, J.S. Mill, and Aristotle, from a behavioral perspective, Skinner's work has rarely commented on which behavior would be considered ethical or moral. Rather, he focused on the contingencies that influence the display and maintenance of behavior. As such, behavior analysts are often tasked with understanding what is known as normative ethics**.** ***Normative ethics*** is the study of ethical behavior which investigates how one ought to act during certain scenarios or ethical decision-making (Brodhead et al., 2018).

Behavior analysis is a discipline with three distinct branches: (1) behaviorism, which focuses on the philosophy of behavior analysis, (2) experimental analysis of behavior, which concentrates on analyzing the basic principles of behavior, and (3) applied behavior analysis (ABA), which centers on solving socially significant problems using the principles of behavior analysis. Applied Behavior Analysis and behavior analytic principles and strategies have been applied toward a number of different areas and subjects. Of the different subspecialties, ABA is best known for its effectiveness in treating autism spectrum disorder (ASD). In fact, at the time of this writing, approximately 73% of all certified practitioners work with individuals with autism spectrum disorder (BACB, n.d.). As such, we will focus on this population when discussing ethical and legal issues within the subsequent section.

Most ABA services are delivered in a tiered model in which a behavior analyst provides clinical oversight to either an assistant behavior analyst or a behavior technician (BACB, 2014). This tiered model operates under the umbrella of a legal entity referred to as an ABA therapy organization (Gershfeld Litvak & Rue, 2020).

While a behavior analyst may only reasonably be responsible for maintaining their own ethical behavior, in an ABA therapy organization, most professionals practicing within the field will find themselves in a position to interact with members of other disciplines. Working within an interdisciplinary team provides the opportunity to support potential clients and provide quality care from multiple vantage points, while also allowing behavior analysts to effectively disseminate and share the value of behavior analytic services across fields. (Brodhead, 2015).

Challenges may arise when the behavior of collaborative members is questionable, as well as when strategies are proposed that are not compatible with behavior analytic principles or are not grounded in research. Though not responsible to the code of ethics for behavior analysts, many professionals who will work with similar populations do follow their own ethical framework. As a result, when cooperating with other disciplines it may be beneficial for the behavior analyst to be conscious of not only their own interaction and representation but also the ethical expectations of other members (Newhouse-Oisten et al., 2017). Similarly, familiarizing themselves with the strategies and interventions commonly utilized by other professionals with whom behavior analysts frequently interact will allow the behavior analyst to more effectively identify and differentiate harmful practices from those that may be appropriately integrated within a behavioral context (Brodhead, 2015). Finally, though common for behavior analysts to work as part of a group, receiving training, supervision, and mentorship should not be overlooked as a strategy to increase competence and teamwork (Luiselli, 2015).

Ethics and Cultural Considerations

Inherent in our work is that behavior analysts must function in accordance with the values, ethics, and standards that govern our field (Litvak & Rue, 2020). Cultural competence is critical to providing ethical service delivery (Fong & Tanaka, 2013). Within the behavior analytic community, some organizations have provided a framework for behavior analysts to consider regarding ethics as it relates to diversity and cultural competence and provide resources and guidance on how to integrate these concepts into practice.

Cultural Considerations from Association for Behavior Analysis International

Per their website, “ABAI seeks to be an organization comprised of people of different ages, races, nationalities, ethnic groups, sexual orientations, genders, classes, religions, abilities, and educational levels. ABAI opposes unfair discrimination." (Fong & Tanaka, 2013) To further this mission, ABAI has created a Culture and Diversity Special Interest Group (SIG). The goal of the SIG at ABAI is to "create a network of behavior analysts who speak a language or have a skill set relevant to a given population with people who need those services, as well as to connect behavior analysts with others who share common interests." (Culture and Diversity SIG, 2019). The SIG publishes and presents on topics related to cultural competence and understanding, as well as mentors students, supports professional advancement, and improves service delivery. The SIG also advocates that diversity enhances our profession, benefits our community, and that culture is an important topic of research. Some efforts made by the SIG include creating awareness around the need to recruit more diverse, global professionals into the field, remove barriers to their education, success, and advancement, and encourage diversity of thought, interdisciplinary expertise, and experience.

Cultural Considerations from Behavior Analyst Certification Board (BACB)

As referenced earlier, the BACB serves as the primary regulatory body for behavior analysts and provides several areas that behavior analysts should be attuned to related to cultural competence cited within the BACB's Ethic's Code for Behavior Analysts (BACB, 2020). A few of these areas are noted in Table 2.1.

Both code items refer to an individual behavior analyst's responsibility to ensure that they have received adequate training with the population they serve. When creating a culturally competent clinical practice, clinical leadership should ensure that their supervisory and clinical staff receive regular training regarding cultural differences and ensure that staff are matched appropriately based on competence.

Table 2.1 BACB's ethic's code for behavior analysts items for cultural competence

1.07	Cultural responsiveness and diversity
4.07	Incorporating and addressing diversity

Cultural Considerations from Behavioral Health Center of Excellence (BHCOE)

BHCOE provides diversity standards to ensure organizations are creating cultural informed practices (BHCOE, 2021). A few of these areas are noted in Table 2.2.

Table 2.2 BHCOE standards for diversity, equity, and inclusion

B.01	B.01 The organization has a diversity statement
B.02	B.02 The organization has access to and when necessary utilizes translation services for oral and written communication and communicates availability of translation services to patients
B.03	B.03 The organization has representation of diverse individuals at a minimum including age, gender, race/ethnicity, and disability. Instructional, training, and marketing materials include diverse images and narratives
B.04	B.04 The organization makes closed captioning available for its videos. This item is not applicable for organization does not have video content
B.05	B.05 The organization provides cultural humility training and competency checks to all employees upon hire, annually, and as required by state and federal guidelines
B.06	B.06 The organization actively recruits and engages in retention strategies to promote a diverse workforce
B.07	B.07 The organization demonstrates engagement in fair hiring practices, as regulated by Equal Employment Opportunity Commission (EEOC)
B.08	B.08 The organization engages in self-assessment of diversity efforts at least annually
B.09	B.09 The organization's physical location is compliant with the Americans with Disabilities Act
B.10	B.10 The organization has a means to and actively allows qualified low-income patients access to services
B.11	The organization assures that leadership have completed conflict resolution training and has process(s) for responding to bias incidents

All items relate to an organization's responsibility to showcase their commitment to creating an environment that promotes equity and inclusion. The standards indicate that the organization should have access to, and when necessary, utilize translation services for oral and written communication and communicate availability of translation services to parents (Fong & Tanaka, 2013; Cheng, Chen, & Cunningham, 2007). The standards also request that organizations provide cultural humility training and competency checks to all employees upon hire, annually, and as required by state and federal guidelines. Along this path, an organization should make reasonable efforts to involve parents/guardians in treatment planning, which relates to an organization's responsibility to consider patient cultural preferences into their treatment program and planning.

It is also required through the BHCOE standards that the organization demonstrates engagement in fair hiring practices, as regulated by United States Equal Employment Opportunity Commission (EEOC). The EEOC is responsible for enforcing federal laws that make it illegal to discriminate against a job applicant or an employee because of the person's race, color, religion, sex (including pregnancy, gender identity, and sexual orientation), national origin, age (40 or older), disability, or genetic information. Organizations must be aware that it is also illegal to discriminate against a person because the person complained about discrimination, filed a charge of discrimination, or participated in an employment discrimination investigation or lawsuit. Lastly, organizations are required to engage in the self-assessment of diversity efforts at least annually.

Legal Considerations in Applied Behavior Analysis

Though laws and ethics codes may be similar in that both maintain a set of rules that must be followed, there are significant differences in the applications, expectations, and ramifications related to each standard. In consideration of the similarities, and despite the contrasts, there are substantial legal implications that span throughout and beyond the clinical work of Applied Behavior Analysis. As ABA has evolved into a medical service, the concepts of waste, fraud, and abuse have arisen as common challenges in delivering care. Fraud typically includes knowingly submitting, or causing to be submitted, false claims or making misrepresentations of fact to obtain a federal health care payment for which no entitlement would otherwise exist or knowingly soliciting, receiving, offering, or paying to induce or reward referrals for items or services reimbursed by health care programs. Anyone can commit healthcare fraud, and while the definition includes the term "knowingly," intent is often challenging to prove. Remember, *ignorantia legis neminem excusat,* or, "ignorance of law excuses no one." Below, we review a few case scenarios of how these could manifest in clinical practice.

Fraud

Knowingly Billing at a Service Level Higher Than Actually Provided

Case Scenario: Johnny is a technician working with a 4-year-old boy. Johnny's supervisor, Keanna, regularly oversees his session. Johnny is unable to join for session one day, so Keanna decides to cover Johnny's session that day. If Keanna billed for this session as if it were a supervisory session, which would be billed at a higher rate, rather than a direct care session, this would be considered billing fraud.

Knowingly Billing for Services That Were Not Furnished, Including Falsifying Records

Case Scenario: Johanna shows up to her regularly scheduled session which typically lasts between 9:00 AM and 11:00 AM and finds that the family is not home. Upon calling the family, her client's parent says that they will be home at 9:30 AM, but tells Johanna she can just "make up the extra 30 minutes" by adding 10 extra minutes to the next few sessions. Johanna decides to bill for the time from 9 AM to 11 AM knowing that she will make up the session later. While seemingly innocuous, by billing for time in which she did not provide services, Johanna is engaging in billing fraud.

Knowingly Ordering Medically Unnecessary Items or Services for Patients

Case Scenario: Ahmed conducts an evaluation on a patient who is moderately impaired. In his professional clinical opinion, he believes the patient would benefit from 20 hours per week of ABA therapy. However, his supervisor lets him know that they would prefer he recommends 30 hours per week as it would be easier to staff a technician on the case if the patient received more hours. The supervisor also told Ahmed "more hours can't hurt." If Ahmed were to alter his prescription recommendation, not only would this violate the ethics code, but he would be engaging in billing fraud.

Billing for Appointments Patients Fail to Keep

Case Scenario: Tunde regularly does not show up for his regularly scheduled ABA therapy sessions because of scheduling miscommunications between his divorced parents. When Tunde doesn't show, Jamie, the direct technician, will not get paid for the hours she was supposed to work with Tunde. Sometimes, when Tunde does not show up to session, Jamie does not mention this to her supervisor so that she can get paid for the scheduled session. This is considered billing fraud.

Defrauding the federal government or a commercial insurance plan is illegal and the consequences can be detrimental to an individual's livelihood and ability to practice within healthcare in the future. In worst case scenarios, committing fraud could lead to imprisonment, fines, and penalties.

Abuse

Abuse refers to practices that may directly or indirectly result in unnecessary cost to the health plan. Abuse refers specifically to a practice that does not provide the patients with the medically necessary services for which they have been authorized. The nuance between fraud and abuse can depend on circumstances, intent, and knowledge. Along with identifying risk of fraud waste and abuse in day to day practice, it is important those practicing ABA familiarize themselves with laws governing fraud, waste, and abuse as summarized below:

False Claims Act (FCA)

The False Claims Act (31 U.S.C. Sections 3729 through 3733), also known as the "Lincoln Law," protects the Federal Government from being overcharged or oversold goods of services. The legal community has cited the False Claims Act to be the most effective antifraud law in the United States. Under the False Claims Act, a person with evidence of fraud against federal programs can sue the alleged on behalf of the United States Government. The government may then intervene and join the litigation.

If the government has already filed a False Claims Act lawsuit against the entity, a new suit cannot be pursued. Violators of the False Claims Act are liable for three times the dollar amount that the government was defrauded and between $10,000 and $20,000 for each false claim. In addition, the plaintiff can receive 15–30% of the recovery from the defendant. The whistleblower only receives the reward if the government recovers money from the defendant as a result of the suit. The financial incentive captured in the False Claims Act has been cited as a key component of bringing to light information about fraud and has been a controversial component of the False Claims Act (Rapp, 2007).

Anti-Kickback Statute (AKS) and Stark Law

The Anti-Kickback Statute, 42 U.S.C. § 1320a-7b(b), is a law that prohibits the knowing and willful payment to induce referrals or generate business. Payment can include anything of value, not just cash, such as gift cards, tickets to an amusement park, or paying for travel. While in many industries, it may be acceptable to reward those who refer business to you, in most healthcare programs, paying for referrals is a crime. Penalties for violating the anti-kickback statute includes fines, imprisonment, exclusion from participating in healthcare programs, or penalties of up to $50,000 per referral and three times the amount of payment received per referral.

Legal Relevance of Clinical Documentation

Clear medical record documentation can play a critical role in providing patients with quality care, ensuring timely and accurate payment, and mitigating risk of malpractice (Pine & Bossen, 2020). It also helps organizations plan for patient treatment and maintain continuity of care (BHCOE, 2020). Clinical documentation not only supports appropriate reimbursement and billing practices, but also increases quality of care provided to patients. Individuals documenting services should also be aware of best practice related to general management of clinical records and ensure they have clear understanding of which documents may be considered part of the medical record. For more information, review the BHCOE Standard for the Documentation of Clinical Records for Applied Behavior Analysis Services (BHCOE, 2020).

HIPAA & Privacy Laws

The Health Insurance Portability and Accountability Act ("HIPAA") is a federal law that protects the privacy of protected health information ("PHI"). PHI is any individually identifiable information pertaining to your patients, including nonclinical records, such as an admission agreement. HIPAA applies to Business Associates who are persons or entities that maintain, transmit, disclose, or use PHI on behalf of a Covered Entity. Business Associates must have a Business Associate Agreement (BAA) with their related Covered Entity. If the Business Associate subcontracts work that would involve the exchange of PHI, the Subcontractor must enter into an Agreement with the Business Associate that meets the same standards as the BAA between the Covered Entity and Business Associate. All staff and volunteers must receive HIPAA training on an annual basis consistent with their job responsibilities.

The Privacy Rule protects all "individually identifiable health information" maintained or transmitted by a Covered Entity or its Business Associate, in any form or media, whether electronic, paper, or oral. The Privacy Rule calls this information protected health information (PHI). "Individually identifiable health information" is information, including demographic data, that relates to: the individual's past, present, or future physical or mental health or condition; or the provision of health care to the individual; or the past, present, or future payment for the provision of health care to the individual; and contains enough information for which there is a reasonable basis to believe it can be used to identify the individual. Individually identifiable health information includes many common identifiers (e.g., name, address, birth date, Social Security Number). Practitioners should be especially mindful about The Privacy Rule in their social media usage and other public communication in which patient communication could be inadvertently shared with those outside of their organization.

A breach is the acquisition, access, use, or disclosure of PHI in a manner that is not permitted by the Privacy Rule and compromises the security of privacy on the PHI. A suspected breach is presumed to be a breach unless the Business Associate demonstrates that there is a low probability that the PHI has been comprised by conducting a Breach Risk Assessment. A Breach Risk Assessments must be documented and assess the following:

- Was the PHI accessible?
- What type of information was included in the PHI?
- What actions can be taken to mitigate the improper disclosure?
  - Mitigating factors include having the information returned or destroyed, obtaining an attestation from the receiving party that the information has not been copied or further disclosed, remotely wiping a lost device, etc.

If it is determined that a breach has occurred, the Business Associate must notify:

- The Covered Entity and, in possible conjunction with the Covered Entity:
- Affected Individuals
- Office for Civil Rights
- Some state licensing agencies also require notification

After a breach, the individual or organization responsible for the breach should perform root cause analysis to determine appropriate actions for preventing a similar breach in the future.

Criminal penalties range from $50,000 and/or imprisonment for one year, to $250,000 and/or imprisonment for up to 10 years. In addition, state attorneys general have authority to bring civil actions on behalf of residents of the state.

Conclusions and Ethical Decision-Making

Ethical behavior, and the decisions guiding ethical behavior, should be held to the same standard of evaluation, analysis, and understanding as all other behavior subject to behavior analytic interpretation (Brodhead, 2019). While an ethics code may provide a set of rules for the practice of behavior analysis, centralizing agreement upon the determination of ethically acceptable representation, individual values continue to influence the interpretation of the code. In a broad sense, ethics codes provide an operational definition of those behaviors that best represent the field; however, without context, such as the situation in which the code is meant to apply, the circumstance requiring analysis and the cultural and personal factors of all parties involved (including the behavior analyst), even the most clear and concise definition, may be rendered inadequate and impractical (Sellers et al., 2020).

Ethical decision-making has evolved and progressed as the complexity of ethical behavior has grown. As behavior analysts come to understand ethical decision-making outside of the determination of what is simply "wrong" or "right," but more so of how decisions may be influenced not only by the standards of the field, but also by the environmental factors surrounding the opportunity to "behave ethically," behavior analytic, ethical decision-making has expanded to include a clearer understanding and thorough review of the antecedent and consequent variables related to the choices and options that have or will occur (Sush & Nadjowski, 2019).

Simply relying on the code as guidance cannot and should not be sufficient when determining and interpreting ethics within behavior analysis. First, it is not possible to include code elements that will apply directly to each and every circumstance and situation encountered. Further, even when clearly addressed within the code, there is a likelihood that elements of the ethics code will not fit the exact mold of the circumstances faced by the behavior analyst. As a result, though the code does provide clear and concise rules from which all those practicing behavior analysis may follow, a degree of interpretation is not only understandable, but necessary and encouraged.

The code was developed as a tool for ethical guidance, as well as in response to previous ethical issues and identified transgressions. Though each circumstance in which the potential for ethical decision-making may be unique, behavior analysts will likely be best served by first identifying the similarities between their clinical practice, the potential challenging circumstance and the relevant areas already identified within the ethics code. The majority of ethical challenges and dilemmas will likely be best served by review of the ethics code and direct application of code elements. Even when there is no exact correspondence between the situation inspiring the ethical review and the code itself, there is likely significant parallels that can be inferred and employed from which to initiate and continue to assess ethical decision-making opportunities that may best serve the situation and those involved. In other words, it would not be appropriate, nor advisable to chart a path in response to an ethically challenging event without reference or guidance from aspects already included within the ethics code, simply because a specific code element does not precisely relate to the issue at hand. Instead, though there might be limitations for each standard as written or described, the general application of the code will provide useful recommendations for preventing or managing most dilemmas.

As with most demonstrations and applications of behavior analysis, following a systematic method in avoidance, anticipation, identification, management, reduction, and reflection of ethical issues and concerns may provide those practicing within the field a conscientious and poised approach that will be of most benefit to the identified client, the field of behavior analysis, and the practitioner.

Though there are multiple suggested approaches in standardizing ethical decision-making, most recommendations focus on first identifying that the incident does in fact pose an ethical concern, and if so, addressing any risk or harm to those impacted by the situation. Recognizing all relevant parties, applicable code elements, contextual factors, and personal values that may impact how one addresses the dilemma and resolves the concern is also of utmost importance, as well as consulting with supportive resources in identifying potential solutions. Finally, continuous data collection and further analysis are generally recommended to not only ensure that challenge does not progress or escalate but also to apply lessons learned in the future (BACB, 2020; Brodhead et al., 2018; Rosenberg & Schwartz, 2019; Sush & Nadjowski, 2019).

3 Social Reinforcers

Makenzie W. Bayles, Claudia L. Dozier, Amy H. Briggs, and Sara Diaz de Villegas

Introduction to Social Reinforcers

Social reinforcers are among the most commonly used reinforcers in applied behavior analysis (Vollmer & Hackenberg, 2001). Social positive reinforcement involves the contingent delivery of a stimulus by another person that results in an increase in the probability of future behavior (Lovaas et al., 1966; Miltenberger, 2016). A common form of social positive reinforcement is the delivery of attention, which may be delivered in various forms. Attention may include vocal-verbal interactions (e.g., praise, conversations, reprimands), physical attention (e.g., hugs, pats on the back), proximity (e.g., approaching a person, sitting beside a person), and facial expressions (e.g., smiles, winks, frowns). Previous research has shown the reinforcing effects of attention for increasing desirable behavior (e.g., Gable & Shores, 1980; McLaughlin, 1982; Neimy et al., 2020), as well as undesirable behavior (e.g., Lovaas & Simmons, 1969; Iwata et al., 1994) in various populations across various contexts and settings. However, less is known about the conditions under which attention functions as a reinforcer (i.e., the variables that may influence the efficacy of attention as a reinforcer; Vollmer & Hackenberg, 2001).

Importance of Attention in Human Interaction

From birth, infants depend on others caring for them for survival. That is, an important role of the parent is to provide positive and negative reinforcers (Bijou & Baer, 1965), and a major determinant in the development of social and intellectual behavior in young children involves parent responses to child behavior (Hart & Risley, 1995; Horowitz, 1963; Lovaas et al., 1966). Later on, our behavior is affected by attention from others (e.g., peers and teachers) in our daily interactions. Whether attention is an unconditioned or conditioned reinforcer is something that is up for debate. An unconditioned reinforcer is a stimulus that works to increase behavior without a learning history with the stimulus. For example, food, water, oxygen, and sexual stimulation are known unconditioned reinforcers. Some researchers suggest that some forms of human interaction can be added to that list (e.g., Gewirtz & Pelaez-Nogueras, 2000; Vollmer & Hackenberg, 2001).

A conditioned reinforcer is a previously neutral stimulus that comes to serve as a reinforcer because it has been paired with one or more unconditioned or conditioned reinforcers. Many behavior analysts have suggested that reinforcers linked to our social behavior are conditioned reinforcers (Axe & Laprime, 2017; Bijou, 1995; Bijou & Baer, 1961, 1965; Dozier et al., 2012; Lovaas et al., 1966; Skinner, 1953). In fact, many forms of attention are often described as generalized conditioned reinforcers (Bijou, 1995; Dudley et al., 2019; Skinner, 1957). A generalized conditioned reinforcer is a conditioned reinforcer that has been paired with so many other reinforcers that it serves as a reinforcer for behavior under various establishing operations. Bijou (1995) suggested that forms of attention can become generalized reinforcers such that they are effective when delivered by various individuals and under various establishing operations. Many forms of attention (e.g., verbal, physical, facial expressions, proximity) have been paired with so many other reinforcers that they come to serve as reinforcers under a variety of antecedent situations. For example, praise may be a generalized conditioned reinforcer for the behavior of many people because praise is often paired with other reinforcers (e.g., edible reinforcers, tangible reinforcers, activity reinforcers) and may serve as a reinforcer for behavior under a variety of antecedent conditions.

Strengths and Limitations of Social Reinforcers

Strengths of Social Reinforcers

There are several advantages to using attention to increase behavior. When a therapist is starting a reinforcement-based program, it's important that they use reinforcers that are easy to administer and that can be delivered immediately following a behavior (Mallott & Shane, 2014). Attention meets both of these criteria and it occurs naturally in the environment. Therefore, attention is almost always used as part of behavior-intervention plans. For example, praise is used as part of most, if not all, skill acquisition programs. Another advantage of using attention as a social reinforcer is that it is a low-to-no-cost approach to increasing behavior (Mathews et al., 1980). Edible and tangible reinforcers can cost money, but it doesn't cost anything to deliver praise, a kind gesture, or a smile. An additional advantage of social reinforcers is that they can be delivered without interrupting behavior (Helton & Ivy, 2016). For example, a teacher can give a pat on the back or a thumbs up while an individual is engaged in the target behavior, such as completing an assignment with a peer. When behavior analysts teach educators and caregivers to implement reinforcement-based procedures, they often teach them to gradually move from delivering contrived reinforcers to delivering naturally occurring reinforcers (Cooper et al., 2020). For example, an educator or caregiver may be instructed to fade the use of a token economy over time. One advantage of attention is that many forms should already be naturally occurring in the environment. Therefore, educators and caregivers can be taught to deliver praise along with other forms of contrived reinforcers (e.g., tokens), and eventually the contrived reinforcers can be faded out and praise may continue to reinforce the behavior. Because praise remains a part of the natural environment, it might also help to maintain the behavior over long periods of time. If attention is a generalized conditioned reinforcer, then attention might also be more resistant to satiation and may be preferred over other types of reinforcers. In addition, it might be easier to individualize social reinforcers compared to other types of reinforcers. For example, if a child prefers high-fives over praise, then it's simple enough to provide their preferred form of attention. However, if a child prefers M&Ms over Skittles, but you're out of M&Ms, then it might take some time to obtain the preferred reinforcer.

Limitations of Social Reinforcers

The use of attention may not serve as a reinforcer for the behavior of all individuals (Dozier et al., 2012). For some individuals, social reinforcers in the form of attention may even be aversive

(Hagopian et al., 2001; Taylor & Carr, 1992). Bijou and Baer (1961) suggested that when behavior is not sensitive to attention as a reinforcer, the individual may exhibit deficits in intellectual and social development. When this occurs, it may be necessary to establish attention as a reinforcer. Despite the fact that individuals frequently experience attention in conjunction with other forms of reinforcers, this natural pairing may not be enough to condition many forms of attention as a reinforcer. Therefore, systematic conditioning procedures may be needed to condition attention as a reinforcer. Researchers have used various methods to try and establish social stimuli as reinforcers including stimulus pairing procedures (see Chap. 10), observation procedures (Leaf et al., 2015), and establishing social stimuli as discriminative stimuli (Lovaas et al., 1966; Rodriguez & Gutierrez, 2017).

Although attention is ubiquitous in everyday life, training is often needed on delivering attention effectively (Hall et al., 1968). It's easy to deliver tangible reinforcers in a standardized way. However, attention is not always delivered in the same standardized manner across individuals. It's not uncommon for individuals to use different facial expressions, verbal expressions, or physical contact to express approval. There are also different factors that may influence the use of attention as a reinforcer (e.g., immediacy, magnitude, schedule, motivating operations, content, quality), and individuals may need to be trained to account for these factors. In addition, researchers have found that attention is often delivered following inappropriate behavior (e.g., McKerchar & Thompson, 2004). Telling an educator or caregiver to deliver more attention for appropriate behavior and less attention for inappropriate behavior sounds easy enough. However, merely telling an individual to do something is not likely to result in a change in their behavior for very long. Several researchers have shown that teachers are likely to deliver more disapproving remarks for inappropriate behavior as compared to approving remarks for appropriate behavior (Nafpaktitis et al., 1985; Strain et al., 1983; Thomas et al., 1978; White, 1975). Therefore, teachers and other professionals will likely need to be trained (e.g., instructions, modeling, rehearsal, feedback) on how to deliver attention for appropriate behavior, and they may need to see and experience the success of contingent attention for increasing appropriate behavior.

Social Reinforcers for Appropriate Adaptive Behavior

Since the conception of the field, applied behavior analysis has addressed the influence of social reinforcers, such as attention, within motivational and instructional domains with respect to critical skills across the lifespan. Social reinforcers can play a vital role in the development and maintenance of appropriate adaptive behavior across populations and environments. Verbal and nonverbal forms of attention have been used to increase a wide variety of adaptive behavior within a variety of skill domains such as on-task behavior (e.g., Allday & Pakurar, 2007), self-help skills (e.g., Poche et al., 1982), communication (e.g., Novak & Pelaez, 2004), contextually appropriate vocalizations (e.g., Wilder et al., 2001), early motor skills (e.g., Correa et al., 1984), outdoor play skills (e.g., Johnston et al., 1966), peer interaction (e.g., Allen et al., 1964), physical activity (e.g., Zerger et al., 2016), and many others.

The Use of Social Reinforcers to Facilitate Critical Skills

In a series of papers on social positive reinforcement, researchers at the University of Washington, led by Montrose Wolf, demonstrated that positive reinforcement, in the form of attention, plays a prominent role in early childhood development (e.g., Allen et al., 1964; Harris et al., 1964; Hart et al., 1964; Johnston et al., 1966). These researchers showed that adult attention could be used to increase verbal skills (Hart et al., 1964), social skills (Allen et al., 1964), and gross motor skills (Harris et al., 1964; Johnston et al., 1966) in young children. The findings of these seminal studies showing the reinforcing efficacy of adult attention for increasing the behavior of young children are thought to be influential in common caregiver and teacher training procedures on how to interact with young children (Risley, 2005). Adult attention is used to help children learn what behaviors are deemed socially appropriate or socially inappropriate and to shape a wide range of appropriate behaviors in early childhood (e.g., verbal behavior, social behavior, leisure skills, and academic and classroom behavior). As we age, attention remains a primary component in most environments that may help to shape new behaviors, refine old behaviors, and maintain adaptive behaviors across our lifespan.

Vocalizations and Verbal Behavior One type of behavior that is uniquely human and, perhaps, particularly sensitive to social reinforcers is complex verbal behavior. Skinner (1957) defined verbal behavior as "behavior reinforced through the mediations of other persons" (p. 2). That is, the behavior of the speaker is effective through the mediation of the listener. From infancy, approximations to verbal behavior are followed by attention. For example, caregivers often deliver vocal attention following infant babbling (e.g., mama, dada), which may shape and reinforce the behavior over time (e.g., Spitz, 1949). Numerous studies have demonstrated that early vocal-verbal behavior can be shaped and reinforced by attention (e.g., Neimy et al., 2020; Pelaez et al., 2011; Pelaez et al., 2018; Poulson, 1983; Reynolds & Risley, 1968; Rheingold, 1956; Rheingold et al., 1959; Routh, 1969; Thompson et al., 2007; Weisberg, 1963).

In addition to shaping verbal behavior, receiving high-quality verbal attention starting in infancy has been correlated with increased verbal repertoires (Hart & Risley, 1995). Hart and Risley (1995) conducted one of the first longitudinal studies examining language development in young children. The study included 42 young children from three different socioeconomic statuses ([SES] i.e., high SES, middle SES, and low SES). The children were observed, and a one-hour audiotape recording was collected once per month for 2.5 years. The authors found that adult verbal attention was provided to the children when they were in their infancy an average of 28 min per hour sample. However, the number of words spoken by the parents to the children differed based on socioeconomic backgrounds. The children in families with a high SES received higher quality attention (larger vocabulary and more affirmations), followed by the children in the families with a middle SES, and then the children from families with a low SES. In the end, the children from the families with a high SES exhibited a much larger number of words in their vocabulary as compared to the other two groups, and the children from families with a low SES exhibited the smallest vocabulary. As children age, more complex verbal behavior is shaped by the attention they receive in their environment. Skinner (1957) suggested that attention helps to establish basic verbal operants, which are classes of verbal behavior that have the same effect on the listener (e.g., echoics, tacts, intraverbals), and several studies have shown that the delivery of attention in combination with various prompting procedures is effective for increasing echoics (Poulson et al., 1991), tacts (Braam & Sundberg, 1991; Partington & Bailey, 1993; Sigafoos et al., 1990), and intraverbals (Sundberg et al., 1990).

For example, Poulson et al. (1991) evaluated the use of parental modeling and praise on increasing the echoic behavior of three infants aged 9–13 months. The parents were told to present a vocal model of the desired word during all conditions. During the model-alone condition, the parents did not deliver praise following infant vocalizations. During the model-and-praise condition, the parents provided praise when the infants imitated their vocal model on training trials. All of the infants increased their echoic behavior when praise was provided for imitating the model.

It is clear that attention is important for the acquisition of vocal-verbal behavior such that we can be effective speakers and others can be effective listeners. However, it remains unclear what the necessary and sufficient conditions are for the acquisition of verbal operants with delivery of attention. Research involving naturalistic observations might be able to provide some information regarding these conditions. For example, researchers might conduct naturalistic observations to determine (a) the correlation between the type of attention (e.g., content of attention and quality of attention) and the occurrence and acquisition of particular verbal operants, (b) the contingency and contiguity between the delivery of attention and the occurrence of verbal operants, and (c) the schedules of reinforcement that are associated with increased acquisition and maintenance of verbal operants. Outcomes of these naturalistic observations could provide information regarding the variables to empirically evaluate in more controlled studies to determine the optimal aspects of attention for increasing and maintaining verbal operants. In addition, most researchers use attention in combination with other social reinforcers (delivery of edible and tangible items) and with prompting procedures when teaching verbal behavior. When the delivery of attention is combined with other procedures, the reinforcing efficacy of attention alone is unknown. To determine the role of attention alone in the acquisition of verbal behavior, attention would need to be evaluated as a stand-alone treatment.

Social Behavior Skinner (1953) defined social behavior as "the behavior of two or more people with respect to one another or in concert with respect to a common environment" (p. 297). Social behavior is behavior that is strengthened or weakened by the behavior of others (Novak & Pelaez, 2004). Social behaviors that are prominent in early development include, but are not limited to, initiating and terminating interactions, taking turns, making eye contact, sharing, playing with others, cooperating with others, and displaying social safety skills (e.g., not interacting with strangers, seeking help, reporting problems to adults). Attention plays a role in the development of early social behavior (Novak & Pelaez, 2004), and attention continues to play a role in our social behavior throughout our lifetime. Attention has been shown to play a role in verbal interaction (Emshoff et al., 1976; Milby, 1970), peer interaction (Allen et al., 1964; Barton & Ascione, 1979; Pinkston et al., 1973; Strain & Timm, 1974), and even facial expressions (Brackbill, 1958; Cooke & Apolloni, 1976).

For example, Pinkston et al. (1973) increased peer interaction and decreased aggression for a 3.5-year-old boy through the use of contingent teacher attention and extinction in a preschool classroom. During the intervention, teachers were instructed to deliver attention to the student when he engaged in appropriate behavior and not to respond to aggression except to physically separate the participant from his peer and console the peer. This intervention was effective for increasing appropriate social behavior and decreasing aggression with this participant. However, it is unclear which component (i.e., attention or extinction) of the intervention made it effective. To determine the effectiveness of attention for the acquisition of social behavior in young children, attention would need to be evaluated as a stand-alone treatment. In some instances, it might be the case that attention is not an effective reinforcer for increasing appropriate social behavior.

Insensitivity to social cues and social reinforcers can have detrimental effects on the development of social behavior (Bijou & Baer, 1961). This situation is often reported with children diagnosed with autism spectrum disorders (ASD) who often show both social deficits and behavioral insensitivity to attention (Dawson et al., 2012). One of the defining characteristics of ASD is impaired social skills, which can include failure to make eye contact, failure to initiate conversations, failure to respond to bids for social interaction, and failure to maintain social interactions (Hyman & Towbin, 2007). When the attention that occurs in the natural environment is ineffective in the shaping and maintenance of social skills, then other forms of reinforcement will be required to teach these important skills.

Leisure Skills and Activities Acquiring leisure skills and the ability to appropriately engage in activities is important for improving quality of life throughout our lifetime. In addition, with the acquisition of these skills, there is potential for increased social interaction. Several studies have used attention alone or in conjunction with other reinforcers or instructional procedures (e.g., prompting and modeling) to increase appropriate leisure skills such as activity engagement (e.g., DiCarlo & Reid, 2004; Duffy & Nietupski, 1985; Whitman et al., 1970), motor play on outside play equipment (Buell et al., 1968; Hardiman et al., 1975; Harris et al., 1964; Johnston et al., 1966), physical activity (Anderson & Kirkpatrick, 2002; Larson et al., 2014; Vintere et al., 2004; Zerger et al., 2016), pretend toy play (DiCarlo & Reid, 2004), and solitary play (Shafto & Sulzbacher, 1977).

Relatively few studies have shown the isolated effects of attention for increasing leisure skills. In an early study, Johnston et al. (1966) showed that the contingent delivery of attention (i.e., proximity; speaking to, smiling at, and touching the child) resulted in an increase in levels of appropriate motor activity on outside play equipment. More recently, Larson et al. (2014) and Zerger et al. (2016) showed that physical activity could be increased through the use of adult attention and interactive play. However, most studies have shown that the delivery of attention in conjunction with other intervention procedures resulted in an increase in leisure activities.

DiCarlo and Reid (2004) showed that pretend toy play increased for five toddlers, who were diagnosed with various disabilities, when praise, choice of classroom center, and prompting were implemented. In another study, Whitman et al. (1970) increased social play (i.e., ball-rolling and a block-placement response) when praise and edibles were delivered on increasing fixed-ratio (FR) schedules. In addition, Buell et al. (1968) increased play on outside motor equipment using the delivery of teacher attention and a priming procedure. Priming included telling the participant to engage in the activity (e.g., “Show me how you play on the ___”). Similarly, Hardiman et al. (1975) evaluated the effects of praise, priming, and training sessions to increase outside motor play skills. Results indicated that all three components together were necessary for appropriately engaging in the motor response for each different activity.

In addition to appropriate motor and social play, several studies have involved increasing interesting leisure skills. Anderson and Kirkpatrick (2002) used a treatment package that included contingent praise, visual feedback of performance, and instructions for improving performance of inline roller speed skaters. The experimenters found that the treatment package was effective at increasing the percentage of correct responses during skating practice. Duffy and Nietupski (1985) showed that a young adult diagnosed with Down syndrome could be taught to initiate, sustain, and terminate video game play. Effective procedures used in this study were a combination of praise, modeling task analysis steps, and physical prompting. Finally, Shafto and Sulzbacher (1977) showed that praise and edibles were effective at reducing activity changes (i.e., short durations spent with a single activity and rapid switching among many different activities) and increasing engagement in a single activity.

Academic and Classroom Behavior Teachers and other professionals are trained to use various social reinforcers to increase appropriate classroom behavior. Many teacher-delivered social reinforcers involve the delivery of different forms of attention and several studies have focused on increasing academic behavior by delivering contingent attention and antecedent attention. Researchers have shown that attention alone is effective for increasing preacademic behavior, academic behavior, and appropriate classroom behavior (e.g., Allday & Pakurar, 2007; Baer & Sherman, 1964; Broden et al., 1970; Hancock, 2002; Schutte & Hopkins, 1970).

For example, Schutte and Hopkins (1970) showed that praise and physical attention could be used to increase the preacademic behavior of instruction following with five girls in a kindergarten classroom. During the baseline conditions, all of the girls were observed to follow teacher instruction approximately 60–69% of the time. When the teachers were taught to deliver praise and physical attention contingent on instruction following, then instruction following increased to approximately 78–84% of the time during the treatment conditions.

Allday and Pakurar (2007) demonstrated that something as simple as teacher greetings could be used to increase the on-task behavior of three middle-school students who engaged in maladaptive behavior. In this study, the researchers instructed the students' teachers to greet the students upon their arrival by saying the student's name and a positive statement (e.g., Kay, you look nice today!). During the baseline condition, the students were observed to start the day on-task during a mean of 37–52% of intervals. When the teachers were taught to greet the students upon their arrival, the students began to start the day on-task during a mean of 66–87% of the intervals. This simple antecedent attention procedure produced an increase in on-task behavior for all three students.

Given that it is commonplace to train teachers and other professionals to use various forms of attention for increasing appropriate classroom behavior, it is important to mention the research on the influence of approval and disapproval rates in classrooms. Several early evaluations on the occurrence of teacher delivery of approval and disapproval have found that there was more disapproval delivered by teachers for inappropriate behavior as compared to approval for appropriate behavior (e.g., Nafpaktitis et al., 1985; Rutter et al., 1979; Strain et al., 1983; Thomas et al., 1978; White, 1975). For example, Thomas et al. (1978) showed that seven out of 10 teachers displayed disapproval rates at least three times greater than their approval rates. In addition, some studies have investigated the effect of approval and disapproval on the classroom behavior of children. Thomas et al. (1968) evaluated the effects of approval and disapproval in varying amounts to demonstrate how these rates influenced child behavior. The experimenters showed that when the delivery of approval for appropriate behaviors was removed (i.e., only disapproval was used), students engaged in significantly lower levels of appropriate behavior and higher levels of disruptive behavior. Moreover, when teachers provided frequent disapproval (twice as much disapproval as compared to previous disapproval phases), similar results were found. In another study, Cossairt et al. (1973) provided instructions, feedback, and feedback plus praise to increase teacher praise for student attending behavior. In all phases of the intervention, when the percentage of intervals with teacher praise increased, the percentage of student attending increased. Overall, these data suggest that increases in approval and a decrease in disapproval in the classroom may result in an increase in appropriate behaviors and a decrease in inappropriate behaviors in the classroom; however, it is unknown what about approval is necessary and sufficient to change important behavior.

In summary, the research on the effects of attention for increasing appropriate behavior suggests several important things. First, most of this research was conducted over 40 years ago, and less research has been recently conducted on the utility of attention for increasing appropriate behavior. Second, the majority of studies on attention for increasing appropriate behavior involve several topographies of attention (e.g., praise, conversation, and physical contact) or the delivery of attention as part of a treatment package. Therefore, it is difficult to determine the effects of single forms of attention and the efficacy of attention alone for behavior change. As suggested by Wacker et al. (1988), this lack of knowledge is likely to interfere with the effectiveness with which we can use attention in acquisition and maintenance programs. Third, the small number of studies that involve determining the effects of attention alone raises questions regarding the utility of attention as a reinforcer for increasing and maintaining appropriate behavior.

There are several possible reasons why fewer studies have been conducted recently on the efficacy of attention and why few researchers have isolated the effects of attention for increasing and maintaining appropriate behavior. First, attention alone may not be an effective reinforcer for the population of individuals for whom behavioral research is mostly published (i.e., individuals with intellectual and developmental disabilities).

Second, attention may be an important component of a treatment package, but may not be a potent reinforcer in isolation. Third, it is possible that attention is already widely assumed to be a reinforcer, and therefore, little research has been conducted to validate this assumption.

Social Reinforcers for Maladaptive Behavior

Most recent research on attention as a reinforcer is in assessment and treatment of behavior disorders, particularly with individuals with intellectual and developmental disabilities. In several large-scale studies, outcomes of indirect assessments (e.g., Maurice & Trudel, 1982) and descriptive assessments (e.g., Lerman & Iwata, 1993; McKerchar & Thompson, 2004; Thompson & Iwata, 2001) have suggested that attention is a common consequence following the occurrence of maladaptive behavior. Furthermore, functional analysis research has suggested that a relatively high percentage of published functional analyses have shown some form of attention as the maintaining variable (Beavers et al., 2013; Hanley et al., 2003; Kurtz et al., 2003). Beavers et al. (2013) compiled data from functional analysis outcomes across all functional analysis cases that were published in behavioral journals through the year 2012. Results showed that social positive reinforcement was the function of problem behavior for 29.2% of the published cases with 17.2% showing maintenance by access to attention only. Overall, functional analysis research has shown that various maladaptive behavior may be maintained by contingent attention including self-injurious behavior (SIB; Lovaas & Simmons, 1969; Iwata et al., 1982/1994), physical aggression (Roscoe et al., 2010), and bizarre vocalizations (DeLeon et al., 2003; Wilder et al., 2001).

If functional analysis results suggest that problem behavior is maintained by social positive reinforcement in the form of attention, various function-based interventions may be developed, which include (a) eliminating access to attention (i.e., extinction), (b) providing access to attention on a time-based schedule (i.e., noncontingent reinforcement [NCR]), (c) providing attention contingent upon an alternative behavior (differential reinforcement of alternative behavior [DRA]), or (d) implementing negative punishment procedures (e.g., time-out) to decrease the occurrence of the maladaptive behavior (Greer & Fisher, 2017; Hagopian et al., 2013b; Iwata et al., 1993). It is important to note that extinction is often used in combination with reinforcement-based procedures such as NCR and DRA for treating attention-maintained maladaptive behavior because (a) it often increases the efficacy of those interventions (Greer & Fisher, 2017; Hagopian et al., 1998; Hagopian et al., 2013a, b) when combined with reinforcement-based procedures, it is less likely to be associated with various side effects (e.g., response bursts, emotional responding, extinction-induced aggression; Lerman et al., 1999).

One type of DRA procedure, functional communication training (FCT), is a highly effective procedure for decreasing maladaptive behavior maintained by attention (Greer & Fisher, 2017; Tiger et al., 2008). FCT involves teaching a form of communication (vocal, sign, picture card) to recruit attention from others and, as mentioned, is often more effective when implemented in combination with extinction or time-out for maladaptive behavior. Furthermore, FCT is often the treatment of choice for attention-maintained maladaptive behavior because the individual (a) is taught a behavior for which they can prompt others to deliver attention, (b) can control when and how much attention they receive, and (c) it is often preferred by the individual over other interventions (Greer & Fisher, 2017; Hanley et al., 1997).

In summary, functional analysis methodology and function-based interventions have been effective in reducing the occurrence of maladaptive behavior maintained by attention, and some common interventions (e.g., FCT) also involve procedures to increase the occurrence of appropriate behavior to access attention. These function-based interventions have resulted in an increase in the efficacy of behavioral interventions to address attention-maintained maladaptive behavior and resulted in a reduction of reliance of intrusive punishment procedures for behavior change. Furthermore, recent research has suggested functional analyses are useful in isolating the specific aspects or parameters of attention (e.g., form, magnitude, and schedule of attention) on the occurrence of maladaptive behavior, which provides us some insight on how these variables influence the efficacy of attention.

Form of Social Reinforcers

Although various studies, review papers, and position papers suggest the utility of attention in the modification of human behavior, we know little about the conditions under which it functions as a reinforcer. Thus, a more in-depth study is needed on the various characteristics of and factors influencing the efficacy of attention. The largest area of research on characteristics of attention that influence its efficacy as a reinforcer is the form (i.e., type, content, and quality) of attention delivery. That is, because of different individuals' conditioning history, it is highly unlikely that all behavior for an individual occurs to access all forms of attention (Brophy, 1981; Fisher et al., 1996a; Harper et al., 2021). For example, a nod may function as a reinforcer for some behavior displayed by one individual, and only vocal-verbal attention that involves a certain quality may function as a reinforcer for another behavior displayed by another individual. Thus, it is important to determine the influence of the form of attention for particular individuals and behaviors in various contexts. Research in this area has included determination of forms of attention for increasing various behavior, as well as research in functional assessment and function-based treatment of maladaptive behavior. Both areas of research provide pertinent information for increasing our knowledge of ways to determine specific forms of attention that may influence behavior.

Type of Attention

Most research on the use of attention as a reinforcer has involved a combination of several types of attention including vocal-verbal attention (e.g., praise, conversation), physical attention (e.g., hugs and high fives), and facial expressions (e.g., smiles and winks). Until recently, little was known about the reinforcing efficacy of specific types of attention. A few exceptions include earlier studies such as Kazdin and Klock (1973) who showed that an increase in delivery of nonvocal attention (i.e., smiling, patting, touching) by a classroom teacher resulted in an increase in student attentive behavior for 11 out of 12 students with IDD. In addition, multiple studies have shown that various forms of physical attention (e.g., pats on the back and hand holding) used in isolation may function as a reinforcer, and a combination of physical (e.g., pats on the back and hand holding) and vocal-verbal attention may be more powerful than either type of attention alone (e.g., Clements & Tracy, 1977; Wheldall et al., 1986).

Recently, researchers have focused on the use of systematic preference and reinforcer assessment methodology to determine preferred types of attention, particularly for children with ASD and individuals with IDD (e.g., Clay et al., 2013; Clay et al., 2018; Kelly et al., 2014; Lang et al., 2014; Morris & Vollmer, 2019, 2020; Nuernberger et al., 2012; Smaby et al., 2007). For example, Kelly et al. (2014) conducted a paired stimulus preference assessment with different picture cards depicting seven different types of attention (e.g., singing, hugs, high-fives, praise) to determine high and low preferred types of attention for five children with ASD. Next, they validated the preference assessment by showing that participants engaged in higher levels of mands to access high preferred types of attention as compared to low preferred types of attention. In a series of studies, Morris & Vollmer (2019, 2020) showed the efficacy of the Social Interaction Preference Assessment (SIPA) for determining preferred types of attention that function as reinforcers. The SIPA is similar to a multiple stimulus without replacement preference assessment

(MSWO; DeLeon & Iwata, 1996) in which pictures that represent the different types of attention are presented in an array from which the participant chooses. However, to allow for determination of a hierarchy of preference, the SIPA involves restriction of access to high preferred types of attention in subsequent MSWO trials. Results of these studies showed the SIPA is a valid procedure for determining individual attention reinforcers for children with ASD. Specifically, reinforcer assessments suggested that high preferred types of attention generally resulted in higher levels of responding as compared to low preferred types of attention. Furthermore, the researchers showed that attention alone can function as reinforcement for increasing behavior in children with ASD.

Although researchers have shown the utility of various preference assessment methods for determining preferred types of attention that function as reinforcers for children with ASD and IDD, little research has been conducted with other populations (e.g., typically developing children, adults with IDD). Furthermore, reinforcer assessments that have validated the outcomes of preference assessments have involved low schedule requirements and simple tasks. Harper et al. (2021) showed that a concurrent-operant preference assessment was effective for determining high preferred types of attention for a large number of typically developing preschool children. The types of attention included were common types of attention delivered in preschool classrooms (i.e., praise, physical attention, conversation). Specific results suggested that either conversation or physical attention was most preferred for most children; few children allocated responding for praise in the preference assessment. Results of a single-operant reinforcer assessment validated the outcomes of their preference assessment (i.e., most participants responding at high levels for at least one type of attention that was preferred in the preference assessment) when the response requirement was an FR 1 schedule. Next, when they increased the response requirement in the reinforcer assessment by using a progressive-ratio (PR) schedule, similar but less robust results were found.

Functional analysis research has also suggested that different types of attention may differentially influence the occurrence of maladaptive behavior (e.g., Britton et al., 2000; Kodak et al., 2007; LeBlanc et al., 2001; Piazza et al., 1999; Richman & Hagopian, 1999; Roscoe et al., 2010). For example, Richman and Hagopian (1999) conducted a functional analysis in which inconclusive results were found. Because destructive behavior was suspected to be maintained by other forms of attention (i.e., physical assistance, picking up, and holding), physical attention was included in the attention condition of the functional analysis, resulting in higher levels of destructive behavior. A treatment package in which physical attention was delivered on a noncontingent schedule and destructive behavior was placed on extinction was effective at reducing destructive behavior.

Kodak et al. (2007) evaluated the effects of different types of attention on the attention-maintained maladaptive behavior of two children (one participant was diagnosed with ADHD and the other with PDD-NOS). Initial functional analysis results showed that problem behavior of the participants was maintained by attention. Next, an attention assessment was conducted to determine the influence of several common types of attention (i.e., reprimands, unrelated comments, tickles, eye contact, praise, and hands-down procedure) on levels of problem behavior. The researchers showed that one participant engaged in higher levels of problem behavior to access reprimands and tickles, whereas the other participant engaged in higher levels of problem behavior when reprimands and unrelated comments were delivered. Thus, results demonstrated that different forms of attention differentially affected problem behavior for particular individuals.

Content of Vocal-Verbal Attention

The content of vocal-verbal attention (i.e., what is said) has been shown to influence both the occurrence of appropriate behavior and maladaptive behavior. For example, recommendations for the use of descriptive praise (i.e., praise that specifies the behavior being praised) over general praise have prompted researchers to compare the two praise types (Chalk & Bizo, 2004; Polick et al., 2012; Senn et al., 2020). Authors of these studies have suggested negligible differences between these two types of praise; however, Senn et al. (2020) suggested descriptive praise may be more preferred by some individuals. In a recent study, Clay et al. (2020) evaluated preference for and reinforcer efficacy of praise delivered in English versus Spanish for bilingual students. Although the researchers suggested no differential preference or reinforcing efficacy for the language in which praise was delivered, this methodology might be useful in working with English Language Learners (ELL) and bilingual students.

Several studies have shown that content of vocal-verbal attention may influence the efficacy of attention for maintaining maladaptive behavior (e.g., DeLeon et al., 2003; Fisher et al., 1996a; Hagopian et al., 2000; Roscoe et al., 2010). For example, Fisher et al. (1996a) compared the effects of a verbal reprimand related to maladaptive behavior (e.g., "don't hit me") versus a statement unrelated to the maladaptive behavior (e.g., "it's sunny today") for occurrence of maladaptive behavior of a 4-year-old boy. Other characteristics of attention such as facial expression and voice intonation were the same across conditions. The researchers showed that maladaptive behavior occurred at higher levels in the verbal reprimand condition. Similarly, Roscoe et al. (2010) showed that shorter latencies to physical aggression were displayed by a 13-year-old girl with ASD when the behavior resulted in high-preferred conversation topics as compared to low-preferred conversation topics. Treatment involved functional communication training (FCT) in which the participant was taught to hand over a card to receive access to high-preferred conversation and physical aggression was on extinction.

Quality of Attention

In addition to type of attention and content of vocal-verbal attention, other qualities of attention (e.g., voice intonation, posture; Blaze et al., 2014; Gardner et al., 2009; Gilboa & Greenbaum, 1978; Richman & Hagopian, 1999; Weyman & Sy, 2018) may influence the efficacy of attention as a reinforcer. For example, Richman and Hagopian (1999) showed voice intonation may influence the degree to which attention functions as a reinforcer for maladaptive behavior. The experimenters included two attention conditions in a functional analysis of maladaptive behavior displayed by a 6-year-old boy. During one attention condition, a reprimand was delivered using a "normal" voice intonation; in the other, a reprimand was delivered using an "exaggerated" voice intonation (i.e., raised voice and physical signs of displeasure). Higher levels of maladaptive behavior occurred in the exaggerated attention condition. Gardner et al. (2009) showed problem behavior by two participants was more likely to occur to escape demands when low-quality attention was provided (i.e., infrequent eye contact, no physical contact, distant physical proximity, negative verbal statements, and a flat monotone voice) as compared to when high-quality attention was provided (i.e., frequent eye contact, physical contact, close proximity, enthusiastic praise). In an additional evaluation, both participants allocated more responding to access play or demand contexts in which the high-quality attention was delivered as compared to the low-quality attention in a concurrent-operants arrangement.

Gilboa and Greenbaum (1978) evaluated the influence of "warm" nonvocal attention and "cold" nonvocal attention on correct responding by a large number of 3rd graders. These different qualities of attention were delivered noncontingently during a session along with vocal-verbal statements (i.e., "correct" or "nice") for correct responding. Aggregate data for all participants showed that higher levels of correct responding occurred when "warm" nonvocal attention was delivered than "cold" nonvocal attention. More recently, Blaze et al. (2014) showed that both loud and quiet praise deliveries were effective for increasing on-task behavior in four high school classrooms. These results suggest that teachers may consider the conditions under which each is most appropriately used.

In summary, recent research has suggested the use of modified functional analysis methodology to determine the influence of specific types of attention on the occurrence of problem behavior. Furthermore, researchers have suggested various options in using preference and reinforcer assessment methodology for determining types of attention that are likely to be most preferred and reinforcing for particular individuals. However, more research is needed on the most efficient and effective methodologies to determine these types of reinforcers. Furthermore, additional research to determine whether these types of attention function as reinforcers under conditions of increased work requirements or acquisition tasks is needed. Finally, additional research on the relation between attention type and other factors discussed below (e.g., duration, schedule) may provide some insight into the conditions under which attention is most likely to be an effective reinforcer. Also, additional research determining the extent to which changing various aspects of the "quality" of attention (or a particular type of attention) may be valuable. For example, if there is a change in voice intonation, nonvocal behavior, or content of what is said, then manipulations can be made to typical types of attention (e.g., praise) such that those types of attention may become more potent reinforcers.

Other Factors that Influence the Effectiveness of Social Reinforcers

In addition to the form of attention, other factors may influence the effectiveness of attention as a reinforcer. However, it is important to note that much of this research has been in the area of assessment and treatment of maladaptive behavior, which is briefly discussed in this section as well as more extensively in various other chapters in this book. In this section, we provide an overview of some of these factors, which include (a) magnitude of attention, (b) immediacy of attention delivery, (c) schedule of attention delivery, (d) motivating operations, and (e) conditioning history.

Magnitude of Attention Delivery

Few applied studies have evaluated the influence of magnitude (duration) on reinforcer efficacy (Lerman et al., 2002), particularly on the efficacy of attention as a reinforcer. Most research on magnitude of reinforcement has been conducted in assessment and treatment of problem behavior, and results of these studies have been conflicting. In studies conducted by Fisher et al. (1996b) and Volkert et al. (2005) on the effects of different reinforcer durations in the context of functional analyses, results of both studies suggested that longer durations of reinforcer access resulted in lower levels of problem behavior as compared to shorter durations of reinforcer access. However, reinforcer access time was not subtracted from overall session time in these studies, which may have influenced the results. Trosclair-Lasserre et al. (2008) evaluated the relation among reinforcer magnitude, preference, and reinforcer efficacy with three children with autism spectrum disorders whose problem behavior was maintained by social positive reinforcement (i.e., tangibles or attention). The experimenters conducted a magnitude preference assessment to determine preference for a large or small magnitude of the reinforcer. Following this assessment, a magnitude reinforcer assessment was conducted to determine the reinforcing efficacy of each magnitude value under progressive-ratio schedules. Overall, results showed that preference for different magnitudes of reinforcers may predict the efficacy of these reinforcers and magnitude effects may be influenced by the schedule requirement.

In summary, researchers suggest that the duration of attention may influence the efficacy of attention as a reinforcer. However, research to date suggests that longer durations of attention may be useful for reduction of maladaptive behavior, whereas shorter durations of attention may be more effective for increasing appropriate behavior. That is, longer durations of attention may result in a satiation effect resulting in a decrease in the occurrence of behavior to access that reinforcer, whereas shorter durations of attention result in the continuation of the relevant establishing operation resulting in a possible increase or continuation of appropriate behavior to access attention. However, it is likely that the degree to which magnitude influences the efficacy of attention is interrelated with other factors such as the quality or form of attention (e.g., conversation may be more reinforcing for longer durations than praise) or the schedule of attention delivery such as shown in Trosclair-Lasserre et al. (2008). In fact, research using other positive reinforcers has suggested that longer durations of access to stimuli such as leisure items or toys may be more preferred and/or effective based on the quality or type of reinforcer (Steinhilber & Johnson, 2007) and the schedule of reinforcement (e.g., DeLeon et al., 2014). Additional research is needed to determine the influence of magnitude on the reinforcing efficacy of attention, particularly with respect to certain forms of attention, various schedules of reinforcement, and the type of task (e.g., acquisition vs. maintenance task).

Immediacy of Attention Delivery

Both basic and applied research studies have suggested that delays to reinforcement can influence responding. Specifically, recommendations suggest reinforcement be provided immediately to increase and maintain responding (Sy & Vollmer, 2013); however, there are various situations that do not allow for immediate reinforcement. Little research has evaluated the influence of delays to reinforcement on skill acquisition (Majdalany et al., 2016; Sy & Vollmer, 2013). Of the studies that have been conducted, most have used stimuli other than attention or a combination of attention and other reinforcers (e.g., edibles, preferred toy). For example, Sy and Vollmer (2013) conducted a multi-experiment study comparing the influence of immediate reinforcement and various delays to reinforcement (praise and small edible or 30-s access to preferred toy; up to 40-s delays) on conditional discrimination skills in children with IDD. Overall, results showed that immediate reinforcement was more effective than delayed reinforcement for some participants; however, for others short delays did not interfere with acquisition. Similar results were found by Majdalany et al. (2016) with short delays (up to 12 s) in teaching tacts to three children with autism spectrum disorders. Finally, only a few studies have focused on immediacy of attention delivery. For example, Ramey and Ourth (1971) and Millar and Watson (1979) investigated the delay in caregiver attention following the occurrence of infant vocalizations. The infant's rate of vocalizations occurred at the highest levels when attention was delivered immediately, whereas lower levels of vocalizations occurred under the 3-s, 6-s, or 10-s delays.

Because delays to delivery of attention may decrease its reinforcing value, it is important to determine procedures that allow for a delay in attention delivery. These procedures might include delay fading and various mediating variables such as rules or instructions, signals, delivery of conditioned reinforcers (e.g., tokens), and the availability of intervening activities. Most research evaluating procedures that allow for delays to attention delivery are in the assessment and treatment of problem behavior (i.e., during fading of reinforcer delivery during FCT interventions). Overall, research has suggested that delay fading (i.e., gradually increasing the period of time between a response and the delivery of attention) alone has not been very effective (e.g., Hagopian et al., 1998; Hanley et al., 2001) for maintaining behavior under delayed reinforcement. However, some studies have shown that providing an activity during the delay with or without delay fading may be effective (Austin & Tiger, 2015; Hagopian et al., 2005). For example, Hagopian et al. (2005) showed that providing access to preferred tangible items during delay fading was effective for maintaining appropriate communication responses to access the functional reinforcer (e.g., attention or tangibles) during FCT. However, the degree to which contingencies for engaging in the intervening task or activity are necessary for efficacy of task/activity provision during delay periods is open to question (see Ghaemmaghami et al., 2016 for preliminary information). A notable limitation of these studies is that delay periods were 5- to 10-min in duration; thus, it is unknown whether similar procedures would be effective during longer delays.

Most research focusing on procedures to maintain responding under delays has been conducted with other reinforcers such as preferred tangibles and edibles. For example, Vollmer et al. (1999) showed that the use of a signal (e.g., countdown timer) was effective for maintaining high levels of appropriate requests and low levels of problem behavior during delays to access edibles. Furthermore, studies have shown that providing access to various activities including work tasks (e.g., Dixon & Cummings, 2001) and high-preferred activities (Newquist et al., 2012) may be an option for maintaining responding to access delayed attention. Finally, it is possible that providing a rule or instruction regarding the delay may be effective for some individuals. For example, Hanley et al. (2007) showed that teaching young children to repeat a rule (i.e., "When I wait, I get what I want") was effective for maintaining appropriate requests and decreasing problem behavior associated with accessing preferred items and activities. Additional research evaluating the procedures that are most effective for increasing delays to the delivery of attention for maintenance and acquisition of appropriate behavior is needed. Furthermore, determining procedures for teaching individuals to seek out other reinforcers or preferred activities during delays to reinforcement might be particularly useful for delay to attention periods in various contexts and environments such as during times when caregivers are busy at home or in preschool classrooms when the teacher is busy interacting with other children or engaged in other tasks.

Schedule of Attention Delivery

Basic and applied research has shown that responding may maintain under both dense and lean schedules of reinforcement; however, few studies have evaluated the influence of the schedule of reinforcement on the efficacy of attention for increasing and maintaining appropriate behavior. One exception is a study by Gable and Shores (1980) showing the rate of oral reading was higher under intermittent as compared to continuous attention schedules. Specifically, the researchers showed that praise delivered on escalating variable-ratio (VR) schedules (i.e., escalating from VR5 to VR15) in which response requirements were increased within or across sessions was more effective at increasing oral reading rates than a VR5 schedule. Furthermore, Brackbill (1958) showed the schedule of attention delivery affected patterns of responding under later conditions of extinction or deprivation from attention. Overall, results showed that infants who were previously exposed to an intermittent schedule of attention smiled at higher rates under extinction as compared to infants who were exposed to a continuous reinforcement schedule of attention. These outcomes are in line with research showing that behavior is more likely to be resistant to extinction when it has been intermittently reinforced (Kazdin & Polster, 1973).

Given that higher levels of appropriate behavior may be maintained under intermittent reinforcement schedules and the fact that it is often difficult to deliver reinforcement on dense schedules in the everyday environment, it is important to determine ways in which the schedule of attention delivery can be thinned while maintaining the occurrence of appropriate behavior. Determining effective schedule thinning procedures has been a focus of research on assessment and treatment of maladaptive behavior, particularly in the application of FCT (Greer et al., 2016; Hagopian et al., 2011) given that schedule thinning is associated with weakening in the contingency between the appropriate communication response and the functional reinforcer. This contingency weakening may result in the reemergence of the maladaptive behavior and a decrease in the occurrence of the functional communication response.

A common schedule thinning procedure for FCT involves the use of a multiple schedule in which distinctive stimuli (e.g., colored cards, different color leis) signal the availability and unavailability of attention for engaging in an appropriate response (e.g., asking for attention; Hanley et al., 2001; Tiger & Hanley, 2004; Tiger et al., 2013). For example, Tiger and Hanley (2004) used different colored floral leis to signal (a) the availability of attention delivery by the teacher for the target child, (b) the unavailability of attention for the target child but the availability of attention for another child, and (c) the unavailability of attention for either child. All three children displayed high levels of requesting attention when the signal was present for availability of attention for that child and low levels of requesting when the other signals were present. In a later study, Tiger et al. (2013) showed that a distinctive stimulus for extinction periods may not be necessary for discriminated responding under reinforcement and extinction periods. Furthermore, research has suggested that discriminated responding based on periods of attention availability and unavailability may be established under more naturalistic conditions (e.g., availability denoted by caregiver writing or talking on phone vs. unavailability denoted by caregiver sitting alone without any activity) rather than having to program colored stimuli such as cards and leis (e.g., Balka et al., 2016; Kuhn et al., 2010; Leon et al., 2010). Overall, researchers suggest that multiple schedules for schedule thinning during FCT are highly effective and preferred procedure for maintaining a functional communication response (Greer et al., 2016; Luczynski & Hanley, 2014; Rooker et al., 2013), particularly if longer periods of reinforcer unavailability are necessary; however, for some individuals, it may be necessary to incorporate additional interventions such as access to alternative activities during reinforcer unavailability periods (Fuhrman et al., 2018).

Future research is needed on the conditions under which continuous and intermittent attention delivery is necessary and sufficient for acquisition and maintenance of appropriate behavior and important skills. Furthermore, research is needed to determine the conditions under which appropriate behavior and relevant skills can be maintained under relatively thinner schedules of attention delivery (e.g., those that involve periods of reinforcer unavailability for periods more than 4 to 8 min). Finally, further research is needed to determine the most efficient and effective way for thinning attention delivery for appropriate behaviors such as academic and social behaviors.

Motivating Operations

Researchers have suggested the reinforcing efficacy of attention is influenced by a recent history of reinforcer availability (i.e., motivating operations). That is, exposure to or restriction from access to attention has been shown to affect subsequent responding to access attention in reinforcer assessments (e.g., Gewirtz & Baer, 1958a, b; Vollmer & Iwata, 1991), tact and intraverbal training (Cengher et al., 2014; Cengher & Fienup, 2020), and functional analyses (e.g., Berg et al., 2000; Iwata et al., 1994; McComas et al., 2003; O'Reilly, 1999; O'Reilly et al., 2006).

Most studies on the effects of immediate histories of reinforcement have evaluated the effects of prior restricted access (no access) or continuous access to attention on subsequent responding for attention. For example, in two early studies, Gewirtz and Baer (1958a, b) found that (a) no access (deprivation period) to attention resulted in an increase in subsequent responding for attention and (b) continuous access (a satiation period) to attention resulted in a decrease in subsequent responding for that stimulus. That is, in the social-deprivation condition, the participant was told that the experimenter needed to go find something and was left alone in a room with access to toys for 20 min. After the 20-min period, the experimenter returned and conducted a 10-min session in which praise was delivered for placing a marble in a prespecified hole. In the social-satiation condition, the experimenter brought the participant to the room and provided continuous social interaction for 20 min. After this 20-min period, the 10-min session in which praise was delivered for correct responding on the marble-dropping task was conducted. Results showed that higher levels of responding occurred to access attention on the task after periods of social deprivation as compared to periods of social satiation. Vollmer and Iwata (1991) evaluated the effects of satiation and deprivation on the reinforcer efficacy of various stimuli including social interaction for two individuals with intellectual and developmental disabilities. Prior to each session, participants were either provided with continuous (satiation) or no access (deprivation) to social interaction. After each of these sessions, praise was delivered for engaging in a block-placement task. Results showed that responding on the task for contingent praise was higher after deprivation presession periods as compared to satiation presession periods and a no reinforcement baseline. Overall, these studies suggest prior exposure to attention influences the levels of responding to access attention.

Research on the assessment and treatment of problem behavior has also shown the influence of access to and restriction from attention on levels of responding to access attention. As mentioned above, NCR is a common treatment for decreasing the occurrence of problem behavior maintained by attention, which may be effective due to altering the establishing operation for attention. This is particularly the case if attention is delivered continuously or on a dense schedule of reinforcement during NCR (Goh et al., 2000). For example, a young child might engage in tantrum behavior to gain access to teacher attention. If NCR in which continuous teacher attention is implemented reduces the occurrence of the tantrum behavior, then this is likely due to an abolishing operation (i.e., free and frequent access to attention reduces the value of attention and results in a reduction in tantrum behavior to access attention). In addition, researchers have shown that access periods and restricted access periods to attention affect subsequent levels of problem behavior (e.g., Berg et al., 2000; O'Reilly, 1999; O'Reilly et al., 2006; O'Reilly et al., 2007). For example, O'Reilly (1999) determined that both yelling and head hitting were maintained by access to attention for a 20-year-old man with IDD. Prior to functional analysis sessions, the participant was exposed to deprivation from attention (no social interaction for one hour) or a high level of attention (attention on an FT 30-s schedule for one hour). Results showed that higher levels of head hitting occurred in sessions that were preceded by deprivation from attention as compared to sessions in which there was a high level of attention. Similarly, Berg et al. (2000) conducted a three-experiment study showing that prior continuous access to attention resulted in lower levels of problem behavior in subsequent attention-contingent conditions as compared to prior no access to attention conditions. McGinnis et al. (2010) evaluated the effects of longer durations (45 min) of presession access and no access to attention on subsequent levels of problem behavior to access attention during 15-min sessions. In addition, the experimenters evaluated the effects of two different presession access conditions involving the fixed-time delivery of attention; one condition involved the delivery of attention on an FT 15-s schedule (denser), whereas the other condition involved the delivery of attention on an FT 120-s schedule (leaner). Overall, results showed lower levels of problem behavior after presession FT schedules as compared to presession no access conditions. Furthermore, somewhat lower levels of problem behavior occurred during subsequent attention-contingent conditions after the denser FT schedule of attention as compared to the thinner FT schedule of attention for two participants.

Overall, researchers suggest prior access to or deprivation from attention is likely to influence the reinforcer efficacy of attention for both appropriate behavior and problem behavior. The implications of these results are that if attention is to be used as a reinforcer for increasing appropriate behavior, then it might be beneficial to provide a period of deprivation prior to teaching or training situations. For example, teachers may find it useful to program periods of individual work time or quiet reading time in which attention is not provided prior to teaching periods in which attention will be delivered for correct responding on acquisition tasks.

There are several areas for future research on motivating operations and the effectiveness of attention as a reinforcer. Future researchers might conduct a parametric evaluation to determine the influence of varying lengths of reinforcer access and no access on subsequent responding for attention as well as a determination of the effects of noncontingent delivery of attention (rather than continuous access to attention) on subsequent appropriate responding for attention or the efficacy of attention for subsequent teaching or training procedures. In addition, it might be interesting to determine whether satiation or deprivation from one form of attention (e.g., praise) influences the efficacy of other forms of attention (e.g., physical attention). Finally, it might be interesting to compare the effects of satiation and deprivation periods on responding for biological versus social reinforcers such as various forms of attention.

Conditioning History

Another factor that may influence the efficacy of attention as a reinforcer is an individual's conditioning history (e.g., Baer & Goldfarb, 1962; Bijou & Baer, 1965; Piazza et al., 1999). Bijou and Baer (1965) suggested that the type of attention provided in an infant or child's environment may affect the degree to which their behavior is later affected by certain forms of attention. For example, some individuals may be more influenced by high-fives and smiles, whereas others may be more influenced by hugs. Similarly, some individuals may be more influenced by attention that involves a certain voice tone, voice level, and body movement. Research on conditioning attention as a reinforcer (e.g., Axe & Laprime, 2017; Dozier et al., 2012; Dudley et al., 2019; Greer et al., 2008; Holth et al., 2009) likely supports this notion. For example, Dozier et al. (2012) showed that response contingent pairing in which praise and edibles were delivered contingent upon a simple operant response resulted in praise becoming a reinforcer for 4 out of 8 participants with IDD. Furthermore, praise functioned as a reinforcer for two additional behaviors that were not included in the pairing procedures. Procedures that allow for conditioning of certain forms or aspects of attention may provide insight into how forms or aspects of attention become reinforcers throughout a person's lifetime.

Another variable that may influence the efficacy of attention as a reinforcer is the individual who is delivering attention, which is likely related to an individual's conditioning history. That is, certain individuals may signal the delivery of attention or certain forms of attention. For example, certain behaviors may be maintained by attention from peers but not adults or by attention delivered by one parent but not the other. Multiple studies have shown that peer attention may function as a reinforcer for maladaptive behavior (e.g., Ervin et al., 1998; Grauvogel-MacAleese & Wallace, 2010; Jones et al., 2000; Lewis & Sugai, 1996) and may be a more potent reinforcer than teacher attention (e.g., Broussard & Northup, 1995; Flood et al., 2002; Northup et al., 1995). For example, Jones et al. (2000) modified traditional functional analysis conditions (Iwata et al., 1982/1994) by evaluating the effects of peer attention, teacher attention, and escape on the percent of disruptive behavior in a functional analysis. Peer attention was found to maintain high levels of disruptive behavior as compared to the other conditions. Treatment results showed that noncontingent peer attention was somewhat successful in reducing disruptive behavior. In a similar study, Northup et al. (1995) showed that peer attention maintained problem behavior of three students with attention deficit hyperactivity disorder (ADHD), and DRO in which access to the peer of choice was provided contingent upon a period of time without problem behavior was successful for reducing disruptive behavior.

Similarly, conditioning history likely plays an important role in research on determining preference for staff in individuals with IDD (e.g., Jerome & Sturmey, 2008, 2014). Jerome and Sturmey (2008) conducted a preference assessment to determine relative preference of staff (i.e., preferred and non-preferred staff) and then evaluated the reinforcing effects of attention delivered by preferred and non-preferred staff. Next, a progressive-ratio (PR) schedule was implemented to determine the amount of work completed for preferred and non-preferred staff attention. For all three participants, access to attention from highly preferred staff (as determined by the preference assessment) resulted in a higher PR break point than for lower preferred staff. Jerome and Sturmey (2014) replicated these results and extended this study by showing that conducting stimulus pairing procedures in which non-preferred staff delivered high preferred items in conjunction with greeting the participant (e.g., smiled and said, "how are you doing?") on a variable time (VT) 1 min schedule resulted in an increase in PR break points and an increase in approach responses toward non-preferred staff during conditions in which participants engaged in a work task for non-preferred staff attention.

In summary, research suggests that conditioning histories likely influence the efficacy of attention and the degree to which attention delivered by certain individuals is reinforcing. However, it remains unclear (a) how attention might be conditioned as a reinforcer during our lifetime and (b) what procedures are the most efficient and effective to condition attention as a reinforcer. Furthermore, little research has determined the influence of conditioning history on different forms and components of attention. Future research might involve programming attention-based conditioning histories and subsequently determining the effects of that conditioning history on behavior to access particular forms or characteristics of attention. For example, one form or characteristic of attention could be conditioned as a reinforcer (e.g., paired with an already established reinforcer using a response-contingent pairing procedure) and another form of attention not conditioned, then a test could be conducted to compare the efficacy of each form of attention in the acquisition and maintenance of responding for a particular individual.

General Conclusions and Recommendations

Attention plays a big part in the acquisition and maintenance of critical behaviors. Attention is an important component in the development of verbal behavior, social behavior, leisure skills, and academic behavior. However, there is still more to learn about what makes social consequences (e.g., attention) effective reinforcers, and research is still needed to identify the types and features of social reinforcement that make it effective (Vollmer & Hackenberg, 2001).

To date, researchers have suggested that attention is most effective in the acquisition and maintenance of appropriate behavior when it (a) involves both nonverbal and verbal forms of attention, (b) involves high-quality verbal attention, (c) is combined with instructional procedures (e.g., prompting and modeling) and other social reinforcers, (d) is delivered close in time to the behavior, (e) is delivered after periods of deprivation, and (f) is short in duration. Researchers should continue to assess (a) the reinforcing effectiveness of attention as a stand-alone intervention, (b) the factors that influence the effectiveness of attention as a reinforcer, and (c) the reinforcing effectiveness of different types of attention across different populations and environments. It is important to also remember that the behavior of some individuals will not be sensitive to attention as a reinforcer, and attention may need to be conditioned as a reinforcer. More research is needed to determine the best methods for conditioning attention as a reinforcer and the generality of the effects.

Descriptive analysis and functional analysis research has shown that attention is a common consequence following problematic behavior in the natural environment and that some form of attention maintains a high percentage of problematic behavior. Research suggests that various forms of attention may reinforce maladaptive behavior and that preference assessments can be used to determine an individual's preferred types of attention. Research also suggests that attention is likely to maintain maladaptive behavior when (a) the verbal attention is related to the maladaptive behavior, (b) the attention is exaggerated (vocal and physical forms of displeasure), (c) the attention is delivered after a period of deprivation, and (d) the attention is longer in duration. Various function-based interventions (e.g., extinction, NCR, DRA) have been suggested for the treatment of problem behavior maintained by attention.

Social reinforcers, such as attention, will likely continue to be a primary component of behavior intervention plans for increasing appropriate behavior and decreasing inappropriate behavior. Given the widely recommended use of social reinforcers, it's important to continue to evaluate the effectiveness of attention as a reinforcer for each of the individuals with whom we work. Practitioners should do all they can to establish attention as a reinforcer and to deliver it effectively. Pairing should be a primary part of working with clients. Pairing should include making sure that the practitioner's attention is paired with known reinforcers for the client. Practitioners should ensure that they deliver attention contingent on appropriate behavior and that high-quality attention is being delivered. Practitioners should vary the forms of attention that they use, and they should realize that not all forms of attention will serve as a reinforcer for the behavior of all individuals. As long as the data do not suggest that attention is aversive, contingent attention should continue to be incorporated in behavior-intervention plans.

4 Tangible Reinforcers: Conceptual Overview and Considerations for Practice

Andrea M. Stephens, Jacqueline A. Pachis, Kayla M. Rinna, Eleah A. Sunde, and Adam M. Briggs

Behavior analysts are responsible for implementing behavior-change strategies that are conceptually consistent with behavioral principles and consider relevant factors (e.g., risks, benefits, side effects, implementation efficiency, cost effectiveness) on their way to producing outcomes likely to maintain under naturalistic conditions (Code 2.14; Behavior Analyst Certification Board [BACB], 2020). Tangible reinforcers (TRs) are among the most common stimuli that are delivered as consequences for individuals with intellectual and developmental disabilities (Graff & Karsten, 2012). Specifically, behavior analysts indicate that they deliver tokens or points (67% of respondents), edible items (50% of respondents), and toys (49% of respondents) regularly in practice.

Given the ubiquity of TR delivery in practice, it is a behavior analyst's responsibility to understand how tangible stimuli come to function as reinforcers in the first place and it is imperative for them to be familiar with their associated effects. For instance, TRs can either function as unconditioned or conditioned reinforcers and certain stimuli can become generalized conditioned reinforcers. Further, there are variables associated with each type of tangible stimulus that will alter its momentary reinforcing effectiveness including: (a) deprivation and satiation, (b) schedules of reinforcement, (c) immediacy of reinforcement delivery, (d) duration of reinforcement delivery, and (e) preference for reinforcers. Behavior analysts should consider all of these variables when incorporating the delivery of TRs into practice. In addition, there are ethical considerations related specifically to the use of TRs that behavior analysts should also be familiar with.

The purpose of this chapter is to provide a conceptual overview of TRs and offer considerations for incorporating TRs into practice. Our goal is for the content of this chapter to serve as a useful resource for practicing behavior analysts. Given the breadth of the content reviewed within this chapter, sometimes we are unable to offer a thorough discussion of certain procedures or topics. Where appropriate, we direct the reader to other chapters within this handbook that offer further depth into these topics (e.g., pairing procedures, reinforcer thinning, token economy).

Overview of Tangible Reinforcers

Prior to describing the conditions under which one might consider programming TRs and suggesting recommendations for incorporating them into one's practice, it is important to understand how tangible stimuli come to function as rein-

forcers in the first place. Below we discuss how TRs can be either unconditioned or conditioned and describe how certain stimuli can become generalized conditioned reinforcers. Although these processes and procedures are not unique to TRs, we will discuss them within the context of these particular stimuli. Our aim is to link our discussion of TRs to our field's conceptual systems, so the reader understands how these stimuli acquire their reinforcing properties and can proceed to accomplish this within their applied clinical practice.

Unconditioned Tangible Reinforcers

An unconditioned tangible reinforcer (UTR), also known as a primary or unlearned reinforcer, is a stimulus that functions as a reinforcer because of its biological importance in the organism's survival (Catania, 2013). For instance, food, water, and oxygen are tangible stimuli that function as reinforcers without a prior learning history (Cooper et al., 2020). Behavior analysts often use access to preferred food, snacks, beverages, or candy as reinforcers because they can be easily delivered, consumed quickly, and serve as potent reinforcers across a variety of skill acquisition (Paden & Kodak, 2015) and behavior reduction programs (Slocum & Vollmer, 2015).

Although use of UTRs is often desirable given their potency and overall effectiveness, reliance on them over time can result in satiation effects or consumption of an unhealthy amount of food (Rincover & Newsom, 1985). In turn, these undesirable side effects can render TRs ineffective or may interfere with establishing a healthy diet. In addition, consistent, high-rate usage of edible reinforcers may become expensive over time, can have harmful health effects on individuals with preexisting health conditions (e.g., diabetes, allergies), and may not be feasible for caregivers to deliver reliably in the home setting. For these reasons, use of UTRs may not be a long-term solution within behavior-change programming and other forms of TRs will need to be considered or even established.

Conditioned Tangible Reinforcers

A conditioned tangible reinforcer (CTR), also known as a secondary or learned reinforcer, is a previously neutral stimulus that comes to function as a reinforcer because of prior pairing with a primary or already established conditioned reinforcer (Skinner, 1953). CTRs play an important role in the development and maintenance of many socially important behaviors. In fact, common CTRs, such as various electronic devices and entertainment media, influence most of our daily activities (Bell & McDevitt, 2014). In some cases, researchers have shown that CTRs may be more preferred by an individual when compared to UTRs depending on age (Ortega et al., 2012), magnitude of reinforcer delivery (e.g., Clark et al., 2020), or the individual's ability to manipulate and contact the item's reinforcing qualities (Hanley et al., 2006). Using a wide variety of CTRs reduces a behavior analyst's reliance on unhealthy edible reinforcers and helps to mitigate satiation effects. Therefore, behavior analysts should be fluent in procedures for establishing CTRs.

Procedurally, establishing CTRs is often akin to respondent conditioning in which previously neutral stimuli acquire response-eliciting properties via repeated associations with an unconditioned stimulus (Williams, 1994). Similarly, CTRs acquire their reinforcing properties via repeated associations with an existing reinforcer (i.e., stimulus-stimulus pairing; e.g., Dozier et al., 2012; see Chap. 10 within this handbook for further discussion of stimulus pairing). Because just about any neutral stimulus can be conditioned as a CTR, behavior analysts may select stimuli that are accessible and easy to deliver to ensure that a variety of effective reinforcers are available across numerous settings.

Despite there being a number of advantages for applying CTRs in behavior change programs, behavior analysts should also be aware of some of their limitations. First, after the CTR has been conditioned, there may be a decrease in responding as a result of the removal of the primary reinforcer (Dozier et al., 2012). Second, CTRs will only maintain their reinforcing properties if they continue to be paired (at least intermittently) with other reinforcers, unless other naturally occurring reinforcers are contacted (Miltenberger, 2016). Otherwise, continuing to provide these stimuli after they have lost their reinforcing properties may result in extinction and its associated undesirable effects. For these reasons, behavior analysts should also consider using generalized CTRs.

Generalized Conditioned Tangible Reinforcers

Generalized conditioned tangible reinforcers (GCTRs) are the result of having been paired with *multiple* unconditioned and conditioned reinforcers (i.e., backup reinforcers; Hackenberg, 2009, 2018). GCTRs include items such as money (Koffarnus et al., 2013), tokens (Ayllon & Azrin, 1965), and vouchers (Meredith et al., 2014). Compared to CTRs, GCTRs are oftentimes more preferred by the individual (Sran & Borrero, 2010) because they can be exchanged for a nearly limitless range of backup reinforcers (Ivy et al., 2017). Given this, GCTRs are typically less susceptible to satiation effects because their effectiveness does not depend on a single type of deprivation. Thus, GCTRs maintain their effectiveness despite changing establishing operations or shifts in individual preference for backup reinforcers (Moher et al., 2008). Primary limitations of this approach are related to the effort and potential complexity associated with operating a token economy due to its dynamic nature (Ivy et al., 2017) and the resources required to maintain a stockpile of putative backup reinforcers (see Chap. 32 within this handbook for further discussion of token economies).

Summary

This section provided a conceptual overview on how TRs acquire their reinforcing properties and provided examples for how behavior analysts can proceed to accomplish this within their applied clinical practice. We briefly described the classification of TRs, as they may be UTRs (e.g., edibles), CTRs (e.g., toys), or GCTRs (e.g., tokens). It is important for behavior analysts to know these classifications and understand how the conceptualization of each is associated with different strengths and limitations which may be important to consider when designing programming to fit the unique needs of the individual or their environment.

Considerations for Incorporating the Delivery of Tangible Reinforcers into Practice

Reinforcement effects of a given stimulus are idiosyncratic, with effects varying across and within individuals (Vollmer & Iwata, 1991). Apart from individual differences, several other variables alter the momentary effectiveness of a stimulus that functions as reinforcement. These variables include (a) deprivation and satiation, (b) schedules of reinforcement, (c) immediacy of TR delivery, (d) duration of TR delivery, and (e) individual preference. The following section will discuss these variables and their effects on TRs. Behavior analysts should consider all of these variables when incorporating the delivery of TRs into practice.

Deprivation and Satiation

The effects of motivating variables such as deprivation and satiation offer a clear example of how the effectiveness of a tangible stimulus can be altered (e.g., DeLeon et al., 2000). Deprivation refers to the reduction in the availability of a reinforcer, resulting in an increase in reinforcer effectiveness (Catania, 2013). For example, if you only eat pumpkin pie once a year on Thanksgiving, it may be a more powerful reinforcer if you have gone without it for some time (e.g., since last Thanksgiving). Conversely, satiation refers to the continued presentation or availability of a reinforcer, resulting in a decrease in reinforcer effectiveness (Catania, 2013). For example, after you consume a large traditional Thanksgiving meal (and several days of leftovers!), you may no longer be motivated to seek out and consume these items for some time (at least until next year). Therefore, it is important for behavior analysts to keep the influence of motivational variables in mind when arranging therapeutic environments.

Considerations and Recommendations

Programming Periods of Deprivation When targeting a behavior to increase, creating an intentional state of deprivation is recommended to increase the likelihood that the learner will be motivated to engage in that behavior to contact the contingencies of reinforcement (e.g., North & Iwata, 2005; Sy & Borrero, 2009). TRs are particularly useful for contriving states of deprivation as they are easily manipulated and controlled. One way to program for periods of deprivation for a TR is to withhold access and make it only available contingent on the occurrence of the target behavior (Gottschalk et al., 2000). By making the item less available, its reinforcing effectiveness is expected to increase. If using edible reinforcers, one can contrive a state of deprivation by implementing the intervention or teaching trials during naturally occurring periods of deprivation (e.g., prior to meal times) when the individual may be more motivated to access the reinforcer (Vollmer & Iwata, 1991). To demonstrate these two strategies, consider the following example: A parent reinforces a child's homework completion by giving the child a snack if they complete their homework after school. To increase the effectiveness of the snack as a reinforcer, the parent can create a state of deprivation by (a) making the snack available contingent on homework completion only (i.e., snacks are unavailable during all other times of the day) and/or (b) requiring the child to complete their homework and receive the snack before dinner when they are more likely to be hungry.

Controlling for Satiation Satiation is likely to occur eventually with *any* type of reinforcer, especially if the reinforcer is repeatedly presented or continuously available (North & Iwata, 2005). This is a particularly important consideration for behavior analysts when designing skill acquisition programming because satiation effects could negatively impact the effectiveness of the intervention. To manage the effects of satiation of TRs, we suggest a few recommendations. First, we recommend that behavior analysts conduct ongoing, systematic assessment of reinforcer effectiveness and replace reinforcers before satiation occurs (DeLeon et al., 2001). Second, we recommend varying the reinforcers used for a single target behavior or using different reinforcers for different target behaviors (Keyl-Austin et al., 2012). This can be done by creating a pool or "menu" of available reinforcers and allowing the individual to choose his or her reinforcement regularly (e.g., prior to each work session or teaching trial; Egel, 1981). Rotating toy sets or providing access to multiple toys has also been demonstrated to be effective at reducing satiation and maintaining intervention effects over time (DeLeon et al., 2000). Third, we recommend that behavior analysts monitor the amount of the reinforcer delivered and only use what is necessary to maintain the target behavior (Zirpoli & Melloy, 1997). It is also important to consider satiation levels on an individual basis. That is, behavior analysts should know how much food the individual is likely to consume or how much time the individual is likely to spend consuming or engaging with an item or activity before experiencing satiation. Finally, tangible items can be paired with "complementary" items (i.e., consumption of one tends to vary positively with consumption of the other) to enhance their effectiveness and reduce satiation effects. For example, a child might play with a toy train when a train track is available but not when the train track is unavailable.

Schedules of Reinforcement

Schedules of reinforcement are rules that describe how often the occurrence of behavior will be followed by a reinforcer (Miltenberger, 2016). In general, these rules may specify whether reinforcement is delivered on a continuous or intermittent reinforcement schedule. Typically, behavior analysts use continuous reinforcement (CRF) schedules when teaching new behavior and intermittent schedules of reinforcement (i.e., fixed or variable) to maintain the behavior after it has already been established. For example, one may use a CRF schedule when initially teaching a child to raise their hand in class; however, after the child starts to reliably engage in this response, performance can be maintained on an intermittent schedule. In addition, these rules can describe whether reinforcement is delivered on a response- or time-based schedule (i.e., ratio or interval, respectively). That is, reinforcement may follow either (a) a prespecified number of responses (i.e., ratio schedule) or (b) the first response following a prespecified amount of time (i.e., interval schedule). Behavior analysts should be familiar with these schedule components and understand the patterns of responding that each combination is associated with so that they may harness their effects when programming TR delivery in practice.

Considerations and Recommendations

Feasibility of Reinforcement Schedules Depending on the type of TR, certain reinforcement schedules may be more feasible than others to implement. For instance, large or bulky leisure items or activities that cannot be immediately presented might be more easily delivered on an intermittent schedule of reinforcement. Conversely, edible items or tokens are usually more feasible to deliver on a CRF schedule because of their small size. However, there are some important considerations when delivering edible reinforcers on a CRF schedule. First, edible items delivered on a CRF schedule are more susceptible to satiation effects and reduced reinforcer effectiveness (North & Iwata, 2005). For these reasons, tokens are preferred over edible items if using a CRF schedule (BACB, 2020). Alternatively (or in addition to), programming intermittent schedules of reinforcement are recommended eventually in order to arrange a schedule of reinforcement that is more feasible to maintain over time. Second, implementing a ratio schedule with high integrity requires consistent monitoring which may be challenging for behavior analysts to adhere to. Therefore, it may be more feasible for behavior analysts to manage an interval schedule of reinforcement given the observation periods are intermittent and the programmed contingency is delivered following the first instance of the target behavior.

Deprivation and Satiation Effects Schedules of reinforcement have a direct impact on states of deprivation and satiation. Tangible items delivered on a continuous schedule of reinforcement are more prone to satiation effects, while tangible items delivered on an intermittent schedule of reinforcement may be less susceptible to satiation. While a CRF schedule is common initially in a teaching procedure, we recommend transitioning from a continuous to an intermittent schedule as soon as possible to prevent satiation (Zirpoli & Melloy, 1997). By shifting to a leaner schedule of reinforcement and reducing how often a TR is delivered, periods of deprivation are introduced for the individual, thus increasing their motivation as well as the effectiveness of the reinforcer. See Chap. 6 within this handbook for further discussion of reinforcer thinning.

While behavior analysts often take steps to prevent satiation, satiation of TRs may be desired if problem behavior is maintained by their access. That is, behavior analysts can use noncontingent reinforcement (NCR) to create an enriched environment and reduce the individual's motivation to engage in problem behavior (e.g., Kahng et al., 2000; Vollmer et al., 1993). By providing the TR that maintains the individual's problem behavior for free (i.e., noncontingently; time-based) and on a dense schedule (e.g., continuously), a temporary state of satiation is created, and problem behavior is expected to decrease (Slocum et al., 2018). Overall, NCR is an effective treatment for problem behavior maintained by various functions, including TR (Hagopian et al., 2001; Wallace et al., 2012). Despite its effectiveness, NCR does not strengthen an adaptive alternative response (e.g., requesting for access; Vollmer et al., 1993) and dense schedules of reinforcement can interfere with other skill acquisition programming (Wallace et al., 2012). Therefore, behavior analysts should consider combining NCR with contingent reinforcement for socially appropriate behavior (e.g., Fritz et al., 2017) and thinning the NCR schedule systematically so that satiation effects do not interfere with the acquisition of the alternative response (Goh et al., 2000).

Immediacy of Reinforcement Delivery

Immediacy of reinforcement delivery is another important consideration that can impact the effectiveness of the TR. Delays to TRs may be problematic because they can result in inadvertently reinforcing a nontarget or disruptive behavior that most immediately preceded TR delivery (Catania et al., 2015; Sidman, 1960) or may disproportionately diminish the value of the TR, thus rendering it a less effective consequence (Blackburn & El-Deredy, 2013). In addition, delays to TRs can result in extinction-induced response variability or resurgence of a previously extinguished response (Briggs et al., 2018b).

That said, there are situations in which immediate TR delivery is not possible and the individual must learn to tolerate delays to the TR. In addition, because delayed TR delivery reduces an individual's ability to clearly discriminate the active contingency, it is desirable to teach delay tolerance to promote generalization and maintenance of the desired response within the natural environment, which is unlikely to provide immediate reinforcement regularly (Hagopian et al., 2011; Stokes & Baer, 1977).

Considerations and Recommendations

Ensuring Immediacy It is necessary to consider ways to decrease the delay to TR delivery, especially during initial skill acquisition programming. For example, TRs should be within arm's reach of the behavior analyst prior to beginning the task. Edible items should be prepared in bite-sized pieces in an easily accessible container, toys should contain working batteries, and videos, music, and games should be preloaded and ready to play. In addition, TR delivery should immediately follow the occurrence of the target behavior, before the behavior analyst begins to conduct other tasks (e.g., clearing session stimuli, collecting data, preparing for the next trial). Ensuring immediacy of TR delivery will result in reinforcement contingencies that effectively strengthen the target behavior.

Maintaining Effectiveness of Delayed Reinforcement Of course, there are times in which immediate TR delivery is not feasible or might even be impossible. For example, riding a bike outside cannot practically be delivered following every instance of target behavior or after every teaching trial. In addition, the skill of delaying gratification and tolerating delays to TR is a valuable intervention in-and-of itself (Hagopian et al., 2011). If this skill is left unaddressed, delays to TRs can result in extinction-induced behavior. Thus, it is important to anticipate and plan for the unwanted effects of delay to TR by teaching tolerance to delayed TRs, while also maintaining the target response.

Delay-tolerance procedures typically include systematically increasing the delay between the response and reinforcer delivery (Fisher et al., 2000). One such strategy for signaling the delay between behavior and reinforcement is to enhance delay tolerance through verbal behavior such as instructional control and rule following (Skinner, 1984). For instance, "first/then" language or other verbal stimuli can be used to inform the individual of the contingency and increase the likelihood of them associating the delayed TR with the correct behavior. There is also evidence that providing intervening activities during the delay, combined with language stating the contingency, may increase tolerance and effectiveness of delayed reinforcement (Ghaemmaghami et al., 2016). However, the efficacy of this strategy may depend on the individual's receptive language abilities and history of receiving reinforcement for following instructions and rules (i.e., rule-governed repertoire; Tarbox et al., 2011). Alternatively, programming salient visual aids (e.g., colored floral leis; Tiger & Hanley, 2004) or signaled schedules of reinforcement (e.g., multiple schedule; Saini et al., 2016) that remain present throughout the delay interval and signal the forthcoming delivery of reinforcement can be used when the transient nature of vocal stimuli or one's rule-following repertoire is weak or ineffective. Similarly, CTRs or GCTRs (e.g., tokens; Scheithauer et al., 2016) may also exert discriminative control over one's behavior by signaling the schedule requirement for accessing the TR, thus serving to bridge the delay to TR delivery. See Chap. 6 within this handbook to review evidence-based strategies for accomplishing delay fading or denial tolerance training while maintaining the target response and mitigating extinction-induced phenomenon.

Duration of Reinforcement Delivery

Optimal duration of TR delivery varies and is dependent upon a variety of factors related to the individual receiving TRs and the type of TR delivered. For instance, some TRs require longer periods of access time to extract their reinforcing value (e.g., a puzzle) compared to other tangible stimuli that require less time (e.g., a skittle). Given these various factors, the following section will review considerations and recommendations related to reinforcement duration.

Considerations and Recommendations

Ensuring Sufficient Reinforcement Duration When considering TR duration for appropriate behaviors, the individual must access the TR for a sufficient duration for the reinforcing qualities of the item or activity to be extracted, otherwise the potency of the TR is likely to be diminished. It is important for the behavior analyst to consider that the required duration likely varies as a function of the item, its value, the response requirement for accessing it, and other individual characteristics. For instance, a child can extract the reinforcing properties of candy within seconds, while reinforcement for playing a video game might not be accessed until a within-game milestone is reached or the game is completed. If the video game is taken away before a milestone is reached, its reinforcing qualities are likely to be diminished and its withdrawal may serve as the antecedent for other problematic behaviors. If access to the TR is not effectively reinforcing (i.e., maintaining) the target behavior, or is occasioning problem behavior, consider evaluating whether increasing the duration of TR delivery results in increased effectiveness or decreased problem behavior. In addition, using a stimulus, such as a timer or verbal statement (e.g., "one more minute"), that signals the duration of TR delivery may help reduce negative behavior associated with the withdrawal of reinforcement (Mace et al., 1998).

Identifying Preference for Work-to-Reinforcement Ratios The required duration of TR access to maximize effectiveness is likely idiosyncratic across individuals. Therefore, behavior analysts should assess the optimal duration of TR delivery, for each individual, while also mitigating effects related to too little or too much TR access. For instance, some individuals prefer delayed, but accumulated and prolonged access to TRs rather than receiving immediate, but brief access following each target response (DeLeon et al., 2014; Fulton et al., 2020). Subjects in a study conducted by Fulton et al. (2020) preferred receiving access to an electronic device for 7.5 min after 15 task trials rather than receiving 30 s access following each trial. Accumulated and delayed TR access may be beneficial for activities that require a longer duration for the individual to extract the reinforcing properties from it, provided the individual is able to effectively delay gratification and understand this contingency. Behavior analysts should also monitor the ratio of work-to-reinforcement duration when programming TR access, as this ratio can impact the effectiveness of the TR (Briggs et al., 2018a). Given that the preference for larger and longer duration of access to TR varies by individual, behavior analysts should assess and compare the individual's preference and performance under contingencies that utilize small, immediate reinforcement and accumulated reinforcement.

Assessing Preference

Preference assessment methodologies include indirect assessments of preferred stimuli (e.g., structured interviews, checklists, survey; Fisher et al., 1996) and direct assessment technologies referred to as stimulus preference assessments (SPAs; Piazza et al., 2011). SPAs involve the systematic and direct assessment of an individual's preference by measuring their differential responses to brief and repeated presentations of various stimuli (Fisher et al., 1992). Tangible items such as food, toys, and leisure activities are commonly used in preference assessment procedures to identify putative TRs for individuals across various populations, including children and adults with developmental disabilities (e.g., Conine & Vollmer, 2019; Hanley et al., 1999), typically developing adults in the workforce (e.g., Wine et al., 2014), and older adults with dementia (e.g., Raetz et al., 2013). In fact, current preference assessment literature more often describes procedures for assessing tangible items as compared to non-tangible items such as praise (e.g., DeLeon & Iwata, 1996; Fisher et al., 1992; Pace et al., 1985). SPA technologies are useful for determining a hierarchical preference value of various stimuli that may serve as effective reinforcers (Horrocks & Higbee, 2008). The following section will review SPAs in the context of TRs as well as considerations and recommendations for conducting them (see Chap. 21 within this handbook for further discussion on SPAs).

Considerations and Recommendation

Presentation Modality Presentation modality is an important consideration when assessing preference of putative TRs. Putative TRs can be assessed by presenting (a) verbal choice of items (e.g., "do you want the car or the ball?"), (b) pictures of the items, or (c) the actual items. Research suggests presentation of items in a tangible format (i.e., presenting the actual item) may result in more accurate identification of preference and better prediction of reinforcer effects for individuals with developmental disabilities (e.g., Conyers et al., 2002; Higbee et al., 1999). Furthermore, Conyers et al. (2002) found that the ability to choose high preference food and non-food items using object, picture, and spoken presentation modalities was predicted by participants' basic discrimination skills. Therefore, it is recommended that choice opportunities be provided in a functional way, such that they match the individual's discrimination skills. For example, if an individual has poor auditory discrimination skills, then you would not provide verbal choice opportunities. Provided the individual has the appropriate discrimination skills, verbal or pictorial choice presentations may be more practical for tangible items that are big in size and difficult to manipulate (e.g., a bicycle) or for events or activities that cannot be immediately presented and involve many stimuli and behaviors (e.g., going to one's favorite restaurant; Conyers et al., 2002).

SPA Methodology Type of SPA methodology is also an important consideration when assessing preference of putative TRs. If using a tangible presentation format to offer choice of items that are large or bulky (e.g., a trampoline or bicycle), SPAs such as free operant observation, single-stimulus, or paired-stimulus presentation may be more appropriate as they can accommodate larger-sized items (Cooper et al., 2020). Furthermore, for individuals who engage in problem behavior maintained by access to TR, a free operant SPA may be preferred when assessing for preference of putative TRs as it may result in lower rates of problem behavior, especially compared to paired-stimulus and multiple-stimulus presentations which involve the removal of items following participant selection (Kang et al., 2010).

It is important to note that SPAs and putative TRs used in these assessments will likely vary based on an individual's age and level of functioning. Behavior analysts should continually run SPAs to account for contextual, temporal, and environmental variables that may influence the individual's preference. Behavior analysts should also account for appropriateness of items used in preference assessments to the individual's environment. For example, a behavior analyst may choose cash, gift cards, lottery tickets, or office supplies as items in an SPA when assessing preference of an adult employed in an integrated workplace setting (Wine et al., 2014).

Displacement of Tangible Items from Different Stimulus Classes Another important consideration when assessing preference of putative TRs is whether to include both leisure items/toys and edible items within a single preference assessment. Several studies have evaluated combined presentation of leisure and edible items in SPAs and have found mixed results in terms of displacement of selection across populations (e.g., Bojak & Carr, 1999; Carter & Zonneveld, 2020; Conine & Vollmer, 2019; DeLeon et al., 1997; Fahmie et al., 2015). Overall, research suggests that there is a tendency for edible items to displace leisure items in combined preference hierarchies, regardless of preference assessment methodology (Bojak & Carr, 1999; Clark et al., 2020; DeLeon et al., 1997).

There are several possible explanations offered for the displacement of leisure items by food in combined-class preference assessments. According to DeLeon et al. (1997), displacement may be due to (a) shifts in establishing operations (i.e., deprivation of edible items may result in greater preference for these items) or (b) differences in response effort (i.e., it may be easier to extract reinforcement from edible items compared to leisure items). Another explanation may be due to the unequal magnitudes of reinforcement used in combined preference assessments (e.g., one small portion of an edible item vs. 30 s access to a leisure item). Clark et al. (2020) found that displacement of leisure items may be due to relatively brief periods of access to leisure items typically used during preference assessments and as the duration of access to leisure items increased, their displacement by edible items decreased. These findings have important implications for behavior analysts who prefer to use leisure items for reinforcement, as leisure items of sufficient magnitude (i.e., a long enough duration of access) may be just as preferred as edible items. Lastly, it may be that individual participant characteristics (e.g., lack of appropriate play skills) are another important factor that may influence preference and displacement in a combined-class SPA (Carter & Zonneveld, 2020).

Some concerns with combined presentation of edible and leisure items are that displacement of one class of stimuli (e.g., toys) for another (e.g., edibles) may mask the identification of putative reinforcing stimuli and lead to false negative outcomes (e.g., DeLeon et al., 1997, Fahmie et al., 2015; Roscoe et al., 1999). For example, Fahmie et al. (2015) found that despite initial differences in relative preference for leisure and edible items (i.e., most subjects showed an exclusive preference for edible items), both classes of stimuli were similarly effective when used as reinforcers for individuals with developmental disabilities, such that they resulted in similar rates of skill acquisition. This finding has important implications given that leisure items are recommended over edible items when used as reinforcers during skills training as they are more natural, less harmful to one's health, and may reduce the likelihood of satiation effects (BACB, 2020).

More recently, research has evaluated the extent to which the inclusion of screen-based devices (e.g., iPads, tablets) in SPAs influences (a) the displacement of edible items in a combined assessment and (b) the displacement of other leisure items or toys within the same stimulus class (e.g., Carter & Zonneveld, 2020; Conine & Vollmer, 2019). Conine and Vollmer (2019) found that screen-based devices were the top-ranked item on a leisure-only assessment for 58% of participants. Furthermore, a screen-based device was the top-ranked item for 89% of participants who had a leisure item as their top-ranked item in a combined preference assessment. The authors also found that other leisure items also outranked edible items for these participants, suggesting that the inclusion of a screen-based device may contribute to a relatively higher selection of leisure items over food. Carter and Zonneveld (2020) demonstrated similar findings with respect to the leisure-only preference assessment, with approximately half of their participants (47%) ranking screen-based devices as their most preferred leisure stimulus. However, their findings were more discrepant when considering the ranking of screen-based devices among other leisure items in a combined preference assessment. That is, among those participants who ranked leisure items over food, only 38% ranked a screen-based device as their highest preferred item. Overall, more research is needed to evaluate preference for screen-based devices and the extent to which these devices displace other items within the same stimulus class as well as items in a different stimulus class (e.g., food); however, behavior analysts should consider the influence of screen-based devices on the displacement of both food and leisure items when conducting preference assessments.

Ethical Considerations When Programming Tangible Reinforcers

Despite TRs offering many benefits in the development and maintenance of behavior, there are several negative aspects of TRs worth reviewing. These ethical considerations are based on the Ethics Code for Behavior Analysts (BACB, 2020; hereafter referred to as the Code). Behavior analysts have the ethical responsibility to adhere to the Code when delivering TRs to individuals. There are several unique ethical considerations that should be monitored prior to and throughout the planning and delivery of TRs. The remainder of this section will review and suggest ways to mitigate ethical dilemmas related to the Code.

Reinforcement Versus Bribery

Teachers, caregivers, and the public can misconstrue TRs as bribes; therefore, TRs are sometimes met with divergent reactions (O'Leary et al., 1972). Merriam-Webster (n.d.) defines the verb "bribe" as "to influence the judgment or conduct of (someone) with or as if with offers of money or favor." In the eyes of the layman, the use of TRs could easily be misconstrued, as the TR itself could be viewed as a bribe, as it is influencing the individual's behavior. Acknowledging this common misconception, behavior analysts must be prepared to defend and educate others on the use of TRs for positive behavior change. The crucial differentiator between bribes and TRs (and most reinforcers in general) is that bribes are generally considered coercive, whereas use of TRs are neutral. Bribes, in a corruption context, are used to benefit the influencer, not the individual behaving. Alternatively, TRs are used in behavior-analytic services to motivate and strengthen behavior to meet the diverse needs of the individual (Codes 2.13 and 2.14; BACB, 2020), such as increasing self-help skills (e.g., toothbrushing, cleaning, cooking, etc.) and social skills. This behavior change is neither illegal nor unethical in nature. Rather, the consequence of TR delivery is often designed to be ethically sound, benefitting the individual behaving rather than the influencer. For example, if the planned consequence of time spent on an iPad for the adaptive living skill of brushing one's teeth helps only to motivate and strengthen the individual's toothbrushing behavior, then there would be no benefit to the influencer (the behavior analyst).

Choice

In their thoughtful article, Bannerman et al. (1990) examined individuals with developmental disabilities' right to "eat too many doughnuts and take a nap." It is essential that behavior analysts respect the personal liberties and rights of individuals with intellectual and developmental disabilities across ages during service delivery (Code 3.01; BACB, 2020). Part of respecting their rights includes giving them the simple freedom to make their own choices. These opportunities for choice can be embedded into programming to ensure the individuals' rights are respected (Bannerman et al., 1990). As such, we recommend that behavior analysts give the individual opportunities for choice, and if the individual does not have the ability to make a choice in their repertoire, the behavior analyst should teach the individual how to do so. When providing an opportunity for choice of TRs (in which the individual has an opportunity to choose from two or more tangible items; Martin et al., 2006, as cited in Howell et al., 2019), behavior analysts should continually run SPAs to assess the individual's preferred choice of TRs (see prior section on SPAs for more information).

Changes in Ethicality of Tangible Reinforcers Over Time

Code 2.15 explains that behavior analysts must minimize the risk of harm for individuals (BACB, 2020), including minimizing the use of harmful reinforcers. More blatant examples of harmful TRs in today's society include, but are not limited to, nicotine products or weapons such as knives and guns. Although these may act to increase behavior, they can be harmful to the individual and those in the environment; therefore, they are generally regarded as dangerous and inappropriate. Despite these items being universally regarded as harmful today, it is important to note that the ethical use of TRs changes over time. For example, when smoking was more socially acceptable, tobacco was used in residential facilities as reinforcers (Bailey & Burch, 2013). Consequently, behavior analysts must be aware of the fluid nature of TRs and how ethical they are in relation to cultural and societal standards. This will require behavior analysts to stay in contact with the scholarly literature in order to monitor best practice recommendations as they evolve over time (Briggs & Mitteer, 2021; Carr & Briggs, 2010).

Quantity and Quality of Tangible Reinforcers Delivered

Edible Reinforcers

In order to minimize risk of harm to individuals (Code 2.15), behavior analysts should avoid using reinforcers that require excessive restriction to establish the necessary motivating operations (BACB, 2020). It might be tempting for behavior analysts to set aside an individual's water or lunch for an extended period of time to create a state of deprivation (as to increase the reinforcing effectiveness of water or food). Although it has been shown that programming periods of deprivation for a reinforcer prior to delivering it increases the effectiveness of a reinforcer (see Michael, 1993; Vollmer & Iwata, 1991), the appropriateness of this practice is largely based on the context and reinforcers involved. For example, a situation in which it would be appropriate to program periods of deprivation for a specific TR (or combination of TRs) could be during intensive toilet training given the importance of effectively teaching this skill in an efficient manner. For instance, a behavior analyst might withhold a piece of the individual's favorite candy (preferred reinforcer) during programming that occurs outside of a bathroom context, using the candy as a reinforcer only when the individual successfully voids in the toilet.

Behavior analysts, however, may cross ethical boundaries when they deprive individuals of food or water just to make the food or water more reinforcing as a TR (Bailey & Burch, 2013). On a larger scale, the deprivation of food and water can break the basic human, civil, and legal rights guaranteed to individuals with intellectual and developmental disabilities in the United States (Code 3.01; BACB, 2020; see The Arc, 2020; U.S. Equal Employment Opportunity Commission, n.d. for more information on basic human, civil, and legal rights of individuals with intellectual and developmental disabilities). Behavior analysts must carefully analyze the function of programming for deprivation of edible reinforcers. In certain circumstances, such as the treatment of severe instances of self-injurious behavior, programming deprivation of edible reinforcers (outside of regularly scheduled meals) may be an appropriate intervention given limited reinforcers and an urgent need to motivate positive behavior change. In other circumstances, deprivation of edible reinforcers for treatment of minor, non-severe behaviors (e.g., programming for deprivation in order to increase letter identification) may not be as appropriate and could cross the ethical boundary if the individual is deprived of their basic, civil, and legal rights to consuming edibles.

Opposite of deprivation, Code 2.15 can be debated in the context of overconsumption of healthy and unhealthy foods. Common foods that are more readily regarded as unhealthy (and thus more readily regarded as harmful reinforcers) include candy, chips, fast food, and desserts. To mitigate the unhealthiness of these reinforcers, behavior analysts often allot a small amount to the individual (e.g., one mini chocolate chip, one small potato chip, one skittle, one bite of a dessert, etc.). Conversely, this mitigation might not be as readily practiced when edibles are considered healthier for the individual, such as fruits, vegetables, or nuts. Regardless of the type of edible, we believe it essential for behavior analysts to take data on how much of each edible is delivered as any edible in excess can cause harmful side effects for the individual. As discussed previously, if an excess of edibles (especially those that are unhealthy) are provided to the individual as reinforcers, potential harmful health effects can occur. Further, overconsumption of foods that function as reinforcers may interfere with structured mealtimes or limit the opportunity for healthier foods to be introduced (and accepted) if the individual feels sufficiently sated.

Other strategies can be used to alleviate the harmful effects of negative reinforcers. When unhealthy foods are preferred by the individual, behavior analysts must attempt to thin the schedule of reinforcement for the unhealthy edible reinforcers. In general, this may consist of delivering a small amount of an edible reinforcer (e.g., one piece of chocolate candy) following every 10 task completions instead of every five (see Chap. 6 within this handbook for further discussion of reinforcer thinning). An alternative method that behavior analysts may consider is to transition to nonedible reinforcers through reinforcement thinning or a pairing procedure. Lastly, if the thinning of potentially harmful edible reinforcers is not feasible, one might consider introducing a healthy alternative to replace the unhealthy edible. This introduction can take multiple forms, including gradual exposure plus escape extinction procedures or simply finding and introducing a healthy alternative to the preferred edible, such as natural fruit chews instead of artificially flavored fruit gummies (see Chawner et al., 2019; Tanner & Andreone, 2015).

Screen Time

Devices with screens, such as iPads, tablets, televisions, or video game devices, are often utilized in ABA treatment as TRs. Devices that utilize screen time often act as potent TRs. By this, we mean that these devices can be used to access a variety of reinforcing activities and applications (from watching videos to playing games) that all may act as reinforcers to the individual. Due to the immense number of reinforcing activities available on these devices, individuals are likely to access high-quality reinforcement continuously (e.g., through the completion of a level of a game, listening to a song, watching a video/show, reading a story, etc.) and easily without satiation occurring within this one stimulus (Hoffman et al., 2019). Given that individuals display a strong preference for these highly valued items, attempting to remove them following a reinforcement interval oftentimes evokes problem behavior. Although this indicates the need to teach delay and denial tolerance training, caregivers may just avoid using these very potent reinforcers altogether in order to prevent instances of problem behavior.

Devices that utilize screens are potent TRs and have been associated with potential harmful effects to the development of young children with and without intellectual and developmental disabilities (such as cognitive, expressive language, receptive language, and social/communication delays; American Academy of Pediatrics [AAP] Council on Communications and Media, 2016; Canadian Paediatric Society, 2017; Hill et al., 2020). Researchers have postulated that these harmful effects could be caused in part by screen time replacing time spent in developmentally enriching activities and tasks, thus interfering with opportunities for learning and growth related to behavioral, cognitive, and motor development (Madigan et al., 2019; Pagani et al., 2010). Behavior analysts must be aware of the harmful effects and know where the line is for the amount of screen time that is ethical under Code 2.15 (BACB, 2020). The AAP recommends the following screen times based on age: (a) no screen time other than video conferencing for children less than 18 months; (b) only high-quality programming (such as slow-paced television shows or media like those found on PBS or Common Sense Media) for a limited amount of time per day (e.g., less than 1 hour), under parental supervision for children aged 18–24 months (as children in this age range require parental reteaching of media content to facilitate learning); (c) 1 hour of high-quality programs (no use of media) for children ages 2–5 years; (d) and limited time spent on media so that it does not interfere with children's sleep, physical activity, or healthy behaviors for children over the age of 6 (AAP, 2016; AAP Council on Communications and Media, 2016).

To help mitigate the harmful reinforcer effects, especially for individuals younger than 5 years old, we recommend that behavior analysts limit screen time (e.g., make other reinforcers available) as much as possible and attempt to follow the recommendations from the AAP (see Trinh et al., 2020 for more information). With this, it is necessary for behavior analysts to coordinate with the individual's caregivers to determine their preferences for the child's screen time during service delivery. For example, if caregivers rely on screen time during certain times of the day (e.g., while they are making a meal) and the child meets the recommended screen time duration from the AAP during these activities, the behavior analyst may need to have an important conversation with the caregiver about where and when the duration of screen time can be reduced across the day and during therapy so that it can be ethically utilized as a potent reinforcer during teaching sessions. However, if there are barriers to limiting screen time outside of sessions, we suggest behavior analysts follow the recommendations found in AAP Council for Communications and Media (2016), including making sure that content consists of high-quality programming and ensuring opportunities to socially interact (co-view; Mendelsohn et al., 2010) with the child to help them apply what they are seeing to their environments.

Concluding Remarks

We suspect behavior analysts will continue to rely on the use of TRs as consequences in skill acquisition and behavior reduction programming for the foreseeable future. Therefore, we hope that the conceptual overview and practical and ethical considerations for incorporating TRs into practice presented within this chapter serve as a useful resource for current and future behavior analysts in training. Finally, because most TRs are extrinsic in nature (O'Leary et al., 1972), behavior analysts should avoid overdependence on TRs during skill acquisition and behavior reduction programming, especially for individuals with restricted interests. As such, behavior analysts should plan to thin reinforcement as soon as possible in programming (see Chap. 6 within this handbook for further discussion of reinforcer thinning) in order to promote generalization and maintenance of behavior change outcomes.

5 Automatic Reinforcement

Catia Cividini-Motta, Hannah MacNaul, Natalie R. Mandel, Alyssa Rojas, and William H. Ahearn

Introduction and Support for Automatic Reinforcement

The role of the environment in shaping behavior has been well described and supported by behavior analytic research (e.g., Skinner, 1938, 1957). Specifically, direct reinforcement has been found to maintain both appropriate (e.g., Falcomata et al., 2013) and inappropriate behaviors (e.g., Iwata et al., 1982/1994). Automatic contingencies have been inferred when an immediate external consequence, typically mediated by another person, is not readily apparent (Vollmer, 1994). For instance, it is often presumed by applied behavior analysts that problem behavior not sensitive to social consequences is likely maintained by the "natural" or intrinsic products of that behavior. That is, behavior is maintained by the sensory consequences engaging in the response produces. Previous research has identified many topographies of presumably automatically reinforced problem behavior including stereotypy (e.g., Rapp & Vollmer, 2005), self-injury (e.g., Iwata et al., 1982/1994), and aggression (Thompson et al., 1998). In the case of self-injury, the hypothesized automatic reinforcer has included auditory (Rincover & Devany, 1982), oral (Favell et al., 1982), and tactile (Goh et al., 1995) stimulation. However, because these plausible reinforcers are not accessible to an observer, the operant mechanism maintaining these responses is often unclear.

Automatic contingencies (see Fig. 5.1) include both positive and negative reinforcement and punishment (Vaughan & Michael, 1982). In automatic positive reinforcement, the behavior produces a reinforcing stimulus such as in problem-solving (e.g., engaging in the necessary chain of covert responses is reinforced by "the solution"; Skinner, 1953). In automatic negative reinforcement, behavior is reinforced by the removal or reduction of aversive stimulation, such as in problem behavior that results in pain attenuation (e.g., scratching a bug bite relieves the itching) or in verbal behavior that has been shaped by conditioned aversive properties (e.g., saying "um" while formulating an appropriate response to avoid aversive stimulation of silence). Lastly, in the case of automatic positive or negative punishment, the behavior itself results in

aversive stimulation (i.e., automatic positive punishment) or in the removal or reduction of appetitive stimulation (i.e., automatic negative punishment), thus decreasing the probability of that response being emitted in the future. The concept of automatic contingencies was also widely used by Skinner in his writings, such as in *Science and Human Behavior* (1953) and in *Verbal Behavior* (1957), to allow for an operant analysis of responses lacking observable sources of reinforcement, such as babbling, problem-solving, and thinking.

Support for the existence of automatic contingencies is available for both research on acquisition of verbal behavior and on the assessment and treatment of disruptive behavior. For instance, findings of previous research suggest that verbal stimuli may be naturally reinforcing (e.g., Matasaka, 1999), reinforcing due to prenatal (e.g., Mampe et al., 2009) or postnatal (e.g., Sundberg et al., 1996) conditioning, or due to achieving parity (e.g., Ostvik et al., 2012). For instance, Matasaka (1999) assessed preference for infant-directed singing (i.e., slower tempo and higher pitch) in 2-day-old hearing infants of deaf families whose primary language was Japanese Sign Language. In this study, newborns preferred infant-directed singing independent of whether the song was in Japanese or English, suggesting that this preference is innate. Mampe and colleagues evaluated the melody in newborns' cry (2–5 days old) from either French or German monolingual families. This study found that melody and intensity differed across the two groups and that it matched the intonation patterns observed in the German and French languages. A plausible interpretation of these findings is that aspects of French and German language were conditioned as reinforcing during prenatal development and that newborns' vocalizations conformed to the vocalizations of their verbal community. A stimulus-stimulus pairing (SSP) procedure was employed by Sundberg et al. to attempt to condition verbal stimuli as a reinforcer and increase vocalizations of five children. In this study, the target vocal stimulus was paired with a reinforcer and no consequences were provided contingent on vocalizations emitted by the participants. In this study frequency of vocalizations increased, although at varying degrees, for all participants (see Shillingsburg et al., 2015 for a literature review on the SSP procedure). Finally, in regard to automatic reinforcement from achieving parity, Ostvik and colleagues evaluated the impact of modeling on the acquisition of the passive voice with Norwegian-speaking children. In this study, modeling alone led to the use of passive construction by 5 out of the 6 participants.

In regard to problem behavior, results of functional analyses and research on sensory extinction, environmental enrichment, contingent access to automatically reinforced behavior, and behavior momentum corroborate the existence of automatic contingencies. For example, in cases where problem behavior persists in the absence of social contingencies (e.g., alone or no interaction session of a functional analysis), it is presumed that the behavior produces its own reinforcer. However, Vollmer (1994) noted that other mechanisms, such as elicitation, or a history of lean reinforcement in the natural environment, may lead behavior to persist in the absence of social consequences. In sensory extinction, the contingency between the target behavior and its sensory product (its presumed reinforcer) is disrupted in some fashion (e.g., Rincover et al., 1979), typically by blocking the behavior or masking its sensory consequences. For instance, Rapp et al. (2000) decreased hair manipulation by requiring the participant to wear gloves that minimized the sensory products (likely tactile) resulting from engaging in the target behavior. Results of this study suggest that sensory consequences are likely the reinforcers (automatically produced) of certain problem behavior. In the case of environmental enrichment, a plausible inference is that manipulation of items and engagement in the target behavior produce sensory consequences, and that in some cases, these responses are members of the same operant class because they result in similar (i.e., matched) consequences (Rapp & Vollmer, 2005). For instance, research suggests that noncontingent access to matched stimulation (e.g., Piazza et al., 2000) and preferred competing items (e.g., Ahearn et al., 2005) suppresses problem behavior. These findings indicate that, at least in some cases, problem behavior and item manipulation result in similar appetitive consequences (i.e., are members of the same response class) that are not socially mediated.

Another source of evidence relative to automatic contingencies comes from studies that have used contingent access to automatically reinforced disruptive behavior to increase other responses (e.g., Charlop et al., 1990; Potter et al., 2013). For instance, Potter et al. increased leisure engagement and decreased stereotypy using a combination of prompts, response blocking, and differential reinforcement. Moreover, intervention components were introduced successively, starting with access to leisure items, prompts to engage with these items, blocking of stereotypy, and then reinforcement of item engagement with access to stereotypy. Results indicated that although leisure engagement increased during the previous phases, stereotypy decreased only when access to stereotypy was contingent on item engagement. As noted by the authors, results suggested that the reinforcement produced by leisure engagement did not compete with reinforcement resulting from stereotypy. In addition, as discussed by Rapp and Vollmer (2005), according to the response deprivation hypothesis (Timberlake & Allison, 1974), withholding access to an automatically reinforced behavior, such as stereotypy, results in a period of deprivation (EO manipulation) and thus should increase the future reinforcing value of the sensory products of that response. The inverse should then occur when prior access to stereotypy (AO manipulation) is in effect. This hypothesis has been evaluated with both socially reinforced behavior (e.g., McComas et al., 2003) and presumably automatically reinforced stereotypy (e.g., Rapp et al., 2004), and the results of these studies were consistent with the response deprivation hypothesis. The results of the aforementioned studies lend additional indirect support for the existence of automatic contingencies by demonstrating that the products of these responses have reinforcing effects (e.g., stereotypy; Charlop et al., 1990) and that this effect is sensitive to motivating operations just as is the case with other operant behavior (Rapp et al., 2004).

Lastly, research informed by the behavior momentum metaphor provides strong, if not definitive, support that automatic contingencies are responsible for the acquisition and/or maintenance of some problem behavior. Nevin's behavioral momentum theory (1984, 1988, 1992) asserts that environmental variables such as contextual stimuli and reinforcer delivery can be used to describe and predict the persistence of operant behavior. A number of investigations (e.g., Dube & McIlvane, 2001; Mace et al., 1990; Sweeney et al., 2014) have shown that when response-independent reinforcers are added to an already existing contingency, behavior was more likely to persist when the contingency was disrupted (e.g., extinction was implemented). Specifically, Sweeney et al. conducted two experiments, one with pigeons and another with children with disabilities, evaluating the impact of analog sensory reinforcers (e.g., animated fireworks display paired with a chime in the experiment with children) on behavior persistence when extinction was implemented following differential reinforcement of alternative behavior (DRA) and noncontingent reinforcement (NCR) conditions. In this study, resistance to extinction was greater when sensory reinforcers were available relative to the absence of sensory reinforcers. The results of these studies support the behavior momentum assertion that behavior, that is discriminated operant responding, is more resistant to change when reinforcement is dense relative to when a lean schedule of reinforcement is in effect.

Results of previous research have also shown that automatically reinforced stereotypy conformed to the prediction of the momentum metaphor (e.g., Ahearn et al., 2003). In this study, stereotypy was higher (more resistant to change) in the test conditions that were preceded by the free reinforcer (VT) condition. This effect was likely due to a history with added reinforcers in that context (a stimulus-reinforcer relation). These results suggest that the stereotypy, presumably maintained by automatic reinforcement, was likely discriminated operant responding. Similarly, in the study by Sweeney et al. socially reinforced responses (i.e., key pecking for pigeons; touching a screen for children) were more resistant to extinction following a condition in which sensory stimulation (e.g., animated fireworks) was available and this effect was independent of the contingency for socially mediated reinforcers (i.e., DRA or NCR). These results indicate that automatic reinforcers play a role in the maintenance of operant responses and that the addition of sensory reinforcers impacted socially mediated responses in a manner consistent with the momentum metaphor.

In summary, applied studies on verbal behavior and the assessment and treatment of problem behavior provide some evidence for automatic contingencies. However, as Rapp and Vollmer (2005) proposed, sensory extinction and environment enrichment provide only indirect support for the existence of automatic contingencies by showing that these behaviors are likely maintained by an unobservable reinforcer (sensory input). Research on the contingent access to these responses and on whether presumably automatically reinforced behavior conforms to the response restriction hypothesis provides further indirect evidence that the product of these responses is reinforcers. In these cases, data are interpreted based on the available information, and a plausible explanation is inferred (i.e., a post hoc analysis). Simply demonstrating that contingent access to a response in which sensory consequences are likely putative increases another response, however, is not sufficient evidence that the response is operant in nature because similar effects have been shown when the contingency involved a reflex. For instance, López et al. (1999) found that running time was shorter when it resulted in ejaculation compared to when it resulted in either intromission or no sexual contact. However, research on behavior momentum has provided a tool to demonstrate some functional control over these presumably automatically reinforced responses.

As noted above, results of functional analyses alone do not provide definitive proof for the existence of automatic contingencies (Vollmer, 1994). Nevertheless, because topographically similar and different responses may belong to the same or different response classes (e.g., head-directed SIB with social and automatic function; Hagopian et al., 2017), functional assessments are warranted to determine the variables responsible for the maintenance of disruptive behavior. Furthermore, functional assessments have allowed for the identification, and subsequent treatment, of various topographies of problem behavior presumably to be automatically reinforced (e.g., Berg et al., 2016). Thus, given the current technology available to behavior analysts, the first step in the intervention planning for problem behavior in which the source of reinforcement is not conspicuous must be a functional assessment.

Common Topographies of Automatically Reinforced Problem Behavior

Although various topographies of disruptive behavior have been shown to be maintained by automatic reinforcement, self-injurious behavior (SIB), stereotypy, higher-order restricted and repetitive behavior (HRRB), and inappropriate sexual behavior (ISB) are common in people with autism spectrum disorder (ASD) and related disabilities. Therefore, in describing assessments and interventions for automatically reinforced behavior, this chapter will focus on examples that relate to these topographies of disruptive behavior.

SIB is a class of behaviors resulting in physical harm to the individual emitting the behavior (Tate & Baroff, 1966). Common topographies of SIB include, but are not limited to, bruxism, head-banging/hitting, self-biting, hand mouthing, body hitting, pica, rumination, self-scratching, hair pulling, eye-poking, skin picking, pinching, and kicking (Shawler et al., 2019). Moreover, the prevalence of SIB among individuals with intellectual or developmental disabilities is 5–41% (Cooper et al., 2009). Rumination, the voluntary regurgitation, chewing, swallowing, or expulsion of stomach contents (Lang et al., 2011), and pica, the consumption of non-nutritive, nonfood substances (Moline et al., 2020), are two topographies of SIB that can result in severe medical problems (Fields, 2019; Wilder & Lipschultz, 2016) and, in the case of pica, even death (Williams & McAdams, 2012) and thus warrant particular attention by clinicians.

Stereotypy consists of repetitive, persistent, and invariant responses that are not contextually appropriate (e.g., Hagopian & Toole, 2009; Rapp & Vollmer, 2005) and can include motor or vocal topographies (i.e., motor (MS) and vocal stereotypy (VS)). Stereotypy is often present during an early age; however, for typically developing children, these behaviors often diminish without requiring intervention; for children with ASD who do not receive treatment, these behaviors tend to persist and increase in severity (Digennaro Reed et al., 2012; MacDonald et al., 2007). ASD is associated with the highest prevalence rate (88%) of stereotypy compared to other diagnoses (Chebli et al., 2016), and on average, 51.8% and 54% of individuals with ASD engage in motor stereotypies (Melo et al., 2020) and in vocal stereotypies (Chebli et al., 2016), respectively. Although repetitive behaviors do not often result in injury, both MS and VS have been found to emerge into more severe forms of stereotypy that persist into adulthood and can impact an individual's adaptive, social, and academic functioning (Crutchfield et al., 2015; Lanovaz, et al., 2013; Akers et al., 2020).

Higher-order restricted and repetitive behaviors (HRRB) are a type of complex stereotypy that can encompass various behavioral topographies. Specifically, these behaviors can be characterized as an individual's rigid adherence to a rule or mental set that can present as compound chains of behavior. Behaviors might include repetitively acting out scenarios in certain environments, insisting parents drive the same route home each day, or consistently straightening, hoarding, or organizing objects (Boyd et al., 2012). RRBs can be broken down into ritualistic behavior and compulsions, which can be found in both ASD and obsessive-compulsive disorder (OCD) diagnoses. However, given that restricted and repetitive behavior (RRB) and interests are a core diagnostic feature of ASD, all children with ASD engage in some form of this behavior. Moreover, in children with ASD, lower-order RRB remain relatively high and stable over time, whereas insistence on sameness, or HRRBs, starts low in prevalence and severity but increases and worsens over time (Richler et al., 2010). Given the overlapping symptomology of ASD and OCD, it is estimated that 17–37% of young people with ASD also experience OCD symptoms (Leyfer et al., 2006). Moreover, a recent study by Martin et al. (2020) found that 25% of youth with OCD also had a diagnosis of ASD, while 5% of those with ASD had a diagnosis of OCD. Thus, it is important to discuss each type of HRRB in regard to the distinguishing factors of each.

Although ritualistic behaviors and compulsions may share the same topography, it is suggested that repetitive behavior in children with ASD may provide a source of pleasure (i.e., automatic positive reinforcement), whereas compulsions are emitted to relieve anxiety (i.e., automatic negative reinforcement; Zandt et al., 2007). Specifically, compulsions are unique in that the individual experiences a type of urge that builds in intensity and can cause significant stress and discomfort when the behavior cannot be carried out (American Psychological Association, n.d.). These urges are a key diagnostic criterion for OCD. However, if the individual also presents with cognitive or language impairments similar to ASD, a comorbid diagnosis of ASD and OCD is not uncommon (Martin et al., 2020; Zandt et al., 2007). These higher-order behaviors are of concern because interruption or prevention of these behaviors often evokes challenging behavior such as tantrums or aggression (Sigafoos et al., 2009).

No consensus exists on what constitutes ISB. For instance, Brown and Barrett (1994) defined inappropriate sexual behavior as sexual offenses or abuse, whereas Tarren-Sweeney (2008) classified sexual behavior that was developmentally and socially inappropriate as ISB. Furthermore, sexual behavior which could result in injury or distress of others (Tarren-Sweeney) or sexual behavior (e.g., public masturbation) that occurs at high levels and thus impedes completions of other activities also constitutes ISB (Hingsburger, 1994). Examples of ISB include nonconsensual sexual interaction or contact, public masturbation, disrobing in public, sexual behavior with inappropriate objects, looking down others' shirts or up others' skirts, and sexually explicit talk (Clay et al., 2018; Tarren-Sweeney, 2008). It is estimated that as many as 6–28% of individuals with intellectual or developmental disabilities (IDDs) engage in ISB (Ruble & Dalrymple, 1993, as cited in Falligant & Pence, 2020) and that sex offenses are the causes of 14–26% of criminal convictions of persons with intellectual disabilities (IDs; Day, 1997). In addition, 65% of caregivers of children with ASD indicated in response to a survey that their child had touched their genitals in public (Ruble & Dalrymple, 1993; cited by Davis et al., 2016).

Functional Assessment

According to Hanley (2012), a functional assessment consists of a process to identify the variables responsible for the maintenance of problem behavior. There are three types of functional assessments: indirect (e.g., interview, rating scales), descriptive (e.g., antecedent-behavior-consequence recording), and functional analysis. A functional analysis (FA; Iwata et al., 1982/1994) involves direct observation and measurement of the target problem behavior while systematically manipulating the environment to assess the impact of environmental variables on problem behavior. FA is the only type of functional assessment that allows for an experimental demonstration of a functional relation between a behavior and reinforcer(s). As such, FA is considered the gold standard in functional assessment technology (Hagopian et al., 2013).

Iwata and colleagues were the first to describe the use of FA to identify the functional reinforcer for problem behavior. In this study, FAs were completed in a multielement format and included test conditions for access to attention and escape, automatic reinforcement, and a control condition (i.e., play). Sessions were 15 min in length, and data were recorded on the occurrence of target behavior. Although many refer to the procedures described by Iwata and colleagues as the "standard functional analysis," it is imperative to note that FA conditions should be individualized, based on results of an indirect assessment alone or in combination with a brief descriptive assessment, for each client. Furthermore, since the publication of this study, various studies have demonstrated the utility of iterations of FA procedures in identifying the function of problem behavior (see Beavers et al., 2013 for a review).

The identification of automatically reinforced behavior, however, is often done by reviewing data on the occurrence of the target behavior during alone or no interaction sessions (e.g., Roscoe et al., 2013; Querim et al., 2013). It is presumed that if responding persists during conditions when behavior does not result in a programmed consequence, then its functional reinforcer must be the sensory consequences produced by the behavior itself. In the case of an FA that includes multiple conditions, an automatic function is presumed when responding persists across all conditions (e.g., Roscoe et al. 2013), or all test conditions but not the control (i.e., play) condition (e.g., Iwata et al., 1994). In cases when responding persists across all conditions, a series of alone or no interaction sessions is usually completed to rule out multiple sources of reinforcement and further support an automatic function (e.g., Roscoe et al., 2013; Vollmer et al., 1995).

Modifications to the FA technology have also been made specifically to identify or rule out an automatic function. For instance, after presuming an automatic function, Roscoe et al. (2013) omitted the play condition and conducted more frequent alone or no-interaction sessions (i.e., 2:1 ratio of alone to attention and to demand conditions) to identify the functional reinforcer of hand mouthing. In this study, the initial FA, which omitted the play condition, successfully identified the function of hand mouthing for 72% (46 out 64) of cases suggesting that this design can increase the efficiency of FA in cases where behavior is presumed to be automatically reinforced.

To further increase the efficiency of the functional assessment process, Querim et al. (2013) evaluated correspondence between results of a screening procedure (i.e., automatic screen) and that of FAs, including multiple conditions in identifying problem behavior maintained by automatic reinforcement. The screening procedure consisted of a series of repeated alone or no interaction sessions that were conducted prior to the multi-condition FA (i.e., attention, demand, and play). In this study, results of the initial screening alone were sufficient to determine whether problem behavior was maintained by automatic or social reinforcement for 28 out of the 30 cases. More specifically, in cases where problem behavior did not persist during the automatic screen, subsequent FA results indicated that problem behavior was maintained by either access to attention or escape from demands, whereas when problem behavior persisted in the automatic screen, results of the FA confirmed an automatic function.

As previously discussed, there are multiple automatic contingencies, and although an FA permits the identification of problem behavior maintained by automatic reinforcement, it does not identify the specific automatic contingency responsible for maintenance of the behavior, making decisions about the best treatment difficult. However, recent research by Hagopian et al. (2015) has used results of FAs (i.e., patterns of responding during FA) and the presence of self-restraint to classify automatically reinforced SIB (ASIB) into subtypes which presumably are maintained by different types of automatic contingencies. Accordingly, Subtype 1 consists of ASIB that occurs at high levels in the alone condition and low levels in the play condition; Subtype 2 refers to ASIB that occurs at high, but potentially variable, levels across all conditions; and for individuals who engage in self-restraint, ASIB is classified as Subtype 3. The authors then investigated whether differences existed in response to treatment for the three subtypes of SIB. For individuals with Subtype 1, access to alternative reinforcement (e.g., preferred activities or materials) was more likely to decrease ASIB compared to Subtype 2 and that reinforcement-based interventions alone were effective in reducing ASIB in most of the cases of Subtype 1 but never effective for Subtype 2. Reinforcement alone was not evaluated with Subtype 3, which required restraint during treatment to prevent injury. That is, more intensive treatments (i.e., interventions with more than two components or that included restraints) were needed for Subtypes 2 and 3, whereas less intrusive interventions were effective for individuals with Subtype 1. Similar results were attained by Hagopian et al. (2017). Thus, it is possible that by analyzing FA results in regard to patterns of responding, certain treatments may be more viable than others.

Given the current status of FA technology for automatically reinforced behavior, for topographies of problem behavior with a presumed automatic function other than SIB, our recommendation is to begin with an automatic screen. Although the automatic screen does not permit the identification of problem behavior with multiple functions (e.g., automatic plus a social function) or the identification of the specific social reinforcer responsible for maintenance of problem behavior, results of Querim et al. (2013) suggest that in most cases where an automatic function is presumed, it is possible to implement an intervention following results of automatic screening. However, in the case of rumination, it is important to consider timing of assessment in relation to meals. For instance, in Wilder et al. (2009), rumination occurred across all conditions of the FA completed after a meal but did not occur during sessions conducted before the meal. Additionally, for an FA of pica, clinicians must bait the room with edible and nonedible items that are safe for consumption (e.g., rice, beans, pasta, turnips (e.g., Piazza et al., 2002); rice paper, fondant (Mitteer et al., 2015)) and, whenever possible, resemble items the individuals often consume (e.g., licorice jelly beans for rocks; Wasano et al., 2009), and block attempts to consume non-baited items (Mitteer et al., 2015).

Nevertheless, in the case of SIB, results of an FA with multiple conditions in addition to information on the occurrence of restraint are necessary to identify the subtype of ASIB (Hagopian et al., 2015, 2017). Thus, we suggest a more comprehensive FA that also includes a control condition and tests for social reinforcement. Results of the FA must then be used to guide treatment selection. For instance, reinforcement-based interventions alone do not appear to be appropriate for Subtype 3 ASIB, whereas access to competing items may be a good starting intervention for Subtype 1 ASIB (Hagopian et al., 2015). Berg et al. (2016) also suggest that if an automatic function is presumed from the FA, a pairwise comparison between NCR and an ignore/alone condition can be used to guide treatment selection. Specifically, if differentiated responding is obtained during the pairwise analysis, then a treatment based on NCR should be employed first. However, if no differentiation is observed, then a concurrent operant assessment with blocking should be completed and for participants that engage with alternative stimuli, treatments involving the manipulation of the availability of reinforcers (i.e., differential reinforcement plus response cost) should be evaluated, and for those that continue to engage in problem behavior, response blocking should be employed.

In regard to HRRB, after attaining inconclusive FA results, Roscoe et al. (2015) used results from additional indirect and descriptive assessments to design a pairwise FA in which access to fix items was manipulated. In the control condition, Jim was allowed to fix and rearrange items in the room and no consequences were provided for aggression. Prior to the onset of the test condition, the researcher allowed Jim to briefly arrange placement of the items in the room but then, while Jim was outside, disrupted the arrangement of these items; during the session the researchers blocked Jim's attempts to rearrange items but the participant was given access to "fixing" contingent on aggression. Higher levels of aggression were observed in the test compared to the control condition, indicating that Jim's aggression was maintained by access to fixing items. Similar methodologies have been used to identify the functional reinforcer for unique rituals such as repeatedly opening and closing doors (Hausman et al., 2009), throwing away important items (Kuhn et al., 2009), arranging game pieces in a straight line (Leon et al., 2013), and access to specific routines (e.g., watching certain shows, lining up or stacking foam letters/trains, and rapidly turning book pages; Rispoli et al., 2014). These results suggest that in the case of HRRBs, results of indirect and direct assessments should be used to design individualized test and control conditions for the FA.

Finally, in the case of pica, rumination, and SIB, before conducting any type of assessment, first a medical evaluation to identify or rule out medical causes (e.g., medication side effect causing rumination (Rogers et al., 1992); iron, zinc, or calcium deficiency leading to pica (Edwards, 1960)) for these behaviors is necessary. Furthermore, clinicians should complete a risk assessment (e.g., Deochand et al., 2020) to determine whether it is possible to complete an FA while ensuring the safety of the participant and implementer. To determine a level of risk (slight, moderate, substantial, and high risk) associated with conducting an FA, the risk assessment tool (a downloadable excel® file) provided by Deochand et al. takes into consideration the level of clinical experience of the person considering conducting an FA, the safety of the environment in which the assessment will be conducted, access to support staff such as medical professionals, and the intensity of the target behavior. In addition, if results deem that an FA is associated with substantial or high risk of injury to the participant, the tool describes ways to reduce the risk of conducting the FA (e.g., seeking additional support staff; conducting a latency-based functional analysis; Thomason-Sassi et al., 2011). Furthermore, this tool includes an extensive list of published resources and description of modifications to FA methodology; thus, this tool may be helpful for all clinicians considering conducting an FA.

Interventions for Automatically Reinforced Problem Behavior

Various behavioral interventions alone or as part of a treatment package have been identified as effective in reducing automatically reinforced SIB, stereotypy, HRRB, and ISB. Here we name and describe some of these interventions and divide them into antecedent-based (i.e., environmental manipulations that occur before the target behavior) and consequence-based interventions (i.e., environmental manipulations that occur after appropriate behavior or the target behavior is emitted). Whenever possible, specific information related to intervention for rumination and pica are included. We then conclude this section with suggestions for future research and clinical recommendations. It is important to note that this is not an exhaustive list and that omission of an example for a particular topography of problem does not imply the intervention has not been used for that disruptive behavior. Furthermore, in much of the published studies on ISB, a functional assessment was not included thus the operant reinforcer for ISB was unclear.

Antecedent-Based Procedures

Noncontingent Reinforcement (NCR)

NCR involves delivering preferred or reinforcing stimuli on a response-independent, time-based, or continuous schedule (Cooper et al., 2019) and it is sometimes referred to as environmental enrichment (Watkins & Rapp, 2014). In previous research, NCR procedures have included access to preferred items (e.g., Watkins & Rapp, 2014), competing items (i.e., associated with high levels of engagement and low levels of disruptive behavior; e.g., Lindberg et al., 2003), or matched stimulation (i.e., stimuli that produce sensory stimulation similar to that resulting from the target behavior; e.g., Lanovaz et al., 2009). NCR has been shown to reduce various topographies of automatically reinforced behavior including SIB (e.g., hand-mouthing, head hitting, forcibly rubbing arms; Lindberg et al., 2003), rumination (e.g., Wilder et al., 2009), pica (e.g., Saini et al., 2016), stereotypy (e.g., Lanovaz et al., 2009), HRRB (e.g., Sigafoos et al., 2009), and ISB (e.g., Kelly & Simpson, 2011).

In regard to SIB, Lindberg et al. (2003) decreased SIB by providing access to competing items (e.g., stringing beads, coloring books) during brief (10 min) sessions with access to a single stimulus and extended (120 min) sessions with various stimuli available. Results of the study indicate that NCR reduced SIB for all participants and that during extended periods, the use of varied competing stimuli was beneficial to prevent satiation. Wilder et al. (2009) reduced rumination by providing access to a preferred food spray (i.e., apple pie) on a 2-s fixed-time (FT) schedule. The schedule was then thinned to FT 10 s and the participant was taught to self-administer the spray. For pica, Saini et al. (2016) assessed the effects of access to competing stimuli (e.g., tone pipe, pretzels, vibrating teether, teething keys) and response blocking for two individuals who engaged in automatically reinforced pica. NCR and response blocking successfully decreased pica. Treatment package was more effective compared to NCR alone for the participant with whom NCR alone was also evaluated.

For stereotypy, Watkins and Rapp (2014) used environmental enrichment consisting of free access to preferred stimuli (e.g., moon dough, DVD) in combination with a punishment procedure (e.g., response cost consisting of removal of preferred stimuli) to decrease levels of stereotypy (e.g., finger twisting, non-contextual vocalizations, object stereotypy, ear play). Matched stimulation in the form of noncontingent music (Gibbs et al., 2018; Love et al., 2012) or access to toys that produced auditory stimulation (e.g., musical toys; Lanovaz et al., 2009) has been used to decrease VS. Furthermore, in Lanovaz et al. (2012), access to preferred songs led to greater reduction of VS than songs identified as non-preferred.

In regard to HRRB, Sigafoos et al. (2009) utilized an enriched environment approach to reduce object rearrangement. Specifically, during the intervention phase the participant was offered a choice between two preferred activities (e.g., book or puzzle), the therapist modeled correct use of the materials, provided them to the participant, and then either stepped away and removed attention (choice condition) or remained next to the participant and interacted (e.g., vocalizations and gestures) with them for 60 s (choice plus social interaction condition); neither condition included prompting for leisure engagement or blocking of object rearrangement. Object rearrangement decreased compared to baseline for both treatment conditions, but more robust effects were observed for choice plus social interaction. Lastly, for ISB, Kelly and Simpson (2011) evaluated the impact of redirection and timeout (i.e., standard intervention) alone or in combination with an NCR component (i.e., fixed-time access to a sex worker) and found that although redirection in combination with timeout led to a decrease in ISB, the addition of the NCR component was necessary to decrease ISB to near-zero levels.

Discrimination Training

During discrimination training, also referred to as stimulus control procedures (e.g., Gould et al., 2019) or multiple schedule training (Slaton & Hanley, 2016), visual stimuli (e.g., green and red cards) signal when a reinforcer is available (discriminative stimulus; SD) or unavailable (S-delta). Discrimination training has been used to decrease stereotypy (e.g., Conroy et al., 2005) and ISB (e.g., Walker et al., 2014) during specified contexts. For instance, in Conroy et al. (2005), MS that occurred in the presence of a 3-in white card with a red circle (i.e., SD) produced no consequences; however, if the participant engaged in MS in the presence of a 3-in white card with a red circle and line through it (i.e., S-delta), the researchers reoriented the participant to the visual cue and vocally reminded them that engaging in MS was inappropriate at that time (i.e., reprimand). Lower rates of MS were observed during the S-delta condition in comparison to the SD condition, indicating that stimulus control over stereotypy had been established. In regard to ISB, Walker et al. (2014) used verbal instruction specifying which stimuli the participant should or should not become aroused, to teach one of the participants to suppress his sexual arousal in the presence of children (inappropriate stimuli) but not in the presence of adults (appropriate stimuli).

Increasing Response Effort

Another intervention to decrease automatically reinforced behavior involves increasing the effort associated with emission of the target response. For example, Van Houten (1993) assessed the use of wrist weights for a participant who engaged in self face-slapping maintained by automatic reinforcement. In this study, when the wrist weights were worn for 30 min daily, SIB decreased during all three observation periods. Treatment effects were maintained during a follow-up conducted 5 months after the study had been completed.

Cognitive Behavior Therapy (CBT)

CBT is a psychological treatment that aims at improving functioning and quality of life by changing covert (i.e., thinking; feelings) and overt behavioral patterns (American Psychological Association, 2017). In regard to HRRB, exposure and response prevention (ERP) has been used to treat compulsions and involves intentionally putting the individual in an anxiety provoking situation, having the individual refrain from engaging in the ritualistic or compulsive behavior, while demonstrating the nonoccurrence of the consequence that is feared by the individual. For example, if an individual engages in excessive or compulsive hand washing after using the restroom, the individual would be brought into the restroom, prompted to touch the toilet seat, and experience that they are physically left unharmed (e.g., nonoccurrence of the feared consequence). Additionally, the individual may be prevented from washing their hands more than one time (Abramowitz, 1996). Thus, the compulsive behavior that routinely accompanies the obsessive thought is no longer negatively reinforced (e.g., placed on extinction) which eventually leads to suppression (Boyd et al., 2012). Additional components may be included such as verbalization of coping statements (e.g., "I know nothing bad will happen") during ERP sessions to ameliorate anxiety (Lehmkul et al., 2008) and having individuals take an active role in the treatment process. Moreover, researchers have shown that a combination of imaginal exposure and in vivo exposure is more effective than exposure alone in reducing symptoms of anxiety (Abramowitz, 1996).

For ISB, Withers and Gaskell (1998) employed CBT to decrease the public masturbation (PM) of an 11-year-old child with a learning disability. The CBT intervention included seven sessions during which the participant was taught to suppress the urge to masturbate by engaging in distracting thoughts, encouraged to engage in an alternative behavior (i.e., play with putty) when anxious or bored, received education on appropriate masturbation and the importance of engaging in this response in privacy (e.g., his bedroom), and praised for his progress. The participant's parents were also instructed to prompt him to use a private space to masturbate. Across the seven sessions, which spanned over 3.5 months, CBT decreased the participant's PM to zero.

Exercise

Antecedent exercise involves instructing and providing opportunities for individuals to engage in some form of exercise (e.g., jogging; Baumeister & MacLean, 1984, jumping on a trampoline; Neely et al., 2014) and then measuring rates of the target behavior following intervention (Morrison et al., 2011). In regard to SIB, Baumeister and MacLean evaluated the effects of a jogging program on SIB (e.g., slapping, hitting of the face, head, and shoulders) and stereotypy (e.g., body rocking) for two individuals with developmental disabilities. The jogging program consisted of a 1 mile jog every afternoon which then increased by 1 mile every 2 weeks (terminal distance of 3 miles) over a 6-week period and resulted in decreased levels of stereotypy and SIB for both participants compared to baseline. For stereotypy, Neely et al. evaluated the effects of antecedent physical exercise on MS (e.g., repetitive bouncing, rocking, arm swinging) in two participants. Before instructional time, each participant was allowed exercise via a trampoline with minimal attention from the experimenter until they engaged in three consecutive behavioral indicators that they were satiated (e.g., getting off the trampoline or ceasing jumping for 1 min). The participant was prompted to exercise until three indicators of satiation were observed. Results indicated that stereotypies occurred at lowest levels when the participant had access to antecedent exercise until satiated.

Behavioral Contract

A behavioral contract specifies the conditions under which a specific reinforcer will be delivered. Wesolowski et al. (1993) used a behavioral contract in combination with verbal and written feedback to decrease the ISB of two adults with traumatic brain injury (TBI) (a third participant experienced feedback only). In this study, the behavioral contract consisted of differential reinforcement of low levels (DRL) of ISB. Specifically, a contract was developed by the participant and the clinical team and it specified the reinforcer available at the end of the week (e.g., trip to a shopping mall) contingent on whether or not ISB occurred at or below the specified criterion. During subsequent weeks, the number of instances of ISB that could occur was slowly decreased. Behavioral contracting, paired with feedback, decreased ISB to zero levels.

Instructional Procedures

A variety of instructional procedures (e.g., prompts, discrete trial teaching, video modeling) can be employed to teach an individual to emit a novel response or new information. For instance, Potter et al. (2013) used a variety of prompts to increase item engagement, and indirectly decrease stereotypy, of three individuals with autism. In this study, access to activities, prompting, blocking of stereotypy, in combination with differential reinforcement of engagement in the form of access to stereotypy, was effective in suppressing stereotypy and increasing item engagement for all participants.

For HRRB, visual schedules and video-based technologies may be used to structure an individual's schedule and promote more independent play skills. For example, a student may have a visual activity schedule that displays images of each part of their daily schedule that they use each day. Then, if a novel event (e.g., pep rally, fire drill) is scheduled for a certain day that is atypical from the student's schedule, an image of this event can be added to the schedule and discussed with the student ahead of time to prevent challenging behavior that may arise from the schedule interruption. Banda et al. (2009) provide an overview of important steps for the construction of visual activity schedules to assist students with transitions. Similarly, video-based technologies such as video modeling utilize assistive technology for the individual to rehearse the target behavior or skill based on video observation (Odom et al., 2010). Video models may be used to model appropriate play and demonstrate how to tolerate changes to routines to prevent the emergence of problem behavior associated with HRRB (Boyd et al., 2012).

In the case of ISB, interventions may focus on teaching steps or procedures associated with a particular sexual behavior. For instance, Kaeser and O'Neill (1987) used a task analysis to teach a 29-year-old male described to have profound intellectual disabilities (ID) the proper steps of masturbation. Specifically, during the intervention phase masturbation was divided into six steps that were directly taught to the participant using a combination of prompts (e.g., verbal, gestural, physical assistance).

Diet Manipulation

Diet manipulation has been evaluated as a treatment for rumination and likely applies to rumination only rather than other topographies of automatically reinforced behavior discussed in this chapter. Lang et al. (2011) identified four approaches to diet manipulation that can reduce rumination. One approach is pacing the presentation of food given to participants to ensure slower consumption (e.g., Luiselli et al., 1994). Luiselli et al. (1994) reduced rumination to near-zero levels using a treatment package which included, amongst other interventions, removing foods associated with rumination from the diet, the availability of more portions at mealtimes and snacks throughout the day, pacing (i.e., 5-min interval between consumption of each portion of food), and no programmed consequences for rumination. However, if vomiting occurred, the participant assisted in cleaning the environment. Another approach is to increase the calories and/or quantity of food (e.g., food satiation; Clauser & Scibak, 1990). For example, Clauser and Scibak provided access to triple portions of food and unlimited cereal with milk at mealtimes. For all participants, food satiation resulted in reduced rumination. An additional approach is removing types of food or liquids associated with increases in rumination from a participant's diet (e.g., Heering et al., 2003). Heering et al. (2003) indicated that rumination occurred at the highest rate when the participant had free access to liquids during meals. As a result, liquids were removed from mealtimes. The last approach involves changing the consistency or texture of food items given to the participant. For instance, Greene et al. (1991) evaluated the impact of peanut butter consumption on rumination, prepared in a variety of consistencies, and found that although the consistency of peanut butter had only a minor impact on rumination, rumination decreased as peanut butter consumption increased.

Consequence-Based Procedures

Feedback

Feedback involves the description of a person's behavior with the goal of changing the likelihood of that response occurring again in the future. Wesolowski et al. (1993) decreased ISB of three adults with a TBI using verbal and written feedback. During the intervention phase, staff recorded data on the occurrence of ISB. During the feedback sessions, which occurred every hour (2 participants) or every 30 min (1 participant) between 7:00 am and 11:00 pm, staff reviewed the completed datasheets and vocally described to the participants whether interactions they had with their peers during the preceding interval were appropriate. In this study feedback led to a decrease in ISB for all three participants.

Differential Reinforcement

Differential reinforcement procedures usually involve withholding reinforcer following the occurrence of the target behavior (i.e., extinction) and delivering a reinforcer contingent on an alternative behavior (DRA; e.g., stereotypy; Lang et al., 2014), an incompatible behavior (DRI; e.g., pica; Donnelly & Olczak, 1990), or other behavior (DRO; e.g., head hitting; Patel et al., 2000). Additionally, in a DRO procedure, a reinforcer is delivered following specific intervals during which the participant does not engage in the target behavior (Cooper et al., 2019).

In regard to pica, Donnelly and Olczak (1990) successfully reduced pica in the form of eating cigarettes by reinforcing the incompatible behavior of chewing gum with amounts of instant coffee. DRI resulted in increased latency of pica and rapid reduction of pica to near-zero levels. Donnelly and Olczak concluded that gum chewing can represent an alternative, socially acceptable oral behavior that competes with pica and for these participants, is a response strengthened by edible reinforcement (e.g., coffee).

For stereotypy, Lang et al. (2014) used DRA to decrease MS (e.g., waving toys in front of face) by providing prompts (e.g., gesture, model, verbal, and physical prompts) to engage in appropriate play and differentially reinforcing play with access to edibles and praise. No programmed consequences were provided for MS, unless the participant did not respond to prompts to play, in which they were then physically guided to engage in appropriate play. Reduced rates of MS and increased rates of appropriate play were found. Also related to stereotypy, Gehrman et al. (2017) evaluated the effects of resetting and not-resetting DRO procedures on MS. For both variations, reinforcement in the form of an edible was delivered upon the absence of MS for an entire interval. In the non-resetting condition, if stereotypy occurred during the interval, reinforcement was not available until the remainder of that interval expired. Reinforcement was only delivered following a subsequent interval without stereotypy, whereas in the resetting condition, contingent on MS during an interval, the interval was simply reset. Reinforcement was provided contingent on the absence of MS during the entire interval. Both variations of DRO procedures were effective in reducing MS.

In regard to HRRB, differential reinforcement of variability (DRV) is similar to other differential reinforcement interventions, but reinforcement is provided for varied behavioral responses (Miller & Neuringer, 2000; Neuringer, 2004). Reinforcement is linked to how novel the alternative behavior is and the novel behavior serves as an incompatible response to the ritualistic behavior or engaging in perseverative responding (Neuringer, 2004). For example, Goetz and Baer (1973) increased the variability of building-block constructions for three participants. Participants were instructed to create structures, but reinforcement was only provided if the construction was different from all previous responses within a session. Results demonstrated that each child's repertoire expanded by between nine and 16 novel responses over the course of treatment. Additionally, studies have combined DRV with response interruption, where the individuals target response is interrupted and novel behaviors are reinforced (Boyd et al., 2011). Additionally, functional communication training (FCT), a type of DRA, has been used to treat HRRB and involves the teaching of a functional communication response that results in access to the reinforcer that maintains that target behavior. Several studies have tailored FCT to treat ritualistic behaviors in individuals with ASD. Specifically, a communication response is taught such as, "Is this trash" to replace straightening behavior (Kuhn et al., 2009), "Laura's way" to rearrange the environment (Leon et al., 2013), or "I don't want that" to reinstate a ritual (Rispoli et al., 2014). The target problem behavior is placed on extinction and the communication response results in access to the maintaining reinforcer. This type of FCT can be adapted to serve idiosyncratic functions or topographies of HRRB. Lastly, in regard to ISB, Dufrene et al. (2005) decreased the ISB (i.e., PM involving the use of her hand) of a 7-year-old girl with a TBI by differential reinforcing the incompatible response of writing (i.e., DRI).

Self-Monitoring

During self-monitoring, the individual is responsible for recording (i.e., monitoring) occurrences of their own behavior (Lee et al., 2007). In regard to stereotypy, Crutchfield et al. (2015) evaluated the effects of self-monitoring via a technology-delivered program, I-Connect, on stereotypy for two students with ASD in a school setting. Participants used a handheld device to self-monitor whether or not they had engaged in stereotypy every 30 s. Self-monitoring resulted in decreased levels of stereotypy for both participants.

For HRRB, Lin and Koegel (2018) coached parents to implement pivotal response treatment (PRT) and had children engage in self-management strategies during treatment sessions to promote flexible responses rather than engaging in RRB. Specifically, parents told their children that it was time to practice being flexible in order to earn a reinforcer. Children were provided with a choice of what to earn and a blank self-management point sheet to track when they had demonstrated being flexible. Every time the child demonstrated "flexibility" instead of engaging in problem behavior, the parent prompted the child to mark on their self-management sheet that they had earned a point. Sessions continued until the child earned the expected number of points, which started at two and increased to five by the end of the evaluation. The intervention improved child behavior for all three participants (e.g., increased behavioral flexibility and reduced challenging behavior), increased children's engagement in family activities, and promoted positive parent and child affect and interactions.

In regard to ISB, Zencius et al. (1990) used self-monitoring to decrease the ISB (i.e., exposing himself) of one individual with TBI (other interventions were used with the other participants). During the self-monitoring intervention, the individual was instructed to record in a notebook all of the "urges and feelings" he experienced prior to engaging in ISB. In addition, the participant was instructed to also masturbate to situations presented to him during a dating-skills training class. In this study, self-monitoring in combination with redirection to appropriate sexual behavior decreased ISB to zero levels.

Timeout

Generally speaking, timeout refers to "time away" from reinforcement (Cooper et al., 2019). For pica, Northup et al. (1997) used a combination treatment of a 30-s DRO and 10-s time out from access to mints to reduce pica in an adult participant with developmental disabilities. When DRO was the only intervention in effect, there was a moderate reduction in pica attempts;

however, the combined treatment resulted in near-zero rates of pica attempts. In regard to ISB, Dozier et al. (2011) decreased the automatically reinforced ISB of an adult male with autism spectrum disorders and ID using response interruption in combination with a brief timeout. During the timeout component, contingent on ISB the participant was prompted to remain at the corner of the room for 1 min. The intervention was effective in decreasing ISB. Effects generalized to novel environments and persisted even after the backpack, which was used to help interrupt ISB, was eliminated.

Response Blocking

Response blocking involves physically preventing (i.e., blocking) the occurrence of the target response and thus preventing access to the reinforcer produced by the response itself (Cooper et al., 2019). For example, Lerman and Iwata (1996) decreased automatically reinforced SIB in form of hand mouthing using response blocking delivered across different schedules ranging from blocking every attempt to every fourth attempt. During the intervention, a therapist was seated behind the participant and attempts to put his hand in his mouth were blocked dependent on the schedule in place. Response blocking resulted in near-zero attempts to hand mouth independent to the schedule of consequence delivery.

Response blocking has also been used in combination with other interventions. For instance, Saini et al. (2016) reduced pica using response blocking in combination with NCR in the form of access to competing stimuli (e.g., tone pipe, pretzels, vibrating teether, teething keys). In this study, response blocking for pica consisted of the therapist placing their hand between the participants hand and mouth. Response blocking alone reduced pica to moderate levels; however, the combination of NCR and response blocking resulted in near-zero levels of pica. In regard to stereotypy, Lerman et al. (2003) evaluated the effects of response blocking as a treatment component for MS (e.g., head and tooth tapping). Response blocking consisted of the therapist physically blocking an attempt to engage in MS. In addition, environmental enrichment was evaluated with response blocking and conditional response blocking (i.e., blocked response if individual was not engaging in leisure items). Response blocking decreased levels of MS; however, it also subsequently decreased engagement in leisure activity and an increase in another form of MS (e.g., hand wringing).

Response Interruption (RI)

During RI, each occurrence of the target behavior is verbally or physically interrupted (Sprague & Horner, 1992). For stereotypy and SIB, Sprague et al. (1997) evaluated the impact of contingent sensory reinforcement (i.e., delivery of sensory item contingent on task performance) alone or in combination with RI (i.e., moving participant's hand down while stating "Please don't do that") on SIB and stereotypy of two individuals. In this study, greater suppression of problem behavior was attained when RI was in effect; however, RI was implemented. In regard to ISB, Dozier et al. (2011) used RI to reduce public masturbation for an adult male with autism. Specifically, the participant wore a backpack and PM was interrupted by pulling on the straps of the backpack.

Response Interruption and Redirection (RIRD)

Although many procedural variations exist, RIRD consists of the interruption of inappropriate behavior in combination with redirection to alternative responses (Ahearn et al., 2007), and this procedure has been shown to be effective in reducing a variety of automatically reinforced behavior (see Steinhauser & Ahearn, in press, for a review). RIRD is often employed to decrease stereotypy. For instance, in Ahearn et al. (2007), contingent on VS the implementer gained the individuals attention by initiating eye contact and verbally interrupted the behavior by prompting the individual to answer a social question (e.g., "What's your name?") or engage in vocal imitation ("say ball"), in which the participant was known to engage in reliably in the past. Termination and reinforcement in the form of social praise were delivered contingent on compliance with three consecutive trials with appropriate vocalizations and absence of VS. A significant decrease in VS compared to baseline levels was noted. In regard to ISB, Cividini-Motta et al. (2019) compared the effects of RI (i.e., physical guidance to interrupt PM paired with verbal instruction) and RIRD (i.e., prompt to stand and complete 1-min of physical activity) on the PM of four individuals ages 6–20 years old. Results of this study indicated that RIRD, as well as RI, was effective in reducing PM. See Chap. 16 in this volume for additional information on RIRD.

Response Cost (RC)

During RC, access to a reinforcing stimulus is terminated contingent on occurrence of problem behavior (Cooper et al., 2019). For SIB, Lerman et al. (1997) reduced hand mouthing and head hitting by removing access to a preferred stimulus (i.e., response cost) or manually holding the participant's arm down for a predetermined period of time (i.e., physical restraint) contingent on SIB. Initially, the punishment procedure was implemented continuously (i.e., every occurrence of SIB), but then the authors thinned the schedule of consequence delivery by providing the consequence following first occurrence of SIB after a predetermined amount of time elapsed (e.g., 120 s). RC was effective for all participants; however, SIB remained low across thinning only for a portion of the participants.

To decrease stereotypy, McNamara and Cividini-Motta (2019) compared the effects of RIRD alone, RC alone, and RIRD plus RC on levels of stereotypy. RIRD procedures were the same as those described in Ahearn et al. (2007). During RC alone, the participants had access to a competing item (e.g., Thomas the Tank™, Tigger), and contingent on VS (e.g., humming, repetitive noises), the item was removed for 10 s and was not returned until a full 10-s interval without VS elapsed. During the RIRD plus RC condition, the participant had access to a highly preferred toy that did not suppress levels of VS. Contingent on VS, the highly preferred toy was removed, RIRD procedures were implemented until termination criteria were met, and then the highly preferred toy was returned. RIRD alone and RIRD plus RC resulted in decreased levels of VS for all participants. RC alone was ineffective in reducing levels of VS for one participant.

LeBlanc et al. (2000) implemented RC to decrease the ISB, and other disruptive behaviors, of a 26-year-old male with ID. In this study, token training was completed first and consisted of a verbal description of the contingencies, the delivery of tokens and praise contingent on an arbitrary response (i.e., shake hands), and opportunities to exchange the tokens for back up reinforcers (e.g., preferred foods). During the intervention, at the onset of each session, the participant received five tokens and throughout the session additional tokens were delivered during a DRO procedure contingent on the absence of the target disruptive behaviors (i.e., inappropriate social interaction, ISB, or verbal aggression) during specific intervals of time. In addition, the DRO interval was reset and a token was removed following each occurrence of disruptive behavior. In this study, the RC procedure, combined with a resetting DRO, successfully decreased all three topographies of disruptive behavior, including ISB, to zero levels.

Overcorrection

According to Foxx and Azrin (1973), overcorrection involves restoring the environment to a better state than prior to the emission of problem behavior (i.e., restitutional overcorrection) and practicing appropriate responses related to the target behavior (i.e., positive practice overcorrection (PPOC)). For SIB, in their first experiment, Foxx and Azrin (1973) compared the use of a DRO procedure (edibles and praise for 10 s without hand mouthing), NCR (i.e., candy or cereal with praise delivered on a variable interval 1-min schedule), contingent aversive stimuli (i.e., slap on the thigh contingent on hand mouthing or distasteful solution), and overcorrection (contingent oral hygiene procedure that included brushing teeth and wiping face with a washcloth). Overall, the NCR and DRO procedures were the least effective, while overcorrection was the most effective and reduced hand mouthing to zero instances.

For ISB, Luiselli et al. (1977) assessed the impact of PPOC in combination with reinforcement (i.e., tokens delivered for work completion; praise for on-task behavior) for an 8-years-old boy with ID and psychosis. The PPOC intervention consisted of requiring the participant to complete a series of motor tasks (i.e., raising arms, extending arms in front and to the side of the body, wrapping arms across the chest) four times. During PPOC, physical guidance was employed if the participant did not comply with the task. In this study, ISB occurred at high levels during the reinforcement only phase; PPOC in combination with reinforcement reduced ISB to zero. Similarly, Polvinale and Lutzker (1980) evaluated the impact of social restitution combined with a DRO on the ISB of a 13-years old male with Down Syndrome. In this study the social restitution component consisted of the participant apologizing to six different individuals (e.g., peers, teachers) for the emission of a specified target behavior (e.g., I am sorry [name], I [behavior]). Results of the component analysis completed only for the treatment sessions conducted in the morning indicated that the DRO procedure alone produced only a slight change in ISB, yet the treatment package resulted in a decrease in ISB for zero levels. These data suggest that social restitution was likely the intervention component responsible for the treatment effects.

Other Punishers

Various studies decreased automatically reinforced behavior by delivering an aversive stimulus contingent on the occurrence of the target behavior. Examples of this include tapioca pudding for pica (e.g., Ferreri et al., 2006), lemon juice for PM (e.g., Cook et al., 1978), and electric shock for ISB (e.g., McGuire & Vallence, 1964). However, given that the contingent delivery of aversive stimulation is discouraged by the BACB® ethics code (2014), we are including here just a few examples and recommend that anyone considering decreasing disruptive behavior by presenting an aversive stimulus considers whether such consequences are warranted, whether reinforcement-based and less intrusive interventions (e.g., RC, RB, RIRD) have been exhausted, and ensures that proper consent and assent are attained.

Recommendations for Clinical Practice and Future Research

As noted earlier, in the case of automatic contingencies, the reinforcing stimulus is a product of the behavior itself; thus, withholding reinforcement for these behaviors is not feasible. Despite this challenge, previous research has described a variety of behavioral interventions that can be used to reduce automatically reinforced behaviors. Additionally, previous research has also identified evidence-based practices (EBPs) for some topographies of automatically reinforced behavior (e.g., RIRD and stereotypy; Hume et al., 2021), but for others, previous literature reviews have highlighted the need for more rigorous experimental procedures to improve the quality of research published (e.g., research on ISB; Mann & Travers, 2020) and the lack of evidence-based procedures (e.g., ISB (Clay et al., 2018); RRB (Boyd et al., 2012)).

Given the current studies of research on the assessment and treatment of automatically reinforced behavior, in cases where an automatic function is hypothesized and to increase the probability of the implementation of a function-based treatment, we recommend that clinicians begin by conducting a functional assessment. Given the complex and idiosyncratic nature of the topographies of behavior discussed in this chapter, it is important that the functional assessment be tailored to the individual's target behavior (e.g., Roscoe et al., 2015) and that it includes, minimally, an automatic screen (Querim et al., 2013). However, in the case of SIB, at least a control condition should be included to allow the clinical team to determine if the response meets criterion for Subtype 1 ASIB (Hagopian et al., 2015). If it does not, then further assessments should be conducted to identify the specific subtype of ASIB. In the case of ISB, clinicians must also consider the legality and ethics of evoking and observing sexual behavior. Specifically, Stein and Dillenburger

(2017) note that evoking sexual behavior in a minor is unethical and in the case of a nonconsenting adult, it is illegal. Thus, it is imperative to determine whether the individual has the capability to provide informed consent or at least assent to treatment.

In regard to treatment, in accordance with the BACB® ethical code (2014) and Vollmer et al. (2011), we also recommend that clinicians use the least restrictive yet effective treatment. Thus, we recommend that whenever available clinicians employ a reinforcement-based procedure that has been deemed to meet criteria for an EBP (e.g., DRA and RIRD for stereotypy; Akers et al., 2020; Hume et al., 2021). In cases where EBPs for a particular topography of automatically reinforced behavior have yet to be identified (e.g., ISB), we recommend that clinicians employ an intervention categorized as evidence-based for another topography of automatically reinforced behavior (e.g., DRA, RIRD are EBPs for stereotypy). Moreover, given that reinforcement-based procedures such as NCR, DRO, and DRA are common interventions for automatically maintained behaviors (e.g., ISB; Clay et al., 2018; SIB; Gregori et al., 2018) and are easy to implement, we suggest that clinicians employ NCR procedures initially, followed by the use of a variety of instructional procedures to establish alternative responses in the client's repertoire and then employ DRA procedures to strength and maintain these appropriate responses.

In designing treatment plans, it is also imperative that clinicians consider the topography of automatically reinforced behavior, it's potential for harm, and human's right in determining appropriate target goals. For instance, stereotypic behaviors typically do not cause injury or harm to others; thus, interventions do not need to result in complete elimination of the behavior (Akers et al., 2020), but aim at teaching the individual when and where these responses are acceptable. Similarly, although not all topographies of RRB warrant immediate treatment, research demonstrates that these repetitive behaviors, specifically insistence on sameness, may become more complex over time if not interceded (Richler et al., 2010). However, in the case of certain topographies of SIB such as pica, a single instance of the behavior can result in severe injury, and potentially death. Thus, the goal should be to eliminate these responses from the individual's repertoire. In regard to ISB, people with disabilities have the right to engage in sexual behavior (American Associated on Intellectual and Developmental Disabilities [AAIDD], 2013). Thus, it is imperative that interventions to address ISB do not violate the individual's human rights and instead aim at teaching the individual how and when to engage in sexual responses, safe sex (e.g., use of condoms), and the skills necessary to give and attain consent. Furthermore, in providing sexual education, clinicians should seek assistance from individuals with the appropriate expertise (e.g., sexuality educators certified by the American Association of Sexuality Educators, Counselors and Therapists (AASECT); Stein & Dillenburger, 2017).

Recent studies on treatment of automatically reinforced behavior tended to use punishment procedures less frequently compared to earlier evaluations (e.g., SIB; Gregori et al., 2018); however, punishment-based treatments may sometimes be necessary to reduce problem behavior (DeRosa et al., 2016). Furthermore, previous research has often evaluated the effect of treatment packages on automatically reinforced behaviors (e.g., ISB; Clay et al., 2018). Thus, in clinical settings it is likely that treatment packages are more likely to have a therapeutic effect in automatically reinforced behavior and that, whenever reinforcement-based interventions alone do not reduce or eliminate problem behavior, clinicians will need to introduce more intrusive interventions such as RIRD, RC, and time out, to further reduce problem behavior. Finally, given that HRRB may present symptomology at both the cognitive and behavioral levels (Boyd et al., 2012), the potential of harm resulting from various topographies of automatically reinforced responses, and the fact that various topographies of automatically reinforced behavior may be caused by medical problems (e.g., pica; Edwards, 1960) or a side effect of medication (e.g., rumination; Rogers et al., 1992), we recommend interdisciplinary collaborations in designing treatments for automatically reinforced behaviors.

There are many avenues for future research, some of which are highlighted here. First, results of previous research (e.g., Hagopian et al., 2015) suggest that there are distinct functional classes of ASIB, thus future research should continue to investigate the most efficient and effective interventions for each subtype of ASIB and whether other topographies of automatically reinforced behavior (e.g., stereotypy; HRRBs) also include subtypes of response classes. Additionally, researchers have suggested that in many cases researches have lacked generality and social validity measures (e.g., Akers et al., 2020; Wang et al., 2020) and have not investigated variables that may influence generalization and maintenance of interventions effects (e.g., Gregori et al., 2018). Furthermore, existing research commonly focuses on reducing repetitive or ritualistic behaviors, but few address the underlying cause of the behavior or general construct of behavioral inflexibility (Boyd et al., 2012), and interventions for rumination may lead to a substantial increase in caloric intake (Lang et al., 2011). These topics and issues should be explored in future research. Specifically, literature on automatically reinforced problem behavior would benefit from a further analysis of the lasting effects of various treatments as well as those that are less intrusive and more socially acceptable.

Moreover, the work by Fahmie et al. (2020) indicates that it is possible to identify sensitivity to social reinforcers before severe problem behavior emerges. It would be important to identify, at an early age, individuals for whom social reinforcers are less likely to compete of automatic reinforcement so this information can hopefully lead to the prevention of automatically reinforced severe problem behavior. Furthermore, future research must focus on individual or behavioral characteristics that may be predictive of the development of more persistent or severe topographies of automatically reinforced behaviors and of treatment efficacy. Finally, disruptive behaviors have a negative impact on the individual displaying these responses and also on their caregiver (e.g., HRRB; Boyd et al., 2012). Therefore, future research must investigate ways to support caregivers as well as ways to increase the feasibility (e.g., omitting intervention components; booster sessions by experts; Colón & Ahearn, 2019) of implementation of treatments by individuals with limited to no training in behavioral interventions.

6 Reinforcer Thinning: General Approaches and Considerations for Maintaining Skills and Mitigating Relapse

Adam M. Briggs, Daniel R. Mitteer, Samantha Bergmann, and Brian D. Greer

Imagine, if you will, a world in which the best medical care produced only temporary improvements in health and overall functioning. In this world, alleviation of pain associated with mild health problems, like a toothache or a fractured bone, comes only from the frequent application of a numbing cream. Treatment of more serious health problems, like cancer, produces only temporary relief and short stints of being cancer free. The world described above may understandably seem foreign to many reading this chapter—a testament to the omnipresence of modern medicine in advanced societies. We live in a time in which modern medicine produces both short- and long-term health benefits—a result of focusing on symptom management, as well as identification and treatment of the underlying malady.

However, this world of temporary treatment effects is not unlike that of much of applied behavior analysis. Even with the advent of functional analysis methodology (Iwata et al., 1982/1994), lasting treatment of many behavior problems requires the continued implementation of key treatment components with high levels of procedural fidelity. For the utility of much of our practice, treatment adherence is inexorably tied to treatment success. Without it, robust behavioral changes often deteriorate until they regress to pretreatment levels. With it, treatment gains are more likely, but they are never guaranteed. Changes in behavioral function (Lerman et al., 1994), reinforcer potency (e.g., Craig et al., 2017), and the context in which treatment occurs (e.g., Saini et al., 2018) are just a few of the factors that can alter treatment effectiveness in addition to those caused by fluctuations in treatment adherence.

The goal of applied behavior analysis as a discipline is to bring about durable behavior change. A highly efficacious treatment that does not lead to highly effective, long-term behavior change is simply insufficient in modern applied behavior analysis. So, then, what does it take to produce durable behavior change? There are many answers to this question, and they come from a variety of sources (e.g., research on treatment integrity, treatment relapse, and the social acceptability of common treatment procedures). The focus of this chapter discusses two general strategies for improving treatment durability.

One of the simplest means of improving treatment durability is likely to reduce caregiver bur-

den associated with treatment implementation (Allen & Warzak, 2000; Stocco & Thompson, 2015). Caregiver burden entails all of the facets of treatment on which behavior analysts train caregivers. This may include how and when to reinforce, prompt, display, and change discriminative stimuli, as well as how to block problem behavior. More involved treatments are likely to require more from caregivers, and the overall expectation can amount to a hefty burden on families, many of which are already in need of additional support and other resources. Reducing caregiver burden associated with treatment implementation is important because it helps ensure that treatment adherence is high when and where it is needed most.

Reducing caregiver-delivered reinforcement can be a crucial step for improving the practicality and acceptability of common behavioral treatments (Hagopian et al., 2011). Treatments that require frequent or prolonged caregiver involvement to deliver reinforcement limit the time for other important activities (e.g., preparing dinner, attending to other siblings) and self-care tasks (e.g., getting proper amounts of sleep, spending leisure time with one's partner). When such activities cannot be ignored, adherence to the treatment plan is likely to suffer, and with it, the associated treatment effects. In practice, decreasing caregiver-delivered reinforcement can be achieved in a few different ways. One option is to decrease the amount of time in which reinforcers are available by limiting reinforcer-availability periods. Another possibility is to decrease the overall number of reinforcers delivered (e.g., by requiring the completion of more work before the reinforcer becomes available). We focus on specific tactics for reducing caregiver-delivered reinforcement in the first sections of the chapter.

A second way of improving treatment durability hinges on producing behavior change at a level more fundamental than that of simply thinning a *schedule* of reinforcement. Continuing the discussion above on reducing caregiver burden as a means of improving long-term treatment effectiveness, it stands to reason that treatments requiring little to no caregiver *involvement* are likely to be the most durable. Removal of caregiver involvement here implies that the caregiver's own behavior is no longer responsible for the treatment effect. At this level of behavior change, caregivers no longer serve as intermediaries for treatment efficacy. Behavior change of this sort implies that treatment effectiveness is determined not by how well others adhere to a prescribed treatment plan but by factors that themselves have become automatic (e.g., maintained by natural contingencies; Stokes & Baer, 1977).

The concept of behavior change at such a fundamental level may be illustrated by an example. When toilet training a child, a behavior analyst is likely to arrange potent and extrinsic reinforcers (e.g., preferred foods) to follow each successful void in the toilet. At this early stage of toilet training, slight deviations in the schedule of caregiver-delivered reinforcement are likely to have direct and consequential implications for the efficacy of the toilet-training program. Success or failure at this early stage is dependent on treatment integrity. However, after the child becomes toilet trained, the continued success of the now-trained child depends not on the caregiver's strict adherence to delivering arbitrary reinforcers, but by factors outside the immediate control of the caregiver (e.g., generalized reinforcement). When such a fundamental change occurs to the variables controlling the child's behavior, the caregiver is no longer bound to delivering extrinsic reinforcers and is no longer burdened by the continued implementation of the treatment procedures. At this point, treatment durability is highly likely because caregiver treatment adherence is no longer necessary for continued treatment success.

This type of highly desirable behavior change is a realistic goal for much of applied behavior analysis, yet achieving behavior change of this sort requires tactics that differ in important ways from those mentioned above. In a latter section of this chapter, we discuss procedures for manipulating the reinforcer(s) maintaining behavior and methods for bringing about the type of fundamental behavior change described above. Taken together, these two procedures can be described as *reinforcer thinning* in that they produce a reduction in how often caregivers are responsible for delivering reinforcers while still maintaining treatment effects.

We arranged this chapter with practitioners in mind. Rather than cover each of a large number of methods for thinning reinforcement, we opted for a framework that aimed to be more functional to readers. We hope that by organizing specific tactics by the goals of each that practitioners will learn as much about the procedure as they will conceptually about the conditions under which one approach may be advantageous over another.

Reducing Functional Reinforcers in Behavior Reduction Procedures

Thinning reinforcement after teaching an appropriate response like a novel mand (e.g., requesting access to an electronic tablet) can be challenging. Thinning reinforcement for that response *while also* minimizing the occurrence of problem behavior previously evoked by that reinforcer's restriction can be a Herculean task. This is often a goal of functional communication training (FCT; Carr & Durand, 1985), which is the most commonly prescribed function-based intervention for socially reinforced problem behavior (Tiger et al., 2008).

FCT involves teaching and differentially reinforcing a mand known as a functional communication response (FCR; e.g., a card exchange or vocal mand), which produces the functional reinforcer that previously maintained problem behavior. During the initial stages of FCT, FCRs are reinforced continuously. Additionally, FCT often involves an extinction contingency for problem behavior. FCT with extinction is an empirically supported treatment for socially reinforced problem behavior (Kurtz et al., 2011) and results in rapid and clinically significant reductions in problem behavior (Greer et al., 2016); however, it can be challenging to thin reinforcement for the FCR to a practical schedule while simultaneously maintaining near-zero levels of problem behavior (Briggs et al., 2018b). In the sections below we will discuss several strategies for accomplishing this by teaching the individual to (a) understand when their FCRs will and will not result in the functional reinforcer or (b) tolerate delays or denied access to the reinforcer following the FCR. For each approach, we will provide an overview, discuss an ideal response pattern, review the thinning progression, highlight several considerations, and discuss some strengths and limitations.

Using Compound Schedules with Discriminative Stimuli

Behavior analysts have used compound schedules (i.e., a schedule that combines two or more component schedules; Catania, 2013), like multiple and chained schedules of reinforcement, to signal the availability of reinforcement for the FCR during FCT. During FCT with multiple and chained schedules, at least two schedules (e.g., most often fixed-ratio 1 [FR1] and extinction for the FCR; Saini et al., 2016) alternate and each schedule is correlated with a different stimulus (e.g., a green wristband for the FR1 and red wristband for extinction). Most often, extinction is always programmed for problem behavior regardless of the schedules for the FCR. Behavior analysts can alternate these schedules simply or randomly (Ferster & Skinner, 1957; e.g., FR1/extinction/FR1/extinction or FR1/extinction/extinction/FR1). In practice, behavior analysts may consider alternating the components quasi-randomly according to a preset rule (e.g., no more than two successive presentations of the same component), but one component or the other is always in effect (Mitteer et al., 2020). In the sections below, we provide an overview of FCT with multiple and chained schedules along with the conditions under which behavior analysts might use them to thin reinforcement for alternative behavior like FCRs.

Overview

When using discriminative stimuli, behavior analysts tend to use FCT with multiple schedules (mult FCT) to thin reinforcement for social-positive reinforcers (e.g., caregiver attention or access to preferred items) and chained schedules (chained FCT) to thin reinforcement for social-negative reinforcers (e.g., escape from academic demands; Saini et al., 2016). As described above, behavior analysts typically implement mult and chained FCT by alternating an FR1 component and extinction component for FCRs that are each correlated with a specific stimulus. The stimuli associated with the reinforcement and extinction contingencies are known as the discriminative stimulus (S^D) and stimulus delta (S^Δ), respectively. Researchers have used a variety of stimuli for these purposes, including arbitrary stimuli (e.g., colored cards or wristbands, Greer et al., 2016) or stimuli that might occur naturally in the target individual's life (e.g., variations in caregiver behavior like talking on the phone or reading a magazine; Kuhn et al., 2010; Shamlian et al., 2016). Both the S^D and S^Δ components switch based upon the passage of time in mult FCT, whereas chained FCT's S^Δ component duration varies and terminates following a response requirement (e.g., compliance). Regardless of the arranged stimuli and contingencies affecting component switches, the therapeutic goal is to make the treatment more practical by reducing the number of FCRs and reinforcer deliveries through the caregiver honoring FCRs only during the S^D component.

Desired Response Pattern

As described by Ferster and Skinner (1957), these compound schedules involve the process of discrimination between the stimuli and the simplest way of determining whether responding discriminates between schedule components is to compare the response rates during each component (*rate of correct and incorrect FCRs*) or evaluate the percentage of responses made in the presence of each stimulus relative to the total number of responses (*percentage of correct FCRs)*, where FCRs during the S^D and S^Δ are labeled "correct" and "incorrect," respectively. Both measures have been used to interpret discriminative control of FCRs in mult-FCT research (e.g., Greer et al., 2016; Hanley et al., 2001) and one or the other may be more helpful at various points in the schedule-thinning progression. For example, the percentage measure could be useful early during schedule thinning because a single FCR during a brief 2-s S^Δ component may produce high rates of incorrect FCRs that do not accurately portray the level of FCR discrimination. Conversely, a percentage measure might be less appropriate during terminal mult-FCT schedules (e.g., 2-min S^D and 10-min S^Δ) because a single FCR in both components would yield a correct-FCR calculation of 50%, which does not account for the considerably longer duration of time spent in the S^Δ component. Thus, behavior analysts might oscillate between discrimination measures over the course of schedule thinning. Because behavior analysts arrange response requirements (e.g., completion of two academic worksheets) during chained FCT, a percentage of compliance or rate of completion measure would be considered alongside FCR discrimination.

Thinning Progression

Behavior analysts tend to begin schedule thinning during mult and chained FCT with a long S^D component (e.g., 1 min) and a brief S^Δ component (e.g., 2 s, 1 response requirement) before gradually increasing the latter component duration or response requirement relative to the former (Mitteer et al., 2020). Progression is often dependent upon the levels of problem behavior and FCR discrimination as well as compliance in chained FCT (see the sections below for how to enhance this progression's pace). For example, Hanley et al. (2001) thinned mult-FCT components from a 45-s S^D and 15-s S^Δ to a 1-min S^D and 4-min S^Δ in approximately eight steps based upon prespecified progression criteria. Further, Fisher et al. (1993) used demand fading to increase the response requirement during chained-FCT components from a 30-s S^D and FR2 response requirement during the S^Δ to a 30-s S^D and FR26 response requirement during the S^Δ in approximately 13 steps based upon prespecified progression criteria of FR2 following two sessions with near-zero levels of problem behavior and high levels of compliance. Terminal schedules have varied widely across the literature, such as the range of 1.5-min to 9-min S^Δ components presented in Greer et al.'s (2016) consecutive-case series of FCT with mult FCT. Further, when using demand fading during chained FCT, the terminal schedule can remain as a chained schedule during the S^{Δ} component (e.g., FR40; Briggs et al., 2018a) or the chained schedule can be converted to a multiple schedule in which the child would continue to work for 240 s for a 60-s break; however, the break would become available regardless of compliance (i.e., on a time-based schedule; Greer et al., 2016). Nevertheless, it is likely that the terminal schedule will be dependent upon stakeholder (e.g., caregiver, teacher) input and the characteristics of the target individual (Saini et al., 2016).

Considerations

Enhancing schedule thinning If the behavior analyst establishes discriminative control over FCRs and maintains low levels of problem behavior, it may be possible to thin rapidly from the initial schedule (e.g., 60-s S^D and 30-s S^{Δ}) to the terminal schedule without degrading treatment effects (e.g., 60-s S^D and 240-s S^{Δ}; Betz et al., 2013; Fisher et al., 2015, Fuhrman et al., 2016). However, it sometimes can be challenging to obtain FCR discrimination even with extended exposure to these compound schedules (e.g., Fisher et al., 2014) or to maintain low levels of problem behavior during schedule thinning (e.g., Briggs et al., 2018b). Although a comprehensive list of mult- and chained-FCT teaching procedures is beyond the scope of this chapter, behavior analysts have used the following strategies to improve performance during schedule thinning: (a) adding contingency-specifying rules (e.g., Fuhrman et al., 2016), (b) embedding prompting and response blocking of FCRs during the S^D and S^{Δ}, respectively (Akers et al., 2018), (c) including alternative activities during the S^{Δ} during mult FCT (Fuhrman et al., 2018), (c) allowing multiple FCRs to occur during the S^D component to increase opportunities for learning (e.g., Fuhrman et al., 2016), and (d) using response restriction and stimulus fading of the FCR during the S^{Δ} to reduce incorrect FCRs (Akers et al., 2018).

Multiple reinforcers When a functional analysis demonstrates that problem behavior is multiply controlled (e.g., by escape and access to preferred activities), behavior analysts might not reduce problem behavior to acceptable levels until they address all relevant establishing operations (Bachmeyer et al., 2009; Ghaemmaghami et al., 2016b). Behavior analysts can accomplish this by teaching FCRs for each reinforcer in separate treatment sessions (individual FCRs; e.g., Borrero & Vollmer, 2006) or a single FCR for all reinforcers in a treatment session (an omnibus FCR; e.g., Mitteer et al., 2019). Just as behavior analysts might teach FCRs under individual or combined establishing operations, they might incorporate FCT with discriminative stimuli for each function and FCR separately using unique pairs of discriminative stimuli (e.g., Greer et al., 2019) or together using more than two schedule components for individual FCRs (e.g., Akers et al., 2018) or an omnibus FCR (Mitteer et al., 2019). For example, Akers et al. taught a four-component schedule to signal the availability of (a) food, (b) beverages, (c) food or beverages, and (d) neither reinforcer using yellow, green, blue, and brown posters, respectively, with multiple FCRs. Mitteer et al. described using a similar four-component schedule, but with an omnibus FCR that produced different numbers of reinforcers for a single FCR depending on the component. Additional research is likely needed to elucidate the efficacy of and individual/caregiver preference for these complex arrangements with multiple stimuli relative to a single pair of discriminative stimuli used across FCRs (e.g., moving FCRs or images of the reinforcers between "Available" and "Unavailable" columns on a visual board).

Mult FCT beyond social-positive reinforcement Although we have focused on mult FCT to reduce the rate of social-positive reinforcement, multiple schedules might also be used to decrease the rate of automatic reinforcement (as inferred by a collateral decrease in the rate of automatically reinforced target behavior). As an example, Doughty et al. (2007) arranged two schedules with three adults with intellectual and developmental disabilities who engaged in automatically reinforced stereotypy. Doughty et al. correlated reinforcement-only and reinforcement-plus-punishment components with separate stimuli (e.g., presence/absence of music, green/red cards) by allowing stereotypy to occur and then contact a punisher (e.g., reprimand and hands-down procedure) in the presence of the respective stimuli. This resulted in near-exclusive stereotypy in the reinforcement-only component. Because stereotypy maintained at similar levels in the reinforcement-only component and decreased to near-zero levels in the other component, this presumably led to overall lower rates of automatic reinforcement produced by the stereotypy. Further, while most behavior analysts have used chained FCT to thin reinforcement for social-negative reinforcement when incorporating discriminative stimuli (Saini et al., 2016), there have been some applications of mult FCT with social-negative reinforcement. For example, for an individual with multiply controlled problem behavior, Álvarez et al. (2014) used mult FCT to thin reinforcement for FCRs to access food while programming various nonpreferred stimuli (e.g., instructions to complete academic work) that had previously evoked escape-maintained problem behavior during the extinction component. This may be effective for individuals whose compliance remains high during the extinction component of mult FCT without making the switch to the reinforcement component contingent upon compliance. Even if behavior analysts have conducted the majority of schedule thinning with chained FCT by incorporating a response requirement during the S^{Δ}, they might switch to a time-based schedule for practicality (e.g., such that a school teacher can deliver reinforcement at the end of a class period rather than tracking each instance of compliance; Greer et al., 2016).

Some Strengths and Limitations of FCT with Discriminative Stimuli

These interventions are highly effective at thinning reinforcement for FCRs while maintaining efficient FCRs within the S^{D} component when used with individuals with various functions and topographies of problem behavior and diagnoses (Greer et al., 2016). And, as noted above, establishing discriminative control over FCRs has allowed for rapid schedule thinning (e.g., Betz et al., 2013). Researchers have demonstrated that using discriminative stimuli can mitigate later treatment relapse produced by extended periods of extinction for FCRs (Fisher et al., 2020; Fuhrman et al., 2016) or contextual changes like implementation by caregivers or in new settings (Fisher et al., 2015; Greer et al., 2019). Additionally, studies have demonstrated high levels of caregiver treatment integrity with these interventions during and after caregiver training, despite the complexity of the interventions (Campos et al., 2020; Greer et al., 2019).

Despite these strong effects, perhaps the looming limitation when using these interventions is their practicality without direct programming for generalization. The vast majority of studies using discriminative stimuli during FCT have incorporated arbitrary stimuli like colored index cards and posters or items worn by caregivers like colored wristbands and Hawaiian leis (Saini et al., 2016). Although a recent study by Campos et al. (2020) obtained high social-validity ratings across three caregivers who implemented mult FCT for up to 3 weeks, one can imagine that arbitrary stimuli might be cumbersome to use and easy to misplace when working with an individual or particularly challenging to manage if working with multiple individuals simultaneously (e.g., in a classroom). The likelihood of a busy caregiver or teacher misplacing the stimuli is concerning because the effects of the interventions do not readily generalize in the absence of the stimuli.

For example, Fisher et al. (2020) demonstrated that presenting the S^{Δ} during longer-than-typical extinction periods (similar to if the tablet battery depleted and the reinforcer could not be delivered for 30 min) was successful in retaining low levels of destructive behavior and incorrect FCRs. However, the same individuals exhibiting these results in Fisher et al. often displayed treatment relapse in an equivalent condition that did not contain the S^{Δ}. The authors of this chapter have used a variety of procedures clinically to address practicality issues, such as by correlating arbitrary stimuli with naturalistic stimuli (e.g., pairing the presentation of arbitrary stimuli with caregiver vocal behavior and fading the former stimuli) and by using common discriminative stimuli with multiple students in a classroom (e.g., all students complete work when a red poster is on the chalkboard and can request breaks and other reinforcers when it is absent). However, a pressing aim for future research using mult and chained FCT should be demonstrating how to minimize practicality issues empirically, perhaps by combining the interventions with some aspects of the delay and denial tolerance training noted below.

Delay and Denial Tolerance Training

As mentioned above, a potential limitation of FCT is that the FCR may occur at times when it is unlikely to produce reinforcement (Fisher et al., 1993). For instance, in applied settings there are times when reinforcement of the FCR may be delayed or even denied. This may occur for several reasons: (a) The requested reinforcer is not readily available (e.g., tablet needs charging), (b) the requested reinforcer is not appropriate (e.g., providing conspicuous attention during a church service), or (c) the FCR may occur more often than is practical for caregivers to deliver (e.g., caregiver is unable to respond immediately to all bids for attention). Or, as we discussed earlier, discriminative stimuli may be cumbersome to manage or may be misplaced. When reinforcement is delayed or denied in these situations, there is a risk that the FCR may be weakened (Lattal, 1984) and problem behavior will resurge (e.g., Briggs et al., 2018b). Thus, behavior analysts might consider arranging tolerance training to prepare the individual for situations when reinforcement of the FCR is delayed or denied or if caregivers do not prefer to, or cannot, use discriminative stimuli.

Common procedures for teaching delay and denial tolerance are to program delays between the FCR and the delivery of the reinforcer (i.e., delay schedule; Fisher et al., 2000) or deliver the reinforcer for only a portion of emitted FCRs (i.e., intermittent schedule; Hanley et al., 2014). These delay and denial trials are initially brief exposures or occur for a very small proportion of total FCRs. Then, over time, the delays are increased systematically or the intermittent schedule of reinforcement is decreased such that a larger proportion of FCRs are denied reinforcement. Because we are describing two separate procedures (i.e., delay schedules and intermittent schedules), we will discuss them as independent components that behavior analysts can choose to implement in isolation (e.g., Fisher et al., 2000; Mace et al., 2011) or in combination (e.g., Ghaemmaghami et al., 2016a; Hanley et al., 2014; Jessel et al., 2018). In the sections below, we provide an overview of delay and denial tolerance training along with the conditions under which behavior analysts might use this approach to thin reinforcement.

Overview

Regardless of whether behavior analysts are programming (a) delay schedules (b) intermittent schedules, or (c) a combination of delay and intermittent reinforcement schedules, this delay and denial period is typically signaled with an auditory stimulus resembling something that might occur naturally in the individual's life (e.g., "Nice asking, but you need to wait," "Not now," or a similar phase; Hagopian et al., 2005; Hanley et al., 2014). The purpose of this "cue" is to serve as a discriminative stimulus that signals reinforcement is either forthcoming or not available. Signaling the delay or unavailability of the reinforcer may decrease the aversiveness of this condition, thus increasing the likelihood of an appropriate tolerance response, which might decrease the likelihood of resurgence. This stimulus may also bridge the delay between the response-reinforcer relation, thus preventing this contingency from weakening (e.g., Fisher et al., 2000). Some iterations of this approach have also found it beneficial to teach the individual to engage in a tolerance response (e.g., to take a breath and say, "Okay") following the denial statement (Hanley et al., 2014; Luczynski & Hanley, 2013) such that the individual will engage in behavior that is calming (i.e., taking a breath) and contingency-based (e.g., "Okay") which might mitigate the aversiveness associated with delayed or denied requests and increase the likelihood of their successful compliance with these events. The therapeutic goal is to strengthen these responses by providing the functional reinforcers following these tolerance responses.

Desired Response Pattern

As indicated above, delay and denial tolerance training procedures are intended to simulate situations when reinforcement of the FCR may be delayed or even denied and prepare individuals to tolerate these situations. That is, the individual will (a) continue to request access to their functional reinforcers, (b) appropriately respond to the denial statement with a tolerance response, and (c) wait for the desired amount of time (or complete the response requirement) during the delay period without engaging in additional requests or problem behavior. The goal is that this desired response pattern will occur across a wide range of evocative situations, denial statements, delay durations, response requirements, individuals (e.g., caregivers and peers), and settings (e.g., therapeutic and home environment). To evaluate whether the intervention is producing the desired effect, behavior analysts would determine if levels of problem behavior (e.g., frequency, rate) are reduced and remain low as a function of the levels of FCRs (e.g., frequency, rate) increasing and maintaining at optimal levels as delays and denials are introduced and the durations of delays are increased until the terminal delay is reached. Additionally, if a response requirement is programmed during the delay, behavior analysts would closely monitor the percentage of compliance to ensure that the individual is complying with a high percentage of these instructions (e.g., greater than 80%).

Thinning Progression

Delay and denial trials can be programmed to follow each FCR (e.g., Fisher et al., 2000) or a proportion of FCRs (e.g., 2 of every 5 FCRs result in immediate reinforcement and 3 of every 5 result in a delay or denial response; i.e., probabilistic delay fading; Hanley et al., 2014) during the delay and denial tolerance training phase. Scheduled delay periods can be either time-based (e.g., Fisher et al., 2000) or contingency-based (e.g., Ghaemmaghami et al., 2016a). That is, the delay period is terminated after a certain amount of time has elapsed (i.e., time-based delay) or the individual must engage in additional specific responses for a period of time in order to terminate the delay (i.e., contingency-based delay). Over time, duration of reinforcer access is gradually reduced by systematically increasing these delay periods. Delays typically increase in a geometric progression starting at 1 s (i.e., 1 s, 2 s, 4 s, 8 s, 15 s, 30 s, …) until the terminal delay is reached (e.g., Hagopian et al., 1998). The target terminal delay is typically determined on an individual basis and is often guided by caregiver and setting requirements (Hanley et al., 2014). Duration of delays can be either fixed at a given level (e.g., 30-s delay following every FCR; e.g., Hagopian et al., 2005) or variable at a given level that averages a particular mean (e.g., 20-s, 40-s, 15-s, 45-s delays that average a 30-s delay level; e.g., Rose & Beaulieu, 2019). Progressing to longer delays or increased response requirements is often based on success at a given step, such as appropriately responding without problem behavior (i.e., differential reinforcement of other behavior; Jessel et al., 2018). However, if problem behavior occurs during the delay period, the delay duration or the response requirement is reset (e.g., Jessel et al., 2018). The duration of time the individual has access to the reinforcer can also be fixed (e.g., 30-s access; e.g., Fisher et al., 2000) or variable (e.g., 30–240-s access; e.g., Rose & Beaulieu, 2019).

Considerations

Enhancing tolerance to reinforcement delay A technique suggested by the basic literature for teaching tolerance to delayed reinforcement has been to provide the participant with an alternative activity during the wait interval (Grosch & Neuringer, 1981; Mischel et al., 1972). This has been accomplished in applied settings by providing noncontingent access to a low-to-moderately preferred activity (e.g., Ghaemmaghami et al., 2016a; Hagopian et al., 2005; Rose & Beaulieu, 2019) or alternative functional reinforcers (e.g., Austin & Tiger, 2015; Sumter et al., 2020). Typically, items are identified through a competing item (e.g., Hagopian et al., 2005) or stimulus preference assessment (e.g., Piazza et al., 1996). Offering free access to other stimuli provides an opportunity for the individual to interact with the alternative activity while they wait for the delay interval to elapse. The mere presence of the alternative activity during the delay may simply enrich the environment, making the delay period more tolerable or it may signal the availability of alternative reinforcement thus evoking interaction with it. Under these potential value altering conditions, the presence of an alternative activity may make the delay context less aversive, decrease the motivation for continued requests or resurgence of problem behavior to access the reinforcer, and facilitate tolerance of delayed or denied reinforcement.

In addition to simply providing an alternative activity noncontingently, another technique is to require that the individual engage in a response during the delay period to terminate the delay (e.g., Drifke et al., 2020; Ghaemmaghami et al., 2016a). This DRA contingency likely helps to suppress continued requests or problem behavior by strengthening an appropriate competing response during the delay. If offering alternative activities or programming contingencies during the delay period does not promote delay tolerance, one might consider adding a punishment component for engaging in the problem behavior during the delay (e.g., Fisher et al., 2000).

Situations in which reinforcement is not available Although the procedures described above program opportunities for teaching delay and denial tolerance, access to the reinforcer is almost always offered eventually. In reality, there are situations wherein reinforcement for a request will not be available for some extended duration (e.g., days, months, years) or at all. Therefore, behavior analysts might need to consider incorporating "denied access" procedures that target "accepting no" in which the individual makes a request, is told "no" and, if they do not engage in problem behavior, they are offered an alternative reinforcer to strengthen the "tolerating no" response. Like the procedures described above, this process would begin with short intervals between denial, being told "no," and alternative reinforcement delivery and then gradually increase the time between denial and reinforcement delivery.

Some Strengths and Limitations of Delay/Denial Tolerance Training

Procedures for training delay and denial tolerance nicely simulate situations encountered in the natural environment in which the individual's requests for reinforcement cannot be honored immediately. Strategies for teaching this initial tolerance to delayed reinforcement, increasing the delay, and enhancing the tolerance during extended delays are based on procedures derived from basic laboratory experiments with nonhuman organisms that have been applied with success to humans in real-world settings and situations. Similar to the approach described above of using compound schedules with discriminative stimuli for effectively thinning schedules of reinforcement, delay and denial tolerance training procedures have seen a recent surge in research and application to offer an additional (or alternative) approach toward the goal of maintaining therapeutic effects under more realistic conditions that are feasible for those responsible for implementing the intervention in the individual's everyday environment.

Despite this noted increase in research and application, a major limitation has yet to be sufficiently addressed. That is, as the delay is increased, the contingency between the communication response and the delivery of reinforcement may be weakened, which may result in the reemergence of problem behavior (Fisher et al., 2000; Hanley et al., 2001). In fact, after examining data presented in the recent research applications of delay and denial tolerance training, multiple examples of resurgence of destructive behavior are observed during the "response chaining" (i.e., Hanley et al., 2014; Santiago et al., 2016; Ghaemmaghami et al., 2016a) and "reinforcement thinning" (i.e., Jessel et al., 2018) phases. Across these cases, at least one instance of resurgence was observed in 8 of the 12 applications (67%; i.e., Gail, Dale, & Bob in Hanley et al., 2014; Zeke in Santiago et al., 2016; Will in Ghaemmaghami et al., 2016a; John, Joe, & Kane in Jessel et al., 2018) using the definition of *schedule-thinning transition* and *resurgence* described by Briggs et al. (2018b; p. 624). In addition, in the three applications in which the investigators identified the individual reinforcement thinning steps (i.e., Jessel et al., 2018), resurgence is observed in 9 of the 20 steps (45%). Overall, the percentage of applications with resurgence (67%) and percentage of thinning steps with resurgence (45%) are nearly identical to the findings of Briggs et al. (2018b; i.e., 76% of applications and 42% of thinning steps). Only one study using delay and denial tolerance training procedures has directly evaluated the durability of their treatment outcomes with two participants by assessing maintenance of effects after 6 weeks without programmed treatment, extended denial probes, and caregiver generalization probes (Rose & Beaulieu, 2019). Problem behavior reemerged at low (Owen) or variable (Anna) levels during the denial probes (Anna), treatment extension (Anna), and caregiver probes (Anna and Owen). These data suggest that delay and denial tolerance training procedures are not immune to relapse and there is a need to investigate strategies for mitigating resurgence caused by the delay between the communication response and the delivery of the reinforcement weakening this contingency, and renewal caused by failure to program for generalization.

To prevent or mitigate relapse, researchers might consider using more salient condition-signaling stimuli to teach individuals to discriminate between periods in which their responses will and will not be reinforced, similar to procedures described above for using compound schedules with discriminative stimuli. Currently, delay and denial tolerance training procedures only program a fleeting auditory stimulus (e.g., "Wait") and future researchers might consider evaluating the effects of long-lasting visual or auditory stimuli (e.g., a colored card or wristband that signals the "Wait" period), as research has shown that signaled delays to reinforcement can be used to facilitate greater tolerance for these delays (e.g., Fuhrman et al., 2016) and promote transfer of treatment effects across caregivers (e.g., Greer et al., 2019).

Given Rose and Beaulieu (2019) represent the only study to conduct extended denial probes (e.g., 20 min) with a participant, there is a need to determine whether currently programmed delay and denial tolerance training adequately promote tolerance to naturally occurring periods of delayed or denied reinforcer access (e.g., 30 min, 1 h, 1 day, 1 week). Currently, training conditions only program a large delay during maybe 1 out of 5 trials that lasts a maximum of 12 min (Rose & Beaulieu, 2019), while denser, more immediate schedules of reinforcement are programmed for the majority of the other responses. Thus, it is unknown whether these current procedures are effective at teaching tolerance to delay or denied reinforcement under more extensive denial scenarios.

Finally, although Ghaemmaghami et al. (2016a) have shown that arranging contingencies during the delay period promotes tolerance, this approach requires caregivers to maintain access to materials and to prompt engagement, which may be effortful, less than ideal, and even undesirable to caregivers who may be expected to implement these procedures over extended periods of time. Complex and highly involved procedures may increase the likelihood that caregivers do not implement the intervention with high integrity, which may lead to errors of omission and commission that could lead to the emergence and intermittent reinforcement of problem behavior. Therefore, future researchers should consider exploring other procedures for promoting delay and denial tolerance or identifying procedures that are less effortful for caregivers to manage (e.g., teaching individuals to use activity schedules).

Reducing Extrinsic Reinforcers in Skill Acquisition Procedures

Many times, individuals receiving behavior-analytic services (e.g., early intensive behavioral intervention) have goals to improve skill acquisition (e.g., learning new tacts) without the need to concurrently reduce problem behavior in a manner we described above. When targeting a new skill, reinforcers may need to be provided after every or nearly every response to produce rapid behavior change (Lovaas, 2003). Ideally, consequences that have a “natural relation” to the response (i.e., intrinsic or automatic reinforcers; Catania, 2013, p. 77) will increase and maintain the response. For instance, coloring on paper is likely maintained by the intrinsic reinforcers produced by the brightly colored lines and patterns that drawing with crayons inherently creates. Sometimes, however, intrinsic consequences may not function as reinforcers and it may be necessary to arrange immediate consequences that have an “arbitrary relation” to the response (i.e., extrinsic or contrived reinforcers; Catania, 2013, p. 77) to produce sustained behavior change. That is, if the product of coloring is not enough to reinforce the child’s behavior, extrinsic reinforcement in the form of caregiver compliments or edible reinforcers could be delivered to achieve the behavior change goal.

Once the newly acquired response is occurring reliably, behavior analysts should reduce extrinsic reinforcers to (a) reduce satiation, (b) increase the number of learning opportunities within a session, (c) maintain the target response, (d) facilitate generalization, (e) transition to intrinsic reinforcers, and (f) potentially improve social validity of the behavior-change procedures (see the overjustification hypothesis/effect; e.g., Akin-Little et al., 2004). The primary method of reducing extrinsic reinforcers discussed in the present chapter is to transition from continuous to intermittent schedules.

Transitioning from Continuous to Intermittent Schedules

Although a dense schedule of continuous (i.e., FR1) reinforcement is initially recommended to produce rapid behavior change (Lovaas, 2003), the schedule should be thinned to an intermittent one once an individual is engaging in high levels of correct independent responses (LeBlanc et al., 2002). Schedule thinning can involve either an increase in the response requirement before delivery of a reinforcer or an increase in the time interval preceding delivery of the reinforcer (LeBlanc et al., 2002). Because behavior analysts tend to focus on thinning the frequency of reinforcement rather than delay (Love et al., 2009), this section will focus on dense-to-lean schedules rather than delay schedules (see Carroll et al., 2016, for an example of the effects of delay on acquisition; see Freeland & Noell, 2002, for an example of delay thinning in special education).

There are few resources to guide reinforcement-schedule thinning during skill-acquisition interventions. For example, manuals by Fovel (2013), Lovaas (2003), and Maurice et al. (1996) all recommend moving to intermittent reinforcement schedules; however, none of them include recommendations for accomplishing this. Given the paucity of clear recommendations, LeBlanc et al. (2002) suggested that behavior analysts are likely relying on “common lore and best guesses.” Below, we offer an overview of strategies researchers have used to transition from continuous (i.e., FR1) to intermittent schedules of reinforcement and describe the conditions under which behavior analysts might select to achieve a leaner schedule of reinforcer delivery.

Overview

In general, behavior analysts begin transitioning from a FR1 to an intermittent schedule once the individual has demonstrated skill acquisition mastery under a FR1 schedule of reinforcement (e.g., Conine et al., 2020). A behavior analyst can accomplish thinning by arranging reinforcers to follow either a certain number of responses (i.e., ratio schedule) or the first response after a certain amount of time has passed since the last reinforcer (i.e., interval schedule). Additionally, these ratio and interval schedules can be arranged in a fixed (i.e., recurring value) or varied (i.e., mixed values) manner, with each combination producing different patterns of responding (Catania, 2013; Ferster & Skinner, 1957). The therapeutic goal of transitioning from a dense schedule to a lean schedule of reinforcement is to maintain the newly acquired response on a schedule of reinforcement that is more feasible for those responsible for managing it in the everyday environment.

Thinning Progression

There is no prescribed process to thin reinforcement in skill-acquisition programs. However, there are general suggestions and examples available throughout the literature that can be drawn upon for behavior analysts to use as a reference when deciding upon an approach to meet their client's needs. First, behavior analysts should begin the thinning process after responding has met a predetermined criterion (e.g., three consecutive sessions with 100% correct responding; see Richling et al., 2019, for a review and experimental analysis of mastery criteria). Second, a reinforcement delivery schedule should be decided upon and followed systematically during the thinning process. There are examples of interval schedules in the behavior analytic literature (e.g., Garner et al., 2018; Martens et al., 2002); however, survey data suggest that most behavior analysts are likely to rely on the use of ratio schedules to thin in practice (Love et al., 2009). In fact, LeBlanc et al. (2002) recommend increasing the number of responses required to produce a reinforcer when target behavior should occur at moderate-to-high levels with a steady or increasing trend. Because this is often the goal for target behavior in skill-acquisition programs, transitioning from dense-to-lean ratio schedules may be most recommended.

Third, a schedule-thinning progression should be decided upon and followed systematically during the thinning process as well. Due to the issues generated by fixed schedules of reinforcement (i.e., pausing, scalloping), the use of variable schedules to thin reinforcement may be most desirable (Bancroft & Bourret, 2008). A behavior analyst can arrange reinforcers to follow an average number of responses or an average amount of time since the last reinforcer in a variable ratio (VR) and a variable interval (VI) schedule, respectively. A VR schedule is likely to lead to steady responding at lower levels than a fixed-ratio schedule, but the VR schedule is also likely to reduce pausing following delivery of the reinforcer. This is because the reinforcer is delivered after a range of responses with a specified mean (Catania, 2013), so the response which will produce a reinforcer varies from one opportunity to the next (DeLeon et al., 2013). A VI schedule is likely to generate moderate and relatively stable levels of responding (Catania, 2013). The selection of the distribution values in VR and VI schedules is important (i.e., more shorter intervals than moderate or long intervals will generate higher response rates following reinforcer delivery, DeLeon et al., 2013).

Fourth, during the thinning process, it is recommended that each thinning step is experienced for at least two sessions to verify that the response is consistent before advancing. Slow, gradual thinning can promote steady progress, but there is no indication that this is an efficient practice (LeBlanc et al., 2002). To potentially increase efficiency, a behavior analyst may decide to probe responding under leaner schedules of reinforcement to determine whether the gradual thinning of reinforcement is necessary (LeBlanc et al., 2002). However, behavior analysts should wait until the individual has progressed through half of the thinning steps before probing performance under the terminal schedule (LeBlanc et al., 2002). The behavior analyst should proceed with caution as gains can be lost if reinforcement is thinned too quickly. Responding may change briefly when each phase of thinning is initiated, but responding should return to similar levels with continued exposure. If responding continues to decrease or stabilizes at a low or moderate level, then the behavior analyst should return to a previous schedule until high, stable levels of responding return before initiating further thinning.

Importantly, behavior analysts should make informed decisions about when to begin and how to proceed with the thinning process if they continually monitor and make changes based on the individual's response to thinning. Additional research needs to be conducted to identify the optimal procedures to thin reinforcement in behavior-analytic skill-acquisition procedures.

Desired Response Pattern

The goal of reinforcement thinning in skill-acquisition interventions is to maintain the levels of performance achieved during dense, FR1 schedules of reinforcement under lean, intermittent schedules of reinforcement. That is, the goal is for the individual to emit the target response under relevant antecedent conditions despite changes in reinforcer delivery.

Considerations

Deciding between variable- or random-ratio schedules Behavior analysts may choose an arithmetic progression with values that change by a fixed constant (e.g., VR2, VR4, VR6, VR8) or a geometric progression by doubling the previous value (e.g., VR2, VR4, VR8, VR16; DeLeon et al., 2013). Using this approach, the probability for reinforcement increases across successive trials without reinforcement, and the passage of unreinforced trials could become a discriminative stimulus. However, doubling the response requirement in this manner can pose a problem when the requirement becomes quite large (LeBlanc et al., 2002), especially if there are few short ratios included. Therefore, DeLeon et al. recommend using a random ratio (RR) schedule when values become relatively large, because the probability that a response will be reinforced remains constant over successive responses. Behavior analysts can incorporate this strategy into their practice by using Microsoft Excel macros to generate RR (and VR) schedules (Bancroft & Bourret, 2008) or rolling a die (available with four to 100 sides; DeLeon et al., 2013) following a response to determine whether it will be reinforced. Additionally, the ubiquity of devices like smartphones and tablets could provide a digital option for creating and applying VR or RR schedules of reinforcement across responses.

Using a VI schedule To use a VI schedule in practice, a behavior analyst must carefully select and specify the distribution of intervals (Catania & Reynolds, 1968). Baker (1979) recommends a VI with values falling within a range of plus or minus one unit (p. 56). For example, a VI 1-min schedule would have a minimum of 1 s and a maximum of 2 min. Like the VR, the probability that a response will be reinforced increases as time passes without a reinforcer in VI (DeLeon et al., 2013). Therefore, the use of a random interval (RI) schedule may be beneficial.

Bancroft and Bourret (2008) provide a tutorial for setting up Microsoft Excel Macros to generate VI and RI schedules to use in practice. Baker (1979) provides instructions on how to create audio recordings that include a stimulus (e.g., tone, beep) at different intervals; the instructions can be updated to take advantage of audio recording applications on electronic devices. A behavior analyst may choose to purchase an interval timer to help with implementation, too. There are many different interval timers available as physical timers or digital applications, but few appear to have the capacity to run a VI or RI schedule. A physical timer with FI, VI, and RI capabilities is the MotivAider® by Behavioral Dynamic, Inc. A digital application with the capacity to use VI schedules with preset mean durations between 1 min and 15 min is R+ Remind™ by Pyramid Educational Consultants.

Some Strengths and Limitations of Transitioning from Continuous to Intermittent Schedules

As already mentioned, there is little practical guidance as to how to thin reinforcement including: (a) when to start the thinning process, (b) how quickly to thin reinforcers, and (c) how to communicate thinning to the individual (Katz & Vinciguerra, 1982). Nevertheless, a behavior analyst should not adopt a train-and-hope approach; rather, a behavior analyst should plan how and when to thin the reinforcement schedule (LeBlanc et al., 2002). No matter which intermittent schedule a behavior analyst selects in practice, one should not expect that a behavior acquired under dense schedules of reinforcement will maintain and generalize when the extrinsic reinforcers are removed or reduced abruptly (Stokes & Baer, 1977). For instance, a behavior analyst should be aware that as the reinforcement schedule is thinned, the reinforcer becomes more "expensive." That is, the individual needs to emit more and more instances of the target behavior to attain the same amount of reinforcement. As the unit price increases, it is possible that the reinforcer may become inefficacious (DeLeon et al., 2013). This may be especially likely if the therapist offers access to the same reinforcers outside of skill-acquisition programs in an open economy (DeLeon et al., 2013). When thinning, it could be beneficial to restrict access to reinforcers outside of instructional time in a closed economy. Further, if the "price" of accessing the item is increased, it may also be advantageous to alter the relevant dimensions of the reinforcer (e.g., quality, magnitude) to maintain an appropriate work-to-reinforcement ratio (Briggs et al., 2018a, 2019). A behavior analyst should also recognize that preferences change over time and conduct preference assessments regularly (Piazza et al., 2011).

It can be difficult to determine the terminal schedule when thinning reinforcement. A behavior analyst may determine the terminal schedule by monitoring the individual's response to thinning and maintenance of responses over time. A behavior analyst could also consider using a progressive-ratio schedule to identify an individual's break point to guide the selection of terminal-reinforcement schedules to use in skill-acquisition interventions (Catania, 2013). Using the learner's response to thinning, duration of responding under maintenance or extinction conditions, and a progressive-ratio schedule to determine the terminal schedule for thinning could be beneficial in practice. These suggestions require systematic investigation in research.

It is important to consider the behavior-change agent's repertoire and competing contingencies when designing a plan for thinning reinforcement. If opting to use an interval schedule, a behavior analyst may select intervals that are easy for therapists and caregivers to use (e.g., 15 s, 1 min; LeBlanc et al., 2002). If opting to use a VR schedule, a behavior analyst should plan which responses will produce a reinforcer. This requires monitoring responding across opportunities, avoiding the presentation of any additional antecedent stimuli that may become correlated with the delivery of reinforcement, and creating different combinations to avoid potential schedule control (Baker, 1979). A behavior-change agent may find a VR2 easy to use in applied contexts because it only requires three ratios (i.e., 1, 2, 3); nevertheless, the order of these ratios needs to be randomized and monitored to ensure that reinforcers are delivered on a truly variable schedule rather than a predictable sequence of numbers.

Concern about additional controlling stimuli may be especially important when reinforcement thinning is used to promote generalization. When arranging indiscriminable contingencies (Stokes & Baer, 1977), it is important that stimuli present in the environment prior to the response do not predict whether a response will be reinforced. For example, the therapist could move her hand close to a reinforcer when the next response will be reinforced. These antecedents could come to be discriminative for reinforcement and negatively affect the likelihood that an individual will respond during generalization probes (i.e., false negative).

Immediate, continuous (i.e., FR1) reinforcement schedules are often unsustainable in most natural settings (Fisher et al., 2000), so another benefit of intermittent schedules is that the reinforcement procedure should be more manageable in the clinic or home environment. In addition, descriptive analyses of treatment integrity of behavioral interventions revealed inconsistent tangible, edible, and social stimuli (e.g., praise) delivery by paraprofessionals, special education teachers, and behavior therapists working with students and clients with autism spectrum disorder (e.g., Breeman et al., 2020; Carroll et al., 2013; Kodak et al., 2018). However, descriptive analyses of treatment integrity in behavioral skill-acquisition programming should examine adherence to different reinforcement schedules more closely.

Concluding Comments

Familiarity with the various methods for thinning reinforcement is critical for behavior analysts if their goal is to promote durable treatment outcomes. That is, when the intervention does not require much caregiver involvement because naturally occurring reinforcement contingencies are in effect, long-term treatment success is much greater. This outcome is accomplished when behavior analysts thoughtfully and systematically thin an intervention's reliance on reinforcement while simultaneously maintaining its desirable treatment effects. We review general approaches for achieving this outcome and provide considerations that may improve the likely success of each thinning progression. Another method for reducing the reliance on delivering potent primary reinforcers on relatively dense schedules of reinforcement is by transitioning from using primary to conditioned reinforcers. Strategies for establishing conditioned reinforcers are discussed in the *Stimulus Pairing* chapter (Chap. 10) and methods for operating a reinforcement system that involves exchanging generalized conditioned reinforcers for backup reinforcers are discussed in the *Token Economies* chapter (Chap. 32) of this book.

7 Behavioral Momentum Theory

Sean W. Smith and Brian D. Greer

The concept of response strength was one of the first principles of behavior to be identified within the field of behavior analysis. Thorndike's (1911) initial formulation of the law of effect is often considered the origin of the concept of response strength (Nevin & Wacker, 2013). Thorndike's initial description suggests that "impulses" would be "stamped in" if they were "successful" and "stamped out" if they were unsuccessful, but the more general finding was that organisms learn based on the consequences of their responses, and this learning influences how the organism responds in the future. Said another way, the consequences of a response would strengthen or weaken the response. Although this strengthening or weakening can influence future responding along numerous dimensions (e.g., resistance to change, amplitude, latency), Skinner staunchly advocated for response probability as the primary measure for the science of behavior (e.g., Skinner, 1963, 1966). Although this conceptualization creates difficulties because response probability cannot be observed or measured directly, Skinner and other researchers argued that response rates measured during free-operant procedures serve as a reliable index of response strength. The field of behavior analysis came to adopt a refined conceptualization of the law of effect in the form of reinforcement theory, which generally states that the consequences that follow a response will influence the future probability (i.e., strength) of that response in similar contexts. A notion implicit in reinforcement theory is that more reinforcement will produce more response strength (Shahan, 2017). Notably, this reformulation not only establishes that consequences influence the strength of a response, it also focuses on response probability, as measured by response rate, as the primary dimension of behavior.

This refined conceptualization of reinforcement theory has had an indelible effect on subsequent behavior-analytic research. In the basic laboratory, development of the matching law

(Herrnstein, 1970) was directly influenced by the idea that reinforcement strengthens behavior and that response rate is the appropriate index for response strength. Indeed, this was the primary theoretical explanation for Herrnstein's successful quantification of the functional relation between reinforcer deliveries and response rates. In the applied domain, Thomasson-Sassi et al. (2011) used the concept of response strength to develop a novel method for assessing severe problem behavior. Behavior-analytic theory has also benefited. Palmer (2009) leveraged the concept of response strength to provide behavior-analytic interpretations of complex verbal behavior. This conceptualization has and continues to influence research with nonhuman and human animals, in basic and applied settings, with simple and complex responses.

Despite the pervasive application of the concept of response strength, there are important limitations to focusing on response rate as an index of response strength. One simple example of this limitation is the different steady-state response patterns generated by ratio and interval schedules of reinforcement. Response rates under ratio schedules tend to be higher than those under interval schedules when obtained reinforcer rates are comparable (Baum, 1993). As noted previously, the concept of response strength generally suggests that more reinforcement will produce greater response strength, but these schedules of reinforcement produce different response rates with the same amount of reinforcement. Other research has shown that varying reinforcer magnitudes have different effects on response rates maintained by interval and ratio schedules of reinforcement (Lowe et al., 1974), suggesting that other aspects of the reinforcement schedule also influence response rate. These and other research findings suggest that response rate is not a reliable measure of response strength because response rate can be influenced by variables that are not hypothesized to be associated with response strength. Said another way, response rate does not fully describe the strength of a response.

Resistance to Change as a Measure of Response Strength

Although Skinner suggested that response strength should be measured by the rate that organisms engage in observable responses, Nevin and Grace (2000) argued that a behavior's resistance to change may be an equally, if not more, valid measure of response strength. Nevin and Grace (2000, p. 75) provided the following analogy:

> Concrete is said to be reinforced with steel rods to make it stronger as a building material. In this expression, "reinforcement" implies an increase in durability or resistance: Under an added load, a reinforced concrete wall does not collapse as readily as an unreinforced wall. However, an observer could not determine, by looking at it before a load test, whether the wall had been reinforced or how many steel rods had been used… By analogy, we suggest that more frequently or generously reinforced behavior becomes more resistant to challenge or disruption, and this increase in its resistance need not imply an observable increase in the rate or probability of currently observed behavior. Instead, the strengthening effects of reinforcement may be evident only when responding is disrupted in some way.

Measuring Resistance to Change

Researchers typically measure resistance to change by establishing steady state responding and then introducing a disrupter to the environment. This allows the researcher to compare response patterns before and after introduction of the disrupter. If the disrupter has little effect on responding, behavior is said to be resistant to change. The greater the disruption in responding, the less resistant to change the behavior is said to be. Notably, resistance to change is not a dichotomous concept, and responses are not typically categorized as resistant to change or not. Rather, researchers typically describe the relative resistance to change of behaviors by comparing the resistance to change of behavior in one context to the same behavior in a different context or by comparing the resistance to change of one behavior to another.

To compare the relative resistance to change of two or more responses, researchers frequently use multiple schedules of reinforcement. A multiple schedule of reinforcement is composed of two or more simple schedules of reinforcement that are presented successively in separate components signaled by discriminative stimuli. For example, in one component of a multiple schedule, a green light is correlated with pressing a lever to produce food according to a fixed ratio (FR) 5 schedule of reinforcement, but in another component, a red light is correlated with pulling a chain to produce the same food according to a variable interval (VI) 10-s schedule of reinforcement. These components alternate successively, and responding comes under the control of each schedule of reinforcement in the presence of each discriminative stimulus. Recall that resistance to change is typically evaluated by comparing the effects of a disrupter across two or more contexts or responses. Multiple schedules of reinforcement facilitate such comparisons by allowing for the presentation of a single disrupter across schedule components. Researchers can then assess response disruption across the schedule components.

Common Disrupters

Disrupters can take many forms depending on the experimental preparation and the experimental question. For example, a researcher using food reinforcers to maintain lever pressing in rats may disrupt responding by delivering food noncontingently between schedule components or immediately before session (e.g., Nevin, 1974, 1992). Such a procedure would affect the rat's motivation to obtain food, which would allow the researcher to evaluate resistance to change under reduced motivation.

Another common disrupter entails changing the schedule of reinforcement (e.g., terminating reinforcement across multiple-schedule components; Nevin, 1974). Initiating extinction allows researchers to evaluate response persistence, or resistance to extinction, produced by the reinforcement schedules previously in effect. Another common disrupter is the simultaneous presentation of alternative reinforcement (e.g., Nevin et al., 1981). For example, Mace et al. (1988) taught adults with disabilities to engage in a beading task maintained by access to preferred edibles across two components of a multiple schedule. Researchers turned on a television in the room to provide an alternative source of reinforcement to evaluate the extent to which this disrupter would change response patterns across the components of the multiple schedule. These are but a few of the environmental events that can disrupt responding.

Proportion of Baseline

Resistance to change is typically quantified as a proportion of baseline responding. Researchers calculate the mean response rate during the portion of baseline in which responding has stabilized. Researchers then divide the response rate from each session with the disrupter present by the mean baseline response rate. This exercise expresses the results of sessions with the disrupter present as a proportion of baseline responding. Values greater than 1.0 indicate responding above baseline rates, and values less than 1.0 indicate responding below baseline rates. Researchers typically present proportion-of-baseline data as a time series to see fluctuations across time.

Although there are multiple reasons why researchers evaluate resistance to change as a proportion of baseline, the primary reason is that it helps when accounting for differences in baseline response rates (i.e., the starting points of each response). This can be helpful when assessing resistance to change, as the rate of change in responding across conditions is a primary consideration for determining relative resistance to change. Plotting responding as a proportion of baseline enables a visual analysis of how quickly and to what extent the same disrupter affected responding across conditions when considering their respective starting points.

Implications of Resistance to Change as Response Strength

Shifting the conceptualization of response strength away from response probability as measured by response rate and toward resistance to change has several implications for both research and clinical practice. The first implication is that it directs focus away from response–reinforcer relations as the sole determiner of response strength. Skinner's hugely influential work focused primarily on how response strength increases or decreases as a function of whether it was followed by a reinforcing stimulus and how response strength could be quantified as response rate. As noted previously, however, response rates do not accurately reflect response strength because other variables appear relevant. Thus, considering resistance to change as the primary measure of response strength represents a significant shift in how researchers and clinicians conceptualize response strength.

Second, measuring resistance to change rather than response rate shifts the focus of research and clinical practice away from current responding toward what responding will look like when disrupted. The earlier conceptualization that response strength was best quantified as response probability, as measured by response rate, focuses research and practice on responding as it is now. By changing the focus of research to resistance to change, researchers shift their evaluations to focus on what will happen to behavior when disrupters are introduced. In other words, researchers evaluate how much a behavior will persist in the future, despite changes in the environment. Not only does this foster a focus on responding in the future, this focus also has broader implications for clinical practice because the environment is constantly changing in applied settings, making it especially important for clinicians to consider how common disrupters (e.g., a change in context or treatment integrity) may affect treatment efficacy. Although research involving response rates can inform conditions to optimize current response patterns, findings from research on resistance to change can inform treatment modifications that reduce the persistence of problem behavior and increase the persistence of appropriate behavior.

Finally, resistance to change itself can be a clinical concern. For example, core symptoms of oppositional defiant disorder (ODD) and autism spectrum disorder (ASD) can be conceptualized as issues related to resistance to change. People diagnosed with ODD may resist change to such an extent that it causes dysfunction in daily life. Similarly, the restricted interests or behaviors associated with ASD can be conceptualized as resistance to change. Treatments that specifically target resistance to change may target the core symptoms of these disorders by targeting the basic behavioral processes underlying their etiology.

Clinical Treatments for Resistance to Change

Few behavior-analytic studies have referred to treating resistance to change; however, this is likely because resistance to change may be an underlying process from which other problem behavior arises. That is, clinical research may have focused on treating problematic topographies of behavior rather than treating the underlying functions of these responses. For example, it is easy to see how behavior that is resistant to change could simply be considered noncompliance, leading clinicians to consider their treatment as targeting noncompliance rather than resistance to change. We will begin this section with a brief review of one strategy, the high-probability (high-p) sequence, that leverages the concept of resistance to change to address noncompliance. Another important consideration for applied work is whether treatments target the *cause* of change-resistant behavior. We end this section with a discussion of a few recent studies that have begun to probe this consideration.

High-P Sequences

Mace et al. (1988) developed the high-p sequence as a treatment for noncompliance. Before applying this treatment, the clinician first identifies instructions with which the client does not comply. These instructions are considered low-probability (low-p) instructions and are the target of treatment. Next, the clinician identifies instructions with which the client does comply. Typically, these high-p instructions often involve brief, simple responses (e.g., clapping hands). To apply the treatment, the clinician presents several high-p instructions in rapid succession, reinforces compliance with each instruction, and then presents a low-p instruction. The clinician also reinforces compliance with the low-p instruction. Researchers have shown the high-p sequence to be efficacious for treating noncompliance across a wide range of ages, diagnoses, and types of instructions (see Lipschultz & Wilder, 2017 for a brief review). The primary advantage of this treatment compared to other treatments for noncompliance is that it does not require physical guidance, which is important when physical guidance is impossible (e.g., vocal responses) or impractical (e.g., guiding an individual of large physical stature).

Mace et al. (1988) originally attributed the efficacy of the high-p sequence to overcoming the resistance to change of noncompliant behavior. In this conceptualization, all compliant responses are considered a single response class, and noncompliance is a separate response class. By presenting high-p instructions first, the clinician provides the client with the opportunity to engage in compliant responses that the client is likely to emit, increasing the probability that the clinician can then reinforce multiple compliant responses. When compliant responses produce reinforcement, the class of compliant responses is strengthened, which increases the response class's resistance to change. This increased resistance to change causes compliant responses to persist despite the presentation of a disrupter—the low-p instruction. Thus, the client engages in a compliant response to the low-p instruction because of the increased resistance to change of the compliant response class.

There are a number of parameters that clinicians must consider when developing a high-p sequence. First, research has shown that providing high-p instructions without reinforcing compliance will not increase compliance with low-p instructions (Pitts & Dymond, 2012; Zuluaga & Normand, 2008). Second, delivery of more highly preferred and more reinforcing stimuli following compliance with high-p instructions produces higher levels of compliance with low-p instructions than stimuli that are less preferred and less reinforcing (Wilder et al., 2015). Third, other research has demonstrated that shorter intervals between high-p instructions enhance the efficacy of the high-p sequence (Mace et al., 1988; Pitts & Dymond, 2012; Wilder et al., 2015). Fourth, some have recommended using the minimal number of high-p instructions that reliably occasion compliance with the low-p instruction (Cooper et al., 2020). Once compliance is occurring with the low-p instruction, the number of high-p instructions can further decrease while maintaining the treatment effect (Axelrod & Zank, 2012; Belfiore et al., 2008). These findings and recommendations are consistent with the conceptualization that the treatment's efficacy comes from modifying resistance to change.

However, not all research findings bode well for a resistance-to-change conceptualization of the high-p sequence, and some findings present serious obstacles for this account. For example, Bullock and Normand (2006) showed that noncontingent delivery of reinforcers for two children produced increases in low-p compliance similar to that produced by arranging a high-p sequence, and a later study by Normand and Beaulieu (2011) replicated this finding. These findings suggest that simply delivering reinforcers close in time to presenting a low-p instruction is primarily responsible for the efficacy of the high-p sequence. Thus, an alternative account consistent with these findings and those of the prior studies discussed above is that the efficacy of the high-p sequence relies on the arousing (Killeen, 1975; Killeen et al., 1978) and/or discriminative (Cowie & Davison, 2016) properties of reinforcement.

Choice-Based Interventions for Resistance to Change

Fisher et al. (2019) theorized that resistance to change can be described in terms of extreme choice behavior across concurrently available response alternatives (i.e., a change-resistant response and an alternative response). In so doing, Fisher et al. invoked the concatenated generalized matching law (Baum, 1974; Baum & Rachlin, 1969) to describe how extreme choice behavior might develop. They pointed to recent fMRI research that suggests that change-resistant behavior in people with ASD might be maintained by both positive and negative reinforcement contingencies. Based on this account, the authors evaluated a choice-based treatment for the change-resistant behavior of four participants with ASD. In the free-choice condition, the participant could engage in either a change-resistant or alternative response and contact the natural reinforcers associated with each response without any additional programmed consequence. The asymmetrical-choice condition was identical except that participants also received their most highly preferred item following alternative behavior, whereas no additional reinforcers were provided following the change-resistant behavior. In the guided/single-choice condition, alternative behavior was the only response option, but it produced the same reinforcer as choosing the alternative response during the asymmetrical-choice condition.

Fisher et al. (2019) found that most participants continued to engage in change-resistant behavior exclusively during the free-choice condition and that initial exposure to the asymmetrical-choice condition either had no effect or caused insufficient alternative responding to be clinically acceptable. Exposure to the guided/single-choice condition always produced high levels of alternative behavior. Importantly, for four of six applications of these procedures, repeated exposures to the guided/single-choice condition resulted in higher levels of alternative behavior during reversals to the asymmetrical-choice condition. This last finding suggests that engaging in an alternative response and experiencing reinforcement following that response may be sufficient to overcome some clinically significant change-resistant behavior.

Crowley et al. (2020) extended the research of Fisher et al. (2019) by applying the same general procedures to seven participants with clinically significant food selectivity. For two participants, the asymmetrical-choice condition was sufficient to allocate responding to the alternative response and away from the change-resistant response. The remaining five participants engaged in similar patterns of responding as participants in the study by Fisher et al., with the asymmetrical-choice condition alone producing clinically significant increases in alternative responses following forced exposure to the consequences associated with the alternative response. Importantly, responding for every participant shifted from the change-resistant response during the asymmetrical-choice condition by the end of the experiment. Further, for five of the seven participants, exposure to the guided/single-choice condition not only shifted response allocation during subsequent asymmetrical-choice conditions for those foods, but also for other, nontarget foods. This last finding is particularly important because it suggests that exposure to reinforcing consequences for engaging in alternative responses can generalize to untreated choice situations.

A Theory of Behavioral Momentum: Extending the Concept of Resistance to Change

Behavioral momentum theory (BMT) asserts that response strength is defined by a behavior's resistance to change and extends this notion using an analogy. Newton's second law of mechanics states that changes in an object's velocity are directly proportional to the magnitude of the force exerted on the object and inversely proportional to the object's mass. This general principle is often reformulated to describe momentum, which is equal to the product of the object's mass and the object's velocity. Nevin et al. (1983) suggested that a similar analogy can be applied to behavior such that response rate is analogous to an object's velocity, a disrupter (as described above) is analogous to the force exerted on the object, and the behavior's resistance to change is analogous to the object's mass. Based on this conceptualization, a change in the response rate of ongoing behavior will be directly proportional to the size of the disrupter and inversely proportional to the behavior's resistance to change. Stated more simply, a larger disrupter will cause a larger change in response rate than a smaller disrupter, and a response with more resistance to change will be disrupted less than a behavior with less resistance to change. Although this may seem intuitive, the implications of this conceptualization are far-reaching and have been highly influential in the field of behavior analysis.

BMT was a major step forward for behavior analysis in that it provided an empirically derived and plausible alternative to the Skinnerian conceptualization that response strength is defined by response probability as expressed by response rate. BMT states that resistance to change is driven by stimulus–reinforcer relations (i.e., Pavlovian conditioning) and not response–reinforcer relations (i.e., operant conditioning) that underpinned prior conceptualizations of response strength. This marked an important change in our understanding of response strength because BMT invoked both a different measure for response strength and a different behavioral process by which response strength was thought to be governed.

A second implication of BMT was that the variables determining behavioral persistence could now be described quantitatively. Although a full description of the mathematics underlying BMT is outside the scope of this chapter (interested readers should refer to Nevin & Grace, 2000), expressing behavioral principles mathematically is advantageous for a number of reasons. Quantitative models allow researchers to (a) efficiently summarize large amounts of data, (b) formalize the behavioral processes believed to underlie the phenomena of interest, (c) clearly describe relations that are difficult to convey in words, (d) make explicit and novel predictions that can be empirically evaluated, and (e) allow for revisions in theory when predictions are not supported by empirical evaluation (Critchfield & Reed, 2009; Greer & Shahan, 2019; Mazur, 2006).

Resistance to Change and Response Rate

In a now seminal study, Nevin et al. (1990) showed that response rate and resistance to change are separate dimensions of behavior. In Experiment 2, pigeons experienced a three-component multiple schedule in which each component was signaled by the color of two response keys. Across components, two schedules of reinforcement were concurrently in effect for pecking the right (target) and left (alternative) response keys. Available reinforcers were delivered according to VI schedules. In Component A, both response keys were green. Target responses produced 15 reinforcers per hour, and alternative responses produced 45 reinforcers per hour for a total of 60 reinforcers available per hour across the two keys. In Component B, both response keys were red. Target responses produced 15 reinforcers per hour, and alternative responses were placed on extinction for a total of 15 reinforcers available per hour across the two keys. In Component C, both response keys were white. Target responses produced 60 reinforcers per hour, and alternative responses were placed on extinction for a total of 60 reinforcers available per hour. The experimenters established steady state responding within each component and then introduced extinction for both responses across the three components to evaluate relative resistance to change. This general arrangement allowed the researchers to compare resistance to change when the total number of reinforcers differed but were held constant for the target response (Component A compared to Component B) and when the total number of reinforcers were held constant but their distribution differed (Component A compared to Component C). Figure 7.1 depicts representative data from this experiment.

In Experiment 2, Nevin et al. (1990) found lower baseline rates of target responding when

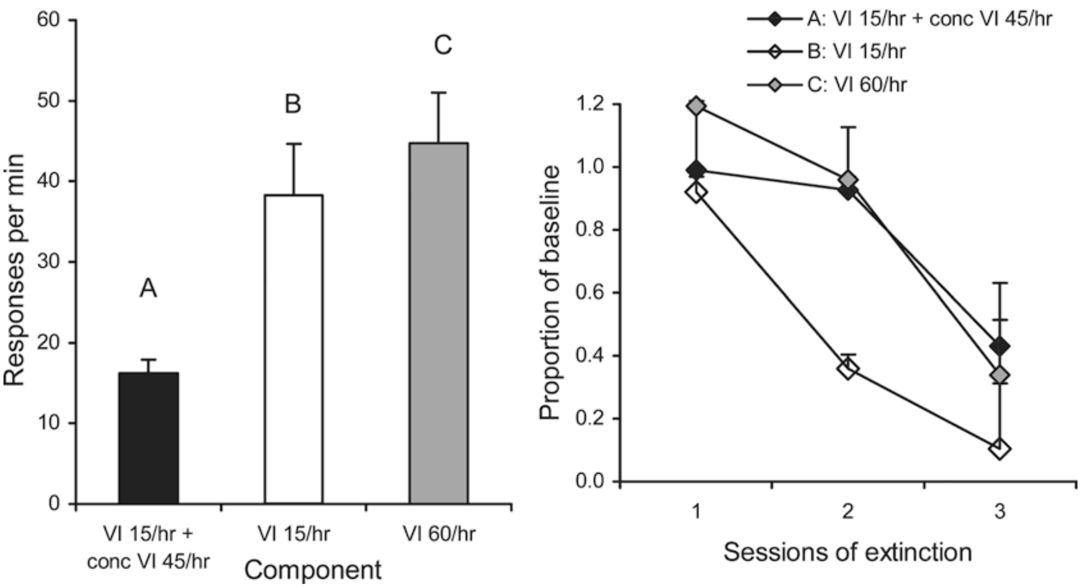

Fig. 7.1 Nevin et al. (1990) Data Reanalyzed by Nevin and Shahan (2011). *Note*. Data represent averages and standard error for three pigeons from Nevin et al. (1990, Experiment 2) as reanalyzed by Nevin and Shahan (2011). In the left panel, each bar represents target response rates. Component A = differential reinforcement of alternative behavior (DRA) available; Component B = DRA unavailable; Component C = DRA unavailable but with reinforcer rate yoked to Component A. The right panel shows target responses for each component during extinction, expressed as a proportion of baseline responding

reinforcers were available for the alternative response (Condition A) as compared to when alternative reinforcement was unavailable (Conditions B and C). However, the most important finding of Experiment 2 was that the total number of reinforcers delivered in baseline determined the persistence of target responding during extinction and that this finding was not attributable to baseline response rates or whether reinforcers were delivered for target or alternative responding. Responding persisted to a similar and greater degree in Components A and C than it did in Component B, even though Components A and B arranged the same schedules of reinforcement for target responding. The additional reinforcers delivered in Component A for alternative responding and in Component C for target responding increased the resistance to change for target responding to a greater extent than in Component B.

The study by Nevin et al. (1990) is important for at least two reasons. First, it demonstrated that response rate and resistance to change are independent dimensions of behavior. A comparison of Components A and B in Fig. 7.1 shows that decreased response rates in baseline did not lead to decreased resistance to change during extinction. Interpreting this finding from another perspective suggests that response rates during disruption cannot be predicted by baseline response rates alone.

Operant vs. Pavlovian Processes

A second important contribution of Nevin et al. (1990) was the demonstration that stimulus–reinforcer pairings impact resistance to change. Recall that when extinction sessions began, the only difference between the components was the discriminative stimuli. This suggests that the discriminative stimuli facilitated the differentiated responding during extinction. More specifically, it was the prior pairing of the discriminative stimuli with different numbers of reinforcer deliveries during baseline that produced differences in resistance to change during extinction. Because Components A and B delivered a similar number of reinforcers contingent on target responding, differences in resistance to change could not have been caused by a different number of response–reinforcer pairings. The additional reinforcer deliveries for the alternative response in the presence of the specific discriminative stimulus likely increased resistance to change. Thus, resistance to change is likely impacted by stimulus–reinforcer pairings.

The development of BMT marked a profound change in how researchers and clinicians conceptualized response strength. It also had important implications for clinical practice in that it placed greater emphasis on response persistence and the role of Pavlovian conditioning histories as they relate to clinical effectiveness. Revisions to what constitutes treatment maintenance were also driven by clinical researchers developing an increased awareness and interest in BMT (Nevin & Wacker, 2013).

Behavioral Momentum Theory and Treatment Relapse

Treatment relapse is the recurrence of problem behavior to clinically unacceptable levels following successful intervention. There are many reasons why treatment relapse occurs (e.g., momentary decreases in reinforcer rate, a change in setting or implementer), and researchers have found some success in extending BMT to explain one form of relapse, called resurgence. Before diving into these extensions of BMT, an overview of resurgence is in order.

Resurgence is a prevalent form of treatment relapse that occurs following treatments involving differential reinforcement of alternative behavior (DRA), such as functional communication training (FCT; Briggs et al., 2018; Muething et al., 2020). Resurgence in the clinic is said to happen when problem behavior recurs because of worsening in alternative reinforcement conditions (Lattal et al., 2017). Such a worsening in alternative reinforcement conditions can take many forms, such as increasing the delay between an alternative response and its reinforcer, decreasing alternative reinforcer magnitude, increasing response effort or the response requirement for an alternative response, thinning the schedule of alternative reinforcement, and programming extinction for an alternative response. From a clinical perspective, some of these events may be planned (e.g., reinforcement schedule thinning), but others occur at unplanned times and can be considered treatment integrity errors. Resurgence is a particularly important phenomenon to understand because treatments involving DRA are common in clinical practice (Petscher et al., 2009).

Shahan and Sweeney (2011) extended BMT by developing a quantitative model of resurgence. We will not get into the weeds so to speak with the nuances of the quantitative model itself but will provide a narrative overview.

According to the BMT account of resurgence described by Shahan and Sweeney (2011), reinforcers delivered during DRA-based treatments serve two important functions. First, they act as a source of disruption for problem behavior, helping to suppress problem behavior when DRA is in effect. Second, reinforcers delivered in treatment strengthen the stimulus–reinforcer relations that enhance resistance to change, regardless of how those reinforcers are delivered (e.g., response independently or for alternative behavior or the nonoccurrence of problem behavior). One important implication of this interpretation is that DRA-based treatments for problem behavior may suppress problem behavior in the here and now, but the delivery of additional reinforcers in treatment increases the strength of alternative behavior, as well as problem behavior. Fast forward to when treatment is challenged by a disrupter (e.g., extinction), alternative reinforcement may suppress problem behavior to a lesser extent (or not at all), and recently strengthened, but not recently occurring, problem behavior is likely to recur.

There are two important considerations worth making at this point. First, a BMT account of resurgence is not limited to DRA-based interventions (see Nevin & Shahan, 2011; Shahan & Sweeney, 2011 for elaboration), meaning that other commonly used treatments for problem behavior that involve alternative reinforcement are also susceptible to resurgence. Second, the quantitative model put forth by Shahan and Sweeney (2011) provided the ability to predict in advance the results of different types of baseline histories and treatment procedures on the magnitude of the resurgence effect. This latter point is especially important because basic and applied researchers alike could now reevaluate previously published resurgence data through a BMT lens and develop new methods for manipulating resurgence in future research (see Greer et al., 2016 for a tutorial on using BMT for such purposes).

Validation of a BMT Account of Resurgence

Figure 7.2 shows target response rates depicted as a proportion of baseline from three laboratory-based studies on resurgence, shown here for the purposes of conveying the accuracy of BMT's quantitative predictions of resurgence. In each of the four panels of Fig. 7.2, dotted and dashed lines are superimposed onto the data paths for two conditions—a treatment phase in which alternative reinforcement was available (labeled "R_a") and a subsequent phase of extinction (labeled "No R_a"). Solid data points and solid lines depict responding and BMT model fits for conditions in which a dense (or rich) schedule of alternative reinforcement was in effect during treatment. Open data points and dashed lines depict responding and BMT model fits for conditions in which a lean schedule of alternative reinforcement was in effect during treatment. In each case, the quantitative model of BMT closely matched the obtained data in both the treatment and extinction phases, accounting for >90% of the variance in the obtained data for each study.

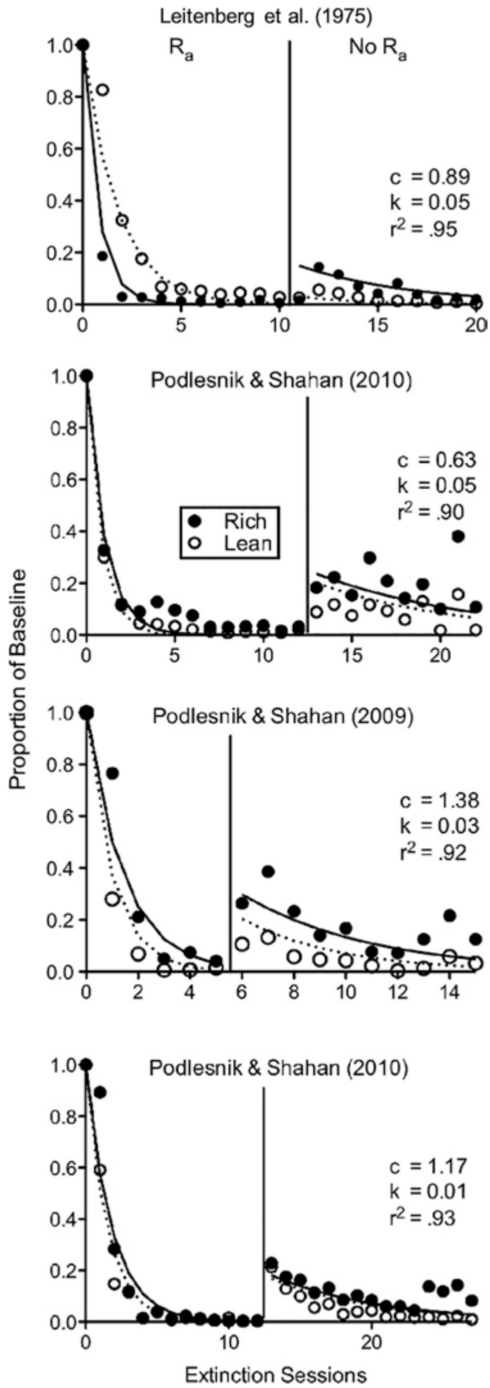

Fig. 7.2 Data Reanalyzed by Shahan and Sweeney (2011). *Note.* Data points represent target responding during extinction of target responses expressed as a proportion of baseline responding obtained during experiments evaluating resurgence with non-human subjects. Solid and dashed lines represent values predicted by BMT for the closed and open data points, respectively. The top panel represents data from an experiment that programed rich

Fig. 7.2 (continued) (closed circles) or lean (open circles) rates of reinforcement for alternative responses in the R_a phase. The bottom three panels represent data from experiments that programed rich or lean rates of reinforcement for target responding during baseline (not depicted)

Perhaps more importantly, each experiment involved a manipulation of some independent variables across experimental groups, and the effect of each manipulation was predicted accurately. For example, in the top panel of Fig. 7.2, after the researchers established stable baseline target responding (not depicted), the researchers delivered reinforcers for alternative responses (i.e., R_a) according to a dense (i.e., VI 30-s) or lean (i.e., VI 240-s) schedule, then implemented extinction (i.e., No R_a). In this experiment, the denser schedule of alternative reinforcement produced more rapid reductions in target responding but resulted in more target responding when alternative reinforcement was suspended. The quantitative model of BMT described these findings well.

The bottom three panels in Fig. 7.2 depict data from similar experiments except that the reinforcement schedules during baseline varied across experimental groups. Because BMT suggests that resistance to change and response strength are caused by Pavlovian stimulus–reinforcer relations, denser schedules in baseline should strengthen the target response to a greater extent than leaner schedules, which should generate more persistence of target responding when the DRA disrupter is introduced and more resurgence when that disrupter is later removed. Data from these three experiments support this assertion as well. These and other promising findings eventually gained the attention of applied researchers who began using the conceptual framework of BMT and its quantitative predictions to refine clinical service delivery.

Applications to Clinical Practice

Numerous translational studies have been conducted based on the predictions of BMT that have suggested improvements to traditional treatment procedures. Fisher et al. (2018a) synthesized the results of four such studies to evaluate the overall predictive validity of BMT as it applies to resurgence and its utility for mitigating resurgence. In this paper, the research team reanalyzed data from studies evaluating (a) the effects of a BMT-informed treatment and a non-BMT-informed treatment on the resurgence of problem behavior (Fisher et al., 2018b), (b) DRA-based treatments for problem behavior with and without discriminative stimuli (Fuhrman et al., 2016), (c) DRA-based treatments with and without extinction in place for problem behavior (Brown et al., 2020), and (d) NCR-based treatments with and without extinction in place for an analogue to problem behavior (Saini et al., 2017). Each study compared two conditions, one informed and one not informed by the predictions of BMT. For example, BMT predicts that arranging leaner schedules of reinforcement in baseline and in treatment and conducting more treatment sessions than typical should lessen resurgence when compared to a condition that arranged dense schedules of reinforcement in baseline and in treatment and fewer treatment sessions. Fisher et al. (2018b) tested this hypothesis using a clinical population and found that the BMT-informed condition better suppressed the resurgence of problem behavior. Each of the other translational studies similarly showed that the BMT-informed condition better suppressed resurgence than did the non-BMT-informed condition. Figure 7.3 displays the results of fitting the BMT model of resurgence to the data from those four studies. Although the model accounts for less of the variability in these datasets compared to the studies with nonhuman animals in Fig. 7.2, the BMT model of resurgence captured the translational data from human participants and clinically relevant responses to a satisfactory degree, suggesting reasonable predictive validity of using BMT to modify clinical interventions.

In addition to the general accuracy of the predictions made by the quantitative model, the BMT-informed condition used in Fisher et al. (2018b) reduced resurgence by an average of 65.1% relative to the non-BMT-informed condition, and the BMT-informed condition in Fuhrman et al. (2016) produced an average reduction of 82% in destructive behavior relative to the non-BMT-informed condition. In a follow-up to the study by Fuhrman et al. (not depicted in Fig. 7.3), Fisher et al. (2020) showed that the same BMT-informed treatment produced 81%

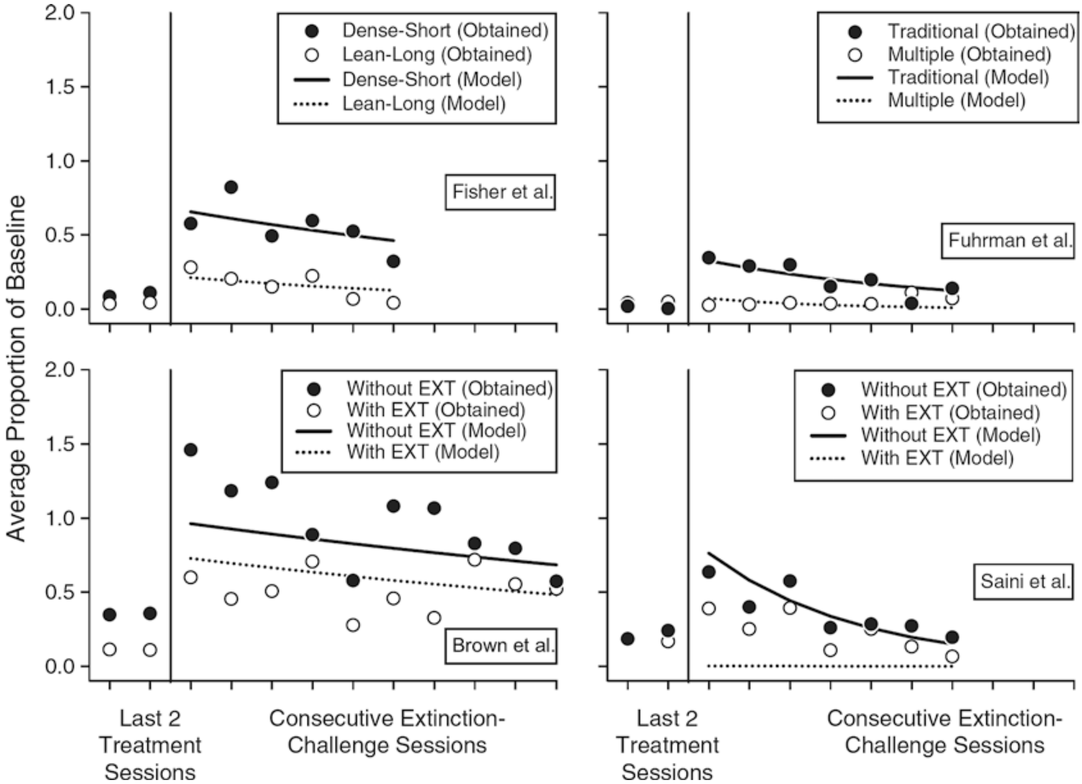

Fig. 7.3 Data Reanalyzed by Fisher et al. (2018a). *Note.* Data points represent the average rate of target responding for participants expressed as a proportion of baseline responding during the last two treatment sessions and extinction-challenge sessions (i.e., when all reinforcement was withheld) during four different studies evaluating resurgence with human participants. Open and closed data points represent BMT-informed conditions and non-BMT-informed conditions, respectively. Dashed and solid lines represent values predicted by BMT for the open and closed data points, respectively

less resurgence on average than a non-BMT-informed treatment for four additional participants. Similar reductions in resurgence can be seen for the other two studies in Fig. 7.2. Taken together, these translational studies demonstrate the potential for BMT to refine clinical practice and the value of translating basic research findings into practice more generally.

Limitations of BMT

Despite the influential role that BMT has played in both the basic and applied realms, there are notable empirical and conceptual limitations to BMT. For example, there are several studies showing that factors other than simple Pavlovian stimulus–reinforcer relations affect resistance to change, and BMT fails to account for extinction bursts (see Nevin & Grace, 2000, p. 84–85 for brief discussions of both topics). Further, the extensions of BMT to applied issues may have conceptual limitations. For example, although the high-p sequences discussed earlier were originally conceptualized as an effect of behavioral momentum, ultimately it seems unlikely that behavioral momentum is responsible for the efficacy of high-p sequences (Nevin, 1996). Based on the results of Nevin et al. (1990) and BMT more generally, delivering reinforcers for compliance with high-p instructions should also increase the strength of noncompliance, so it remains unclear whether the principles of BMT are actually related to the efficacy of high-p sequences (see Nevin, 1996 for a discussion of this and other considerations).

Other conceptual concerns arise with the extension of BMT to resurgence (see Craig & Shahan, 2016; Greer & Shahan, 2019; Shahan & Craig, 2017 for more comprehensive discussions of the points that follow). One conceptual flaw with the extension of BMT to resurgence comes from the underlying assumption that resistance to extinction is caused by Pavlovian stimulus–reinforcer relations. Based on this assumption, the extension of BMT to resurgence asserts that reinforcers delivered for both target and alternative responses are additive, which leads to unusual predictions. First, it suggests that exclusively reinforcing a target response and then exclusively reinforcing an alternative response will produce twice as much Pavlovian stimulus–reinforcer relations than reinforcing either response in isolation. Second, it suggests that each reinforcer-rate change must be additive, but this suggests that gradually thinning reinforcer rates would produce more Pavlovian conditioning, not less. Both of these predictions are counterintuitive and not supported by empirical findings. An additional conceptual flaw is that BMT fails to account for numerous dimensions of reinforcers that are likely to be relevant to resurgence. For example, BMT does not make predictions about how reinforcer quality or response effort may affect resurgence. Both the concatenated generalized matching law (Baum, 1974; Baum & Rachlin, 1969) and clinical experience suggest that these types of variables affect resurgence, but BMT has no way of accounting for such variables.

Beyond these conceptual limitations, there are important empirical flaws. For example, BMT predicts that target behavior will recur to the greatest extent immediately upon removal of the disrupter. However, a recent review of the literature has revealed that target responding can be low at first and increase before subsequently decreasing (i.e., a bitonic function, Podlesnik & Kelley, 2014). BMT also predicts that introducing DRA as a disrupter will decrease target response rates. However, empirical studies have shown that introducing low rates of reinforcers for alternative responses can increase target responding relative to an extinction control (e.g., Craig & Shahan, 2016; Sweeney & Shahan, 2013). Further, BMT predicts that complete removal of differential reinforcement as a disrupter will produce more recurrence of target behavior than partial removal. However, empirical studies have shown the opposite effect (e.g., Craig & Shahan, 2016; Sweeney & Shahan, 2013). Unfortunately, these empirical shortcomings are caused by inaccuracies in the core assumptions made by BMT as it applies to resurgence, which is why research on resurgence has largely shifted toward applying other conceptual frameworks, such as Resurgence as Choice in Context (Shahan & Craig, 2017; Shahan et al., 2020) and Context Theory (Bouton & Todd, 2014).

Response Strength Revisited

With the aforementioned limitations in mind, it is worth noting that another potentially major conceptual issue with BMT is that it continues to leverage the concept of response strength. Researchers have recently begun to highlight significant concerns inherent in the concept of response strength (see Shahan, 2017 for discussion).

For the present purposes, it is sufficient to note that response strength is a hypothetical construct that provides little to no explanatory power. Response strength cannot be observed or measured directly. Indeed, a good deal of the beginning of this chapter explained how certain behavioral parameters, specifically response probability and resistance to change, have been assumed to be indicators of response strength, but even these dimensions of behavior cannot be measured directly. These dimensions (i.e., response probability and resistance to change) are inferred based on response rates or changes in response rates before and after disruption. Thus, to obtain a measure of response strength, researchers have resorted to measuring behavior directly, inferring that different patterns represent different dimensions of behavior (i.e., response probability or resistance to change) and then making another inference that this is related to response strength. Based on these inferences, it seems problematic to suggest that response strength determines behavior or behavioral persistence.

Further, the concept of response strength is typically used to explain how reinforcement works. However, as Catania (2013) explains, the term reinforcement is merely descriptive, not explanatory. Using reinforcement to explain why behavior is occurring introduces circular reasoning into the explanation. Reinforcement describes "a response–consequence functional relation in which a response is followed immediately by a stimulus change that results in similar responses occurring more often" (Cooper et al., 2020). Saying reinforcement *caused* the response to increase would involve circular reasoning because it uses the definition of the process to explain why the process is occurring. Beyond the fact that circular reasoning is conceptually problematic, such reasoning fails to provide additional insight into the relevant behavioral processes, and it stifles additional exploration into the actual mechanisms behind this process.

Instead of relying on the concept of response strength to explain reinforcement, clinicians and researchers should explore alternative accounts of behavior. Indeed, several alternative accounts from within the field of behavior analysis have been proposed (e.g., Baum, 2012; Cowie & Davison, 2020; Gallistel & Balsam, 2014; Killeen & Jacobs, 2017; Shahan, 2010; see Shahan, 2017 for a discussion of these alternatives). These alternative explanations are too complex to cover in substantive detail, but in general, they tend to focus on the role of timing processes and stimulus control rather than the strengthening process of reinforcement. They hinge on the premise that organisms learn correlations between stimuli in the environment, and their histories with these correlations influence current and future behavior. These newer conceptualizations can account for a broader range of behavior that cannot be explained by reinforcement as a strengthening process alone (see Cowie & Davison, 2016 for a review). Perhaps most importantly, these new conceptualizations allow for the possibility that learning can occur without reinforcement, which is an empirically supported finding (e.g., St. Claire-Smith & MacLaren, 1983), and they shift research towards understanding what organisms perceive regarding the correlations among stimuli (Shahan, 2017). Just as the development of BMT marked a paradigm shift in how researchers approached the basic principles of behavior analysis, the growing shift toward an account of behavior focused on timing processes and stimulus control may mark yet another fundamental shift in how behavior analysts approach their science.

Conclusion

Despite the aforementioned limitations, BMT has had an extensive and important impact on research and practice. The development of BMT marked an important divergence from the traditional conceptualization of response strength and, perhaps more importantly, has led to the development of numerous strategies to address socially significant behavior, such as noncompliance, resistance to change, and treatment relapse.

Differential Reinforcement Procedures

8

Catalina N. Rey and Kaitlynn M. Gokey

Differential reinforcement is a procedure in which one response class is reinforced to a greater degree than another response class. Differential reinforcement can consist of reinforcement for one response class and extinction for another, or it can involve a difference in reinforcement along some other dimension (Vollmer et al., 2020). For example, one form of behavior could result in more frequent, immediate, or higher quality reinforcement than another form of behavior (Athens & Vollmer, 2010). The rationale for differential reinforcement procedures is based on the matching law, which states that the rate of behavior matches the relative rate of reinforcement for that behavior (Herrnstein, 1961; Reed & Kaplan, 2011). In other words, organisms allocate responding in a manner that maximizes reinforcement. Differential reinforcement procedures, therefore, are those that alter concurrent schedules in a way that favors the emission of appropriate behavior over that of problem behavior.

This chapter is dedicated to Dr. Jose Martinez-Diaz, who never failed to inspire his students.

Differential Reinforcement of Alternative Behavior

Differential reinforcement of alternative behavior (DRA) is a procedure used to decrease problem behavior by replacing it with an appropriate, alternative response. This is achieved by minimizing or withholding reinforcement for the problem behavior and reinforcing an alternative response (Deitz & Repp, 1983). Often times in a DRA, the function of problem behavior is identified and an alternate means of meeting that same need is taught and reinforced. In other words, an appropriate, alternative behavior that results in the same reinforcer as the problem behavior is prompted and reinforced. For example, a student who engages in disruptive behavior maintained by teacher attention might be taught to raise their hand rather than blurt out answers or stomp their feet. It should be noted, however, that a functionally equivalent alternative response is not a defining feature of a DRA. For example, Lalli et al. (1999) used a DRA to treat problem behavior maintained by escape by reinforcing compliance with edible reinforcers.

DRA is preferable to extinction or punishment alone for eliminating problem behavior. As problem behavior is maintained by reinforcement, the use of extinction or punishment alone to eliminate problem behavior could result in a client losing access to a source of reinforcement, or possibly developing other problem behaviors to

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_8

access it again. For example, if a child's only means of accessing parent attention is emitting a tantrum, punishing the tantrum may eliminate it, but will not give the child a means to access parent attention. As attention deprivation increases, the child may engage in more severe behavior that would be hard for a parent to ignore, such as property destruction or aggression. In cases like this, failing to teach an alternative response could result in an escalation of the problem behavior, or social isolation of a child with no clear way to access adult attention. DRA procedures offer a constructive approach for decelerating problem behavior by expanding a client's repertoire.

Implementing DRA

Implementing a DRA procedure involves several steps including identifying the function of the problem behavior, selecting an alternative response, teaching the new contingency, and thinning the schedule of reinforcement for the alternative response. There are several variables one should take into account when implementing a DRA; the guidelines below are meant to inform and guide the successful implementation of a DRA procedure.

Identify the Function of the Problem Behavior A functional assessment of the problem behavior is necessary to identify the reinforcer(s) that maintain the problem behavior. Identifying these reinforcers is important because it allows practitioners to withhold (or minimize) the relevant stimuli contingent on problem behavior and select an alternative response that serves the same function, if possible. While there are many forms of behavioral assessments, the current 'gold standard' remains the functional analysis (Iwata et al., 1994; Iwata & Dozier, 2008; Saini et al., 2020). A functional analysis is a type of behavior assessment that uses experimental comparisons to identify the function of problem behavior. As the functional analysis is carefully controlled, it allows for the determination of function, rather than only hypothesizing function. Several variants have been developed to allow for assessment of dangerous or otherwise difficult to assess responses, such as latency-based, trial-based, and synthesized analyses (Hanley, 2012; Hanley et al., 2014; Lambert et al., 2012; Thomason-Sassi et al., 2011). In the event that barriers prevent conducting a functional analysis, descriptive assessments may be an appropriate alternative, or beneficial supplemental assessment (Hollo & Burt, 2018).

Select the Alternative Response The two foremost considerations for the alternative response are response effort and access to reinforcement (Horner & Day, 1991). The effort required to emit the response is an important consideration because effort affects reinforcement value, with greater effort requiring greater reinforcement magnitudes to sustain it. If the alternative response requires more effort than the problem behavior, it will be difficult for it to completely replace the problem behavior (Wilder et al., 2020). Selecting brief, simple responses is preferred to complex or lengthy responses for this reason. For example, a brief vocal response such as, "Cookie," may be preferable, at least initially, to longer responses such as, "May I have a cookie, please?" Selecting an alternative behavior in which the client is already fluent, or, if not, training it to fluency can assist with response effort.

When selecting an alternative response, it is also important to consider the extent to which the response will access reinforcement in the natural environment. If the behavior is maintained by socially-mediated reinforcement, the ideal alternative response would be one that is likely to evoke the relevant reinforcer from novel people who are not familiar with the treatment plan. Selecting a response topography that will reliably contact reinforcement in the natural environment is important for the generalization and maintenance of treatment effects.

Consider Motivation Motivating operations should be considered when developing a DRA procedure. Establishing operations for reinforcement increase the reinforcer's value and efficacy, evoking behavior that produces that reinforcer. In a DRA procedure, the establishing operation should be directly tied to the reinforcer for the alternative response and the problem behavior. To produce strong motivation to emit the relevant behaviors, one might need to schedule a deprivation period for the relevant reinforcers prior to treatment sessions.

As DRA procedures are often combined with other procedures in an intervention package, it is important to consider what impact other treatment components might have on motivation. Behavior-change procedures that rely on abolishing effects, such as noncontingent reinforcement (NCR), may interfere with acquisition of a function-based alternative response because NCR could abate the response, limiting the opportunities for reinforcement and decreasing the value of the reinforcer when the alternative response does occur (Goh et al., 2000; Wallace et al., 2012).

Consequences Differential consequences for the problem behavior and the alternative response are integral parts of the DRA procedure. In a DRA procedure, the alternative response that replaces the problem behavior should result in richer reinforcement than the problem behavior (e.g., denser schedule, higher magnitude). In the event that the alternative response does not reliably produce the reinforcer in the natural environment, the practitioner will need to teach the mediators in the natural environment (e.g., teachers, caregivers, employers, etc.) to reinforce the alternative response. For example, if a client is taught to request a break by signing "break," it is important for all of the relevant people in the natural environment to learn what the sign means and to provide adequate breaks when they are requested.

It is equally as important that mediators learn to minimize, if not completely eliminate, reinforcement for the problem behavior as much as possible. Researchers have shown that treatment integrity failures during DRA that provide reinforcement for the problem behavior, even intermittently, can have detrimental effects (St. Peter-Pipkin et al., 2010). Intermittent schedules of reinforcement can increase resistance to extinction. This is especially true if such errors occur at the beginning of treatment. This may occur when a caregiver begins implementing a DRA procedure and makes errors in the initial sessions by accidentally reinforcing the problem behavior. The impact of these errors may slow the acquisition of the alternative response. For this reason, it is recommended that problem behavior be placed on extinction, when possible, and that all implementers be trained to fluency before implementation begins.

However, while extinction for the problem behavior is ideal, it is not always feasible. For example, some automatic reinforcers directly produced by the behavior may be difficult or impossible to prevent. Additionally, extinction for behavior maintained by attention may not be possible with severe behaviors such as self-injury or aggression, which often require blocking due to health and safety concerns. Though DRA procedures require a difference in reinforcement between the alternative response and the problem behavior in order to be effective, they do not necessarily require that the problem behavior be placed on extinction (Vollmer et al., 2020). In these cases, minimizing reinforcement may be the best available option. Athens and Vollmer (2010) found that a combination of manipulations to reinforcer duration, quality, and delay to delivery produced larger and more consistent changes to behavior rates than manipulating a single dimension alone. One should consider combining differences across multiple dimensions of reinforcement for best treatment results.

Schedule Thinning A continuous schedule of reinforcement for the alternative response is often used in the initial implementation of a DRA procedure. However, such a schedule is likely difficult for caregivers or instructors to implement with consistency in the long-term, as it can be disruptive to other activities. For example, a student whose requests for breaks are continuously reinforced throughout the day may never complete tasks necessary for learning. In most cases, in order for the alternative response to maintain in the natural environment, the schedule should be thinned from the dense training schedule to a leaner schedule. Gradually thinning the schedule of reinforcement for the alternative response will reduce the likelihood of ratio strain when transferring to contexts that do not support high rates of reinforcement.

Chain schedules of reinforcement are one common method for thinning reinforcement for the alternative response in a DRA procedure. Chain schedules involve gradually increasing either the number of tasks that must be completed, or the duration of time spent engaging in a specific activity, before the alternative response will be reinforced (Hagopian et al., 2011; Hanley et al., 2014; Lalli et al., 1995). For example, say a student's problem behavior was maintained by escape from academic tasks and the teacher implemented a DRA procedure in which the student learned to request a break as an alternative to engaging in problem behavior during class time. Initially, the teacher would provide a break each time the student requested one, but this arrangement would not be sustainable long term if the student's requests were excessive. To thin the schedule of reinforcement, the teacher could use a chain schedule by requiring the student to complete a task before allowing a break. The student's requests after task completion would be reinforced, but requests prior to task completion would not. With time, the teacher could slowly increase the number of completed tasks required before a break request would be reinforced. This method is also known as *demand fading*.

Multiple schedules are another common method used to thin the schedule of reinforcement for the alternative response. In a multiple schedule, discriminative stimuli signal alternating 'on' and 'off' periods of reinforcement and extinction for the alternative response (i.e., one schedule provides reinforcement for the alternative response and the other schedule does not). Thinning the reinforcement schedule using this method involves gradually decreasing the duration of the signaled reinforcement period while increasing the signaled extinction duration. Betz et al. (2013) used such a schedule with four children with autism, using bracelets, posters, or colored vests as the discriminative stimuli for the reinforcement. As sessions continued, rates of the alternative response and the problem behavior remained stable even as the duration of the extinction schedule gradually increased and the duration of reinforcement schedule decreased. The researchers also compared a multiple schedule to the same arrangement as a mixed schedule, without discriminative stimuli, and found that rates of problem behavior reemerged, demonstrating that the discriminative stimuli were a critical component of the fading procedure. Establishing stimulus control over the alternative response may facilitate schedule thinning and transfer of stimulus control to contexts outside of the training environment.

Functional Communication Training

Functional communication training (FCT) is a variation of DRA in which the alternative response is a mand, often referred to in the context of FCT as a *functional communication response* (FCR; Carr & Durand, 1985). A mand is a type of verbal operant that is primarily controlled by an establishing operation and reinforced through the actions of others, specifically the reinforcer requested or indicated. For example, if a child has not eaten in a while, they may say, "Can I have a cookie, please?" to a parent, and the parent may give them a cookie as a consequence. "Can I have a cookie, please?" would be considered the mand, or the FCR if it were used as an alternative response in a DRA procedure. In an FCT procedure, the FCR serves the same function as the problem behavior and may take any of a variety of communication forms, such as vocalizations, sign language, written text, card exchange, sound buttons, or pointing and other gestures (Sundberg & Sundberg, 1990). The specific form that is taught should be tailored to the needs and repertoire of the individual.

Carr and Durand (1985) introduced FCT as a treatment for problem behavior in a study with four children in a classroom setting. First, the researchers assessed the function of the participants' problem behavior. Of the four participants, two were disruptive when tasks were difficult and attention was plentiful, indicating the behavior was likely maintained by escape from difficult tasks. One participant was disruptive when tasks were easy but attention was low rate, indicating attention-maintained disruption. The final participant was disruptive when easy tasks were presented with low rates of attention and when difficult tasks were presented with high rates of attention, suggesting multiple functions for their disruptive behavior.

Next, the researchers identified and taught appropriate FCRs to each participant. The FCR for escape from difficult tasks was, "I don't understand," as it directly solicited help. Similarly, the FCR for attention was, "Am I doing good work?" as it not only evoked interaction from the adult, but solicited praise specifically. In order to evaluate whether teaching any communicative response, functionally related or not, would produce improvements in problem behavior, the researchers also taught an irrelevant communication response that produced an outcome unrelated to the functional reinforcer. For example, if problem behavior was maintained by escape from difficult tasks, the irrelevant response would be, "Am I doing good work?" because it did not result in any assistance. Results showed that, for all four participants, rates of FCRs were highest, and disruption lowest, in the relevant FCR condition. Rates of disruptive behavior in the irrelevant FCR condition were similar to responding in baseline, occurring at high rates. This indicates that merely teaching *a* communicative response is insufficient; the response must meet the same need as the problem behavior it is to supplant.

FCT is one of the most common and empirically supported interventions for problem behavior among children with autism spectrum disorder (ASD; Anderson & St. Peter, 2013; Tiger et al., 2008). However, its utility is not limited to ASD populations. A review by Durand and Moskowitz (2015) found FCT effectively decreased a variety of problem behaviors across multiple developmental or speech and language disorders, and Hollo and Burt (2018) found similar results with children with or at risk of developing emotional and behavioral disorders. FCT has also been shown to be effective in educational settings (Walker et al., 2018), as well as with adults (Gregori et al., 2019). This is particularly noteworthy as adults typically have more extensive learning histories supporting challenging behavior than children, often leading to more resistance to behavior change (Heath et al., 2015).

Implementing FCT Precise descriptions of FCT procedures and components vary across studies. In general, FCT programming has similar steps to general DRA procedures: (1) functional assessment of the problem behavior, (2) FCR selection, (3) training FCR, and (4) testing for maintenance and generalization (Tiger et al., 2008; Mancil & Boman, 2010). Because FCT is a DRA treatment, the same considerations listed above for DRA also apply to FCT.

Selecting an FCR FCRs can be either specific, in which a particular reinforcer is identified, or a broader mand that includes multiple functions at once, known as an omnibus mand (Bachmeyer et al., 2009; Ward et al., 2020). When the problem behavior has a specific function, it is best to have the FCR specify the function of the problem behavior as precisely as possible. For example, if problem behavior is maintained by escape from task demands, an appropriate FCR would be a request for a break (e.g., "Can I have a break?"). However, if problem behavior reliably produces multiple, different consequences, it may be more efficient to teach an omnibus FCR. For example, if problem behavior consistently results in attention, escape from task demands, and access to toys, an appropriate FCR might be less specific (e.g., "Can I have my way?").

Omnibus FCRs could be less likely to have broad social recognition of the response (e.g., a substitute teacher might not know exactly what "my way" means), but the tradeoff is that an omnibus FCR could make FCT more effective and efficient when problem behavior is multiply maintained. Teaching individual FCRs for each consequence may require more time to teach and could result in the client needing to emit multiple responses in quick succession to access the same combination of reinforcers as a single maladaptive response (Mitteer et al., 2019). In other words, an omnibus FCR may be appropriate when addressing problem behavior with multiple functions, whereas a specific FCR may be more appropriate for problem behavior with a single function.

Differential Reinforcement of Incompatible Behavior

Differential reinforcement of incompatible behavior (DRI) is a variation of DRA in which the alternative response is incompatible with the problem behavior, meaning both responses cannot occur at the same time. For example, if a client is causing self-injury from high rates of skin picking, an incompatible response would be anything that occupies the hands so that fingers cannot pick on the skin, such as toy play. As the incompatible response increases in rate, opportunities to engage in the problem behavior decrease.

Smith (1987) successfully applied a DRI procedure to decrease pica in a 23-year-old man with an intellectual disability. The participant consumed nonfood items such as paper clips, bottle caps, and other hazardous materials, which could be potentially life-threatening. Additionally, he would engage in aggression whenever his attempts to engage in pica resulted in the removal of these items. In the DRI treatment, completing work tasks and interacting with work materials at the desk were reinforced, which was incompatible with the problem behavior because pica required leaving the work area and picking up nonfood items. While pica was not entirely eliminated, the DRI procedure reduced pica to less than a third of baseline rates and did not evoke aggression.

Differential Reinforcement of Other Behavior (DRO)

Differential reinforcement of other behavior (DRO) is a reinforcement schedule in which reinforcement is delivered contingent upon the nonoccurrence of a target response (Reynolds, 1961). That is, a reinforcer is presented after a predetermined interval of time during which the target response does not occur. Contingent on the target response, the reinforcer is withheld or delayed. This schedule results in a decrease in rate for the target response. The DRO schedule is commonly used to treat a wide range of problem behavior (Matson et al., 2011; Weston et al., 2018) including severe problem behavior (e.g., aggression, self-injurious behavior, and disruption; Iannaccone et al., 2020), elopement (e.g., Roane & DeRosa, 2014), stereotypy (e.g., Healy et al., 2019), chronic tic disorders (e.g., Capriotti et al., 2017), substance use disorders (e.g., Higgins et al., 1991), and medical noncompliance (e.g., Dufour & Lanovaz, 2020).

DRO Behavior Reduction Processes

Though the term DRO implies that this procedure is similar to the DRA in that it reinforces "other" behavior, the contingency only specifies that the target response does not occur during the interval, independent of the occurrence or nonoccurrence of any other behavior. For this reason, some researchers prefer different terms for the DRO including omission training (Uhl & Garcia, 1969) and differential reinforcement of no responding or zero responding (Poling & Ryan, 1982; Zeiler, 1970). Though the DRO is commonly used, the behavioral processes responsible for the decelerative effects of the DRO schedule remain unclear. There are three main hypotheses for the behavioral processes responsible for the decreases observed in the target response during a DRO: extinction, adventitious reinforcement, and negative punishment. These processes are not mutually exclusive and it is likely that more than one influence responding simultaneously or in conjunction with one another (see Jessel & Ingvarsson, 2016 for a discussion).

Extinction Some researchers have suggested that the DRO contingency simply disrupts the contingency between the reinforcer and the target response, consistent with the effects of extinction (e.g., Lattal et al., 2013; Mazaleski et al., 1993). Extinction is certainly at least partially responsible for behavior reduction when reinforcement for the target response is withheld. However, it is unlikely that extinction is the sole mechanism responsible for behavior reduction because many applied studies have shown that DRO schedules can successfully reduce problem behavior even without the use of extinction (e.g., Cowdery et al., 1990; Lanovaz et al., 2014; Lustig et al., 2014; Ringdahl et al., 2002; Roane et al., 2007; Vance et al., 2012).

Adventitious Reinforcement Adventitious reinforcement of other behavior is another hypothesis for the process underlying the effectiveness of DRO schedules (e.g., Jessel et al., 2015; Reynolds, 1961). This hypothesis relies on the temporal relation between nontarget behaviors and the delivery of reinforcers. Specifically, the DRO schedule adventitiously reinforces any nontarget response occurring in close temporal contiguity with the delivery of reinforcers. This interpretation implies that any other, nontarget behavior reinforced with DRO contingencies is considered "superstitious" (see Skinner, 1948). For adventitious reinforcement to decrease the target response in a DRO, these other behaviors must be incompatible with the target response and strengthened to the extent they compete with target responding. The question as to whether or not adventitious reinforcement increases other, nontargeted behavior during DRO has received a lot of attention, but research directly addressing this matter thus far has yielded mixed results likely due to differences in research methodology (e.g., Hangen et al., 2020; Harman, 1973; Jessel et al., 2015; Rey et al., 2020a; Rey et al., 2020b; Zeiler, 1970).

Negative Punishment Rather than considering the DRO schedule a type of differential reinforcement procedure, it might be more conceptually coherent to include it under a negative punishment paradigm (Catania, 2013; Goldiamond, 1975; Lattal, 2013; Malott & Trojan Suarez, 2004; Rolider & Van Houten, 1990). Specifically, engaging in the target response during DRO postpones the reinforcer delivery, which decreases target responding. To illustrate, contrast it with the two types of negative reinforcement: escape and avoidance. In the *escape* type of negative reinforcement, an aversive stimulus is *present* and removed contingent upon some response. Escape, then, would be analogous to negative punishment, in which an appetitive stimulus is *present* and withdrawn contingent upon some response. However, in the *avoidance* type of negative reinforcement, an aversive stimulus is not present, but has historically been presented. The presentation of the aversive stimulus is withheld or delayed contingent upon some response. The DRO may operate under a similar type of contingency, albeit a punishing one, in which an *appetitive* stimulus which has previously been presented is withheld or delayed contingent upon some response, resulting in a decrease in that response (Rolider & Van Houten, 1990). For example, a child may spend her Saturday afternoons at the park with her father, but when she tantrums at school, the father cancels the typical Saturday trip to the park.

Whole-Interval DRO

In a *whole-interval DRO*, a reinforcer is delivered only if the target response is omitted during the entire duration of the interval. The first response to occur within the interval will cancel the opportunity for reinforcement for that interval. The interval for this procedure can be fixed or varied. A *fixed interval* is set at the same duration for each interval in a session. For example, if the interval is set at 5 min, after a successful interval in which there is no occurrence of the target response, a reinforcer will be delivered and another 5-min trial will begin. A *varied interval* is set at varying durations, centering on some average value. For example, in a varied interval of 5 min, each interval would be set at different durations that average to 5 min (e.g., intervals ranging from 1 to 10 min).

Resetting Versus Non-resetting Intervals In whole-interval DRO schedules, the target response can either reset the DRO time interval or have no effect on the time interval. In a *resetting DRO*, the time interval starts over each time that the target response occurs. For example, if the DRO interval is 30 s, and the target response is emitted after 15 s, the 30-s interval is reset to zero. This immediately begins a new opportunity for reinforcement. Alternatively, in a *non-resetting DRO*, the target response does not restart the interval. Instead, the current interval must elapse before the new interval with an opportunity for reinforcement begins. For example, if the DRO interval is 30 s, and the target response is emitted after 15 s, the rest of the interval (15 s) must elapse before a new 30-s interval begins. Until a new interval begins, there is no consequence for the target response after the interval has already lost the opportunity for reinforcement. Both the resetting and non-resetting DRO variations have been used to effectively reduce problem behavior, but there is limited research directly comparing their effects. Thus far, basic (Nighbor et al., 2020) and applied (Gehrman et al., 2017) research has found no difference in their relative efficacy.

Momentary DRO

In a *momentary DRO*, a reinforcer is delivered if the target response is not occurring at the end of the DRO interval. The occurrence of the target response before the end of the interval does not affect the delivery of reinforcement. For example, if the DRO interval is set at 5 min and the target response is emitted after 2 min, a reinforcer would be delivered at the end of the 5-min interval. On the other hand, if the target response was instead emitted after 5 min, a reinforcer would not be delivered for that interval. Because responses that occur before the end of an interval do not affect reinforcer delivery in a momentary DRO, a resetting interval is irrelevant for this procedure.

Like the whole-interval DRO, the momentary DRO can be implemented with a *fixed interval* or a *varied interval*. Research on the effectiveness of momentary DROs is rather mixed (e.g., Miller & Jones, 1997; Repp et al., 1983; Sisson et al., 1988; Toussaint & Tiger, 2012). Because the momentary DRO delays reinforcement only if the target response occurs at the specific moment at the end of the interval and at no other times, the effectiveness of the momentary DRO might depend on either (a) the indiscriminability of the contingency (specifically, the momentary response criterion), or (b) the inability to detect the end of the interval. Indeed, there is evidence indicating momentary DROs are more effective when there are no cues signaling the end of the interval (Hammond et al., 2011). Similarly, momentary DROs with variable intervals might be more effective than fixed intervals because changes in interval length make the end of the interval more difficult to predict.

DRO Reinforcer

Functional Reinforcers Function-based reinforcers are the same reinforcers that maintain the target behavior. For example, if disruptive behavior is maintained by attention, the functional reinforcer is attention. In this case, using a functional reinforcer within a DRO procedure would consist of providing attention contingent on the absence of disruptive behavior. It is advisable to use extinction or minimize reinforcement for the target behavior as much as possible during a DRO. This is especially important in a function-based DRO because otherwise, responding and non-responding will both result in the same reinforcer and the contingency would likely favor high rates of target responding.

For example, say a child engages in attention-maintained disruption during class and the teacher implements a DRO in which they provide attention at the end of every 15-min interval that the child does not engage in disruptions. If the teacher is unable to put the disruption on extinction by withholding their attention contingent on disruptions, the child can access attention by both, engaging in disruptions and by not engaging in disruptions. In this scenario, the child will access attention a maximum of four times per hour by not engaging in disruptions during the DRO, but they would access a higher rate of attention if they engaged in disruptions more than four times an hour.

Arbitrary Reinforcers Arbitrary reinforcers are any stimuli different from the reinforcers that maintain the target behavior. For example, if the target response is maintained by attention, edibles presented within the DRO contingency would be considered arbitrary reinforcers. Arbitrary reinforcers are often used when it is not possible to manipulate the functional reinforcer (e.g., automatic reinforcement) or when the function of the problem behavior is unclear. When using arbitrary reinforcers, extinction of the problem behavior might not be critical if the arbitrary reinforcer is of higher value, or more preferred, than the functional reinforcer.

Setting the DRO Interval

The initial DRO interval should be set at the mean inter-response time (IRT) during baseline (Repp et al., 1974; Repp et al., 1991). The IRT is the time between two successive responses. Mean IRT is calculated by dividing the total number of minutes in a session by the total number of responses that occurred during that time. Setting the DRO interval equal to the mean IRT during baseline increases the likelihood that the behavior will regularly contact the DRO contingency. Shorter initial DRO intervals are more likely to be effective than longer intervals (Rozenblat et al., 2009). Setting the initial DRO interval longer than the mean baseline IRT can decrease the likelihood that the DRO will be effective in reducing responding because the nonresponding might seldom contact reinforcement. This is especially the case if one is not able to use extinction for the problem behavior.

The initial DRO interval might not be conducive for implementing the procedure in the natural environment or to maintain over time with treatment integrity. Once the DRO procedure has effectively reduced the problem behavior, the initial interval can be slowly increased over time to thin the schedule of reinforcement and make the DRO procedure more manageable to implement. The DRO interval can be increased by a constant duration each time (e.g., 30 s), by a proportion of the interval (e.g., 30%), or by adjusting the interval to match mean IRT from previous session each new session (Poling & Ryan, 1982).

Additional Considerations

Including additional components to the DRO or combining it with other interventions can enhance treatment effectiveness. Providing rules or statements describing the DRO contingency (e.g., "If you do not pick your skin for 5 min, you will get a token") can enhance treatment effects for some learners (Watts et al., 2013). Providing feedback or a statement indicating that the opportunity for accessing reinforcement has been lost contingent on problem behavior (e.g., "You don't get a token because you picked your skin") can also enhance the effectiveness of a DRO treatment (Iannaccone et al., 2020). Finally, practitioners should consider combining a DRO with DRA when possible. For example, instead of directly presenting a reinforcer at the end of a successful DRO interval, one can consider presenting a discriminative stimulus signaling that requests for the reinforcer will be honored. Incorporating a DRA component to the DRO ensures that a client acquires or maintains the ability to appropriately request the reinforcer.

Differential Reinforcement of Low Rate Responding (DRL)

Differential reinforcement of low rate of responding (DRL) is a schedule of reinforcement in which a reinforcer is delivered contingent on a reduced rate of responding. This is an approach to reducing behavior that is often used when the goal is to reduce but not to eliminate responding completely, either because the behavior is mild enough to tolerate at low levels (e.g., classroom disruptions), or because the behavior itself is appropriate and desirable but the rate at which it occurs makes it problematic (e.g., excessive requests for assistance during independent work time). There are several procedural variations of the DRL: spaced responding, full session, and interval (Deitz, 1977).

Spaced-Responding DRL

In a *spaced-responding DRL* (*s*-DRL), also known as DRL-IRT, a response is reinforced if it occurs after a minimum amount of time since the previous response (Deitz, 1977; see also Ferster & Skinner, 1957). As rate and IRT are inversely related, this variation of DRL decreases response rates by differentially reinforcing longer IRTs. The purpose of this procedure is to space out responding. For example, Wright and Vollmer (2002) used an *s*-DRL to decrease dangerously high rates of food ingestion in a teenage girl with developmental disabilities. During the intervention, a timer was set with a predetermined IRT interval. Each attempt to take a bite of food before the minimum IRT elapsed resulted in the bite being blocked and the timer reset. Only bites that occurred after the interval elapsed resulted in successful access to food. In another example, Deitz (1977) decreased students' excessive inappropriate questions by having the teacher answer a student's question only if a set amount of time had passed since their last question. Because the target response must occur to access reinforcement in the *s*-DRL, this procedure maintains some level of target responding.

***s*-DRL Reinforcers** Typically, the reinforcer used in *s*-DRL procedures is the same reinforcer that naturally maintains the target behavior. For example, food is the reinforcer for taking bites (e.g., Wright & Vollmer, 2002), and teacher responses to questions are the reinforcer for asking questions (e.g., Deitz, 1977). Those responses that meet the *s*-DRL criterion are reinforced and those that do not are placed on extinction (or reinforcement is otherwise minimized). However, it is possible to implement an *s*-DRL with arbitrary reinforcers when the functional reinforcer cannot be easily manipulated.

For example, Singh et al. (1981) used an *s*-DRL to reduce excessive rates of stereotypy among three adolescents with intellectual disabilities. Though the researchers did not conduct a functional assessment, stereotypy occurred at high rates during baseline sessions in which socially mediated reinforcers were unavailable, indicating a likely automatic function. During the *s*-DRL intervention, each stereotypic response that met the IRT criterion resulted in praise, while responses that did not meet the criterion reset the *s*-DRL interval but were not otherwise affected (i.e., they were not blocked, interrupted, or provided programmed consequences). Assuming these stereotypic responses were indeed automatically reinforced, extinction was not a component of the intervention because all responses—including those that did not meet the *s*-DRL criterion—were continuously reinforced. As with the DRA, when extinction cannot be implemented consistently, the reinforcer used for the *s*-DRL procedure should be of higher value or magnitude than the functional reinforcer that naturally maintains responding.

Non-Resetting *s*-DRL Interval Because an *s*-DRL requires that a response is separated from the previous response by a minimum IRT to access reinforcement, responses that occur before the end of the IRT criterion will reset the interval. In other words, each response that occurs before the end of the IRT interval requires that the interval starts over. However, a common modification found in applied *s*-DRL research is not resetting the interval with each response that does not meet the reinforcement criterion. Instead, those responses go unreinforced and the first response that occurs after the end of the interval is reinforced independent of IRT. This modification makes use of a simple interval schedule by changing the reinforcement contingency so that instead of requiring a minimum amount of time between two successive responses, the contingency only requires a set amount of time to pass before a response is eligible for reinforcement.

Anglesea et al. (2008) effectively used a non-resetting *s*-DRL to reduce rapid eating among three teenage boys with autism by using a vibrating pager that was set to vibrate at predetermined intervals and indicated when taking a bite of food would be reinforced. Attempts to take a bite before the end of the interval were blocked but did not reset the interval. The effectiveness of the non-resetting *s*-DRL likely depends on whether one can arrange extinction contingencies for the responses that occur within the interval (i.e., those that do not meet *s*-DRL reinforcement criteria).

Setting the *s*-DRL Interval The *s*-DRL interval should be initially set at the mean IRT during baseline. Setting the *s*-DRL interval within the range of baseline IRTs increases the likelihood that the behavior will contact the *s*-DRL reinforcement contingency. Setting the initial criterion at an interval longer than IRTs observed during baseline can decrease the likelihood that the procedure will effectively reduce responding because the behavior will seldom contact reinforcement. Once the *s*-DRL schedule is successfully met with some consistency, practitioners can further decrease rate of responding by slowly increasing the length of the *s*-DRL interval criterion.

Full-Session DRL

In a *full-session DRL* (*f*-DRL), the reinforcer is delivered at the end of a session or specified time period if the number of responses during that time are less than or equal to a specified criterion (Deitz, 1977). In this procedure, it does not matter when the responses occur, as long as the total number does not exceed a specified limit. For example, if the *f*-DRL criterion is five responses, an individual would receive a reinforcer at the end of the session if they engaged in the target response no more than 5 times (i.e., engaging in the response 0–5 times would result in reinforcement, 6 would not).

A common use of an *f*-DRL, at the group level, can be found in a classroom management procedure called the Good Behavior Game. The Good Behavior Game typically involves splitting a class into two or more teams, setting class rules (e.g., no getting out of seat without permission), setting a maximum number of points allowed, and marking a point for a team each time a member of that teams breaks a rule (Joslyn et al., 2019). The team that remains at or below the set point criterion wins the game and gets access to some reward. In the first demonstration of the Good Behavior Game, Barrish et al. (1969) divided a fourth grade class of 24 students into two groups to play the game in which each time a student engaged in out-of-seat behavior or talking-out behavior, their team received a mark on the chalkboard. A team would win the game if they received the fewest marks or if neither team received more than five marks. The winning teams earned special privileges such as wearing victory badges and 30 min of extra recess. Barrish et al. found that the game reduced occurrences of talking-out behavior from 96% of intervals to 19% of intervals and out-of-seat behavior from 82% to 9% of intervals.

Reinforcement for Individual Responses The *f*-DRL prescribes reinforcer delivery at the end of a session contingent on a maximum number of responses, but there is no specification regarding reinforcement for each individual response. There are several considerations one must take into account when deciding whether or not to reinforce individual responses within the session. First, one must determine if withholding reinforcement for individual responses is possible. Extinction may not be an option if the practitioner is not in control of the reinforcers that maintain the problem behavior. For example, if disruptive behavior in the classroom is reinforced by peer attention, a teacher is unlikely to be able to completely withhold that attention.

Second, one must consider whether complete elimination of the behavior would be preferable to low rates, or vice versa. In cases when complete elimination of the behavior is desirable, withholding reinforcement for each individual response would be ideal. For example, if disruptive classroom behavior is maintained by teacher attention, the teacher would withhold their attention during disruptions and only provide attention at the end of the session if disruptions did not exceed the *f*-DRL criterion. In cases where the occurrence of the response is desirable (e.g., hand raising), it is important that the occurrence of the desirable behavior continues to contact reinforcement.

When a practitioner is able to control the reinforcer that maintains the target response, an alternative way to implement an *f*-DRL is to reinforce only a limited number of responses in a session (e.g., a maximum of three responses will be reinforced and any response that exceeds that threshold in the session will not be reinforced). For example, Friman et al. (1999) used a version of the *f*-DRL in an intervention called the bedtime pass to decrease bedtime resistance (e.g., leaving the bedroom after bedtime) with two brothers aged 3 and 10 years. During the intervention, the children were each given a card that they were allowed to exchange for one visit out of the room after bedtime. The visit had to be short and had to have a specific purpose that could be met with an action (e.g., going to the bathroom, getting a hug, etc.) and then the child was expected to give up the card and return to their room for the remainder of the night. After the bedtime pass was used, any further attempts to leave the room would result in parents returning the child to the room while providing minimal attention. Results showed that the bedtime pass intervention effectively reduced bedtime resistance to no more than the one allowable opportunity to use the bedtime pass in one night for both children.

Another option is to combine these strategies so that there are both, limits to the number of responses that access reinforcement within a session as well as a criterion for a reinforcer at the end of session. Austin and Bevan (2011) effectively used this approach to reduce children's rate of requests for their teacher's attention during independent work time in an elementary school classroom (see also Otalvaro et al., 2019). Three children were identified by the teacher because their requests for teacher attention were excessive and interfered with completing their work. During the *f*-DRL intervention, each child received an index card with boxes corresponding to the *f*-DRL response criterion plus one. For example, if the criterion was set at two requests, the card would have three boxes. The teacher then responded only to the first 2 requests for attention and provided additional reinforcement at the end of the work period if the child did not exceed the specified number of requests.

Setting the *f*-DRL Response Criterion The number of responses allowed per session should be determined, in part, by the number of responses that occur during baseline or prior to treatment. To be successful, one should select a number that is roughly equal to average baseline levels. If the criterion number of responses is set too low, the client's behavior might not contact the *f*-DRL reinforcement contingency, which would make the procedure ineffective. Once the reinforcement criterion is consistently met and there is a reduction in behavior, one can gradually decrease the response criterion to further reduce levels of responding.

Interval DRL

In the interval DRL (*i*-DRL), a session is divided into a number of intervals and a reinforcer is delivered at the end of each interval if no more than one response occurs; if a second response occurs, the interval is reset and the opportunity for reinforcement is postponed (Deitz, 1977). This procedure is similar to a DRO except that the reinforcement criterion allows for up to one response to occur during the interval. The duration of the interval is set at the average IRT during baseline and can be gradually increased to further reduce responding as the procedure reduces behavior. Deitz (1977) used an *i*-DRL to effectively reduce classroom talk-outs by a

6-year-old girl in the first grade. During the *i*-DRL, the 30-min session was divided into 5-min intervals in which the child received a piece of chocolate caramel if she did not talk-out more than one time. Each 5-min interval was reset upon the second occurrence of a talk-out.

According to Deitz (1977), the *i*-DRL is similar to the *s*-DRL in that it decreases response rates by separating each response by some amount of time. Instead of differentially reinforcing discrete IRTs like in the *s*-DRL, the *i*-DRL targets average or variable IRTs because the response can occur anywhere in the interval. Another critical difference between the *i*-DRL and the *s*-DRL is that the reinforcement contingency in the i-DRL does not require the occurrence of a response. Over time, it seems that the definition of the *i*-DRL has shifted in the literature and many researchers now describe the *i*-DRL as a variation of the *f*-DRL differing only in that the session is broken up into smaller intervals and that the reinforcement criterion is met for each interval instead of the full session. This shift differs from the original definition in two ways: First, the one-response-limit criterion is no longer specified and it is left open for the practitioner to set (as is the case with the *f*-DRL). Second, the resetting interval is rarely mentioned as an inherent part of the procedure.

Selecting the Appropriate DRL Procedure

When deciding which variation of the DRL to implement, one must take several factors into consideration. First, it is important to consider the feasibility of each procedure. The *s*-DRL is the most cumbersome of the three procedures because each response resets the interval and it requires close monitoring. The *f*-DRL, on the other hand, is much easier to implement and is likely more manageable for someone with other demands on their time, such as a teacher who is attending to more than one child at a time. The *i*-DRL is less cumbersome that the s-DRL, but more so than the *f*-DRL.

Second, one should consider whether it is important to space out responding or whether low overall rate of responding is sufficient. For example, if the target behavior is rapid food consumption that puts an individual at risk for choking, the goal would not be to decrease the number of bites taken in a session. Instead, one would aim to space out the bites by targeting longer IRTs. In such cases, the *s*-DRL procedure would be most appropriate for achieving the desired outcome. If, on the other hand, lower overall rate of responding is the goal, and the time between each response does not matter (e.g., student talk-outs), then an *f*-DRL would be appropriate. For example, if the goal is to decrease excessive tardiness, it might only be important to reduce tardiness to three instances in the month and not necessarily to evenly distribute when in the month they occur.

Finally, it is important to determine whether complete elimination of the response is a desirable outcome or if it is important to maintain some level of responding. Because the *s*-DRL procedure requires the occurrence of a response to access reinforcement, this procedure is most likely to maintain responding. The *f*-DRL and *i*-DRL procedures, on the other hand, do not require a response because a reinforcer can be earned at the end of an interval or session if a response does not occur at all. As a result, these procedures can sometimes eliminate responding completely (Jessel & Borrero, 2014). Therefore, if response elimination would be detrimental, one might want to avoid the *i*-DRL and *s*-DRL variations.

Conflict of Interest We have no known conflict of interest to disclose.

Part II

Applied Behavior Analysis

9 Prompt and Prompt-Fading Procedures

Lauren K. Schnell, Mirela Cengher, and April N. Kisamore

Let us begin with an exercise—take a few seconds to explore your environment with all your senses. One of the first things that you may notice is that you perceive numerous stimuli, of different modalities (e.g., visual, auditory, tactile), concurrently. Our behavior continuously changes as a function of these stimuli. When presented with multiple stimuli or with multimodal stimuli, we are likely to attend and respond to the more salient ones (i.e., novel, surprising, or that stand out for other reasons; Hall et al., 1977). We are also more likely to respond and learn from stimuli that we have been exposed to before (Coon & Miguel, 2012; Kay et al., 2019; Roncati et al., 2019). In this way, stimuli come to control behavior, by evoking behavior that has in the past been followed by reinforcement.

Stimulus control is demonstrated when (a) stimuli come to indicate that a reinforcer is available given a response and (b) the absence of stimuli or another, unrelated stimulus comes to indicate that a reinforcer is not available given a response. Stimuli that indicate the availability of reinforcers are called *discriminative stimuli* (S^D), whereas stimuli that indicate the unavailability of reinforcement are called *delta stimuli* (S^Δ). For example, we have learned that the sign "Open" on a restaurant's door indicates that, if we walk in and order, we will get food. Therefore, for most of us, the sign "Open" functions as an S^D for walking in restaurants to get food. We have also learned that walking into a restaurant that does not have a visible "Open" sign or that has a "Closed" sign is not likely to be reinforced, in that the door may be locked or that the servers may ask us to leave. Therefore, for most of us, the sign "Closed" functions as an S^Δ for walking in restaurants to get food.

Assume that upon seeing the sign "Open" (antecedent) we enter the restaurant (behavior) and, as a result, we receive food (consequence). This sequence of events is called the *three-term contingency*. We all likely learned the three-term contingencies involving "Open" and "Closed" signs on restaurants' doors incidentally, through everyday life experiences. However, some things are difficult to learn incidentally—and this is where direct teaching comes in place. Stimulus control is especially important when learning new responses in school environments. From preschool to higher education, the instructors' job is to teach new, appropriate behavior repertoires and to bring these repertoires under stimulus control. For example, an instructor would be unlikely

to teach her learners to raise their hands under all circumstances. Instead, she would likely reinforce the learners raising their hands during lectures, only when they have a question or when they want to respond to a question.

Most often, teaching someone to perform a response and to bring it under the appropriate stimulus control requires careful selection and use of prompts and prompt-fading procedures. In the first part of this chapter, we will describe different types of prompts and their use, and the second part of this chapter will describe how these prompts can be faded to promote independent, correct responding. Finally, we will describe how to select prompts and prompt-fading procedures, as well as how to develop individualized assessments to increase the effectiveness and efficiency of instruction.

Prompts

We define prompts as supplemental stimuli that evoke correct responding, but that are not a critical part of the three-term contingency (Cengher et al., 2018, 2020). For example, an instructor may want to teach a child to identify numbers. In this case, the three-term contingency consists of the sight of a number, the verbal response (e.g., "five"), and a reinforcing consequence (e.g., praise). Because initially the child cannot respond correctly when presented with a number alone, the instructor may use a verbal prompt, such as telling the child the correct response. In time, this prompt can be faded to facilitate the development of the desired three-term contingency, which in this case consists of number identification.

In the example above, the prompt consisted of telling the child the correct response (e.g., verbal prompt). However, other antecedent stimuli can effectively evoke the behavior of saying numbers, such as visual prompts (e.g., a picture of five little monkeys next to the number 5). Any stimulus that evokes correct responding can be used as a prompt. The difference between these different prompts is not functional, in that they have the same effect on behavior. Rather, the difference between these prompts is formal, in that each of them has a different topography.

Prompts fall into two categories, based on whether the prompt is embedded in the natural S^D or not. In *stimulus-prompting procedures*, the configuration of the S^D is changed to evoke correct responses (Cengher et al., 2018). This can be accomplished in two ways, and, as such, there are two stimulus-prompting procedures: *stimulus fading* and *stimulus shaping*. Given that their configuration and how it changes is related to fading, these are described in detail in the prompt-fading procedures section below.

In *response-prompting procedures*, the prompt is a supplemental stimulus that is added to the three-term contingency. The prompt can be presented at the same time as the S^D, or the two stimuli can be presented in succession: first the prompt, and after a brief delay the S^D (Cengher et al., 2018). Response-prompting procedures are: model, gestural, visual, textual, and physical prompt. A model prompt consists of showing the learner how to perform the response. An example of a model prompt is the instructor raising her hand to prompt the child to raise their hand. The child can observe the modeled behavior of the instructor by orienting to them (e.g., standing face to face). However, being able to observe both the modeled behavior and the imitative behavior can provide better visual feedback, in that it makes it possible for the learner to evaluate how well the two match. Assuming that parity between the modeled and the imitative response is reinforcing (Palmer, 1996), administering model prompts through a mirror should facilitate the correct performance of the behavior. Indeed, Miller et al. (2015) compared two procedures to teach children with Autism Spectrum Disorder (ASD) to imitate: one where modeled prompts were delivered through a mirror, and one where model prompts were delivered face-to-face (no mirror). Participants learned to imitate more effectively and efficiently when the model prompt was delivered via the mirror.

A gestural prompt consists of pointing to or touching the S^D or other stimuli relevant to performing a response, for example, pointing to the child's arm to have them raise their hand. A visual prompt consists of a picture or a video[1] that displays a cue to perform the response. Examples of visual prompts are a picture of hands being washed displayed in a public restroom or a video of someone washing hands. A textual prompt displays written instructions to perform the respective behavior, or behavior chain, for example, displaying a sign with the words “Employees must wash hands at all times” in a public restroom. Finally, a physical prompt consists of physically guiding the learner to perform a behavior. Physical prompts can range from a gentle touch (e.g., gently pushing someone’s hands in the direction of the sink to prompt washing hands) to a full physical prompt (e.g., assisting someone hand-over-hand to prompt washing hands).

Use of Prompts

By now, it should be clear that prompts and prompt-fading procedures are at the front-end of teaching new behaviors. However, there are other important uses of prompts, including (a) to bring behavior under stimulus control, and (c) establishing a chain of previously mastered behaviors. We will discuss each of these below.

Using prompts to bring behavior under stimulus control is not just useful when teaching children, but adults as well. Workplaces are abundant with signs and pictograms that are meant to prompt employees to engage in safe behaviors, such as wash hands each time using the bathroom, use of protective equipment, or wearing a seat belt while driving. The problem is not that employees have not learned how to engage in these behaviors independently, but rather that these behaviors do not occur reliably under the conditions that their employers want them to. For example, Davis et al. (2013) assessed hand washing in public restrooms under three conditions: (a) baseline (no intervention), (b) handwashing sign, and (c) posters displaying the effects of influenza along with the handwashing sign. The sign increased handwashing as compared to baseline, whereas, surprisingly, the posters decreased hand washing at or below baseline levels. These results suggest that signs can function as effective prompts that can bring safe workplace behaviors under the appropriate stimulus control.

Another use of prompts is to establish a chain of previously mastered behaviors. Anyone who has ever baked or cooked has likely, at one or more points in time, followed a recipe. A recipe consists of written, pictorial, or video instructions (prompts) that involve multiple behaviors that should be performed sequentially. None of these behaviors are likely new to adult individuals, but their combination can be novel. For example, most individuals have performed some or all of the following behaviors: preheated the oven, mixed ingredients in a bowl, beat eggs, roll dough on cookie sheets, and placed the tray into the oven. However, one may engage in this unique combination of behaviors for the first time when following a recipe, and as a result, enjoy freshly homemade cookies. After following a recipe a few times, one may learn to make it in the absence of prompts. However, prompts are a necessary first step in learning how to bake and cook, among other complex behavior chains.

Finally, prompts for behavior chains are very helpful in establishing and maintaining routines, two very important goals of education. Anyone who has ever been in a classroom has probably noticed that there are visual and written schedules on the walls. Such schedules can help establish and maintain routines that can increase the productivity of children.

Procedures to Fade Prompts

In most cases, prompts are considered artificial, as the instructor arranges their presence and they are unlikely to occur in the natural environment. Thus, the ultimate goal is to fade these prompts to ensure that the natural antecedent accrues stimulus control and becomes an S^D. To achieve this goal, we employ transfer of stimulus control procedures. Procedures to fade prompts, known as

[1]The use of video prompts is commonly referred to as *video modeling*.

prompt-fading procedures, are used to systematically fade prompts and transfer responding to naturally occurring S^Ds (Cengher et al., 2018; Green, 2001). For example, in teaching a learner to differentially respond to pictures of common objects, the instructor may place three cards in front of the learner, each depicting a different picture of common objects, and say “find the ball,” then prompt the response by manually guiding the learner’s hand to the picture of the ball. As the learner responds correctly with the prompt, the instructor can start to implement a prompt-fading procedure until the learner can point to the picture of the ball, when verbally instructed to do so, in the absence of prompts. In the previous example, the terminal goal is for the learner to select the picture of the ball when asked by the instructor.

Common response prompt-fading procedures include decreasing assistance (most-to-least), increasing assistance (least-to-most), and time delay procedures (MacDuff et al., 2001).

When using most-to-least prompt fading, the instructor uses the most intrusive prompt type then systematically fades the intrusiveness of the prompt as instruction continues and the learner responds correctly (Fentress & Lerman, 2012; Seaver & Bourret, 2014). For example, when teaching a learner to complete a block design, the instructor may initially implement a full physical prompt (i.e., a hand-over-hand physical prompt). Then, contingent on the learner demonstrating responding at a certain mastery criterion, the prompt is faded such that the instructor uses a less intense form of the prompt, changes the location of the prompt (i.e., graduated guidance; hand-over -wrist, -forearm, -elbow, -shoulder, then shadow prompt; MacDuff et al., 2001), or uses a less intrusive prompt type (i.e., model prompt).

When using least-to-most prompt fading, the intrusiveness of the prompt is increased as necessary to occasion correct learner responding. For example, when teaching a learner to complete a block design, the learner might initially be allowed to engage in an independent response. If the learner engages in an incorrect response the instructor may lightly guide the learner’s arm at the elbow in an attempt to occasion the correct response. If unsuccessful, the instructor may then increase the intrusiveness of the prompt by guiding the learner at the wrist or use a hand-over-hand prompt (Fentress & Lerman, 2012; Seaver & Bourret, 2014).

A prompt delay involves fading prompts by imposing a period of time between the presentation of the antecedent stimulus and the delivery of the prompt (MacDuff et al., 2001). This period of time is systematically increased during or across instructional sessions (i.e., progressive prompt delay) or held constant (i.e., constant prompt delay). When using a progressive prompt delay or constant prompt delay, it is common for the initial instructional trials or sessions to include a 0-s prompt delay (Walker, 2008). During 0-s prompt delay trials, the instructor provides a prompt immediately following the presentation of the antecedent stimulus. After a predetermined number of instructional trials or sessions with the 0-s prompt delay in place, a brief period is provided following the presentation of the antecedent stimulus and the prompt. For example, when teaching a learner to respond to the social question, “What’s your address?,” the instructor may initially provide an immediate vocal model prompt (e.g., “120 Bloomfield Ave.”) that the learner should imitate. Then, after two instructional sessions with the 0-s prompt delay in place, the instructor delivers the vocal model prompt if the learner does not respond correctly within 5 s (i.e., 5-s prompt delay).

Graduated guidance occurs in conjunction with other prompt-fading procedures (e.g., most-to-least, least-to-most, progressive prompt delay, time delay) and involves manipulation of the intensity or location of a manual prompt (Jimenez & Alamer, 2018). For example, the instructor may initially use a hand-over-hand manual prompt during teaching, and over successive trials will move the prompt to the learner’s wrist, elbow, and then shoulder before removing the manual prompt and providing a gesture and then allowing for independent responding.

Common stimulus prompt-fading procedures include stimulus fading and stimulus shaping (MacDuff et al., 2001). In stimulus fading, only one dimension of the S^D is manipulated, whereas in stimulus shaping the entire configuration of the S^D is manipulated. For example, in teaching a child to respond differentially to the words, *car and cat*, a stimulus fading procedure would consist of highlighting the letters *r* and *t,* respectively. In contrast, a stimulus shaping procedure may consist of superimposing a picture of a car on the word *car* and a picture of a cat on the word *cat.* These prompts would be gradually faded so that the words *car* and *cat* come to evoke correct responding, in the absence of the prompt (i.e., the picture of the car and the cat).

Prompt Dependency

Whenever prompts are used during instruction, there is a risk that the learner will become prompt-dependent. *Prompt dependency* refers to occasions in which a learner's correct responding becomes consistently dependent on the controlling prompt and attempts to fade prompts during teaching are unsuccessful (Cividini-Motta & Ahearn, 2013). Prompt dependency may occur for several reasons. One reason may be that the instructor does not systematically fade prompt use. In these cases, the controlling prompt gains stimulus control over the learner's response while the natural S^D does not, resulting in the continued requirement for the prompt to be present for responding to occur (Clark & Green, 2004; Jones & Zarcone, 2014). For example, when teaching a learner to match to sample, the instructor may initially begin teaching trials by using a gestural prompt. During these trials, the instructor gestures to the correct corresponding stimulus immediately after delivering the vocal antecedent "match." Reinforcement is then delivered for prompted correct responses, establishing a teaching contingency (i.e., antecedent, controlling prompt, response, consequence) and involving the controlling prompt. Without the use of a systematic prompt-fading procedure, it is likely that the learner's response will continue to occur only when the prompt is presented.

Schedules of reinforcement play an integral role in preventing the development of prompt dependency. During instruction, instructors must be cautious when delivering the same quality reinforcer contingent upon learner prompted or unprompted responses (Cooper et al., 2020) and be prepared to shift reinforcement from prompted responses to unprompted responses as early as possible (MacDuff et al., 2001). This strategy, referred to as *differential reinforcement*, occurs when higher quality, higher magnitude, or denser schedules of reinforcement follow unprompted responses, whereas prompted responses result in lower quality, smaller magnitude, or leaner schedule of reinforcement. Research shows that a differential reinforcement procedure facilitates the transfer of stimulus control from the prompt to the natural S^D (Johnson et al., 2017; Karsten & Carr, 2009). For example, when teaching a learner to imitate a model, the instructor may initially deliver a manual prompt to evoke a correct response. Praise is then delivered contingent upon the learner engaging in the prompted correct response. After several learning trials, the instructor may deliver the S^D and withhold the prompt. When the learner engages in an unprompted, correct response, the instructor delivers praise plus access to the learner's favorite toy.

Given that there are several variables that can be manipulated in a differential reinforcement schedule, it can be arranged in different ways. Research has examined the optimal arrangements to promote transfer of stimulus control from prompts to natural S^Ds. Johnson et al. (2017) evaluated the effects of reinforcement schedules on responses to intraverbal, tact, and auditory-visual matching tasks. Assessments of differential reinforcement (i.e., quality, schedule, and magnitude) and nondifferential reinforcement were conducted to determine the most efficient arrangement for participants. Differential reinforcement procedures yielded superior outcomes when compared to nondifferential reinforcement procedures, and this outcome is consistent with previous research (Johnson et al., 2017; Karsten & Carr, 2009). However, there were within and across-participant differences concerning which schedule of differential reinforcement (i.e., quality, magnitude) yielded more efficient acquisition.

These outcomes speak about the necessity of using individualized differential reinforcement procedures to establish independent and efficient responses in learners.

Variables that Influence the Selection of Prompt Topographies and Prompt-Fading Procedures

With so many prompt topographies and prompt-fading procedures, one is left with the somewhat daunting task of choosing among them. This choice should be guided by: (a) the learner's behavioral repertoire, (b) the learner's instructional history, (c) the natural S^D, (d) the response being taught, (e) preference, and (f) professional ethics. We will discuss each of these below.

It is important to consider that each learner has a unique repertoire of skill and skill deficits. This is especially true for heterogeneous groups such as individuals with developmental disabilities, such as ASD, who typically benefit most from instruction that involves a carefully designed technology of prompt and prompt-fading procedures. One should assess each individual's repertoire of skills and skill deficits to choose a procedure that is not only effective but also least intrusive. For example, remember that we should only use prompts that are effective in evoking the desired behavior. If we are trying to teach a child to perform one-step directions (e.g., touch nose when instructed to do so), a model prompt is only going to be effective insofar the child can imitate other people's actions. If a child does not have a generalized imitation repertoire, another prompt topography, such as a physical prompt, should be selected. In sum, it is important to determine whether a specific stimulus topography has stimulus control over the desired behavior and, thus, is in the learner's repertoire before prescribing it as a prompt.

The learner's instructional history is equally important in the selection of prompt topographies and prompt-fading procedures. Research (Coon & Miguel, 2012; Kay et al., 2019; Roncati et al., 2019) shows that learners perform better when using a prompt topography and prompt-fading procedure to which they had been exposed previously. For example, a learner who was taught to tact a set of stimuli using an echoic (model) prompt using a gradual time delay procedure will learn a new set of tacts more efficiently when using an echoic prompt as compared to a never-before-experienced prompt topography (e.g., textual prompt; Coon & Miguel, 2012). These outcomes suggest that clinicians should choose the optimal prompt topography and prompt-fading procedure for each learner and use it consistently across skills taught and in time.

Since in most cases the goal of instruction is to fade the prompts and to transfer stimulus control from the prompt to the natural S^D, it is important to choose a prompt that can facilitate that transition. In other words, the prompt should guide the learner's attention to the natural S^D, rather than away from it. In this respect, stimulus-prompting procedures are more effective and efficient than response-prompting procedures (Arick & Krug, 1978; Collier & Reid, 1987; Richmond & Bell, 1983; Schreibman, 1975; Wolfe & Cuvo, 1978). However, stimulus-prompting procedures are not amendable to all S^Ds and responses. For example, if a child doesn't know how to clap hands and the clinician wants to teach them to clap on command, using a stimulus prompt (e.g., emphasizing the sounds of the command) is not likely to yield correct responding. Instead, a response prompting procedure, such as a model prompt, may be effective if the child has a generalized imitation repertoire. Similarly, the response being taught can influence the choice of prompt. Specifically, a response that is not in someone's repertoire can only be taught using response-prompting procedures. For example, if a child cannot tie the shoelaces, an appropriate prompt would be a model prompt, a visual prompt, or a physical prompt.

Preference for prompting procedure has not been considered until very recently. For example, Halbur et al. (2020) taught parents to implement three commonly used prompt-fading procedures, each assigned to a different set of stimuli. Throughout the study, the authors evaluated the parents' acceptability of the procedures. After the children met the mastery criterion with all three procedures, they evaluated preference for procedures in a concurrent arrangement, whereby the parents could choose between the three prompt-fading procedures available at the same time. The results showed that parents preferred the least-to-most prompt-fading procedure and that their acceptability ratings improved throughout the study. These results are important because treatment acceptability may be correlated (or is a causal factor) for treatment adherence. However, no studies to date evaluated learners' and caregivers' preference for prompt topographies. Clinicians and researchers should evaluate preference and its indirect effect on performance, as it is very likely that some prompt topographies are more preferred than others. For example, many individuals with developmental disabilities find physical contact aversive (Vostanis et al., 1998). If a clinician had this information, she could design teaching procedures that utilize prompt topographies that do not involve physical contact. Such a selection of prompt topographies may not only have implications for the effectiveness of instruction but may also be more ethical.

Finally, behavior analysts and educators should aim to teach using the least intrusive procedures necessary and should fade all supports as the child performs well to increase the child's independence and foster the transition to less restrictive teaching environments. In that respect, some prompt topographies and prompt-fading procedures are better than others. Let's get back to the example above with physical prompts—putting your hand on someone to guide them in doing something is, by all accounts, more intrusive than asking or showing someone how to do something. Therefore, physical prompts should only be used when necessary. Similarly, procedures that minimize the number of errors (i.e., stimulus fading, stimulus shaping, gradual time delay, progressive time delay, and most-to-least prompting) during transfer of stimulus control from the prompt to the S^D should be used over procedures that allow errors to occur for two reasons. First, learners can acquire new responses while almost continually contacting reinforcement when using errorless teaching procedures, assuming a continuous schedule of reinforcement is programmed for correct responses (Touchette & Howard, 1984). Second, Schilmoeller et al. (1979) found that procedures that allowed participants to make errors not only hindered the acquisition of new skills but also precluded their acquisition when the experimenters attempted to teach them using errorless teaching procedures (i.e., a final-best treatment approach). Possibly, the participants developed faulty (in the eye of the experimenter) stimulus control, which subsequently blocked the acquisition of stimulus control as intended by the experimenters. In sum, errorless teaching procedures are more ethical and more effective and should be used over procedures that allow errors to occur during the transfer of stimulus control from the prompt to the natural S^D.

Using prompts in the classroom requires other ethical considerations. If prompts are used in a classroom environment where peers are present, educators should make all efforts to minimize the use of intrusive prompts and to decrease their salience to others to avoid the learner being stigmatized. For example, if a child needs visual reminders to stay on task, the educator may make small visual stimuli and place them on the child's desk, in a space where it is not visible to her peers, rather than provide verbal reminders or physical prompts to stay on task that the other children can observe.

If an instructor considers all the aforementioned variables when selecting procedures, they should be able to narrow down the number of prompt topographies and prompt-fading procedures that are optimal for a learner. However, recall that the effectiveness, efficiency, and possibly preference for these procedures vary across individuals. As such, to identify the optimal procedure for each learner, an instructor should conduct individualized assessments of prompt topographies and prompt-fading procedures.

Recent research focused on developing assessments to identify the most effective and efficient prompt topographies and prompt-fading procedures for individuals with ASD (Cengher et al., 2015; Schnell et al., 2020; Seaver & Bourret, 2014). For example, Schnell et al. (2020)

conducted what they referred to as a *prompt-topography assessment* followed by a *prompt-fading assessment*. During the prompt-topography assessment, experimenters compared responses on a visual-auditory conditional discrimination task (i.e., also known as receptive labeling) across the use of model, partial physical, and full physical prompts. In each experimental condition, the participants were exposed to a different set of auditory-visual conditional discriminations using a different prompt topography. The experimenters evaluated the acquisition of these auditory-visual conditional discriminations across conditions. Trials were presented in a matching-to-sample format, whereby the experimenter presented an instruction (e.g., "Point to the car!") along with three pictures of different items that the participant could choose from. During the prompt-fading assessment, the authors compared response acquisition under three different conditions, each employing a different prompt-fading procedure: most-to-least prompting, least-to-most prompting, and progressive time delay. For each participant, the prompt topography that was identified as most efficient during the prompt-topography assessment was included in the design of the prompt-fading procedure. For example, if for a participant the model prompt was identified as most effective and efficient, the authors only used model prompts and gradually increased the time interval between the presentation of the natural S^D and the prompt in the progressive time delay condition. The outcomes of these assessments were replicated both within participants (i.e., across different sets of stimuli) and across participants. The authors identified the optimal prompt topography and prompt-fading procedure for each participant.

Instructors could easily replicate the procedures described above in clinical practice. Instructors routinely design protocols to teach skills, such as audio-visual conditional discriminations. Conducting such an assessment of prompt topographies and prompt-fading procedures would only involve teaching such skills concurrently, using different procedures. For example, if the instructor planned to teach auditory-visual conditional discriminations, instead of only using one procedure they may assign sets of stimuli to two or more different procedures (e.g., most-to-least prompting, progressive time delay, least-to-most prompting) and compare the efficiency of skill acquisition across them, as described by Schnell et al. (2020). Such assessments can be especially helpful for learners who do not make adequate progress (i.e., as estimated by the instructor) or for learners who demonstrate prompt dependence. For such learners, identifying the optimal prompt topography and prompt-fading assessment and using it consistently across programs can result in a meaningful increase in the number of skills learned, or a reduction in the number of sessions to mastery criterion across targets and programs.

Recent research focused on developing assessments to identify the most effective and efficient prompt topographies and prompt-fading procedures for individuals with ASD (Cengher et al., 2015; Schnell et al., 2020; Seaver & Bourret, 2014). For example, Schnell et al. (2020) conducted what they referred to as a *prompt-topography assessment* followed by a *prompt-fading assessment*. During the prompt-topography assessment, experimenters compared responses on a visual-auditory conditional discrimination task (i.e., also known as receptive labeling) across the use of model, partial physical, and full physical prompts. In each experimental condition, the participants were exposed to a different set of auditory-visual conditional discriminations using a different prompt topography. The experimenters evaluated the acquisition of these auditory-visual conditional discriminations across conditions. Trials were presented in a matching-to-sample format, whereby the experimenter presented an instruction (e.g., "Point to the car!") along with three pictures of different items that the participant could choose from. During the prompt-fading assessment, the authors compared response acquisition under three different conditions, each employing a different prompt-fading procedure: most-to-least prompting, least-to-most prompting, and progressive time delay. For each participant, the prompt topography that was identified as most efficient during the prompt-topography assessment was included in the design of the prompt-fading procedure. For example, if for a participant the model prompt was identified as most effective and efficient, the authors only used model prompts and gradually increased the time interval between the presentation of the natural S^D and the prompt in the progressive time delay condition. The outcomes of these assessments were replicated both within participants (i.e., across different sets of stimuli) and across participants. The authors identified the optimal prompt topography and prompt-fading procedure for each participant.

Instructors could easily replicate the procedures described above in clinical practice. Instructors routinely design protocols to teach skills, such as audio-visual conditional discriminations. Conducting such an assessment of prompt topographies and prompt-fading procedures would only involve teaching such skills concurrently, using different procedures. For example, if the instructor planned to teach auditory-visual conditional discriminations, instead of only using one procedure they may assign sets of stimuli to two or more different procedures (e.g., most-to-least prompting, progressive time delay, least-to-most prompting) and compare the efficiency of skill acquisition across them, as described by Schnell et al. (2020). Such assessments can be especially helpful for learners who do not make adequate progress (i.e., as estimated by the instructor) or for learners who demonstrate prompt dependence. For such learners, identifying the optimal prompt topography and prompt-fading assessment and using it consistently across programs can result in a meaningful increase in the number of skills learned, or a reduction in the number of sessions to mastery criterion across targets and programs.

Conclusion

Let us finish with the same exercise that we started with—take a few seconds to explore your environment with all your senses. Think about something that you may learn from your environment or something you may want to teach a learner about your environment (e.g., labeling items in a foreign language, responding differentially to colors, labeling locations). Next, think about how you would arrange the environment to facilitate learning. How can you increase directing the learner's attention to your programmed natural S^D? What kind of prompts would you use, and how would you fade them? What variables would you consider when making these decisions? How would you develop individualized assessments to identify the optimal prompt topography and prompt-fading procedures for learners? We hope this chapter provided the foundational knowledge that can help make such decisions in clinical practice and sparked an interest in learning more about learning.

Natalia A. Baires and Mitch Fryling

Chapter Overview

This chapter focuses on the use of stimulus-stimulus pairing (SSP) procedures in the development of behavior. In particular, this chapter focuses upon the use of these procedures in the development of early language, with a focus upon using SSP to promote language with individuals with language delays (e.g., those associated with autism spectrum disorder; ASD), and in particular, individuals with very minimal or no vocal language. The chapter begins with a conceptual overview of the principles involved in SSP intervention strategies. This includes a consideration of both the respondent and operant principles that are thought to be the foundation of SSP. In addition, as some of the literature on stimulus pairing is related to other areas of application and research (e.g., derived stimulus relations), the chapter concludes with a brief consideration of how stimulus pairing procedures are fundamental to many areas in applied behavior analysis.

One more thing before we begin. Although this chapter focuses upon stimulus pairing procedures in the development of behavior (especially language skills), we recognize that stimulus pairing procedures are also used to reduce challenging behavior. For example, the literature on environmental enrichment could be interpreted from the perspective of SSP in the sense that stimuli are paired with (or added to) the current environment (e.g., Gover et al., 2019). In addition, many fearful or "phobic" responses likely develop as a result of stimulus pairings, and behavioral intervention to reduce those responses involves stimulus pairing, specifically stimulus *un*-pairing (e.g., Shabani & Fisher, 2006). Although these lines of research are interesting and pertain to meaningful clinical issues, they are not the focus of the present chapter. We mention them to acknowledge that a multitude of interventions may be considered to involve stimulus pairing; the focus of this chapter is rather specific in this regard. We turn now to conceptual foundations pertinent to our review of stimulus pairing and the development of language.

Conceptual Foundations

Applied behavior analysis (ABA) has a long history of scholarly work in the area of verbal behavior. Like many areas of behavior analysis, this particular area of application has been heavily influenced by the work of B. F. Skinner. In particular, Skinner's (1957) text *Verbal Behavior* has had a significant influence on research and practice in ABA for many years (e.g., Dixon et al., 2011; Sundberg, 2008; Sundberg & Michael, 2001). Consistent with much of Skinner's work, this area of focus has largely focused on an operant analysis of verbal behavior in an effort to understand how contingencies participate in language development. Other chapters in this text (Chaps. 22 and 68) have focused on providing an overview of this work, including the

verbal operants and the various areas where Skinner's analysis has been demonstrated to be particularly helpful (also consult Garcia et al., 2020; Rosales et al., 2020 for recent reviews of the research in this area).

Approaches to language development within ABA have not been limited to applications based on operant conditioning, however. Like other areas of practice (e.g., the treatment of phobias), the area of language development has also been influenced by the respondent conditioning paradigm. Respondent processes may be particularly relevant in circumstances when there is no behavior to reinforce, such as when an individual has not yet begun to engage in vocal behavior or only engages in very minimal vocal behavior. Whereas operant conditioning places heavy emphasis on the assessment and manipulation of the *consequences* of behavior to develop and influence particular behavioral targets (in this case verbal behavior), respondent procedures place emphasis on the pairing (i.e., co-occurrence) of stimulus events together in space and time to develop and influence the development of behavior. We turn now to reviewing the conceptual foundations of SSP more specifically.

Stimulus-Stimulus Pairing

This section provides an overview of the respondent and operant processes involved in SSP. While it is unlikely that the processes occur in a precise order, we attempt to review them sequentially to lay out the mechanisms involved in the procedure.

The stimulus-stimulus pairing (SSP) procedure is derived from conceptual work in the area of behavioral development (e.g., Bijou, 1993) and Skinner's (1957) verbal behavior. Interestingly, this area of conceptual analysis may have developed, at least partially, in response to the traditional idea that some language seems to develop in the absence of a specific history of reinforcement. Indeed, at first thought, the idea that language might develop in the absence of a particular history of reinforcement would seem to threaten the most fundamental assumptions in behavioral thinking. Not surprisingly, this issue has been used as a critique of the behavioral position as an explanation of language development for years (consult Sundberg et al., 1996 for an overview). Behaviorists have attempted to explain this development of behavior in the absence of a history of reinforcement by emphasizing the distinct processes involved – and they are fundamental to understanding SSP.

From the behavioral perspective of language development, a great deal of language may be influenced by a sequence of three processes and related outcomes (e.g., Sundberg et al., 1996). *First*, and perhaps most fundamentally, there is the pairing of sounds with preferred or non-preferred stimulus events. For example, parents/caregivers often make sounds and say words while holding an infant, providing access to food, playing with the infant, and more (i.e., the sounds are paired with stimulus events). Following the respondent conditioning paradigm, the sounds, words, and more may be considered neutral stimuli that are paired with unconditioned reinforcers (e.g., food) or stimuli that are already conditioned reinforcers (e.g., the sight of a toy). As a result of these stimulus-stimulus pairings, those sounds, words, and more, while previously neutral stimuli, become conditioned stimuli themselves. This sort of pairing is pervasive throughout the lives of young children, and a great deal of early learning likely involves respondent conditioning. Readers of this chapter are encouraged to pause for a moment and consider the extensive number of sound-event pairing trials that likely occur in the day-to-day lives of young children from the time they wake until they go to sleep. At the same time, considering this may also lead to the understanding of the impact of childhood neglect on language development (e.g., Hart & Risley, 1995).

This first step explains how sounds and words first develop the stimulus properties of unconditioned and already conditioned stimuli – how those sounds become conditioned stimuli themselves. The *second step* points to the development of operant functions for the sounds targeted in step one. Specifically, it is hypothesized that this history of respondent conditioning (i.e., the stimulus-stimulus pairing) leads to those previously neutral stimuli (i.e., the sounds) now functioning as conditioned reinforcers in the operant sense of the phrase (and indeed, all conditioned reinforcers are established via respondent processes). In this sense, the respondent conditioning (Step 1) sets the stage for subsequent operant conditioning. Furthermore, when something functions as a conditioned reinforcer, the presentation of the conditioned reinforcer increases the future frequency of behavior that resulted in its presentation. In this case the conditioned reinforcer is the sound (i.e., the previously neutral stimulus), and the presentation of the sound (i.e., the hearing of the sound) may reinforce the behavior that produces it (i.e., the vocal behavior on behalf of the person who is developing language). It is this operant conditioning that serves to explain how the initial vocalizations of the individual (e.g., babbling) may begin to increase in frequency.

The *third step* in the process is automatic reinforcement. It probably is not a “step” in the sense that it does not happen *after* step two (more on this in a moment), but it is more of a concept that may be useful in explaining a critical part of SSP. Recall that one of the main issues that may be used to critique the behavioral position is that language seems to develop in the absence of a specific history of reinforcement, for example, that an adult did not mediate reinforcement contingent upon every single vocalization that a child engages in. In fact, it seems likely that it is often the case that a child begins to engage in some vocal behavior *without* there being a particular history of reinforcement to point to as the explanation. Given the respondent conditioning involved in step one, and the establishment of sounds as conditioned reinforcers in step two, engaging in any behavior that produces a target sound may be reinforced. However, this particular behavior is unique in that the reinforcement is “built in”; it occurs *automatically*. Nobody needs to *do* anything to mediate the reinforcement for engaging in the vocal behavior, and the delivery of reinforcement is not contingent upon any particular environmental condition. In other words, both the behavior (i.e., engaging in the vocalization) and the reinforcer (i.e., hearing the sound of the vocalization) can occur at anytime and anywhere.

Moreover, the shaping process may also occur automatically, whereby the vocalizations and related sound products become more and more similar to the sounds involved in the initial respondent conditioning, still without any requirement that someone mediates reinforcement. All of these make the SSP particularly unique, conceptually speaking, since environmental support is not needed beyond the initial respondent pairing in step one. Although automatic reinforcement may often cause problems when challenging behavior is involved, it is quite helpful when it is built into the process of behavioral development. The automatic reinforcement concept seems to be rather important, not only to finish explaining this part of the behavior analysis of language development, but also to respond to common critiques of behavior analytic approaches to language (readers interested in this may also consult Palmer [1996]).

We have described the respondent and operant processes involved in SSP in a somewhat sequential manner. However, it is important to note that the respondent and operant processes described thus far are more likely to be ongoing (i.e., to co-occur) or to sort of go back and forth. For example, imagine an infant who has a caregiver that says “ba-ba-ba” while playing with the infant. Respondent conditioning may occur, and the infant’s vocalizations may begin to be exposed to operant contingencies. However, it is likely that additional SSP will occur, for example the parent saying “yes, ba-ba-ba!” while tickling the infant after the infant engages in an approximation, meaning that additional respondent conditioning may occur. This respondent conditioning may influence operant processes, and vice versa. Our point here is that while we have described the processes involved in SSP as a series of sequential steps, it seems more likely that they co-occur and together contribute to the development of vocal behavior.

Why Stimulus-Stimulus Pairing?

So far we have described the processes that explain the development of vocal behavior, the processes that are the foundation for SSP as an intervention. That is, the above is a description of how early vocalizations develop, whereas SSP involves the specific application of techniques based upon those processes. The former is a conceptual explanation, whereas the latter is a technique derived from that conceptualization.

Importantly, the SSP is not just any technique, and developing early vocalizations is just one component in a larger effort to develop language. Indeed, these early vocalizations provide the context by which additional conditioning might be applied. The sound "mmm" is not an end goal in itself; it allows for further conditioning that may lead to the word "mom" and "milk", for example. Moreover, applied behavior analysts frequently work with individuals with language delays, including individuals with autism spectrum disorder and related intellectual disabilities, some of whom are minimally vocal or nonvocal altogether (e.g., Centers for Disease Control and Prevention, 2020). Therefore, it may be the case that applications of SSP are crucial to the development of early language. Given the significance of developing language in many areas of day-to-day living, it would seem that applied behavior analysts working on language development should have knowledge of interventions that may be helpful.

On this note, we turn to the research literature on the SSP. We review some of the early studies on SSP, two recent literature reviews, and literature that has been published after these literature reviews (post-2014).

Stimulus-Stimulus Pairing Research

Early Research

To our knowledge, SSP was first empirically examined by Sundberg et al. (1996). In this study, researchers examined the effects of SSP on novel vocal behavior, specifically the babbling repertoires of four children with severe to moderate language delays and one child without any language delays. In the first of two experiments, the four participants were exposed to the SSP procedure, which involved a novel sound, word, or phrase that was paired with a previously established conditioned or unconditioned reinforcer during play periods. During the post-pairing condition, all participants were observed to emit unprompted vocal and verbal behavior, with occasional emissions during participants' vocal play outside of pairing sessions. Moreover, an increase in the overall vocal responses of some participants was seen following SSP. Sundberg et al. suggested that the effect on overall vocal responses might have been a result of SSP functioning as direct reinforcement for vocalizations emitted during baseline conditions (i.e., adventitious reinforcement may have occurred). Yet, there were some instances in which an increase in vocal behavior was not observed following SSP. In order to examine a variety of parameters of the SSP procedure, a second experiment was conducted with the participant whose overall vocal responses did not increase in the first experiment.

A number of variations to the SSP procedure were included in the second experiment. The first procedural variation examined the lack of an increase in vocal behavior during play following SSP. Sundberg et al. (1996) suggested that failures to increase vocal behavior were a result of procedures being delivered by adults unfamiliar to the participant, as well as the participant's current emotional state during procedures. Specifically, Sundberg et al. observed that when the participant was "quiet and sullen," an increase in vocal behavior during periods of play was not observed following SSP. Therefore, the novel topography of a previous vocalization was paired more frequently and with longer durations of reinforcement. Results demonstrated the effectiveness of SSP.

The second procedural variation examined the maintenance of pairing by including an extended baseline and post-pairing condition. Here, procedures were identical to experiment one, with the exception that the session did not conclude until the participant no longer engaged in new topographies of vocal behavior. Results indicated that the post-training condition ceased after five minutes; compared to the pretraining conditioning lasting approximately nine minutes, these results suggested that the effects of SSP were temporary. Sundberg et al. (1996) hypothesized that such effects could be a result of the number of pairings, the extent to which the preferred stimulus functioned as a reinforcer, and the participant's current establishing operations.

Finally, Sundberg et al. (1996)'s third procedural variation introduced a similar sounding, but incomplete phrase in order to disrupt a previously paired vocalization, since it was observed that such vocalizations were emitted after each new pairing. Procedures mirrored those of experiment one, with the exception of the use of a novel yet incompatible vocalization. Results from the post-pairing condition demonstrated that this procedural variation failed to alter the previously paired vocalization, which Sundberg et al. suggest is due to the saliency of history of reinforcement when the previous vocalization compared to contingencies associated with the novel vocalization. In light of the findings obtained from both experiments, Sundberg et al. were the first, to our knowledge, to examine and demonstrate the effectiveness of SSP on increasing vocalizations of children with minimal language.

In a follow-up study, Smith et al. (1996) studied the impact of three pairing procedures on the vocal behavior of two infants without language delays. The first procedure included the neutral condition, where any vocalizations that participants emitted during play were recorded (i.e., pre-pairing and post-pairing) and a sole phoneme was emitted by researchers without being followed by reinforcement (i.e., neutral presentation). The second procedure included the positive condition which was similar to the neutral condition, with the exception of the phoneme that was emitted by researchers being paired with an established reinforcer. To not directly reinforce emitted vocalizations or other behaviors (e.g., eye contact) of participants during pairing in the positive condition, a 15 s time-out period was included, where reinforcement was not delivered following such vocalizations or behaviors (i.e., this procedure was to control for potential operant conditioning, since the study focused on learning about the effects of SSP and not direct reinforcement). The final condition was the negative condition, which was also similar to previous conditions. Here, the researcher-emitted phoneme was paired with an established punisher (e.g., verbal reprimand). The findings of Smith et al. extended those of Sundberg et al. (1996), which demonstrated that the infants' vocalizations increased following the positive pairing condition. Moreover, results from Smith et al. demonstrated minimal effects on vocalizations following the neutral condition and immediate and decreasing effects following the negative pairing condition, which suggested an automatic punishment effect. This study highlighted the importance of pairing a vocalization with a reinforcer during SSP.

These early studies set the stage for subsequent research on SSP, and indeed, there is a growing body of research in the area. In fact, review papers on SSP have been published in recent years, and in the subsequent section we provide attention to these overviews of the SSP literature. As the SSP procedure may be implemented in a variety of ways, the first review (Shillingsburg et al., 2015) analyzes the extent to which studies on SSP have varied across several dimensions. After reviewing this analysis of the SSP literature, we will provide an overview of a second review done by Petursdottir and Lepper (2015). This second review paper builds upon the work of Shillingsburg et al. in the sense that additional procedural variations on the SSP procedure are suggested. There are many opportunities for further research on SSP, and we call attention to these opportunities throughout.

Reviews of the Stimulus-Stimulus Pairing Literature

Shillingsburg and colleagues (2015) conducted a review of the research on SSP as a means to induce vocalizations. The researchers specifically looked at all of the literature published between the years 1996 and 2014 in an effort to assess how effective the SSP is, its variations, implications for practice, and opportunities for additional research. The review is noteworthy, as the researchers found a number of variations within the literature on SSP that may account for the varied outcomes found when the procedure has been researched.

The review by Shillingsburg et al. (2015) included 13 studies and a total of 39 participants. While many variables were coded in their review, we focus on those that seem especially relevant to further research and practice in this chapter. For example, one area that Shillingsburg et al. considered in their review of the literature was the participants' language skills at the time of the study. It would make sense that the participants' prerequisite skills may impact the extent to which the procedure is effective in promoting language. The researchers noted that a variety of measurements have been used in the literature (e.g., the Early Echoic Skills Assessment; Esch, 2008; the Peabody Picture Vocabulary Test-III; Dunn & Dunn, 1997), whereas some studies described the participants' verbal skills but it was not clear whether or not an assessment was used. The researchers also distinguished between participants with functional language skills (i.e., those who vocally mand, tact, and/or engage in intraverbals) and those who did not have functional language skills (i.e., participants who make some sounds and/or engage in echoics). The authors found that 28/39 (72%) of the participants in the SSP studies reviewed did *not* have any functional language skills, whereas 11/39 (28%) did have some functional language. Thus, there have been differences regarding the incoming prerequisite skills of participants within the SSP literature.

Shillingsburg et al. (2015) also found that there was some variation regarding the sounds targeted during intervention across the SSP literature. Specifically, Shillingsburg et al. were interested in the extent to which entirely novel sounds were targeted relative to sounds that were already in the participants' repertoire to some extent. Researchers found that 17/39 participants (44%) were exposed to SSP with novel target sounds, and 22/39 (56%) of participants were exposed to SSP with sounds that were already in their repertoires to some extent. In addition to these broad differences, the researchers noted that specific studies identified sounds to be targeted during SSP in idiosyncratic ways. That is to say that there is a lack of consistency with how sounds are identified within the "novel" and "within repertoire" groupings. This topic appears to be ripe with implications for additional research, as targeting a sound which has never occurred, occurs very rarely, or occurs with some reliability seems like it could differentially impact the effectiveness of the SSP procedure.

As we have described earlier in the chapter, SSP involves the pairing of a sound with another stimulus (i.e., a stimulus that already functions as an unconditioned stimulus, conditioned stimulus, and/or operant reinforcer). What is not specified in this general framework is the *number* of times the researcher/therapist makes the sound during each pairing trial. As with the areas described above, this topic too seems to be one where there is some inconsistency across the literature reviewed. In some studies, the target sound was made once per pairing; in others it was made three times, five times, and even seven times. Thus, there is great variety in how the specific pairings occur across the SSP literature reviewed by Shillingsburg et al. (2015). Interestingly, Shillingsburg et al. did not find that more pairings corresponded to better outcomes. Still, as the data on this are preliminary, more data are needed.

Another variable analyzed by Shillingsburg et al. (2015) is the *number of pairings per minute.* While a previous variable pertained to the number of times a sound was made *per pairing trial,* the present variable pertains to the number of sound-stimulus pairings per minute. In some ways, this could be considered a measure of the intensity of the intervention. The authors noted that this information is not always specifically stated within the research literature, but that it may be derived from descriptions of experimental procedures. Here too, Shillingsburg et al. noted great variation across studies, with the number of pairings per minute ranging from 1 to 15. This means that, in the same amount of time, participants in the SSP studies reviewed were exposed to 1–15 pairing trials per minute. This too is another area where the procedure is implemented quite differently across studies.

As a procedure involving respondent processes, Shillingsburg et al. (2015) also evaluated the *type* of pairing procedure that was used across SSP studies. The authors specifically evaluated the studies for the use of simultaneous, delay, trace, and discrimination training procedures. *Simultaneous* was defined as the sound and item/reinforcer being presented at the same time, *delay* was defined as the sound being presented (alone initially) with the preferred item being presented while the sound was still active, *trace* conditioning involved the presentation of the sound, with the sound stopping, and then the preferred item being presented, and finally, *discrimination training* involved the sound serving as a discriminative stimulus, such that a response was reinforced with the item, but only when the sound was present. As with other variables assessed in this review, Shillingsburg et al. found that this is yet another area indicative of inconsistency across the literature on SSP (conditioning procedures are given additional consideration in our review of Petursdottir and Lepper (2015) in the subsequent section).

Shillingsburg et al. (2015) also assessed the extent to which studies in the SSP literature controlled for adventitious (i.e., accidental) operant reinforcement. As we noted in the introduction to the chapter, the SSP procedure is based upon respondent conditioning, with stimulus-stimulus pairing being the fundamental feature of the intervention (in this case it is a sound-stimulus pairing). However, the *participants* in the studies may engage in the target sound at any time. Given this, it would be possible for the participants to engage in the target sound just before the preferred item is presented, resulting in the potential for operant conditioning (i.e., the participant engages in the target sound and this is followed by the presentation of an unconditioned or already conditioned reinforcer). If this happened, the target vocalization may increase in frequency, but this outcome may occur by way of operant conditioning, direct reinforcement contingencies, and not necessarily because of the SSP procedure. Given that the research studies reviewed aimed to study the SSP procedure, and not operant reinforcement contingencies, it is interesting to consider how many of the studies controlled for such adventitious reinforcement. Shillingsburg et al. found that 48% of the participants in the studies reviewed participated in studies that controlled for adventitious reinforcement, and 52% of the participants in the studies did not. Moreover, the procedures used by studies that did attempt to control for adventitious reinforcement were not consistent. This too seems to be an area with opportunities for further research, with specific implications for understanding the mechanisms responsible for the behavior change found in SSP studies. These issues may seem less important from a clinical perspective at first, but they may help to focus the attention of clinical work such that practitioners place emphasis on behavioral processes that are more critical to effective outcomes.

Yet another variable related to the use of SSP as an intervention pertains to the specific stimulus paired with the sound (remember the early study by Smith et al. related to this topic). Given that the pairing (in space and time) between the sound and the stimulus is the foundation of the SSP, it would make sense that the stimulus being paired with the sound be given a great deal of consideration. Generally, we might assume that pairing a sound with an item that is highly preferred, and demonstrated to function as a very reliable reinforcer, might result in better outcomes than pairing the sound with an item that is only somewhat or moderately preferred, and a less reliable reinforcer. Shillingsburg et al. (2015) noted that there was some effort to identify and use highly preferred and reinforcing stimuli within the SSP studies reviewed, but that the exact way in which these stimuli were identified varied across studies. Moreover, Shillingsburg et al. found that a range of types of stimuli were used in SSP studies, including social, tangible, and edible stimuli. While it is noteworthy that some consistency is observed in the sense that there seems to be a general effort to identify and use preferred and reinforcing items within this literature, there is room to improve standardization across studies to better understand the extent to which specific stimuli facilitate (or not) the effectiveness of the SSP intervention.

The previous paragraphs focused on reviewing some of the variables targeted in the Shillingsburg et al. (2015) review of the SSP literature. Importantly, the authors concluded their review by considering the overall effectiveness of the SSP intervention, as well as the extent to which different variables were associated with intervention effectiveness. We consider some of these conclusions in the next section.

Overall Effectiveness of the SSP/ Results Obtained

As we have mentioned in the paragraphs above, studies evaluating SSP have been conducted in a variety of ways. This broad finding makes it difficult to draw any firm conclusions regarding the research literature. Still, Shillingsburg et al. (2015) note that there are some themes that may be emerging and point to opportunities for additional research on the procedure. Perhaps most interesting is the overall analysis of the effects of the SSP intervention. When looking at specific evaluations for specific sounds, Shillingsburg et al. found that 34% of the evaluations had a weak effect, 49% had a moderate effect, and 17% had a strong effect. Thus, the effects of the intervention appear to be mixed when they are considered on the whole, while at the same time the majority (66%) of the evaluations of SSP were associated with some effect (moderate or strong). The authors also found that children 5 and younger were more likely to have moderate or strong effects when compared to older children, though at the same time recognized that evaluations with older children were fewer in number. In addition, while assessments of prerequisite language/skills varied across the studies, the authors found that participants with no functional language (i.e., those who only engaged in some vocal behavior and/or echoics) were more likely to have a stronger effect with SSP. This area seems to be of interest to both researchers and practitioners – and again, while firm conclusions are difficult to make, it seems possible that there are implications for future research and practice here.

Also, as the number of specific evaluations the authors reviewed for effect size was limited, the authors were not able to determine potential differences between interventions that involved novel relative to in-repertoire stimuli within SSP. Other factors seemed to be associated with more effective applications of SSP, including the use of procedures to control for adventitious reinforcement, the use of edibles, and delayed pairing procedures. The authors found that the number of researcher/therapist pairings per trial did not necessarily result in better outcomes; and related to this, when there were 5 or more pairings per minute the results were actually more likely to be weak. It seems possible that habituation processes may contribute to this finding. At the same time, there are many variables at play in the research on SSP, and it is difficult to draw any conclusions, let alone any firm conclusions. Much more research is needed to better understand these issues.

As mentioned earlier, a second review paper was published around the same time as the Shillingsburg et al. (2015) paper, and among other things, it focused on additional procedural variations that may warrant consideration within the SSP research.

Procedural Variations

A second review of the stimulus-stimulus pairing procedure was published in 2015, though with a bit of a different focus. Similar to Shillingsburg et al. (2015), Petursdottir and Lepper (2015) provided a general overview of the literature on SSP, noting the range of ways in which SSP has been studied within the research literature as well as the inconsistent outcomes it is associated with. Interestingly, Petursdottir and Lepper noted that there may be many reasons for the inconsistent findings of the research literature, and that one of the factors to consider might be the more general approach to conditioning sounds as reinforcers within the SSP literature; in particular, the fact that the SSP involves presenting stimuli in the absence of any particular response requirement. The authors describe some research which has focused on alternative procedures to condition reinforcers, research with implications for understanding how the SSP might be further studied and refined. We review some of these studies below. For the purposes of this chapter, these conditioning procedures might be categorized as discrimination training and response independent/dependent pairings.

Discrimination Training

One conditioning procedure that involves a response requirement for participants is discrimination training. Whereas the SSP model generally involves presenting sounds and preferred stimuli together in the absence of a response, discrimination training involves the sound being a discriminative stimulus, where engaging in a target response in the presence of the sound results in reinforcement, and engaging in the target response in the absence of the sound does not. In this model the sound becomes a discriminative stimulus, and perhaps as a result of this conditioning, the sound may become a conditioned reinforcer itself. A couple of studies have compared discrimination training with stimulus-stimulus pairing procedures (Isakesen & Holth, 2009; Lepper et al., 2013). Lepper et al. compared the effects of a discrimination training and stimulus-stimulus pairing procedure to establish vocalizations with nonvocal children with Autism Spectrum Disorder. Results showed that both conditioning procedures were effective at increasing vocalizations among the participants, with no difference as far as one being more effective than another. Petursdottir and Lepper (2015) note that this might make the traditional SSP more desirable as it is easier to implement. It is noteworthy that participants in the Lepper et al. study preferred the discrimination training procedure, however. Regardless of all of this, given that we know the traditional SSP procedure has mixed results, Petursdottir and Lepper suggest that the discrimination training procedure may represent an option to explore when SSP is not effective. Though again, much more research is needed to explore this possibility.

Response-Independent/-Dependent Pairings

A study by Dozier et al. (2012) examined two different pairing procedures to condition praise statements as reinforcers. In one of the conditions (Experiment 1), praise statements, which were determined to be neutral and not function as reinforcers prior to the pairing intervention, were paired with highly preferred edible items. This condition was similar to the stimulus-stimulus pairing procedure in that two stimuli, praise statements and preferred edible items, were paired together in space and time. Results showed that this pairing condition was not effective for 3 of the 4 participants, with one participant showing some effect initially though this did not maintain over time. In the second condition, evaluated in Experiment 2, the pairing condition involved a *response*-stimulus pairing, where participants engaged in a target response and this was followed by the presentation of the praise statement and preferred edible item. Subsequent to this response-stimulus pairing condition, there was a test for the reinforcing effects of praise alone – to evaluate the extent to which the response-stimulus pairing condition established praise as a reinforcer. The response-stimulus pairing condition was effective for four of the eight participants in Experiment 2. Moreover, praise was also found to function as a reinforcer for additional responses with these four participants. While Dozier et al. were focused on conditioning praise statements as reinforcers, the response-stimulus pairing procedure studied may have implications for understanding how to improve the effects of SSP to increase vocalizations. Indeed, this was specifically explored in a recent study by Lepper and Petursdottir (2017), which is described in detail in the following section.

In general, the Petursdottir and Lepper (2015) review reminds us that while we may need to focus on understanding some of the details associated with successful applications of SSP, we also need to consider the more general pairing procedure and the extent to which alternatives, particularly those which require a response on behalf of the individual, could increase the effects of intervention efforts.

Recent Research

Following the literature reviews of Shillingsburg et al. (2015) and Petursdottir and Lepper (2015) on the SSP, empirical research on the effects of SSP to increase novel vocalizations and condition vocalizations as reinforcers has continued. In 2017, Lepper and Petursdottir conducted two experiments which evaluated the effects of a response-contingent pairing (RCP) procedure on vocalizations of target syllables for three children with ASD who engaged in minimal functional vocal verbal behavior. As the name suggests, RCP is used to establish vocalizations as reinforcers by pairing a neutral stimulus with a reinforcer and delivering the reinforcer contingent on a response. This procedure was compared to the response-independent pairing (RIP) procedure, similar to the SSP that we have been describing thus far in the chapter, where two stimuli (e.g., a sound and a reinforcer) are presented in the absence of a particular response from the individual.

In the first experiment, Lepper and Petursdottir (2017) compared RCP and RIP. During RCP sessions, 20 sound presentations were included and consisted of 10 target and 10 nontarget sounds presentations. Before undergoing experimental procedures, participants were taught to engage in a button-pressing response, which allowed for delivery of preferred items. RCP sessions began with the button being placed in front of the participants so that an opportunity to press it was presented. After participants pressed the button (in the presence or absence of a prompt), a target or nontarget sound was presented three times with 1 s between presentations, along with the simultaneous delivery of a preferred item and the removal of the button. Once the preferred stimuli were consumed, an intertrial interval began. The button was presented again 10 s into the intertrial interval, with the intertrial interval ending when the participant pressed the button again. If participants engaged in a target or nontarget vocalization just before a preferred item was to be delivered, the item and button were removed and represented after 20 s of no vocalizations; this was done to prevent direct reinforcement of such vocalizations (recall our description of procedures that control for adventitious reinforcement earlier in the chapter).

Sessions of RIP mirrored those of RCP, with the exception of the button not being presented, eye contact being obtained prior to the presentation of nontarget sounds or presentation of target sounds and delivery of a preferred item, the set of target and nontarget sounds differing, and each intertrial interval being yoked to a previous RCP session to equate durations of sessions and to increase deprivation or satiation of preferred items across the two interventions. Results from the first experiment demonstrated that more target vocalizations per minute occurred following RCP, despite absolute rates of such vocalizations being low and ranging from 0 to 1.69 per minute. To increase the rates of these target vocalizations to clinically acceptable levels, Lepper and Petursdottir (2017) utilized differential reinforcement with social reinforcement in a second experiment while including pairings for maintenance.

Procedures of the second experiment consisted of RCP, with the exception of the immediate delivery of preferred items following target vocalizations and the simultaneous removal of the response button if it was present, the response button being presented again only after a 10 s absence of a target vocalization, and prolonged contact with preferred stimuli when target vocalizations occurred while participants were already consuming a preferred stimulus. Data indicated that differential reinforcement increased target vocalizations compared to RCP alone for all participants. While target vocalizations occurred at low rates during extinction in the first experiment and during baseline of the second experiment, the rates of such target sounds increased to clinically relevant levels following differential reinforcement. Results from Lepper and Petursdottir (2017) demonstrated that the efficacy of pairing procedures such as SSP may be enhanced when stimuli are presented contingent on responses and that the effects of pairing procedures such as RCP may be enhanced when differential reinforcement is used in conjunction with maintenance pairings.

Another recent study was conducted by Cividini-Motta et al. (2017), who were specifically interested in better understanding procedures to improve echoic training given the mixed results within this literature. Cividini-Motta et al. devised an assessment protocol to identify the most effective echoic teaching procedure among vocal imitation training, SSP, and the mand-model procedure. The researchers also conducted functional analyses to determine whether trained responses functioned as echoics or mands. Six children diagnosed with autism and related disorders, ranging in age from 7 to 17 years old, completed a series of echoic probes and functional analysis probes, as well as a semi-random order of vocal imitation training, mand-model teaching, SSP, and play sessions. Specifically during the SSP condition, the target sound was presented five times, with 1 s intertrial intervals. Prior to beginning sessions, participants were allowed to select a preferred item, which was presented between the second and fifth presentation of the target sound during SSP sessions. The assessment protocol identified an effective echoic training procedure for five of six participants. Although SSP was the most effective procedure for some participants, authors suggested that carry-over effects might have impacted results. Specifically, participants' echoics were directly reinforced during vocal imitation training and mand-model teaching, which could have increased the likelihood of engaging in vocal imitation during SSP as a result of the novel history of reinforcement for this response. As a result, Cividini-Motta et al. (2017) proposed evaluating the effects of SSP first prior to vocal imitation training and mand-model procedures, in addition to providing direct reinforcement of vocal imitation when utilizing SSP to increase echoic responding.

While early research on SSP involved adults who had a history of implementing procedures with participants (Smith et al., 1996; Sundberg et al., 1996), the majority of SSP evaluations within the research literature have been delivered by researchers (i.e., unfamiliar adults), which may impact outcomes as well as the maintenance and generalization of clinical gains. Moreover, the conceptual model described earlier in the chapter is generally assumed to involve someone who has been paired with a variety of reinforcers (i.e., someone who is likely to be established as a generalized conditioned reinforcer for various behavior the child engages in). Therefore, Barry et al. (2019) assessed the impact of a parent-implemented SSP intervention with two children with ASD who did not engage in vocal verbal behavior. Experimental procedures consisted of five phases: baseline, SSP, direct reinforcement, noncontingent reinforcement, and a return to direct reinforcement. During SSP, one pairing sound per trial was utilized. Prior to intervention phases, behavioral skills training was used to train parents on the delivery of SSP.

Across both participants, higher frequencies of target responses were seen across all experimental procedures relative to baseline, while nontarget responses remained the same. SSP initially increased target responses, such increases continued when differential reinforcement was utilized, and SSP was effective in conditioning vocalizations as reinforcers. Barry et al. (2019) also assessed social validity via a questionnaire inquiring about parents' experiences with the intervention. With mean scores being 4.3 out of five, responses from both parents suggested high social validity in areas such as SSP allowing for meaningful one-on-one time with their children, confidence in the ability to conduct SSP, and increased vocalizations following the intervention. The research of Barry et al. not only extended the literature of SSP, but more importantly provided preliminary support for training parents to deliver procedures to increase their children's early vocalizations, which can allow for increased learning opportunities and generalize and sustain vocalizations.

The most recent study evaluating SSP is that of Freitas et al. (2020). As there has been little attention to how different respondent conditioning procedures influence the outcomes of SSP, Freitas et al. aimed to further link SSP with respondent conditioning research by comparing the effects of forward versus backward pairing on echoics and quantitatively assessing the relation between participants' current skill levels and the efficacy of SSP. Twelve children with ASD, seven residing in the United States and five residing in Brazil, with limited vocal verbal behavior and delays in language served as participants. During baseline, participants' vocalizations were recorded during free play; of those one syllable recorded vocalizations, three were selected to serve as target sounds and were randomly assigned as forward sounds or backward sounds. During the forward conditioning sessions, the forward sound was presented first by researchers, followed by the immediate delivery of the preferred item; this differed from the backward conditioning sessions, where sounds emitted by researchers were also paired with a preferred item, but the order was reversed (i.e., the preferred item was delivered immediately before the backward sound). Control sounds were also included, which consisted of a sound uttered by researchers in the absence of preferred items.

Intervention consisted of target sounds being emitted for 2 s and participants engaged with preferred stimuli for 10 s. Results obtained from Freitas et al. (2020) demonstrated that SSP increased the mean response count per session when forward pairing was utilized. Moreover, there were differences in the effects of forward and backward sounds with SSP; specifically, fewer echoics were emitted with backward sounds in comparison to other sounds (i.e., forward and control). The results also pointed to an inverse relation between the Behavioral Language Assessment Form (BLAF; Sundberg & Partington, 1998) and the effectiveness of SSP. Overall, SSP was more effective for participants who had fewer skills at the beginning of the study. Moreover, results suggested that the forward pairing procedure was more effective than the backward pairing procedure for participants of the study.

Implications for Research and Practice

As we have noted throughout, there are many opportunities for further research to better understand the SSP procedure and its use to develop early vocalizations. We offer some general recommendations and highlight themes for further analysis below, as well as some implications for practice. As always, decisions that researchers and practitioners make should always be informed by research and ongoing progress monitoring. Given what we know about SSP, it should not be *assumed* that SSP will effectively increase early vocalizations. As we have noted throughout this chapter, findings are not consistent and it is difficult to know the exact conditions under which the procedure is most likely to be effective. Practitioners considering the SSP procedure should monitor progress carefully and consider alternative procedures (some of which have been described in this chapter) and discontinue the use of SSP if desired behavior change is not occurring. For example, procedures described by Petursdottir and Lepper (2015) may be promising when traditional SSP is not effective; and this too represents an area for further investigation. Next, current data suggest that SSP is most effective with children who are younger (i.e., 5 and under; Shillingsburg et al., 2015). Though this is quite tentative and additional research is needed to support or counter this hypothesis, it is something that practitioners should be aware of.

Behavior analysts should also always consider the learner's prerequisite skills when conducting studies in this area; even when the SSP procedure does not increase target vocalizations or establish novel vocalizations, the circumstances surrounding less effective applications can still be identified. Paying closer attention to prerequisite skills will not only aid in the understanding of when SSP is more or less likely to be effective, but also help to understand the overall progression of early behavioral development more generally (e.g., to help identify critical cusps to target before SSP). In addition, relatively little is known about the differential effects of targeting novel sounds relative to sounds that are already in the individual's repertoire (even just minimally). Moreover, it's possible that sounds should be targeted in a particular sequence, or that if one or two particular sounds are occurring minimally, one might be a better candidate to target next, etc. These issues, both the topic of assessing prerequisite skills and identifying specific targets for intervention, present opportunities for applied behavior analysts to collaborate with speech-language pathologists who have specific expertise in these areas (Association for Behavior Analysis International, 2021).

Finally, researchers and practitioners should consider the implications of participant histories with different therapists implementing SSP, including familiar adults, unfamiliar adults, and parents/caregivers, and others. It seems possible that different therapist histories with participants will influence the effects of SSP, and this factor is deserving of more attention from researchers and clinicians. Moreover, if results using SSP continue to suggest that the procedure is most effective for children under 5 years old, training parents/caregivers to utilize SSP with high fidelity may facilitate more widespread and lasting influence on child vocalizations.

Conclusion

Before we conclude, we would like to again acknowledge that a great deal of interventions may fall under the purview of stimulus-stimulus pairing. For example, researchers interested in the development of stimulus equivalence have studied the extent to which two stimuli may be presented in a respondent manner in efforts to promote the development of equivalence relations (e.g., Leader & Barnes-Holmes, 2001). Related to this, stimulus pairing has also been involved in research on the Stimulus Pairing Observation Procedure, where picture-word relations have been presented to participants and found to be functionally related to the development of listener responses (e.g., point to the "word"; Byrne et al., 2014). Other studies have also focused on pairing procedures to condition other responses, such as conditioning observing responses (e.g., Greer & Ross, 2008). We mention these areas here to acknowledge that stimulus-stimulus pairing is related to many areas of research in behavior analysis, including derived stimulus relations and the development of many important behavioral cusps.

We have provided a general overview of the stimulus-stimulus pairing procedure as it has been used to produce novel vocalizations among individuals with language delays. If there are any broad conclusions to make, it is that we have much more to learn regarding how and when the SSP procedure is likely to be more or less effective. Given the importance of developing early vocalizations as a foundation for subsequent language development, detailed analyses of variables we have discussed in this chapter seem warranted.

Psychological Modeling and the Treatment of Obsessive-Compulsive and Related Disorders

11

Michael Upston, Matthew Jacofsky, and Fugen Neziroglu

Psychological Modeling

Modeling was made popular as a psychological intervention in the latter part of the twentieth century by the psychologist Albert Bandura. Bandura (1969, 1971, 1977a) viewed modeling as an essential aspect of learning new behaviors. As he suggests, if we had to rely solely on learning from the consequences of our own individual actions, we would have died off as a species long ago (Bandura, 1971). We also learn through observational learning, i.e., through witnessing the consequences of other people's behavior (Bandura, 1971, 1977a). It is on this idea that the importance of modeling as a treatment technique is based. In this chapter we will explain psychological modeling and why it is beneficial in the treatment of anxiety and avoidant behavior in general. We will then discuss how it can be used specifically in the treatment of obsessive-compulsive and related disorders.

A study by Bandura et al. (1961) demonstrated the effectiveness of learning through the modeling process. In this study of 72 nursery school children, 24 children witnessed a model aggress toward a five foot Bobo doll, 24 children witnessed a subdued model who ignored the Bobo doll and did not display any aggressive behavior toward it, and 24 children were in a control group with no exposure to the model. The children were tested on the extent to which they would imitate the modeled behavior after the model was no longer present. Children who witnessed the aggressive model displayed similar aggressive behavior as was modeled toward the Bobo doll to a much greater extent than children in the other two groups. Further, children who witnessed the non-aggressive, subdued model displayed less aggression than the children in either of the other two groups.

Spiegler and Guevremont (2010) describe different aspects of modeling as follows. At a basic level, a model is simply someone who demonstrates a behavior to an observer; in other words, models the behavior. There are two parts to this. The first is that the observer witnesses the steps that are involved in performing the behavior. The second is that the observer witnesses the consequences of performing the behavior. These consequences are called vicarious consequences. Vicarious reinforcement is when the observer witnesses the modeled behavior being rewarded, which increases the likelihood that the behavior will be imitated. Vicarious punishment is when the observer witnesses the modeled behavior being punished, which decreases the likelihood the behavior will be imitated. If a person is afraid of negative consequences being the result of an

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_11

action, and then witnesses that action happening without the feared consequences occurring, there may be a reduction in the anxiety triggered by that event. If so, this process is called vicarious extinction. An observer can either witness something being modeled in-person through the use of a live model, or an observer can witness something being modeled symbolically through the use of mediums such as stories, films, or photographs.

Albert Bandura (1969, 1971, 1977a) broke modeling down into four basic components: attentional processes, retention processes, motor reproduction processes, and motivational processes. The first aspect, attentional processes, is based on the idea that behaviors cannot be imitated if the person does not pay attention to the behavior and the necessary ingredients of performing the behavior effectively. Features such as the frequency with which one is exposed to the modeled behavior, the value and consequences of the behavior, as well as the attractiveness and social power of the model will influence whose behavior will receive more attention (Bandura 1971, 1977a; Brewer & Wann, 1998).

The second process speaks to how, once a behavior has been attended to, it must be retained in order for it to be reproduced without the model being present, i.e., the behavior must be remembered. Once behaviors have been encoded in memory, rehearsal, either overt or covert, can work to enhance the retention process (Bandura, 1977a). This fact highlights the importance of therapists assigning homework when teaching patients new behaviors. If the patient is not able to practice the behavior overtly, then rehearsing it mentally can also work to enhance the learning process.

The motor reproduction processes component involves translating the behavior into specific actions. For modeled behaviors to be reproduced, the behavior must not only be cognitively processed, but the observing individual must have the skill set needed to perform the behavior. If this skill set is lacking, then the person needs to acquire it through practice (Bandura, 1977a). This again speaks to the importance of assigning homework when teaching new behaviors, so the individual can develop the necessary skill set through a process of trial and error.

Lastly, for the behavior to be imitated, motivation to perform the behavior must be enhanced through reinforcement. If there are no appropriate incentives to engage in a behavior, then there is less likelihood the behavior will be reproduced (Bandura, 1971). These consequences can either be directly experienced or observed. Witnessing models engage in behaviors which produce desired outcomes provides an incentive to imitate that behavior (Bandura, 1977a).

The likelihood of a task being initiated increases significantly if the person believes both in the benefits of doing the activity and in his or her ability to accomplish the activity (Bandura, 1977b). However, these two aspects are different. An individual can believe in the benefits of doing a task, without believing in his or her ability to do the task. Both need to be present for there to be the necessary motivation. This speaks of the importance of self-efficacy, meaning one's belief in one's ability to accomplish a task (Bandura, 1977b).

Bandura (1977b) speculated that the therapeutic value of psychological modeling is in it helping the patient to achieve a greater sense of self efficacy, which increases a sense of mastery, and as a result, decreases anxiety and avoidant behavior. The more a person believes in his or her ability to accomplish a task, the greater the likelihood that person will attempt the activity. If a patient experiences being able to master a task he or she previously believed to be impossible, then that person will grow in confidence as related to his or her abilities to do the activity. This will decrease the likelihood the person will avoid doing the activity and the anxiety associated with the activity. Along the same lines, if a patient can perform a task (or witnesses a task being performed) without the subjectively experienced feared consequences being realized, then that person will be less reluctant to do the activity. For these reasons, enhancing a sense of self-efficacy is a central mechanism in the interventions we will be exploring in this chapter.

There have been several studies demonstrating the effectiveness of modeling in reducing anxiety and avoidant behavior. Bandura (1967) studied the extent to which vicarious extinction occurred through the observation of modeled behavior toward a feared stimulus where the model did not experience any negative consequences. The study involved 24 boys and 24 girls aged 3–5 years, all of whom exhibited avoidant behavior toward dogs. The study found that observing a model engage in gradual exposures to more anxiety provoking situations involving a dog reduced avoidant behavior in the children. Studies have also found modeling to be effective in treating snake phobias in both children and adults (Blanchard, 1970; Murphy & Bootzin, 1973; Ritter, 1968) as well as injection phobias (Trijsburg et al., 1996). Modeling has also been found to be helpful in treating phobias in children with Autism Spectrum Disorder traits (Musket et al., 2020) and Development Delays (Davis et al., 2007).

Bandura and Menlove (1968) studied the effects of symbolic modeling through the use of films on children aged 3–5 who exhibited a fear of dogs. This study demonstrated that the children observing films of the models interacting with the feared stimulus without experiencing any negative consequences was an effective way of reducing fearful responses and avoidant behavior toward dogs. A study by Hill et al. (1968) also demonstrated the effectiveness of symbolic modeling in the forms of films in reducing avoidant behavior in children toward dogs. Fryrear and Werner (1970) used videotape modeling to successfully treat a college student's fear of animal dissection.

So far we have provided a description of psychological modeling as well as evidence supporting its effectiveness as a therapeutic intervention for anxiety and avoidant behavior in general. Modeling has also been demonstrated to be effective in the treatment of obsessive-compulsive and related disorders (Silverman, 1986; Thyer, 1985). We will now focus specifically on the use of this technique to treat these conditions.

The Treatment of Obsessive-Compulsive and Related Disorders

Prior to the Diagnostic and Statistical Manual of Mental Disorders-Fifth Edition (DSM-V), obsessive-compulsive disorder (OCD) was classified in the anxiety disorders section of the DSM. However, based on an expanding conceptualization it was determined that OCD be moved to its own DSM category. Furthermore, it was decided that additional disorders that were previously included in other sections of prior editions of the DSM be included in this newly formed section as well. These changes resulted in the new DSM-5 category of obsessive-compulsive and related disorders (OCRDs) (American Psychiatric Association, 2013).

The following disorders are included in the OCRDs DSM-5 category: obsessive-compulsive disorder (OCD); body dysmorphic disorder (BDD); hoarding disorder; trichotillomania (hair pulling disorder); and excoriation (skin picking) disorder. In addition, several other disorders are included in this category: substance/medication-induced obsessive-compulsive related disorder; obsessive-compulsive and related disorder due to another medical condition; other specified obsessive and compulsive and related disorders; and unspecified obsessive-compulsive and related disorders.

The rationalization for combining these disorders is not new. Indeed, research on the idea of an "OCD Spectrum" has been accruing over the last 40 years (Yaryura-Tobias & Neziroglu, 1983, 1997). The main premise underlying the OCD Spectrum is that several disorders share a high resemblance in various aspects, especially symptom similarity. One of the main similarities between the OCRDs is the persistent preoccupation with thoughts and repetitive behaviors. Moreover, research suggests that there is a high comorbidity rate among these disorders, which again underscores the rationale for grouping these disorders together.

Of special note is that although these disorders share similar overall categories of symptoms (i.e., obsessions/compulsive behavior), they have their own unique obsession content and compulsive behaviors, as well as additional features. For example, while OCD obsessions may vary among several different categories such as harm, sexual, and/or contamination, within body dysmorphic disorder (BDD), obsession content focus primarily on an "imagined and or slight defect" in one's appearance, while compulsive behavior usually manifests as mirror checking, camouflaging one's appearance, and severe avoidance.

Not surprisingly, based on the overlap between symptomatology, similar treatment inventions (i.e., exposure response prevention, skills training, etc.) are often used to treat these disorders and/or modified to address the unique features of each disorder. In addition, several other procedures are often used in conjunction with these more traditional interventions to enhance treatment outcomes.

Modeling is one such intervention. Subsequently, the remaining portion of this section of the chapter will focus on the incorporation of modeling in the treatment of OCRDs. Specific examples of different uses of modeling will be given for each of the main disorders within this category.

Modeling and OCRDs

As clinicians, whether we realize it or not, we are using the techniques of modeling in every exchange we have with our patients. Indeed, not only do patients learn from direct instruction, but also from what they see their therapists do. Moreover, not only can behaviors be modeled, but also thoughts, attitudes, and emotional responses. Subsequently, not only must therapists focus on the appropriate selection of interventions, but they must also be aware of how they themselves apply and come across during intervention implementation. By being aware of the concepts and procedures of modeling, therapists can purposefully incorporate them into their interactions with patients in order to increase the efficacy and efficiency of their treatment approach. This is especially relevant when it comes to the treatment of OCRDs.

Obsessive Compulsive Disorder

When it comes to the treatment of OCD, cognitive behavioral therapy (CBT) is a first-line treatment approach. Although a CBT package can contain many elements, a primary technique for treating OCRD is exposure/response prevention (EX/RP). Simply stated, EX/RP is a treatment intervention where individuals are assisted in confronting feared stimuli and/or situations, while simultaneously being coached to refrain from engaging in compulsive and/or safety behaviors. In therapy, EX/RP is applied in what has been referred to as either "therapist assigned" and/or "therapist assisted" exposure. In therapist assigned exposure, the therapist will often explain the rationale and instructions for EX/RP, as well as assist the patient in creating a hierarchy (i.e., a list of feared/avoided stimuli and situations that are in order from least fearful to most fearful). Once the hierarchy is complete, the therapist will assign the patient the task of carrying out the EX/RP assignment on their own between sessions.

In contrast, with therapist-assisted EX/RP, the therapist will actually assist the patient in carrying out the exposure exercises either by providing in-person support and corrective feedback in real time, and/or fully participating in the exposure alongside the patient. In comparing the two approaches, therapist-assisted EX/RP has the advantage of capitalizing on the therapist's ability to indirectly, or purposefully, incorporate modeling into the intervention. Research has demonstrated that therapist-assisted EX/RP can lead to enhanced treatment outcomes (Abramowitz, 1996). In addition to other factors (i.e., support/validation), it is hypothesized that part of this effect is directly related to the use of modeling during these exchanges.

To illustrate, we will focus on a scenario that often arises when working with an individual suffering from OCD that has contamination and hand washing rituals. It is often observed in clinical practice that patients with contamination fears will often engage in excessive/ritualistic hand washing behaviors. Although the patient may have some level of insight into the excessiveness of their behavior, they often do not possess a clear sense of what may be considered “reasonable” washing behavior. In this case, the therapist can serve as a live model of appropriate washing behavior, while the patient serves as an active observer (i.e., the key elements of modeling) (Spiegler & Guevremont, 2010).

In order to carry out modeling effectively and efficiently, the therapist would provide a rationale for why they will be serving as a model of an alternative behavior, as well as elicit the patient’s cooperation and agreement. It is important to first elicit agreement from the patient. Indeed, even seeing another person carry out a fearful behavior and/or not engage in a compulsion can be frightening to the patient and inadvertently sensitize and “turn them off” to EX/RP before they have even gotten the chance to participate and try it for themselves. Unfortunately, earlier on in the depiction of EX/RP, the therapist was presented as surprising the patient with feared situations or objects. Nothing is as far from the truth. Modeling is always with the consent of the patient.

Once agreement has been obtained, the therapist will first verbally go through the steps of what they are going to do and how they will do it. Next the therapist will actually demonstrate the goal behavior (i.e., in this case appropriate hand washing). The therapist will purposefully demonstrate every aspect of the desired behavior. For example, the therapist makes sure to demonstrate how to turn on the faucet with their full hand and to not use anything like a towel to avoid touching it (i.e., the opposite of which are often strategies used by individuals with OCD to avoid germs and/or recontamination).

Next the therapist would demonstrate the appropriate temperature of the water to be used (i.e., lukewarm as opposed to scolding hot, which is typically seen). The next steps would include demonstrating how to wet one’s hands and what is a reasonable amount of soap (i.e., one pump) to be used. The patient would then be taken through what would be considered appropriate lathering of their hands in a general sense (i.e., as opposed to specifically and methodically focusing on each individual finger and/or lathering not only the hands but wrists, arms, etc.). Finally, the therapist will demonstrate how long to rinse and dry their hands while simultaneously again focusing on shutting off the faucet and leaving the bathroom in a non-avoidant manner.

During this whole process, the therapist is cognizant of purposefully not only demonstrating overt behaviors accompanied by verbal prompts and explanations of their behavior, but also making sure to model appropriate emotional reactions to the task, as well as sharing their accompanying thoughts throughout the process (i.e., “I am comfortable with this level of cleaning” “This level of cleaning is reasonable,” etc.). Hopefully as a result of this approach, the patient will be willing to engage in similar behavior as the therapist. Patients may differ on their willingness to directly imitate the therapist’s behavior. However, hopefully the process will provide a model to strive toward, as well as assist in treatment engagement. Indeed, observing is not a guarantee that patients will accept the therapist’s behavior as a guide for their future behavior. Notwithstanding, by demonstrating realistic patterns of behavior and not suffering any harm, we hope to help reduce the patient’s initial anxiety (Spiegler & Guevremont, 2010).

In contrast, there are times when a therapist may purposefully model an exaggerated form of a behavior. Often in OCD treatment, the therapist and patient not only attempt to engage in “reasonable” behavior, but also in an exaggerated form of the patient’s disastrous consequences (i.e., the harm they believe will happen if they do not engage in their compulsions). For example, if a patient is afraid to eat food that “might” be contaminated in some way, the therapist may purposefully “contaminate” the food (i.e., by dropping on the floor, eating the food without washing their hands, etc.) and then eat it.

Although these may not be behaviors the therapist typically engages in everyday living, they are modeling that even a “risk” of that magnitude can be carried out and they will remain “safe.” Through the observation of this behavior, the patient can come to learn through vicarious learning that a feared consequence does not happen (Spiegler & Guevremont, 2010). Once the patient sees that this behavior did not result in anything bad happening, this will hopefully help to put their original fear in perspective and motivate them to take reasonable risks that were previously avoided. This also provides an additional opportunity for the therapist to model a different mindset and emotional reaction than the patient is accustomed to. It should be noted that when a therapist engages in an exposure exercise, it could be very motivating for the patient. Indeed, it can often motivate the patient to challenge him or herself and/or increase the therapeutic alliance since the therapist's behavior demonstrates a real investment in the patient's treatment and respect for their fears.

Imaginal Exposure

In the above examples so far, EX/RP has been carried out in vivo with the therapist serving as the live model for the patient. However, exposure can also be conducted imaginally. Similar to in vivo exposure, the patient confronts an avoided situation. However, instead of taking place in the actual environment, the event is encountered in the patient's mind. Imaginal exposure can be helpful for people who are not quite ready to enter into actual situations and/or situations that are hard to recreate (e.g., starting a fire). As with in vivo exposure, the goal is for the patient to experience a decrease in anxiety by continually confronting more difficult scenarios on their anxiety hierarchy.

Modeling procedures can be purposefully used in imaginal exposure. This type of modeling is called covert self-modeling. Covert modeling is when the patient imagines themselves (or the therapist) performing a desired behavior and/or entering a feared situation (Spiegler & Guevremont, 2010). This procedure can be carried out in alternative ways and across feared situations.

To start, the therapist would explain the rationale and procedure to the patient verbally. Next the therapist would physically demonstrate sitting comfortably in a chair with their eyes closed. The therapist would then inform the patient that they are selecting an anxiety-provoking situation that they will imagine. Like all exposures, the therapist would make sure that the selected image is challenging yet not overwhelming (Dryden, 2012).

Once selected, the therapist would then begin to imagine the scenario in their head while verbalizing exactly what they are imagining as to model the type of scenario the patient will be imagining in their head. For example, the therapist would begin by saying "I am walking in the park with my son and we are approaching the swings. There are four swings and no one is on them. My son is running up to the swing and jumping on. I see my son going back and forth on the swing. I feel my breathing getting fast but I am staying here and now he is getting off. I am walking out of the park." Once this is completed, the therapist would invite the patient to imitate what they just demonstrated, as well as provide feedback and reinforcement along the way. Initially, the therapist may ask the patient to repeat what they are imagining in their head to make sure they are following the procedure correctly. Eventually, the patient would be able to practice without verbalizing out loud what they are imagining.

At times, having the patient immediately picture themselves in a scenario may be anxiety producing itself. Therefore, as an alternative the patient can imagine the therapist entering the scenario instead of himself/herself. This serves two purposes. First, although the patient is not in the image, they are at least confronting the feared situation on some level. Second, the image of the therapist serves as a model for the patient just as in in vivo exposure. Alternatively, the patient can imagine the therapist entering the situation with them. This approach again capitalizes on modeling and the benefits of therapist-assisted exposure as described above.

Finally, patients often come in with the belief that "This is just the way I am" and the thought of acting with mastery in an anxiety producing situation is just too difficult to fathom. Subsequently, as a spin-off of the patient imagining the therapist in their mind, we ask the patient to imagine himself or herself as someone who is able to manage anxiety differently. Once they have this, they can imagine their "masterful" self, assisting their "anxious" self through the anxiety situation. This approach has the advantage of the patient serving as their own "mastery" model as opposed to the therapist, thus enhancing the patient's sense of self-efficacy and ownership of the reduced anxiety reaction (Spiegler & Guevremont, 2010).

Hoarding Disorder

Although multifaceted, the primary symptoms of hoarding disorder are the excessive acquisition of items (i.e., newspapers, books, jewelry, plastic bags, appliances, etc.) and an avoidance and/or refusal to discard items. These behaviors persist despite the significant distress and/or interference they may have for the person suffering from hoarding disorder, as well as in other important people in their life (Neziroglu et al., 2020). Often due to high overvalued ideation (Neziroglu et al., 2012) and/or poor insight, individuals with hoarding disorder are reluctant to engage in the treatment process. Subsequently, many individuals may come into treatment due to legal issues, strained living conditions, and/or the ultimatums from family members.

Not surprisingly, when it comes to treatment not only may these individuals be reluctant to engage in EX/RP, but efforts at modeling may even cause some to "counterimitate" a therapist's behavior (Spiegler & Guevremont, 2010). Therefore, in these cases it is important to focus on the functionality of the presenting issues and the therapist may even (i.e., at least initially) model behavior that is somewhat less than "reasonable" (e.g., be willing to throw away one newspaper as opposed to a stack). This approach is used to build trust and rapport with the patient, as well as keep them engaged.

Assuming the patient participates, again, traditional EX/RP and modeling procedures will be modified. To illustrate, one aspect of hoarding disorder treatment that patients find difficult is between session homework assignments of actually physically throwing away items. Indeed, it is one thing to determine with a therapist that certain items will be thrown away, while it's another thing to actually throw them away. It is not uncommon to work with a patient with hoarding disorder during a session and select items to be discarded only to return next session and find the items still there. Therefore, it is important not only to throw away items in session, but also to actually make sure the items are making it out of the home. This is where participant modeling can be an especially appropriate approach for this aspect of the treatment for hoarding disorder (Spiegler & Guevremont, 2010).

Participant modeling encompasses several steps often seen with traditional exposure therapy with certain purposefully added aspects to facilitate behavior change. For example, the therapist first models the behavior they would like the patient to perform. In the case of hoarding, this would include first selecting an item to discard. Next the therapist would demonstrate actually throwing away this item into a garbage bag. The therapist would then verbally prompt the patient to perform the same task they had just completed in an attempt to shape a desired behavioral sequence (i.e., the treatment goal of discarding items).

Once this sequence is established, the therapist would then model taking the garbage bag actually out of the patient's home and putting it on the street for garbage pick-up. Again just like any other step in a behavior sequence, the therapist is not only modeling behavior, but also the different thoughts and emotional reactions they may be having to throwing away an item. It is important to realize that the behaviors, thoughts, and feelings of the patient may be significantly different when throwing an item outside than when they are throwing away an item in a bag in their home. Therefore, it is important to not take this step of treatment for granted and instead apply the same exposure/modeling techniques used in the preceding steps. This would entail specifically walking with the patient and guiding/prompting them to put the garbage out and not take it back into their home.

Although therapists often can model putting discarded bags on the street for garbage pick-up, initially in treatment it is preferable to have the therapist actually take the bag away from the outside garbage. In the beginning of treatment, patients are likely to bring back the bag inside after the therapist leaves, therefore, to assist in dealing with the anxiety the therapist may take the bag away permanently. Gradually, the therapist can evaluate whether the patient can tolerate leaving the bag for garbage pick-up. Once this behavior sequence has been practiced repeatedly, the therapist may then consider implementing fading procedures where the patient becomes more responsible for implementing the different behaviors of the sequence on their own.

Group Treatment for Hoarding Disorder

Struggling with a disorder can often feel very isolating. This is why appropriate participation in treatment/support groups can be a welcomed adjunctive treatment modality. What is so important about such groups is not only can participants share their concerns and troubles, but they can also share their successes. What better way to benefit from modeling than to actually model your behavior off someone who intimately knows the same struggles you have dealt with and has come out on the other side. Indeed, research suggests that modeling gains can be increased when the model is more similar to ourselves (Spiegler & Guevremont, 2010).

Within the area of modeling, this is referred to as the coping model. This type of modeling is contrasted with mastery modeling where an expert (e.g., the therapist) serves as the model (Spiegler & Guevremont, 2010). Although the modeling of behavior by a therapist clearly has it merits as outlined thus far in the preceding sections, it is often observed that patients may feel other patients are easier to relate to when it comes to appreciating the difficulty of carrying out the tasks included in hoarding disorder treatment. By patients sharing their experiences of success, others not only learn strategies to help them engage in adaptive behavior, but more importantly through vicarious learning see that not only are the behaviors possible, but also they are "survivable."

Body Dysmorphic Disorder

Up until now, the focus on modeling and the OCRDs has been on exposure-based interventions. This makes sense given the symptom similarities among the OCRDs. However, another major component of modeling, especially relevant to these disorders, is skill-training. Indeed, the complete lack of important skills and/or the use of ineffective/maladaptive behaviors and strategies can lead to the maintenance of OCRDs. Therefore, teaching patients skills is an integral part of treatment. Not surprisingly, modeling is an important and efficient means for transferring skills to patients (Spiegler & Guevremont, 2010).

Body dysmorphic disorder (BDD) is an OCRD disorder where the modeling of different types of skills is just as important as exposure interventions. To illustrate, one of the maladaptive behaviors/compulsions seen in BDD is mirror checking. Typically, individuals suffering from BDD will not only check their defect in the mirror or reflective surfaces, but they will do so in a way that perceptually distorts or exaggerates their perceived defect. For example, by going close to a mirror, it gives the impression that the perceived/slight defect (e.g., pimple) is bigger than it actually is, thus reinforcing the already maladaptive beliefs/perceptions about the defect.

Similar to instruction in hand washing, instruction in how to look into a mirror is an important skill for treatment progress. More specifically, mirror retraining is a technique where the patient is instructed in how to look into the mirror in a functional manner while simultaneously learning how to describe their appearance more objectively (i.e., without using global labels or affect laden descriptions) (Wilhelm et al., 2013; Veale & Neziroglu, 2010).

For example, the therapist would first physically demonstrate how to stand in front of the mirror at an appropriate distance. Next the therapist would model how to describe each part of their body instead of just focusing on a specific area. These descriptions are based on objective language as opposed to labels (e.g., "I am looking at my hair, it is down to my ears, it is the color brown" as opposed to "I am looking at my hair, it looks too short, it makes me look ugly"). Throughout this process, not only is the therapist modeling the appropriate skill, but also modeling adaptive behaviors, thoughts, and feelings relating to their appearance. Slowly the therapist would then have the patient engage in the same behavioral sequence while simultaneously giving the patient corrective feedback and reinforcement along the way. Eventually, as in the above examples, the therapist would slowly reduce their assistance in helping the patient carry out the task in order to facilitate the "transference of the skills" needed for improvement.

In addition, in order to generalize these skills into other environments in the patients' life (e.g., home), symbolic, as opposed to live, modeling can be utilized (Spiegler & Guevremont, 2010). Although there are different forms of symbolic modeling, one technique often used for generalizing skills is some type of tape or recording on an individual's phone. Here, the therapist would verbally instruct the patient on times when to use this skill, how to use the skill, and key points to remember while carrying out the task (i.e., using objective vs. emotional laden descriptions when describing one's body parts).

Recordings can vary from complete scripts of how to complete the skills or recorded transcripts of the therapist carrying out the task to him or herself. Moreover, once the patient has achieved an adequate level of mastery, it is suggested that they create their own version of the skills instruction in order to utilize themselves as the model of new reasonable/functional behavior.

Hair Pulling (Trichotillomania) and Skin Picking (Excoriation) Disorder

Hair pulling and skin picking disorders are two separate disorders that share similar symptoms in that they both involve repetitive body focused behaviors. As their respective names suggest, the behavior may involve the pulling out of one's hair (i.e., often from scalp, but may occur in other areas) and picking of one's skin (i.e., cuticles, feet, mouth, etc.) These behaviors may be carried out either automatically and/or purposefully (Gupta & Dass Gargi, 2012). Moreover, the behaviors themselves may serve different "functions," such as self-soothing, the reduction of a preexisting urge, and/or negative affect reduction (Neziroglu et al., 2008).

Regarding treatment, for the final section we will combine hair pulling disorder and skin picking disorder together since not only do they share similar symptoms (i.e., repetitive body focused behaviors), but their treatment also relies heavily on the skills training modality known as habit reversal. Habit reversal is a multiple component treatment aimed at increasing the patient's awareness of their behavior, as well as providing instruction in alternative behaviors aimed at reducing/substituting pulling or picking behavior (Gupta & Dass Gargi, 2012). Habit reversal is often used in conjunction with EX/RP as is seen with the other OCDRs. A comprehensive explanation of all the components of habit reversal is beyond the scope of the current chapter; however, an explanation of "competing response" will be provided as it pertains to modeling.

After a period of self-monitoring of situations, as well as determining the behavioral components of the target behavior, patients are instructed in the process of competing response. To illustrate, suppose a patient is being treated for picking their cuticles. The therapist would first help the patient identify what specific behaviors are part of the picking behavior sequence (i.e., bringing their hands together, rubbing their cuticle with their index finger, bringing fingers together to lift loose skin, etc.). Behaviors will also be examined across different situations to determine if there are certain body positions that make the person more prone to engaging in the target behavior (e.g., a person who is bored with homework may begin to bring their hand to their other hand without realizing).

Once these behaviors are identified, the therapist will suggest a competing behavior response that is incompatible with the picking behavior. For example, if a person often brings their hands together while studying, they will be instructed to use alternative behaviors such as keeping their hands apart by holding the side of a desk, sitting on their hands, holding an object in their hand, etc. These changes in the environment make it more likely that their hands will not come together and start the picking sequence.

These same instructions can be used in pulling. Again the behaviors that make up the target behavior will be identified. In the case of pulling a typical behavior is flexing the arm at the elbow in order to raise the patient's hand to their head to pull. In contrast, the patient would be instructed to extend their arm when they feel an urge to pull, thus interfering with their ability to raise their hand to their head. Once a verbal explanation and rationale is given, the therapist will demonstrate the desired behaviors for the patient. Next the therapist will have the patient model the therapist's behavior simultaneously (i.e., while the therapist is actually performing the behavior). The therapist will then have the patient carry out the behavior himself or herself with the therapist providing feedback and reinforcement as possible.

Once this behavior sequence is rehearsed numerous times, the therapist and patient will try to practice the sequence in actual situations where picking and pulling are normally triggered and/or the therapist will attempt to trigger the urge in their office. Once triggered, the patient is instructed to use their competing response as practiced. Again the therapist can model the behavioral sequence exactly how the patient would carry it out if they were alone in a particular situation (i.e., doing homework).

As adjunctive instruction to the above description, therapists and patients can capitalize on smart phone technology and actually video record the patient and/or therapist carrying out the behavioral sequence. These recordings represent a form of "video modeling" (Spiegler & Guevremont, 2010) where the patient has a visual representation of the desired behavioral sequence that they can review between therapy sessions, during times of increased urges, and prior or during high picking/pulling situations (e.g., doing homework, watching TV, when distressed). Again, based on the principles of modeling, having a visual representation of the desired behavior that includes the patient themselves can be highly motivating and instructive.

Summary

In this chapter we have described how psychological modeling can be used to supplement cognitive behavioral therapy (CBT) and exposure response prevention therapy (EX/RP) in the treatment of anxiety and obsessive-compulsive and related disorders (OCRDs). Whereas CBT and EX/RP focus on the use of direct experience to reduce unhelpful cognitive, emotional, and behavioral responses and to develop the necessary skills to manage stressors, modeling expands this process by providing the opportunity to learn from other people's experience. As discussed, studies suggest the effectiveness of this modality in the treatment of anxiety and avoidant behaviors. In this chapter we reviewed specific modeling techniques that can be used in the treatment of obsessive-compulsive disorder, hoarding disorder, body dysmorphic disorder, trichotillomania, and excoriation. The ideas discussed in this chapter demonstrate ways psychological modeling can be incorporated when planning for, and engaging in, the treatment of these disorders.

12 Conditional Discrimination: What's in a Name?

Joseph H. Cihon, Julia L. Ferguson, and Justin B. Leaf

It is not uncommon to overhear behavior analysts uttering phrases such as "behavior is selected by its consequences" or "behavior is a product of reinforcing contingencies." While this is absolutely true, it is also a bit of an oversimplification of the effect of consequences, particularly reinforcing consequences. Sure, reinforcement selects particular forms, or topographies, of behavior—that is, reinforcement increases the likelihood of future instances of similar behavior—but it also selects the environmental conditions that will set the occasion for similar responses in the future. When human and non-human animals respond differentially in two different conditions, it is commonly referred to as stimulus control, discriminated responding, or a discriminated operant (Catania, 1998).

Simple and Conditional Discriminations

With respect to discriminated responding, we generally distinguish between two basic types of discriminations: simple and conditional. A *simple discrimination* does not rely on contextual control of other conditions or stimuli. A simple discrimination describes a situation in which only one stimulus condition exerts control over a response (Axe, 2008; Green, 2001; Grow & LeBlanc, 2013). Simple discriminative responding is commonly developed by reinforcing responses in the presence of one stimulus and not in its absence. The left side of Fig. 12.1 provides an example of a simple discrimination. In this example, anytime the circle is selected, it results in access to a reinforcing consequence. Selecting another stimulus (e.g., the square) in the field will not result in reinforcement. Therefore, the circle becomes the only stimulus that exerts control over responding, regardless of the other stimuli that may be present.

Only a small portion of human behavior can be explained by simple discriminations. Much of human behavior depends on context, that is, conditional on other stimuli. *Conditional discriminations* describe situations in which behavior comes under the control of one stimulus when it is in the presence or context of another stimulus (Catania, 1998). Said differently, "the function of a discriminative stimulus (whether it is S+ or S–) changes based on the presence of another stimulus—the conditional stimulus" (Saunders & Williams, 1998, pp. 210–211). While simple discriminations are established by reinforcing a response in one stimulus condition or to one stimulus, conditional discriminations are "established by reinforcing responses to particular ante-

cedent stimuli *if and only if* they are preceded or accompanied by particular additional stimuli" (Green, 2001, p. 75). The right side of Fig. 12.1 provides an example of a conditional discrimination. In this example, selecting the stimulus that corresponds with the instruction results in reinforcement (e.g., touching the circle when a practitioner says "touch the circle"). Selecting another stimulus in the field (e.g., touching a square when a practitioner says "touch the circle") will not result in reinforcement. It is important to note that each stimulus in this example serves as a discriminative stimulus and a stimulus delta.

Conditional Discriminations and Relational Responding

Conditional discriminative responding is commonly confused with relational responding, and for good reason (Stewart & McElwee, 2009). Some definitions of relational responding used within the literature include "responding to one stimulus in terms of another stimulus" (Stewart & McElwee, 2009, p. 310). A definition such as this one would make it seem as though all conditional discriminative responding are examples of relational responding. For instance, in the conditional discrimination example in Fig. 12.1, the organism is responding to the comparison array (i.e., one stimulus) in terms of the instruction (i.e., another stimulus). To address this challenge, some have put forth an alternative definition to ensure that descriptions of relational responding involve responding that can be "generalized so that it involves responding in accordance with some type of pattern rather than on the basis of one or a limited number of associations" (Stewart & McElwee, 2009, p. 311). For example, telling a child "Lisa is faster than Tionne and Tionne is faster than Rozonda," and based on a previously established learning history, the child responds that Lisa is faster than Rozonda and that Tionne is slower than Lisa. Based on this stricter definition, the conditional discrimination example in Fig. 12.1 would no longer meet the definition for relational responding.

Confusion may be furthered by the commonalities found across preparations within the conditional discrimination, equivalence, and relational responding research (see Sidman & Tailby, 1982). One can find the use of procedures commonly referred to as "match-to-sample" across the literature in each of these areas (e.g., Iversen et al., 1986; Nissen et al., 1948; Pilgrim et al., 2000). It should, however, be noted that other procedures are in use within conditional discrimination research (e.g., go/no-go; Dube et al., 1993). Within match-to-sample procedures, the organism is presented with a stimulus (i.e., sample). The organism is commonly required to engage in what is referred to as an "observing response." Depending on the species of the organism and the procedure the observing response can be, but is not limited to, pointing to or pecking the sample, revealing the sample by lifting a flap, or vocally stating the name of the sample. Following an observing response, an array of stimuli is presented that includes the sample stimulus and other stimuli (i.e., the comparison array). The presentation of the array can occur with the sample remaining visible (e.g., if the sample stimulus is the middle key and the comparisons are outer keys, the middle key can remain illuminated when the outer keys are illuminated) or with the sample being removed (e.g., the center key is darkened when the comparison stimuli are illuminated). Upon selecting the correct comparison, access to reinforcement is provided while selecting the incorrect comparison results in a variety of different outcomes (e.g., ending the trial and starting an intertrial interval, representation of the trial until a correct match occurs). Even though match-to-sample or elements of match-to-sample procedures are used within the literature on conditional discrimination, equivalence, and relational responding, it is important to note that the subject of study is commonly different (e.g., trained versus untrained relations).

Misconceptions

From the outset, it is important to remind the reader that all organisms, human or otherwise, simply behave. That is, organisms engage in behavior (e.g., operant, respondent) based on a large variety of environmental variables (e.g., deprivation, the presence of absence of discriminative stimuli, a past history of reinforcement and punishment). Colloquially, we tend to categorize behavior in ways that make it easier to understand, describe, and communicate with others (e.g., discriminate, correct, incorrect, aberrant). While this vernacular may be convenient in everyday communication, it can set the occasion for terminological errors and other potential challenges. For instance, when discussing behaviorally based interventions for autistics and other individuals diagnosed with autism spectrum disorder (ASD)[1] it is not uncommon to hear phrases such as, "Sara can discriminate between green and red" (i.e., a conditional discrimination). While this statement is well intended, it is not entirely accurate with respect to a behavioral analysis of Sara's behavior. Remember, organisms simply behave, they do not discriminate. That is simply our convenient description of Sara's behavior in everyday language. Said more accurately with respect to a behavioral analysis, "Sara responds differentially in the presence or absence of green and red." This statement, although more accurate, is much more verbose and the use of the former statement makes sense, especially when conversing with those who may not be behavior analysts.

While this may seem like a simple semantic argument, the challenges it can create are nothing but simple. Imagine when the previous example, "Sara can discriminate between green and red," is changed to "Sara cannot discriminate between green and red" (i.e., the lack of the development of a conditional discriminative responding). This phrasing states that Sara is unable to discriminate between two colors and places the problem as a feature of Sara (i.e., an inability to discriminate). Intervention may now be more likely to focus on Sara having a discrimination problem rather than environmental variables contributing to the lack of conditional discriminative responding. However, Sara does not have a discrimination problem, she is simply behaving in accordance with the circumstances (i.e., organisms simply behave). The problem is Sara's behavior is not differentiated in the desired context; that is, she is not differentially responding in the presence of

[1]Terminology selected to adhere to the 7th edition of the American Psychological Association Publication Manual and to be inclusive of readers who prefer person-first as well as identity-first language.

green or red. This phrasing shifts the focus to the environmental variables that may be responsible for Sara's behavior (e.g., a lack of differential reinforcement) and what changes to the environment will be required to obtain the desired differential responding. In any event, the audience (e.g., other behavior analysts, non-behavior analysts) and the effect of our language on the audience should be the main deciding factor of the topography of our language (Becirevic et al., 2016).

Another misconception related to descriptions of conditional discriminative responding relates to stimulus control. As previously stated, stimulus control describes when behavior is more likely to ensue in the presence of a discriminative stimulus than in its absence. Sometimes when attempting to establish conditional discriminative responding in the clinical setting, behavior comes under the control of stimuli other than the desired instructional stimuli. For example, matching a red card to a red card may occur only when the interventionist is looking at the red card in the comparison array. This performance may also involve matching any sample to the comparison that the interventionist is directing their gaze at within the array. Situations like this are commonly referred to as "faulty" stimulus control (e.g., Green, 2001; Grow & LeBlanc, 2013). To describe stimulus control as faulty in these situations seems inappropriate and can lead to problems similar to those described in the preceding paragraph. Stimulus control, and a conditional discrimination at that, was developed in this example. The learner matches the sample conditional on where the interventionist is directing their gaze. To describe this as faulty negates the stimulus control that was established. A better way to describe this relationship would be *undesired* stimulus control. That is, the conditional discrimination that was established is not the desired conditional discrimination of the interventionist. Adopting this terminology may promote a better understanding of the lawfulness of environment–behavior relationships, especially with the growing number of minimally trained behavior analysts (Leaf et al., 2016b, 2017).

Conditional Discrimination Research

There is extensive research related specifically to the development and evaluation of conditional discriminative responding that some have suggested started all the way back in 1799 (Carter & Werner, 1978). When this research is paired with research that develops and evaluates conditional discriminative responding without explicitly stating it as the purpose (e.g., Keinz et al., 2011; Pérez-González, 1994), the literature base is immense. In fact, over 40 years ago in 1978, Carter and Werner stated, "the literature contains hundreds of conditional discrimination experiments" (p. 565) when reviewing the conditional learning literature with only pigeons! Research on conditional discriminative responding has also occurred with, but not limited to, rats (e.g., Lashley, 1938), non-human primates (e.g., Nissen et al., 1948), deaf children (e.g., Almeida-Verdu et al., 2008), neurotypical adults (e.g., Pérez-González & Alonso-Alvarez, 2008), Alzheimer's patients (e.g., Steingrimsdottir & Arntzen, 2011), and autistics and other individuals diagnosed with ASD (e.g., Fisher et al., 2007). What follows is a greatly abbreviated overview as well as descriptions of selected studies from this literature base organized across organisms commonly used within this literature (i.e., rat, pigeon, and human) as well other examples with lesser used organisms.

Basic Research

Rats In a classic and seminal paper in conditional discrimination learning, Lashley (1938) described several experiments in which conditional discriminations were developed with three rats. In the first set of experiments, the rats were trained through a series of steps to respond with few errors to two pairs of stimuli. A white erect triangle and a white inverted triangle on a solid black background served as one pair of stimuli, and the same triangles with a black background with horizontal white stripes served as the second pair of stimuli. Which stimulus functioned as the positive discriminative stimulus (S+) varied across training steps. To further evaluate if differential responding was controlled by the stimuli, Lashley evaluated responding across several more pairs of stimuli with triangles and various other patterns (e.g., a triangle with a circle around it, striped triangles). In the second set of experiments, Lashley evaluated if responding would generalize to figures other than triangles (e.g., cross vs. X, star vs. square) using a similar series of training steps. This performance was established with two of the three rats, while the third rat failed to reach the criterion. While Lashley was not the first to evaluate conditional discriminations, this study provided the first demonstrations of identifying and defining the physical properties of the controlling stimuli and laid the groundwork for later models of conceptualizing conditional discrimination learning (Carter & Werner, 1978).

North et al. (1958) replicated and extended Lashley (1938) with a larger number of rats and conditions. That is, North and colleagues included 17 rats and several pairs of stimuli that differed in terms of the background while keeping the form consistent. North et al. also included an additional test of patterning to evaluate if responding could be explained on the basis of the compound of the stimuli presented on each card (i.e., what the stimuli were painted on), independent of the other stimuli, or on the basis of the stimuli presented on both cards as a whole. The 17 rats were randomly divided into eight subgroups with two different problems, which referred to the combination of stimuli presented, and which stimulus resulted in access to reinforcement (i.e., the stimulus that resulted in reinforcement was reversed, making the second problem). North and colleagues' results aligned with Lashley's findings and demonstrated through the test of patterning that stimulus complexities can be evaluated based on form and background as functional units.

More recently, Bruce et al. (2018) examined conditional discriminative responding (i.e., matching-to-sample and non-matching-to-sample) with 15 rats using an automated olfactometer. Following an initial shaping phase to establish simple discriminations to four scents, conditional discrimination training began. Rats were randomly assigned to matching-to-sample and non-matching-to-sample conditions both of which used a successive go/no-go procedure. Following an observing response on each trial, a sample odor was presented and the first nose poke after 5 s terminated the sample and the comparison odors were presented. Responding was reinforced on a fixed-interval 5 s schedule on positive trials, and the comparison was presented for 5 s and then terminated on negative trials. Once a rat was responding with minimal errors, a new set of odors was presented using the same procedures as the previous odors. Bruce and colleagues also conducted a reversal phase once three sets of odors had been introduced in which the contingences were reversed (i.e., matching-to-sample rats were reversed to non-matching-to-sample and vice versa). Results revealed that most of the rats acquired conditional discriminative responding rapidly and maintained responding on the original contingencies with novel stimuli during the reversal phase.

Pigeons For an early review and summary on some of the founding literature on conditional discriminative responding with pigeons, we refer the reader to Carter and Werner (1978) (but also see Schrier & Thompson, 1980). The following articles were selected as examples of the establishment of conditional discriminative responding, and should not be taken as an exhaustive or comprehensive list. In Skinner's (1950) discussion of "Are theories of learning necessary?," he described and illustrated data on the maintenance of a chain of conditional discriminative responding (i.e., matching to sample) under intermittent reinforcement. Within this procedure, the center key was illuminated by one color for a minute which was changed with another color at random. When the pigeon responded (i.e., pecked) this center key the side keys illuminated with two different colors, one matching and one not matching the color of the pecked center key. Following a peck to one of the side keys, both side keys extinguished and the center key re-illuminated. Pecking the side key that matched the center key operated the food magazine. Not only was conditional discriminative responding established, but it was also maintained when reinforcement occurred no more often than once per minute on average.

A decade after Skinner's (1950) description, Cumming and Berryman (1961) trained three pigeons using a match-to-sample procedure almost identical to Skinner's procedure. To begin each trial, a center key on a three key display would illuminate red, green, or blue (i.e., the sample). Pecking the sample then illuminated the two side keys (i.e., the comparison array) while the center key remained illuminated. Pecking the comparison that matched the same resulted in 3 s of access to grain and pecking the other comparison resulted in all keys and the house light being turned off for 3 s. Following a 25 s intertrial interval, the next trial began. Conditional discriminative responding was established with all three pigeons. Cumming and Berryman also analyzed if responding was under the control of position (i.e., left or right) or color. The results of this analysis demonstrated that early during training position controlled the pigeons' behavior, and this gradually shifted to color (i.e., matching) by the 5th session.

In a more recent example, Mondragón and Hall (2015) evaluated the role of stimulus comparison on conditional discriminative responding across two experiment with 16 pigeons. In the first experiment, pigeons were presented with a color and a shape that signaled the availability of reinforcement for one response, and a different color and a different shape that signaled the availability of reinforcement for a different response. The pigeons were divided into two conditions: (a) comparison and (b) no comparison. Both conditions involved a successive, conditional, go-left/go-right task. In the comparison condition, sessions consisted of presenting both colors or both shapes. In the no comparison condition, sessions consisted of presenting one color and one shape or the other color and shape. Conditional discriminative responding was acquired more readily by the pigeons assigned to the no comparison condition. Differences between the pigeons in each condition were maintained in the second experiment which involved a successive go/no-go discrimination in which responding to one of the colors and one of the shapes resulted in access to reinforcement while responding to the other color and shape did not result in access to reinforcement. Mondragón and Hall concluded that the performance of the pigeons was suggestive of responses governed by the absolute properties of stimuli.

Non-human Primates/Monkeys For an early review and summary some of the founding literature on conditional discriminative responding with primates, we refer the reader to Spence (1937). The following articles were selected as examples of the establishment of conditional discriminative responding and should not be taken as an exhaustive or comprehensive list. Nissen et al. (1948) described an early evaluation of developing conditional discriminative responding with seven chimpanzees in a match-to-sample procedure. On each trial, three stimuli were presented (i.e., two cups and one box or two boxes and one cup) on a tray in a semi-randomized order in which the middle stimulus was the sample stimulus. A response to the sample stimulus (i.e., lifting the cup or box) revealed a small piece of food. The side stimuli served as the comparison stimuli. Responding to the correct comparison stimulus also revealed a small piece of food while selecting the incorrect comparison resulted in removing, resetting, and representing the same trial again (i.e., a correction trial). Correction trials were not counted as new trials. Although variability was observed across the seven chimpanzees, all developed conditional discriminative responding. Generalization of matching was also evaluated immediately following completion of the training across a variety of objects and colors. The results demonstrated that the chimpanzees did not just learn matching in specific arrangements, but their responding generalized to matching based on sameness.

Riopelle and Copelan (1954) evaluated the development of simple discriminative responding while minimizing unreinforced responses (i.e., errors) with five rhesus monkeys. Prior to this study many simple discrimination preparations involved shifting from one stimulus to the other without warning (i.e., the S+ becoming the S−). In an attempt to solve this problem, the five rhesus monkeys actually developed conditional discriminative responding. In Riopelle and Copelan's preparation, any time a stimulus change occurred the stimuli were presented on a different colored tray. Conditional discriminative responding was demonstrated when the monkeys changed the stimulus they selected without error. Following continued training, all five monkeys changed their responding based upon a change in the color of the tray and this responding generalized to new color sequences.

Leal et al. (2020) provided a great, recent example of an approach to translational research to develop non-verbal memory testing procedures for those with limited verbal repertoires. Across two experiments Leal and colleagues evaluated the development of delayed matching-to-sample with long delays and manipulation of intertrial intervals with three tufted capuchin monkeys. In Experiment 1, the monkeys were trained to respond on a delayed match-to-sample preparation across three different sets of stimuli. Depending on the monkeys' performance, the researchers either increased of delay (i.e., if the performance criterion was met) or the intertrial interval (i.e., if the performance criterion was not met) from session to session. Results of Experiment 1 demonstrated that gradual increases in delay and intertrial interval generated high accuracy on the delayed matching-to-sample preparation. However, with varying delay and intertrial interval values, Experiment 1 provided no data on the effect of intertrial interval changes for any given delay value. As such, Experiment 2 involved only one delay value and different intertrial interval values. The results of Experiment 2 demonstrated that all three monkeys displayed fairly high accuracy regardless of the ratio of intertrial interval to delay value.

Humans As previously stated, much of human behavior is contextual or conditional, so it is not surprising that the development of and variables affecting conditional discriminative responding has been examined with humans. North and Leedy (1952) hypothesized that marked interference is likely in the development of conditional discriminative responding as a result of generalization along incorrect stimulus dimensions (e.g., shape instead of color) or common stimulus elements (e.g., color instead of shape). To evaluate this hypothesis, North and Leedy evaluated the responding of 51 adult women to stimuli that had two critical components, one of which varied more than the other. There was a total of nine stimuli, which were differentiated by three based on shared outer or inner components. That is, three stimuli may have the same outer component (e.g., flower petals) while having differing inner components (e.g., different color inner circle) or three stimuli may have the same inner component (e.g., solid inner circle) while having differing outer components (e.g., different shaped flower petals). Initial teaching occurred across two conditions: (a) the outer component remained consistent, but the inner component varied and (b) the inner component remained consistent, but the outer component varied. Following initial teaching a test condition occurring in which the two components varied with equal frequency. The results indicated that the stimulus component that varied the most frequently in training resulted in better discriminated responding.

Gollin and Liss (1962) explored the development of discriminated responding with 35 young children across two experiments. Experiment 1 first evaluated the establishment of a simple discrimination, and, of most interest to the topic of this chapter, Experiment 2 evaluated conditional discriminated responding using methods similar to Lashley (1938). Following the development of simple discriminations in Experiment 1, an alternation and random condition were used to evaluate conditional discriminated responding across three different age groups (i.e., 3.5–4, 4.5–5, and 5.5–6 years). In the alternation condition, trials alternated between stimuli from the original training in Experiment 1 and stimuli from reversal training. In the random condition, stimuli from the reversal training were randomized. To engage in conditional discriminative responding, "help" was required for all but one, two, and seven members of the 3.5- to 4-, 4.5- to 5-, and 5.5- to 6-year-old groups, respectively (i.e., the younger the child the more likely help was required to acquire the conditional discrimination). Help consisted of identifying a mutually agreed upon name for the stimuli and naming the background prior to each trial. Taken together, Gollin and Liss's results indicated that age played an important role in the development of conditional discriminations within their preparation.

In an interesting recent study, Pérez and Polín (2016) evaluated conditional discriminative responding when 109 college students were exposed to three different conditions: (a) sample and comparisons presented at the same time and requiring sample observation (i.e., simultaneous discrimination); (b) comparisons presented when the sample disappeared and

Requiring sample observation (i.e., successive discrimination); and (c) simultaneous discrimination without requiring sample observation. Across all three conditions, two training blocks occurred and were counterbalanced (i.e., half the participants were exposed to Block A then Block B, and the other half to Block B then Block A). Block A consisted of a match-to-sample procedure with one sample and three comparisons. Block B consisted of trials that were superficially identical to Block A, but reinforcement contingencies involved a simple discrimination across 75% of trials a conditional discrimination across 25% of trials. While simple discrimination trials resembled conditional discrimination trials in Block B, the sample stimulus remained constant and did not affect the reinforcement contingencies associated with the comparison stimuli. The results indicated no differences in acquisition between Blocks A and B, which led Pérez and Polín to conclude that the participants responded as if exposed to a conditional discrimination even though reinforcement was not dependent on the relation between the sample and the comparison stimulus chosen.

Other In a unique example of conditional discriminative responding, Roitblat et al. (1990) evaluated matching-to-sample via echolocation with a dolphin. With some engineering ingenuity, a floating apparatus was designed that controlled when echolocating could and could not occur with the sample and comparison stimuli. Additionally, vision occluders were placed over the dolphin's eyes to prevent the possibility that any matching performance could be due to seeing the stimuli. Sample stimuli were placed in the water and remained until the dolphin failed to emit echolocation clicks for 5 s. The comparison stimuli were presented in the same manner as the sample, and the dolphin could select a comparison by making contact with one of three response wands (i.e., one for each comparison stimulus). While design and procedural limitations prevented Roitblat and colleagues from demonstrating a functional relationship, the dolphin responded with high accuracy as demonstrated in the final 48 sessions (i.e., averaged 94.5% correct matches). Roitblat et al. noted that echolocation allowed more precision in the determination of attending to the sample and comparison stimuli that is sometimes lacking or difficult in other preparations.

Tokuda et al. (2015) were interested in evaluating if successive discrimination training would be effective at developing conditional discriminative responding with 11 octopuses (Octopus vulgaris). The octopuses were divided into two groups. One group accessed reinforcement for responses to a barrel-shaped white object when the when the tank was aerated. The other group accessed reinforcement for responses to a barrel-shaped white object when the aeration was switched off. Following initial training, testing for the development of conditional discriminative responding consisted of alternating aeration on and off during each trial. Tokuda and colleagues evaluated the number of trials and the latency the octopuses responded to the barrel-shaped white object. The results demonstrated that both groups responded in accordance with the conditionality of the aeration being on or off.

Dürckheim et al. (2018) evaluated conditional discriminative responding (i.e., match-to-sample) with three elephants using human scents (all obtained from unspecified body parts of a diverse group of 26 humans). The elephants were first trained to detect a single scent by presenting a cloth with the target scent, placing that cloth in one of nine jars, and requiring the elephants to find the matching cloth. Training gradually changed based on the elephants' performance to include blank cloths without scents and, eventually, cloths with varied non-matching scents. The elephants were randomly provided with trials that involved all non-matching scents throughout training and testing phases in which reinforcement was contingent upon not selecting any of the comparison stimuli. Dürckheim and colleagues' results demonstrated that all three elephants were efficient and accurate in matching human scents, which extended findings of previous research demonstrating the same effects with dogs (e.g., Marchal et al., 2016).

Applied Research

In addition to the extensive basic research literature base on conditional discriminations, there are numerous studies on conditional discriminations that would be considered "applied" (Baer et al., 1968). Given the expansive literature base, only a small sample of this literature will be described here and does not represent a comprehensive or exhaustive list. The articles were selected with an acknowledged bias of the authors' behavioral histories and are meant to provide a wide sampling of applications. It should also be noted that while the literature on the development of equivalence classes is applicable here, it was excluded based on the purpose of the chapter.

Saunders and Spradlin (1989) noted that matching in a match-to-sample preparation requires two component discriminations: (a) a successive discrimination between samples and (b) a simultaneous discrimination between the comparisons. Their hypothesis was that for learners for whom conditional discriminative responding is commonly difficult to establish (e.g., individuals diagnosed with intellectual disabilities), it may be advantageous if training procedures directly established a successive discrimination between samples and a simultaneous discrimination between the comparisons. Their participants included two individuals diagnosed with intellectual disabilities each of whom had previous histories of difficulties in establishing arbitrary matching (i.e., conditional discriminations). Saunders and Spradlin first trained the participants to respond to two different sample stimuli based on two different schedules of reinforcement then conducted conditional discrimination training (i.e., match-to-sample) in which the reinforcement schedule requirement for the sample had to be met prior to exposing the comparison array. Despite the prior schedule training with the sample stimuli, both participants continued to respond at chance levels during conditional discrimination training. This responding continued even after directly training a comparison discrimination. However, both participants acquired conditional discriminative responding when trials were presented in blocks as opposed to alternating randomly which also maintained after the schedule requirement the for the sample was removed.

Pérez-González and Williams (2002) extended the research related to blocking procedures when evaluating the efficacy of a combination of two blocking procedures when teaching conditional discriminative responding with five children diagnosed with autism who did not learn with previously attempted conventional procedures. Conditional discriminative responses consisted of matching objects in response to spoken names and amounts to numbers. Procedures for both responses occurred across several stages and consisted of presenting sample until 10 consecutive correct responses occurred and leaving the location comparisons constant. Following 10 consecutive correct responses, the requirement for changing sample was reduced. Finally, the samples were presented randomly, and, in the final stage, the position of the comparison stimuli was randomized. Pérez-González and Williams' results indicated that all five participants acquired the targeted conditional discriminative responses with minimal errors.

Fisher et al. (2007) further evaluated the development of conditional discriminative responding for individuals whom have had previous histories of difficulties learning in match-to-sample procedures. Using a multi-element design, Fisher and colleagues compared the use of two variations of least-to-most prompting to develop conditional discriminative responding with two individuals diagnosed with autism. In one condition, least-to-most prompting, prompts consisted of a model prompt and a model prompt plus physical guidance. The other condition, identity matching, was identical in all aspects but replaced the model prompt with presenting an identical comparison stimulus, stating the sample stimulus again, and pointing to the correct comparison stimulus. The results indicated that least-to-most prompting with identity matching as one of the prompting hierarchies was more effective for the two participants.

Implications

Research on conditional discriminations has opened the door for a wide variety of interventions, behavioral discoveries, and additional research. The doors conditional discrimination research has opened have several implications for behavior analysts conducting research and applying behavior analytic principles in practice. As such, there are undoubtably numerous clinical implications and areas for future research. What is presented here are examples in light of the authors' repertoires and current and past research and are not meant to be exhaustive by any means.

Future Research

Much of the research involving conditional discrimination has evolved into examining higher order operant behavior (e.g., Almeida-Verdu et al., 2008; Green et al., 1993; Stewart & McElwee, 2009), the emergence of untrained relations (e.g. Keintz et al., 2011), and verbal behavior (e.g., Axe, 2008), to name a few. There is no doubt this research should and will continue to yield fruitful data, interventions, and additional research endeavors. For instance, Axe (2008) reviewed previous researchers' examination of conditional discriminations in the intraverbal relation and provided recommendations for future directions for research. Among Axe's findings were that there was little research on training individuals to engage in conditional discriminative responding for intraverbal relations and that conditional discriminative responding is often lacking for individuals diagnosed with developmental disabilities. Axe recommended that individuals diagnosed with developmental disabilities may benefit from direct training to develop conditional discriminative repertoires, future research examining prerequisite skills, stimulus arrangements, and teaching procedures, and informing research from previous research on auditory conditional discriminations and matrix training. As evident from Axe's review and recommendations, there is clearly room left for continued research related to conditional discrimination and the development of conditional discriminative responding.

Research should continue to evaluate teaching procedures common within practice, especially those for individuals with whom they have documented challenges in the development of conditional discrimination repertoires (e.g., individuals diagnosed with ASD). In addition to Axe's (2008) recommendations (i.e., transfer of stimulus control, errorless learning, and stimulus arrangements), research is needed which evaluates the use of various prompt types (e.g., within conditional discrimination teaching procedures. Prompting adds additional stimuli into the teaching environment, and the effect of the addition of these stimuli on the development of the desired conditional discriminative responding is warranted. This research should examine specific prompt types (e.g., response-prompts) and fading procedures (e.g., constant time delay; see Walker, 2008 for a review) in isolation and combination as well as across varied stimulus arrangements. This research could inform practice as to methods to evaluate the conditions under which (e.g., certain combinations of prompt fading procedures and stimulus arrangements) are more likely to develop undesired stimulus control (e.g., simple rather than conditional discriminations).

Future research should also continue examining prerequisite skills related to conditional discriminative responding. This would include prerequisite skills for acquiring various conditional discriminative responding (e.g., intraverbal relations, matching) and the skills for which conditional discriminative responding serves as a prerequisite. While the data are scarce on prerequisite skills for acquiring various conditional discriminative responding (Axe, 2008) it is likely that skills commonly referred to as "learning how to learn" skills are necessary. These commonly include repertoires related, but not limited to, attending, matching, imitation, and responding to the language of others (Lovaas, 2003; Smith, 2001). Research evaluating the presence, absence, or amount of development of each of these repertoires and the effect on teaching procedures for developing conditional discriminative responding will provide useful data to inform clinical practice. Furthermore, the development of a conditional discriminative repertoire may also serve as a prerequisite for other skills (e.g., more complex intraverbal relations, social interactions). Research that evaluates the effects of the presence, absence, or amount of development of conditional discriminative responding on various other skills could also help inform the scope and sequence of curricula within the clinical setting.

Clinical

The implications of conditional discriminative learning and research for the clinical setting are numerous. As previously discussed, the majority of human behavior is context dependent, or conditional. As such, the majority of clinical applications of the science and principles of behavior analysis related closely to conditional discriminative responding. The application for which these implications are most visible is perhaps within behavioral interventions for autistics and other individuals diagnosed with ASD. This is particularly the case given the common use of discrete trial teaching (DTT; Lovaas, 1987, but also see Leaf & McEachin, 2016) within these interventions. DTT is a systematic approach to instruction involving three primary components: (a) an instruction from the interventionist, (b) the learner's response, and (c) a consequence provided by the interventionist based on the learner's response (e.g., access to reinforcement following a correct response). Additional procedures used within DTT, and relevant to the current chapter, include providing a prompt to increase the likelihood of the desired learner response (MacDuff et al., 2001). The commonalities in the description of DTT here and previous descriptions of the match-to-sample approach used within conditional discrimination research highlights why implications of this research are exceptionally relevant to behavioral interventions for autistics and other individuals diagnosed with ASD.

There have been several discussions within the literature related to the use of prompts while using DTT (e.g., Green, 2001; Grow & LeBlanc, 2013; Leaf et al., 2016a). Some of which directly discussed conditional discrimination teaching methods and how some arrangements can result in undesired stimulus control (i.e., Green, 2001; Grow & LeBlanc, 2013). One of these arrangements involves presenting the same sample stimulus and only one (correct) comparison stimulus across numerous subsequent trials. If this arrangement develops discriminative responding, it is likely to be a simple, rather than a conditional, discrimination. If this instructional arrangement is in use, the interventionist could test for the development of a simple discrimination by giving the learner different samples while keeping the comparison stimulus the same or vice versa. The interventionist could also test which type of discrimination was developed by expanding the comparison array. If the learner matches the sample to the comparisons seemingly at random, it is likely that a simple discrimination has been developed. As Saunders and Spradlin (1989) demonstrated, it may be important to ensure blocks of trials are alternated with other relations to prevent the development of undesired stimulus control such as a simple discrimination when targeting a conditional discrimination.

Clinical application could also benefit from the research identifying and defining the properties of the controlling stimuli within conditional discriminative responding. As previously discussed, the development of undesired stimulus control is common within practice. Using the techniques within the research on conditional discriminative responding may help clinicians identify the stimuli and/or properties of stimuli that have acquired control. If an interventionist identifies patterns responding that is suggestive of undesired stimulus control, methods similar to Lashley (1938) and Saunders and Spradlin (1989) could be employed. For example, the interventionist could alter one component of a sample stimulus and conduct matching trials with just the sample or do the same with the comparison stimuli. Ultimately this may require some level of clinical judgement on the part of the interventionist (Leaf et al., 2016b). That is, changes to intervention would be informed by research, clinical experience, and current environmental variables (e.g., client responding; Redelmeier et al., 2001). In fact, some have provided data and suggested that interventions that involve flexibility and clinical judgement from the interventionists may yield better results (e.g., Cihon et al., 2020; Leaf et al., 2016a, b), and this may be extended to the development of conditional discriminative responding.

Conclusion

The behavior of human and non-human animals is discriminative. A distinction is commonly made between two general types of discriminative responding: simple and conditional. Though useful, only a small portion of human behavior can be accounted for by simple discriminations given much of human behavior is conditional. As a result, conditional discriminative responding has a rich history within research and practice within the field of behavior analysis. This chapter distinguished between simple and conditional discriminative responding, discussed the difference between conditional discriminative and relational responding, described selected samples of historical and current research related to conditional discriminative responding, highlighted misconceptions related to conditional discriminative responding, and outlined implications for future research and clinical practice. Much of the current literature related to conditional discriminative responding involves relational responding and emergent relations, and, as such, was outside the scope of this chapter. The reader is encouraged to seek out the vast literature and resources related to those topics.

Given the remarkable growth in the number of practicing behavior analysts (Behavior Analyst Certification Board, n.d.), it is possible that many of the misconceptions related to conditional discriminative responding could be avoided with a full adaption of the scientist-practitioner model (see Malott, 1992; Reid, 1992) and a focus on increasing standards with respect to training of behavior analysts (see Leaf et al., 2016b, 2017, 2020; Schlinger, 2015). Within the scientist-practitioner model behavior analysts would receive thorough training in conducting and interpreting research, even if they plan on working within clinical settings and not academic or research settings. This training would also focus on developing a thorough conceptual understanding of behavior analysis. That is, training on concepts and principles rather than tools and procedures. Perhaps this training would provide all practitioner's the research and conceptual understanding to avoid these mishaps as well as others.

13 Auditory–Visual Discriminations: Stimulus Control, Teaching Procedures, and Considerations

Samantha Bergmann and Tiffany Kodak

Every day, nearly every behavior of an individual involves stimulus control (Saunders & Williams, 1998). Without stimulus control, the world “would be chaotic” (Skinner, 1953, p. 108). Thankfully, stimulus control makes it so that behaviors previously reinforced in the presence of certain stimuli are more likely to occur when the stimuli are present again. Stimuli—events to which an organism can attend—become correlated with reinforcement. When our behavior comes to be controlled by stimuli in our environment, we can behave more effectively and efficiently. An example of stimulus control occurs in the kitchen when you reach into the fridge to grab a bottle of a new type of mineral water. You find that attempts to twist the cap do not produce an open bottle but using a bottle opener does. The next time you grab a bottle of the new mineral water, you are much more likely to use a bottle opener and unlikely to twist the cap. The change in response probability is due to a history of differential reinforcement wherein one response (prying cap off with an opener) produced an open bottle, but another response (twisting cap with your hand) did not. Whether you are likely to use the bottle opener or twist the cap depends on which brand of water is in your hand. The result is that you spend less time trying to twist caps that need a bottle opener.

All behavior analysts should know the prevalence and power of stimulus control. Stimulus discrimination training, whether that training occurs incidentally in one’s life or is programmed in a structured learning environment like an early intensive behavioral intervention program, creates the conditions for stimulus control. Behavior analysts serving individuals with autism spectrum disorder (ASD) should be well-versed in stimulus discrimination training because some of the most common treatment goals are related to stimulus-control excesses and deficits (Pilgrim, 2015). Behavior analysts should be familiar with discrimination training with auditory and visual stimuli, which are prevalent in many interactions and instructional programs.

Stimulus Discrimination

Most operant behavior involves interaction with antecedent stimuli in the environment (Dinsmoor, 1995a; Saunders & Williams, 1998). Behavior that occurs more often in the presence of a stimulus than in its absence is a discriminated operant (Catania, 2013). Skinner’s early laboratory work (1933) demonstrated that discriminated operants

result from discrimination training. Discrimination training involves reinforcing a behavior in the presence of one stimulus—the discriminative stimulus (S^D or positive stimulus, S+ [hereafter, we will use S+])—and extinguishing (i.e., withholding a reinforcer) the same behavior in its absence (i.e., S-delta, S^Δ, negative stimulus, S− [hereafter, we will use S−]). The S− can include the absence of the S+ (e.g., the absence of light in the operant chamber; i.e., presence vs. absence discrimination) or the presence of stimulus conditions other than the S+ (e.g., red light when the S+ light is green; i.e., quality discrimination). Research on discrimination training has shown that whether one trains a response in the presence of the S+ only or both an S+ and an S− influences training outcomes (Dinsmoor, 1995a). With repeated stimulus discrimination training, the effects of stimulus control should be a narrowing of the effects of reinforcement (Catania, 2013). That is, behavior becomes highly probable in the S+ condition and improbable under conditions that do not resemble the S+.

To illustrate discrimination training outside of the laboratory, consider a young child who learns to sign *square* (i.e., drawing both index fingers to meet at the center and outlining the shape of a square by bringing both fingers out, down, and in to meet in the middle) when shown a drawing of a square. When the parent shows the square, the child forms and moves her hands correctly, and the parent smiles and nods. If the parent's smiles and nods are reinforcers, then the child will emit the same sign when shown the square in the future. The parent may be surprised to see the child sign *square* when the picture is a circle, triangle, or diamond. The child signs *square* because the child's sign was reinforced only in the presence of the square and not extinguished in the presence of other shapes. Therefore, it is unlikely the sign *square* is under the control of the specific shape; instead, it is controlled by the presence of any shape drawing. A parent can remediate this control by showing the child multiple shapes in training. When the child signs *square* in the presence of a circle, the parent neither smiles nor nods. That is, the same response does not contact reinforcement in the presence of the new antecedent stimulus. With experience, this differential reinforcement contingency should strengthen signing *square* in the presence of the square (S+) and weaken signing *square* in the presence of the circle (S−). Due to differential reinforcement, the emission of the response becomes more probable under conditions that resemble the S+ (i.e., other square-like forms) and less probable under conditions that resemble the S− (i.e., other circle-like forms). Observing more responses in the presence of S+ than in its absence suggests discriminative control by the S+, which is stimulus control (Saunders & Williams, 1998).

Types of Discriminations

Simple Discrimination

The basic form of stimulus control is the three-term contingency that includes an antecedent stimulus, response, and reinforcer (Saunders & Williams, 1998). In a three-term contingency, a response is reinforced in the presence of an S+, and the same response is not reinforced in the presence of an S−. The three-term contingency is a simple discrimination. The everyday environment abounds with simple discriminations. However, one observation is insufficient to say that a response is under stimulus control; instead, we require repeated observations to determine that the response indeed occurs more often in the presence of the S+ than the S− (Dinsmoor, 1995a).

In a simple discrimination, the response is reinforced in the presence of one stimulus (i.e., S+) across opportunities. In other words, there is never a situation wherein emitting the response in the presence of the S+ is not reinforced (although one can use different reinforcement schedules). There is an extensive literature base on the acquisition of simple discrimination with nonhuman subjects and human participants with and without intellectual, developmental, or physical disabilities (cf. Saunders & Williams, 1998).

Successive Simple Discrimination When the S+ and the S− are shown separately across trials, intervals, or opportunities, this is an arrangement for a successive discrimination. The learner can observe either the S+ or the S− but never the S+ and S− at the same time. If the S+ is present, the response is reinforced. If the S− is present, the response is not reinforced. The presentations are separated by time: the intertrial interval (ITI). Successive discriminations can be acquired more slowly than simultaneous discriminations (Carter & Eckerman, 1975). An example of a successive simple discrimination is reinforcing the sign *square* when a parent shows a child a square but not when a parent shows a circle.

Simultaneous Simple Discrimination When the S+ and S− are shown together within a trial, interval, or opportunity, this is an arrangement for simultaneous discrimination. That is, the learner can observe both the S+ and S−. Although both stimuli are present in a simultaneous discrimination, only responses to the S+ will be reinforced. An example of a simultaneous simple discrimination is providing a reinforcer for touching the picture of the square in the presence of both the square and the circle picture.

Conditional Discrimination

In a conditional discrimination, reinforcer delivery for responding in the presence of an antecedent stimulus depends on whether an additional antecedent stimulus is present. This additional antecedent stimulus is called a conditional stimulus (also referred to as a sample stimulus) and creates a four-term contingency. To illustrate this, let us consider a child who is learning shapes. Imagine that her parent shows both a picture of the square and the circle, and her parent begins the learning opportunity by signing *square*. When the child touches the picture of the square, the parent smiles and nods. The sign for square determines that the S+ is the picture of the square, and the S− is the picture of the circle. If the parent signs *circle,* then smiles and nods follow the child touching the circle. The sign for the circle determines that the S+ is the picture of the circle, and the S− is the picture of the square. Nothing about the physical properties of the square and circle changed in this example, but the correlation with reinforcement changed because of the parent's sign—the conditional stimulus. The conditional stimulus can also be the context in which the behavior occurs. For example, a child listens to a teacher's instruction, "Get your materials out." The child extracts different materials from his desk depending on whether the teacher just started a math or reading lesson.

Antecedent Stimuli

Any stimulus to which a learner can attend may come to control behavior if the learner's behavior is more likely to be reinforced in the presence of the stimulus than its absence. Thus, behavior can be controlled by isolated or combined auditory, gustatory, olfactory, proprioceptive, tactile, and visual stimuli. Given their prevalence in the everyday environment, auditory and visual stimuli, the foci of the present chapter, are likely to serve as discriminative and conditional stimuli for individuals with intact hearing and sight.

Auditory Stimuli

Auditory stimulus control involves differential behavior in the presence of auditory stimuli. Auditory stimuli may be spoken words, environmental sounds, pure tones, etc. The acquisition of a discriminated operant requires that a learner tells the difference between two or more sounds in their environment, which is observed via differential behavior in the presence of auditory stimuli. An example from a hearing screening test involves a child raising his hand when the tone is present and not raising his hand when the tone is not present.

There are many examples of auditory stimulus control in our daily lives (Saunders & Williams, 1998), and some auditory discriminations may be more important than others. For example, seeking shelter when one hears a tornado siren instead of running outside is an auditory discrimination. Auditory discrimination is important because this stimulus control allows a learner to act on the sounds they hear and is part of many instructional tasks (Serna, 2016). Many children with hearing within normal limits can acquire auditory discrimination of speech sounds through naturally occurring learning opportunities and in a relatively rapid fashion, but these discriminations can be challenging for individuals with intellectual or developmental disabilities (ID and DD, respectively; Serna, 2016). Difficulties acquiring auditory discriminations can render interventions to address social communication skills and verbal behavior less effective (Serna, 2016).

Dimensions and Parameters of Auditory Stimuli Auditory stimuli can be complicated and include multiple dimensions that necessary for discrimination, such as frequency, amplitude, and sound patterns (Serna, 2016). The dimensions of auditory stimuli may be overlooked when behavior analysts design applied-behavior-analytic programs to assess and teach this repertoire. For example, the discrimination of speech sounds, perhaps the most ubiquitous of all auditory stimuli for individuals with hearing within normal limits, requires the learner to differentiate between the individual phonemes that make up a word (Serna, 2016). For example, the difference between the words *van* and *fan* is the voiced or voiceless initial consonant. However, the learner must be able to differentiate between more than the phonetics; a learner must also attend to differences in pitch (i.e., rise and fall), amplitude (i.e., loudness), duration, content (e.g., tense of verbs), and intonation (Schreibman, 1975; Serna, 2016). For example, a caregiver may say a child's name—a stimulus with the same phonemes—with various pitches, amplitude, duration, or intonation. Each variation may be under the control of different stimuli in the caregiver's environment (e.g., a messy room, a low score on a test, beautiful artwork) and suggest reinforcers will follow different behaviors (e.g., cleaning room, studying the course content, creating more artwork). Variations in auditory stimuli create a challenge when one attempts to ensure behavior has come under the control of the relevant stimulus properties instead of irrelevant properties (Halbur et al., 2021).

Visual Stimuli

Visual stimulus control involves differential behavior in the presence of visual stimuli. Visual stimuli can be anything that we can see in our environment like pictures, text (textual stimuli; Skinner, 1957), objects, patterns, and textures. An example from the Ishihara test for colorblindness ("Ishihara Test", 2020) involves individuals saying the numbers in color combinations that they can see and remaining quiet when numbers are in color combinations that they cannot see. There are many examples of visual stimulus control in our daily lives (Saunders & Williams, 1998), and some visual discriminations may be more important than others. For example, stopping at a red light at a busy intersection instead of pressing down on the gas pedal is a visual discrimination. Many individuals of typical development can learn visual discriminations from trial-and-error experiences, whereas individuals with ID or DD may have difficulty acquiring visual discriminations and require intervention (Serna et al., 1997).

Dimensions and Parameters of Visual Stimuli Visual stimuli are reflections of light on an object (Harrison, 1991) and include wavelength (i.e., color), intensity (e.g., brightness, thickness), geometric (e.g., shapes, forms), spatial (e.g., position, orientation), and temporal properties (Balsam, 1988, p. 124). Many basic studies use light sources (e.g., colored keys), quantified with specialized tools (i.e., photometers that can measure the light of any wavelength; Harrison, 1991). The stimuli used in applied discrimination training are not so easily quantifiable, and it can be challenging to define the boundaries which separate the S+ and S−. The visual stimuli may be 2-D or 3-D stimuli that are multidimensional and range from simple (e.g., a card of a single hue) to complex (e.g., a scene of people and animals in a park).

Stimulus Disparity and Stimulus Salience

Two parameters of stimuli used in discrimination training that can affect acquisition are stimulus disparity and stimulus salience (Dinsmoor, 1995b). Although some authors believe that disparity and salience are undifferentiated in applied research (e.g., McIlvane & Dube, 2003), a behavior analyst should consider both, separately and jointly, when selecting antecedent stimuli and analyzing responding for sources of stimulus control (see Halbur et al., 2021, for a discussion of disparity and salience in research and practice).

Disparity of Auditory and Visual Stimuli Stimulus disparity is the degree of physical difference between the S+ and the S− (Dinsmoor, 1995b). When stimuli used in discrimination training are minimally different from one another, then stimulus discrimination acquisition is likely to occur more slowly than when stimuli differ to a greater degree (Dinsmoor, 1995b). There are examples of assessments and interventions which recommend altering auditory stimuli to create more disparate stimuli. One example is the Assessment of Basic Learning Abilities (ABLA-R, Martin et al., 2014) wherein assessors present spoken stimuli "red box" and "yellow can" with different pitches and tempos (e.g., "red box" with low pitch and staccato tempo). In another example, the sequence recommended in an auditory-matching procedure decreases stimulus disparity as a learner moves through the phases: environmental sound vs. no sound, environmental sound vs. white noise, environmental sounds vs. environmental sound, word vs. environmental sound, word vs. nonsense word, word vs. phonetically dissimilar word, and word vs. phonetically similar word (e.g., Du et al., 2017). Research has not evaluated whether each phase in the auditory-matching procedure is necessary; however, programming highly disparate stimuli for the S+ and S− at the beginning of training could promote faster acquisition (Halbur et al., 2021).

Disparity is important to consider with visual stimuli, too. The degree of difference between visual stimuli can affect acquisition speed (e.g., Hannula et al., 2020). Hannula et al. (2020) manipulated the stimulus disparity between the sample (Experiment 1) and comparison stimuli (Experiment 2) in conditional discrimination training. The experimenters manipulated the disparity by increasing and decreasing the red saturation (i.e., from light pink to dark red). The three participants in Experiment 1 responded with lower accuracy when the sample stimuli were similar in red saturation (i.e., low disparity) compared to their responses when the sample stimuli were dissimilar (i.e., high disparity). The three participants in Experiment 2 responded with lower accuracy when the comparison stimuli were similar in red saturation (i.e., low disparity) compared to their responses when the comparison stimuli were dissimilar (i.e., high disparity). Therefore, instructors should consider initiating training with highly disparate stimuli and gradually transitioning to just barely disparate stimuli; this process is a progressive discrimination (Dinsmoor, 1995b).

In addition to quantifiable differences in intensity or wavelength, the disparity of visual stimuli may include parts or elements of a stimulus that come to control responding (Balsam, 1988). The critical features are those components of a stimulus class that define or differentiate stimuli that fall within the boundaries of the class (i.e., "must have" attributes; Layng, 2019). The noncritical or variable features are the components of stimuli that do not define class membership but can occur in one or more exemplars (i.e., "can have" attributes; Layng, 2019). Learners acquire discriminations within and between stimulus classes because of differential reinforcement in the presence and absence of critical features. For example, the critical feature of a bowl is its concave shape with edges and bottom creating a curve without seams ("Bowl", 2020). Bowls can vary in their size, color, material, design, and depth. To acquire the stimulus class of "bowl," a learner's behavior must be reinforced in the presence of stimuli that retain the critical feature and include different variable features. The same behavior should not be reinforced in the presence of stimuli that lack the critical feature. Varying noncritical features across members and nonmembers of a stimulus class can lead to faster acquisition and generalization to untrained exemplars (Song et al., 2021).

Salience of Auditory and Visual Stimuli Stimulus salience refers to the difference between the S+ and the surrounding environment (Dinsmoor, 1995b). If the S+ is easily discriminable from stimulation in the background—in intensity or identifiable features—it will be more likely to occasion responding (cf. Halbur et al., 2021). Pierrel et al. (1970) evaluated the effects of the salience of auditory stimuli in discrimination training with rats. The disparity between the S+ and S− was held constant at 10 dB, but the salience was manipulated by selecting dB levels that were either more or less intense based on their loudness against the background (i.e., 90–100 dB and 60–70 dB). Pierrel et al. found that the rats assigned to the conditions with stimuli with higher dB levels acquired the discrimination more quickly. The salience (i.e., loudness) of auditory stimuli has been included in investigations on vocal imitation (Risley & Reynolds, 1970) and listener discriminations (e.g., following spoken instructions; Smeets & Striefel, 1980). The use of a differential observing response (described below) when teaching discriminations of auditory stimuli could make the relevant auditory stimuli stand out from the background stimulation (i.e., increase their salience).

The importance of stimulus salience in visual discrimination was discovered in research designed to study selective control and stimulus disparity on observing (Dinsmoor, 1995b). For example, Johnson (1970) found that pigeons learned the discrimination between a horizontal and vertical line at different rates due to the brightness of the line (i.e., how much the line stood out from the background of the response key). In general, the more that a visual stimulus or a component of the visual stimulus stands out from the background, the greater control the stimulus will come to have over responding (Balsam, 1988).

Importance of Stimulus Disparity and Salience when Teaching Discriminations The selection of auditory and visual stimuli should be considered carefully when teaching discriminations. Programs that aim to teach listener discriminations (i.e., auditory discrimination; e.g., instruction following, AVCD) recommend that auditory stimuli do not include additional words (e.g., "Show me;" Grow & LeBlanc, 2013) nor overlapping actions in the beginning of training (Lovaas, 2003). As the learner acquires some discriminated operants, additional words and overlapping actions should be added to verify conditional control of the S+. Programs to teach visual–visual or auditory–visual discriminations should consider how visual similarities can affect acquisition. When beginning instruction, selecting visual stimuli with few overlapping or common features will likely result in more rapid acquisition (Grow & LeBlanc, 2013; Halbur et al., 2021). The program can progress from easy discriminations (i.e., high disparity and salience) to more difficult discriminations (i.e., low disparity and salience).

When conducting comparative analyses on procedures to teach discriminations, it is important to consider how stimuli are assigned to different conditions to equate disparity and salience (Wolery et al., 2018). For auditory stimuli, it is recommended that one avoids assigning stimuli with the same phonemes or rhymes within the same condition because this could increase the difficulty of the condition and influence internal validity (Cariveau et al., 2021). Unlike the relatively strong recommendations for identifying and assigning auditory stimuli using a logical analysis procedure (Cariveau et al., 2021; Grow & LeBlanc, 2013), there are fewer recommended practices for visual stimuli. Cariveau et al. (2021) recommended we consider features such as background and shape. It may also be important to consider the number of overlapping variables or noncritical features (Halbur et al., 2021).

Assessing and Teaching Stimulus Discriminations

Auditory, visual, and auditory–visual simple and conditional discriminations can be arranged in various ways and taught with several empirically validated procedures. However, the conditions under which procedures are implemented should be considered when selecting interventions. Furthermore, intervention components may be added during training to increase the salience of the sample and comparison stimuli, provide additional opportunities to respond to the stimuli following an error, and arrange different consequences for independent and prompted correct responses.

Procedural Arrangements

Several procedural arrangements have been employed to assess and teach simple and conditional auditory and visual discriminations. The procedures include at least one antecedent stimulus, the S+ or the S−, and may include additional antecedent stimuli like a conditional stimulus (referred to as a sample stimulus in match-to-sample [MTS] procedures). Some procedures present two or more stimuli in an array, and these stimuli are referred to as comparison (i.e., choice) stimuli (Green, 2001). One of the comparisons is correct (S+), and the other(s) is incorrect (S−). The learner's selection behavior (e.g., pointing to, picking up, handing to the instructor, tacting [i.e., labeling]) toward the S+ is reinforced. Whether antecedents serve as only the S+ or S− or both the S+ and S− determines whether the discrimination is simple or conditional, respectively. The number of antecedent stimuli present at one time determine whether the discrimination is successive or simultaneous, respectively.

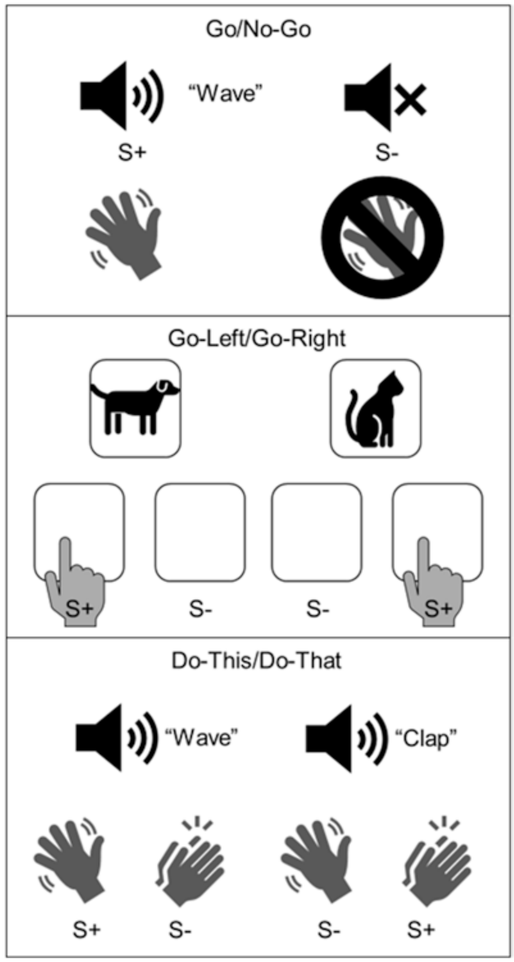

Fig. 13.1 Example trials of Go/No-Go, Go-Left/Go-Right, and Do-This/Do-That procedures. *Note.* In Go/No-Go (top), waving is reinforced when the auditory stimulus "Wave" is present and is not reinforced in its absence. In Go-Left/Go-Right (middle), touching the left stimulus is reinforced when the dog is present, and touching the right stimulus is reinforced when the cat is present. The comparison stimuli can be blank, as shown, or may have arbitrary forms or figures. The location remains static throughout all Go-Left/Go-Right trials. In Do-This/Do-That (bottom), waving is reinforced when "Wave" is present, and clapping is reinforced when "Clap" is present

Go/No-Go Procedures

In go/no-go procedures (Fig. 13.1, top panel), emitting the target behavior in the presence of the S+ is reinforced, and emitting the target behavior in the presence of the S− is extinguished. Typically, the two stimuli are presented for a specific duration or until a response occurs. Emitting the response in the presence of the S+ and not emitting the response in the presence of the S− is correct, and the opposite patterns are incorrect (Saunders & Williams, 1998). A go/no-go procedure includes reinforcing the target response during the S+ interval. It may include the presentation of a reinforcer if the learner does not emit the response during the S− interval (Saunders & Williams, 1998). The go/no-go procedure is a simple successive discrimination (see Saunders & Williams, 1998, for a discussion about conditionality).

Some go/no-go procedures use a presence vs. absence discrimination, whereas others use two different stimuli in a quality discrimination (Serna, 2016). An example of a quality discrimination is presenting the instructions “Clap hands” and “Touch tummy” and reinforcing hand clapping only in the presence of the former. The go/no-go procedure would not teach the touch tummy action, as the function of including another instruction would be to verify that “Clap hands” rather than any vocal stimulus evokes hand clapping. Serna et al. (1992) used go/no-go to teach two women with ID to touch a screen only when the computer said “Touch.”

Serna (2016) highlights a potential issue when using go/no-go procedures with individuals with ID or DD, especially if the individual has a history of reinforcement for touching stimuli in the past. Serna described a predisposition to “go” (i.e., emit the target response) regardless of the presentation of the S+ or S−. Serna (2016, p. 244) reported that go/no-go “yielded less successful results” when it was used with additional adults with ID following the success of the Serna et al. (1992) study. Bergmann et al. (2021) reported that three of the five child participants, two of whom were diagnosed with ASD and one of whom was typically developing, touched the card on 100% of trials regardless of which auditory stimulus was present. A predisposition to “go” is a potential limitation of the go/no-go procedure that behavior analysts should consider before using it in a learner’s intervention programming.

Go-Left/Go-Right or Yes/No Procedures

An alternative to the go/no-go procedure that requires a response on each trial is referred to as a go-left/go-right or yes/no procedure (Fig. 13.1, middle panel). In this procedure, there are two visual stimuli in an array. The visual stimuli may be blank or have figures or words written on top. One stimulus is positioned to one side of the response field, and the other stimulus is positioned on the other side; the stimuli may be arranged on the left and right or top and bottom, but their positions remain fixed from trial to trial. The conditional stimulus is presented, and a selection response is directed toward the comparison in the left or right position depending on which stimulus is present. Because the comparison stimulus on the left is either the S+ or S− depending on which antecedent stimulus is presented, this is a simultaneous conditional discrimination procedure. Schlund (2000) used a go-left/go-right procedure with one adult participant with a traumatic brain injury. The participant picked up a red poker chip when he could hear the tone and picked up a white poker chip when he could not hear it. The topography (i.e., form) of the response looked the same across trials, and the tone’s presence or absence determined which poker chip was the S+.

Do-This/Do-That Procedures

In contrast to the topographically similar responses in go-left/go-right procedures, the do-this/do-that procedure (Fig. 13.1, bottom panel) involves emitting topographically distinct responses in the presence of two or more stimuli. When one stimulus is present, “doing this” is reinforced, and when another stimulus is present, “doing that” is reinforced. For example, in the presence of “Clap your hands,” clapping is reinforced, and in the presence of “Stomp your feet,” stomping is reinforced. More than one stimulus and response should be included in training from the outset to increase the likelihood that the auditory or visual stimulus controls behavior. No comparison array is used with do-this/do-that, so it is a simple successive discrimination.

Schlund (2000) taught one adult male with a traumatic brain injury to engage in two different behaviors to complete a hearing screening assessment. The participant learned to wave his arms above his head and nod when he could hear the tone and shake his head when he could not hear the tone. Bergmann et al. (2021) included do-this/do-that in an auditory discrimination assessment. For example, participants knocked on the table in the presence of the word "foam" and waved in the presence of the word "gift." The do-this/do-that procedure was the arrangement that led to mastery in 90% of the evaluations conducted by Bergmann et al.

Matching-to-Sample (MTS) Procedures

A robust literature base has investigated MTS in basic, translational, and applied studies with a variety of nonhuman subjects and human participants. Although the MTS procedure can be used with stimuli across an organism's senses (e.g., see Dass et al., 2018 for an example of MTS with olfactory stimuli), this chapter will focus on preparations with auditory and visual (2-D and 3-D) stimuli. The MTS procedure (Fig. 13.2) includes presenting a sample stimulus and comparison array, and it is a conditional discrimination procedure. In MTS, the learner must observe the sample stimulus, discriminate the sample stimulus from other sample stimuli presented on successive opportunities, discriminate the sample stimulus from the comparison stimuli, and discriminate each comparison stimulus from one another (Green, 2001). Therefore, this procedure involves successive simple discrimination and simultaneous conditional discrimination. The MTS procedure can be either simultaneous—the sample stimulus remains in the environment when the comparison stimuli are available—or delayed—the sample stimulus is removed from the environment before the comparison stimuli are available (Pilgrim, 2015). Time to acquisition increases with the duration of delay (Mackay, 1991).

Identity In identity MTS (Fig. 13.2, top left panel), at least three stimuli are presented, including one sample and two or more comparison stimuli. The sample and S+ comparison stimuli are identical physically. Stimuli could include the same auditory stimuli (e.g., "Cat" and "Cat") or visual stimuli (e.g., two pictures of a cat). A reinforcer is provided when the learner selects the identical S+ in the presence of the sample stimulus. Kodak et al. (2015) included an identity MTS procedure. Participants with ASD touched the comparison stimulus that matched the 2-D sample stimulus, and all nine participants passed the identity MTS subtest. Some behavior analysts reserve the term "identity matching" for a conditional discrimination repertoire that extends beyond matching with a limited stimulus set and should only be used when a learner can match novel samples and comparisons (Catania, 2013, p. 158).

Oddity The oddity MTS procedure (Fig. 13.2, top right panel) is arranged like the identity MTS procedure with one sample stimulus and at least two comparison stimuli. In the oddity procedure, there will be at least one comparison stimulus physically identical to the sample stimulus and one stimulus that is physically different (Pilgrim, 2015). The difference between the identity and oddity MTS procedures is that the physically identical comparison stimulus is the S− and the physically different stimulus is the S+. Therefore, a reinforcer is provided when the learner selects the comparison stimulus that does not match the sample stimulus. Soraci et al. (1987) evaluated the performance of five preschool children who were at risk for ID on an oddity task. The participants acquired the oddity relation only after the experimenters increased the number of non-odd stimuli (S−) in the array. In Soraci et al., accurate performance was maintained as they faded the modification. The authors reported that this outcome was significant because children with ID and DD routinely perform below peers in oddity procedures, perhaps due to insensitivity to the relations between stimuli.

Arbitrary In an arbitrary MTS procedure (Fig. 13.2, bottom left panel), the samples and comparison stimuli are all physically different. The sameness relation of the sample stimulus and the S+ comparison stimulus is based on something other than identity. For example, an arbitrary MTS procedure could include the number 8 and a grouping of eight items or the word "eight." There may be other relations included in an arbitrary MTS procedure like similarities based on category or class (e.g., sample is a coat and the

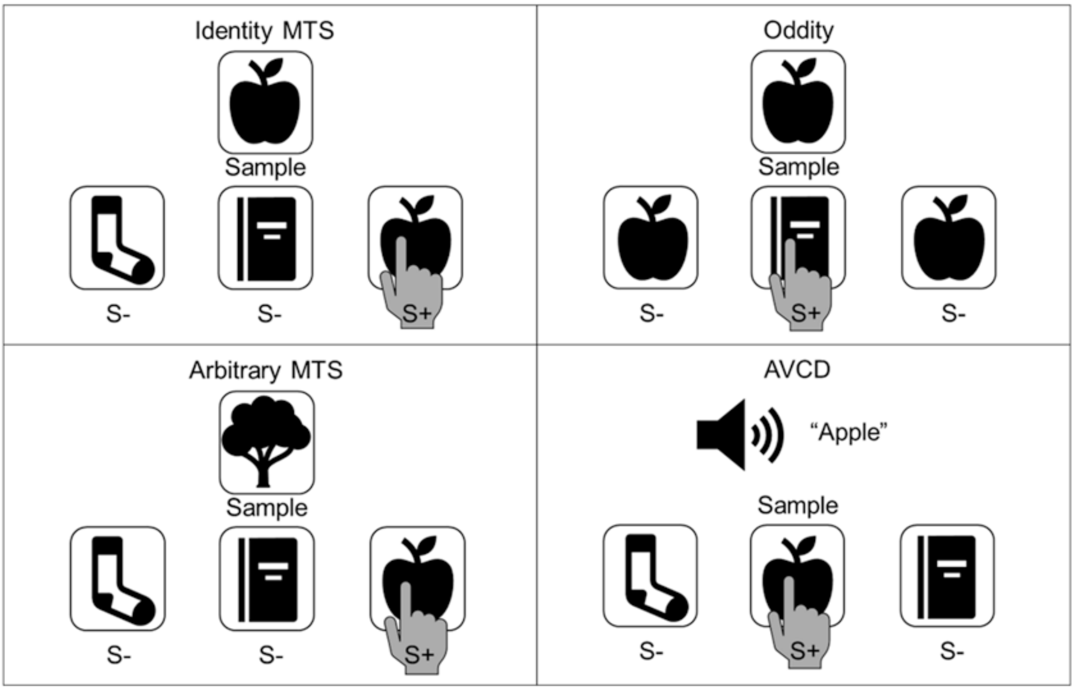

Fig. 13.2 Example trials of MTS procedural arrangements. *Note.* In identity MTS (top left), the sample and S+ are physically identical stimuli. In oddity (top right), the sample and S+ are not physically identical. In arbitrary MTS (bottom left), the sample stimulus and S+ are not physically similar, and the instructor determines the relation. In this figure, the apple is the S+ because it grows on a tree. In AVCD (bottom right), a type of arbitrary MTS, the sample and S+ are not physically similar, and the auditory sample determines which visual stimulus in the array is the S+

S+ is a pair of pants because they are clothing), function (e.g., sample is an oven and the S+ is a microwave because they heat food), or feature (e.g., sample is a horse and S+ is a cat because they have tails). Arbitrary relations can be used with an oddity MTS procedure, too.

An arbitrary MTS procedure may include control by a spoken sample and visual comparison stimuli. For example, the sample stimulus "Red" is spoken in the presence of a red card (S+) and a green card (S−); touching the red card would be selected. This type of discrimination is an auditory–visual conditional discrimination (AVCD; Fig. 13.2, bottom right panel). There are many examples of AVCDs in our day-to-day interactions. For example, if a parent asked a child to get her spelling list from her bedroom, the child would scan the visual stimuli in her room. The auditory stimulus "spelling list" would evoke picking up the spelling list instead of other items like a soccer ball or sweatshirt. Many individuals acquire an AVCD repertoire through these everyday experiences, yet some individuals, including children with ASD, require an intervention.

Teaching Procedures

Simple Discriminations

Trial-and-error procedures, which reinforce correct responses and move to an ITI following an error, can teach stimulus discriminations. Trial-and-error procedures are not recommended for individuals with ID, DD, ASD, or other learning difficulties (Saunders & Williams, 1998). An errorless procedure that can be used to teach a successive simple discrimination involves gradually modifying the duration of the S+ and S− intervals. The training begins with the S+ present, and the target response is reinforced. For very brief periods, the S+ is replaced by the S−. Brief presentations decrease the probability that the learner will emit a response in the presence of the S−. If the learner does not respond in the presence of the S−, the instructor presents the reinforcer or switches to the S+; emitting the response in the presence of the S− delays the presentation of the S+ (i.e., changeover delay). Terrace (1963) trained pigeons to peck only in the presence of a red light (S+) and not peck in the presence of an unlit key (S−) by gradually increasing the duration of the S−.

Conditional Discriminations: Simple-Conditional and Conditional-Only

Several early intervention curricula recommend a simple-conditional method for AVCD training (e.g., Lovaas, 1981). In initial steps of the simple-conditional method, simple discrimination is taught in isolation in a massed-trial format (e.g., the spoken word “apple” and only the picture of the apple). Only after several steps does training target a conditional discrimination among the three stimuli wherein the sample stimulus varies, and each stimulus serves as an S+ and S− across trials. Refer to Grow et al. (2011) for a diagram of the nine steps of the simple-to-conditional method. In comparison, AVCD may be taught with a conditional-only method in which the discriminations of multiple samples and comparison stimuli are targeted from the outset. Throughout all trials in conditional-only, a learner must attend to the auditory sample (e.g., the spoken word “apple,” “book,” or “sock”), scan the array of comparison stimuli (pictures of the apple, book, and sock), and select the comparison that matches the sample.

Research comparing the simple-conditional and conditional-only method supports the use of the conditional-only method with learners with DD. Grow et al. (2011) compared these two methods of AVCD training with three participants with ASD; they replicated the comparison several times with each participant. The conditional-only method was effective in seven of the eight comparisons, whereas the simple-conditional method was effective in four of eight comparisons. The conditional-only method often required fewer training trials, too. In addition, participants required modified intervention in the simple-conditional method to reduce biases and error patterns (i.e., faulty control; see below) in four of the eight comparisons.

Researchers have proposed that the simple-conditional method may be unnecessarily lengthy and more likely to establish biased responding due to the inclusion of isolation training (Grow et al., 2011; see Grow & Van Der Hijde, 2017, for a replication which omitted isolation training; see Fisher et al., 2019 and Lin & Zhu, 2020 for a potential relationship between novice and experienced learners and the simple-conditional method). When stimuli are presented in isolation (e.g., there is only one picture in an array), the learner is not required to attend to the auditory sample stimulus (e.g., the spoken word “apple”). Instead, the learner can touch one picture in the array across trials, and this pattern of responding produces reinforcers consistently. Thus, responding may come under the restricted stimulus control of one picture rather than the combination of the picture in the comparison array and the auditory sample stimulus. Furthermore, Green (2001) recommended careful arrangement of instruction to promote the development of relevant sources of stimulus control, which includes training conditionally and avoiding training in isolation or with distractors (Table 13.1).

Procedural Components and Arrangements

Trial-Initiation Response Before an instructor begins a learning trial, the learner emits a specific response (e.g., places hands in lap, raises hand) to initiate the trial (see Campanaro et al., 2020, for an example teaching procedure). The use of a trial-initiation response can increase the likelihood that the learner attends to the conditional stimulus, which could be especially beneficial when the conditional stimulus is not repeated (e.g., a non-repeated auditory stimulus, delayed MTS; Saunders & Williams, 1998).

Table 13.1 Arrangements to promote appropriate stimulus control in conditional discrimination training

Arrangement	Description	Purpose
Counterbalance S+, S− presentations and positions	Present each S+ the same number of times but never more than two times in a row. Arrange S+ and S− in each position an equal number of times.	Decrease the likelihood that discrimination comes to be controlled by position or location.
Number of comparison stimuli	Include at least three comparison stimuli in an array.	Reduce the likelihood of stimulus or position biases because reinforcement schedule is thinned.
Same comparison stimuli	Include the same comparison stimuli on every trial. Do not include novel S−.	Learners can come to respond away from novel stimuli. Functions like an array of one or two.
No distractor stimuli	Include comparison stimuli that are both S+ and S−. Do not include stimuli that are always S−.	Learners can come to respond away from stimuli that are only S−. Functions like an array of one or two.
Comparison stimuli out of view	Arrange comparison stimuli out of the learner's view (e.g., hook-and-loop tape on board, use barrier).	Avoid providing extraneous, inadvertent prompts (e.g., straightening S+) that can control responding.
Observing response	Program an observing response for sample stimuli before the comparison stimuli are available.	Increase the likelihood a learner attends to the sample stimulus. Without attending to the sample, other stimuli likely to control the response.
Auditory sample stimulus	Provide only auditory stimuli necessary to determine the S+. Do not add additional like "give me."	Increase the likelihood a learner attends to the relevant auditory stimulus. Increase disparity.
Teach pointing	Teach the learner to point to the stimulus instead of handing the S+ or placing the sample atop the S+.	Pointing is a functional response, applicable regardless of S+ size. Placing the sample could teach the learner to attend to identical features only.
Prompts and prompt fading	Use prompts and prompt fading rather than trial-and-error (differential reinforcement alone).	Prompt the response and reinforce. Differential reinforcement without prompts can create error patterns.

Note. The arrangements to promote appropriate stimulus control do not guarantee that instructor-defined stimulus control will develop. These recommendations are from Green (2001), Grow and LeBlanc (2013), and Saunders and Williams (1998)

Stimulus-Presentation Order When conducting discrimination training with multiple antecedent stimuli (e.g., AVCD, AMTS), the instructor can present the conditional stimulus before, after, or at the same time as the comparison stimuli. Green (2001) recommended presenting the conditional stimulus before the comparison stimuli, whereas McIlvane et al. (1990) recommended presenting the comparison stimuli first. Several studies have compared acquisition with different stimulus-presentation orders (e.g., Cubicciotti et al., 2019) with either a relative advantage of sample-first presentations or learner-specific outcomes.

Observing Response and Differential Observing Response (DOR) Learners must observe all relevant features of stimuli arranged in discrimination training to acquire the targeted discrimination. If the relevant features are not observed, the discrimination will not be established or may come under the control of one or more irrelevant features (i.e., faulty, restricted stimulus control). For example, if a child attends only to the first letter of words while reading, the child's behavior is under restricted stimulus control. Until this child attends to all letters in written text, she will not become a fluent reader nor comprehend written text.

Observing responses are emitted in the presence of a sample stimulus and must occur before the comparison stimuli are presented. When using an observing response, the learner emits the same response in the presence of each sample stimulus. Observing responses can increase the likelihood that a learner has observed the sample stimulus (Green, 2001). A DOR also occurs in the presence of the sample stimulus, but it requires a distinct response to each sample stimulus (or each component of a sample stimulus) included in discrimination training. A DOR provides an overt response to indicate attending to each sample and may prevent or remediate restricted stimulus control.

Researchers have programmed different topographies of DORs in training, such as requiring an echoic response (e.g., Fisher et al., 2019) and motor responses (e.g., sign; Elias & Goyos, 2013). Walpole et al. (2007) had a participant with ASD match unique letters in words with overlapping components (e.g., matched n and t for *man* and *mat*, respectively) before matching whole words. The inclusion of a DOR in training increased levels of correct matching, and accurate responding maintained following the removal of the DOR.

Nevertheless, other researchers found that removing the DOR from training resulted in a return to low or intermediate levels of accuracy (e.g., Farber et al., 2017). Thus, Farber et al. evaluated a gradual reduction in the frequency of DORs during conditional discrimination training and found this approach resulted in maintained accuracy and overall improvements in observing behavior during training. Therefore, it is recommended that practitioners who include DORs in discrimination training carefully review the effects of removing the DOR on discriminated responding and consider gradually thinning the frequency of DORs during training if highly accurate responding does not maintain without the DOR.

Prompts Prompts are used to occasion a correct response in the presence of one or more programmed stimuli—either a visual stimulus, auditory stimulus, or both—during the initial stages of discrimination training. Prompts are a type of assistance or modification made to instruction that increases the likelihood of a correct response, which produces a reinforcer, and increases the future likelihood of the response under similar stimulus conditions.

Extra-Stimulus Prompts An extra-stimulus prompt involves adding a stimulus to the environment to occasion a correct response to the target stimulus. For example, an instructor points to an apple in an array of visual comparison stimuli immediately after saying, "apple." The instructor's point is an extra-stimulus prompt, and it should result in the learner imitating the instructor by pointing to the picture of the apple, which produces a reinforcer.

Early research on extra-stimulus prompts showed they might be challenging to fade because learners made errors as the prompts were removed and failed to acquire the stimulus discrimination (e.g., Schreibman, 1975). For example, Schreibman et al. (1982) used a point prompt as an extra-stimulus prompt to teach four children with ASD to point to a visual S+ in an array of three visual stimuli. This training targeted a simple visual discrimination, because one stimulus remained the S+ across all trials. Training began with the point prompt positioned immediately in front of the stimulus, and this prompt was faded by increasing the distance between the point prompt and the S+. The fading procedure was terminated and considered unsuccessful for all participants due to frequent errors.

Based on the results of Schreibman et al. (1982) and others (e.g., Koegel & Rincover, 1976), researchers hypothesized that early studies on extra-stimulus prompts were unsuccessful in teaching simple and conditional discrimination to children with ASD due to restricted attending to the point prompt rather than the aspects of the stimulus necessary to acquire the discrimination. However, research that followed showed that extra-stimulus prompts could be successful when combined with prompt-fading procedures, such as a prompt delay (Wolery et al., 1988). Wolery et al. (1988) combined an extra-stimulus prompt with a progressive-prompt delay in which the authors gradually increased the latency from the presentation of the visual stimulus to the extra-stimulus prompt. All three participants learned the targeted simple discriminations, and the extra-stimulus prompt was faded successfully. Thereafter, researchers have combined extra-stimulus prompts and prompt-fading procedures to teach simple and conditional discrimination to children with ASD (e.g., Kodak et al., 2011; McGhan & Lerman, 2013). Based on empirical support for extra-stimulus prompts combined with prompt-fading procedures over the past 30 years, these prompts are commonly used in early intervention services for children with ASD and other DD (Love et al., 2009).

Within-Stimulus Prompts A within-stimulus prompt involves manipulating one or more features of the S+ or S− to assist the learner in responding to the correct comparison stimulus. Once consistent responding to the stimulus is achieved, aspects of the manipulation are removed gradually to return stimuli to their original forms. Within-stimulus prompts can be arranged in several ways, including superimposition (e.g., Birkan et al., 2007), size (e.g., Zawlocki & Walls, 1983), and intensity (e.g., Schreibman, 1975). For example, Zawlocki and Walls (1983) used within-stimulus prompts of size fading to teach visual discriminations to 13 individuals with ID. The S+ circles were initially increased in size to occasion responding to them, and then the size was faded gradually across trials as the size of the S− circle remained consistent. Participants acquired the targeted discriminations with fewer errors when compared to a no-fading condition. Fading is a crucial component of transferring control from the within-stimulus prompt to the relevant features of the S+. It is recommended that instructors modify the S+ rather than the S− to facilitate the transfer of stimulus control (Dinsmoor, 1995b). In addition, Fields (1978) suggested inserting terminal-probe trials into fading to determine whether all fading steps are necessary and to detect transfer of control.

Despite the efficacy of within-stimulus prompts, there are drawbacks to using this type of prompt fading during instruction. Several features may be critical to the targeted discrimination among stimuli, making it difficult for the instructor to select the feature(s) to manipulate. Material preparation can be time-consuming due to the production of stimuli that contain small variations among many fading steps (Green, 2001). Furthermore, materials management can be cumbersome for an instructor who must organize these materials and present the stimuli related to the current fading level. The use of technology (e.g., slideshows of stimuli presented on tablets) may alleviate the burden of managing printed materials, although empirical evidence for this recommendation is needed. Practitioners should consider the costs and benefits of within-stimulus prompts when selecting prompts in discrimination training.

Error Correction When a learner errs during discrimination training, an instructor has several options for correcting the error. In early discrimination training studies, instructors said “no” following an error and moved to the next trial (e.g., Schreibman, 1975). However, other—more effective strategies—have replaced this practice, such as providing one or more active response opportunities to the learner following an error (McGhan & Lerman, 2013). For example, following a response to the S− on a trial, an instructor repeats the auditory sample stimulus (e.g., says, “apple”) while pointing to the S+ (the picture of the apple in the array) and provides a learner with an opportunity to imitate pointing to the S+. After that, an instructor could move on to the next instructional trial or repeat the erred trial until the learner engages in an independent correct response to the S+ one time (a procedure called re-present until independent; Carroll et al., 2015) or multiple times (a procedure called directed rehearsal; McGhan & Lerman, 2013). The most effective and efficient error-correction procedure to include in discrimination training may be specific to the learner, suggesting that an assessment could inform intervention (e.g., Carroll et al., 2015; McGhan & Lerman, 2013).

Differential Reinforcement Differential reinforcement is a treatment component that is commonly combined with other interventions, such as a prompt delay (Vladescu & Kodak, 2010). Differential reinforcement is a critical component of discrimination training because responses to the S+ are reinforced, whereas responses to the S− are not reinforced (referred to as trial-and-error; Saunders & Williams, 1998). However, differential reinforcement is commonly arranged for independent and prompted correct responses as well (Love et al., 2009). For example, Hausman et al. (2014) arranged varying reinforcement schedules for prompted responses during discrimination training for three participants with ID. Independent correct responses produced reinforcement on a fixed-ratio 1 (FR 1) schedule, whereas the reinforcement schedule for prompted responses varied across three conditions (FR 1, FR 3, and extinction). Two participants had higher levels of independent correct responding when prompted correct responses were never reinforced.

Several types of differential reinforcement may be arranged during discrimination training. In addition to different reinforcement schedules described above, researchers and practitioners may arrange differential qualities and magnitudes of reinforcers for independent and prompted responses. During intervention, independent correct responses produce higher quality or larger magnitude reinforcers, whereas prompted correct responses produce lower quality or smaller magnitude reinforcers (e.g., Johnson et al., 2017). The most effective and efficient differential reinforcement arrangement may be learner-specific; an assessment may help select an arrangement for discrimination training for a learner (Boudreau et al., 2015).

Furthermore, differential reinforcement has often been implemented at varying times during instruction, such as being implemented from the onset of instruction (e.g., Karsten & Carr, 2009) or after independent correct responding meets a criterion (e.g., Carroll et al., 2015). One study that assessed the onset of differential reinforcement found immediate onset resulted in the most efficient mastery of skills in six of the seven comparisons (Campanaro et al., 2020).

Differential Outcomes Effect Conditional discriminations may be more readily acquired if a different consequence is provided following responses emitted in the presence of different antecedent stimuli—this is the differential outcomes effect (DOE; McCormack et al., 2019). When arranging instruction for a conditional discrimination, the instructor provides different reinforcers following responses to each conditional stimulus. For example, an instructor provides an airplane toy when the child waves his hand after the instruction "Wave" and a superhero action figure when the child stomps his feet after the instruction "Stomp." McIlvane and Dube (2003) posited that differential consequences increase the discriminability between antecedent and response relations and may promote the acquisition of the instructor-defined discriminations rather than faulty stimulus control. Basic research with humans and nonhumans and applied research with adults and children with and without disabilities supports DOE to enhance acquisition of conditional discrimination, especially in MTS arrangements (see McCormack et al., 2019, for a review). For example, Estévez et al. (2003) found that arranging differential outcomes in conditional discrimination training led to better accuracy and faster learning for 19 of 24 children and adults with Down syndrome.

Over 40 studies on the DOE have been published, and a meta-analysis found medium-to-large effect sizes (McCormack et al., 2019). Still, it is unknown how frequently the DOE is used in applied-behavior-analytic intervention. To incorporate the DOE into practice, an instructor must identify many reinforcing stimuli and pair these reinforcers with specific antecedents and responses. If the learner's reinforcers are limited, there will be insufficient variation for programming. Thus, the instructor may need to provide exposure to various items, activities, and edibles to expand available reinforcers before using the DOE. Technology may permit incorporating the DOE in practice if a variety of pictures, games, and video clips increase a learner's behavior; however, this needs to be evaluated empirically.

Issues and Modifications to Consider when Establishing Stimulus Control

Whether one is establishing simple or conditional discriminations, there are recommended arrangements to reduce unwanted sources of stimulus control (Table 13.1).

Identifying Unwanted Sources of Control

Identifying the source of control when a learner fails to acquire conditional discriminations could inform manipulations of antecedent- and consequence-based interventions to resolve problematic response patterns (Hannula et al., 2020). An analysis of stimulus control topography coherence (McIlvane & Dube, 2003) with a kernel analysis (Fields et al., 2010) could inform decisions regarding stimulus control in conditional discrimination training. A component analysis can be used to detect the stimulus component controlling responding, which may be pertinent when concerned about stimulus overselectivity (i.e., restricted control by one or subset of stimulus components, Lovaas et al., 1979). Additionally, an instructor can use error analyses to determine if the learner is emitting molecular (i.e., controlled by the previous trial) or molar (i.e., controlled by previous training conditions) error patterns that suggest faulty sources of control (Grow et al., 2011; Hannula et al., 2020).

Error analyses conducted within conditional discrimination training can reveal patterns of responding like win-stay, lose-shift, win-shift, and position biases (Fig. 13.3). Sometimes these response patterns are beneficial (e.g., shifting responding away from an S− is a hallmark pattern of rapid acquisition in learning sets; McIlvane, 2013), but these response patterns can be problematic. Win-stay errors (Fig. 13.3, top left panel) occur when a learner engages in the same response or selects the same comparison stimulus that was reinforced in a previous trial(s) or training condition (Grow et al., 2011; Lovaas, 2003). A win-stay response pattern is more likely to occur when one stimulus is presented as the S+ in successive trials (Lovaas, 2003). Lose-shift errors (Fig. 13.3, top right panel) occur when a learner engages in a response or selects a stimulus other than the response or stimulus, respectively, that was not reinforced in the previous trial or training condition (Grow et al., 2011; Lovaas, 2003). Lose-shift errors are more likely to occur when the instructor alternates between two stimuli in a non-random fashion (Lovaas, 2003). Win-shift errors (Fig. 13.3, bottom left panel) occur when a learner emits the other response or selects the other stimulus when a response or stimulus produced reinforcement in the previous trial (Lovaas, 2003). Win-shift responses are more likely to occur when the instructor alternates between two stimuli (Lovaas, 2003). A position bias (Fig. 13.3, bottom right panel) occurs when the learner continues to select the stimulus in a specific position in the array regardless of which conditional stimulus is presented (Hannula et al., 2020). A position bias may be more likely when the location of the S+ is not counterbalanced across trials and samples and when there are fewer than three comparison stimuli (Green, 2001).

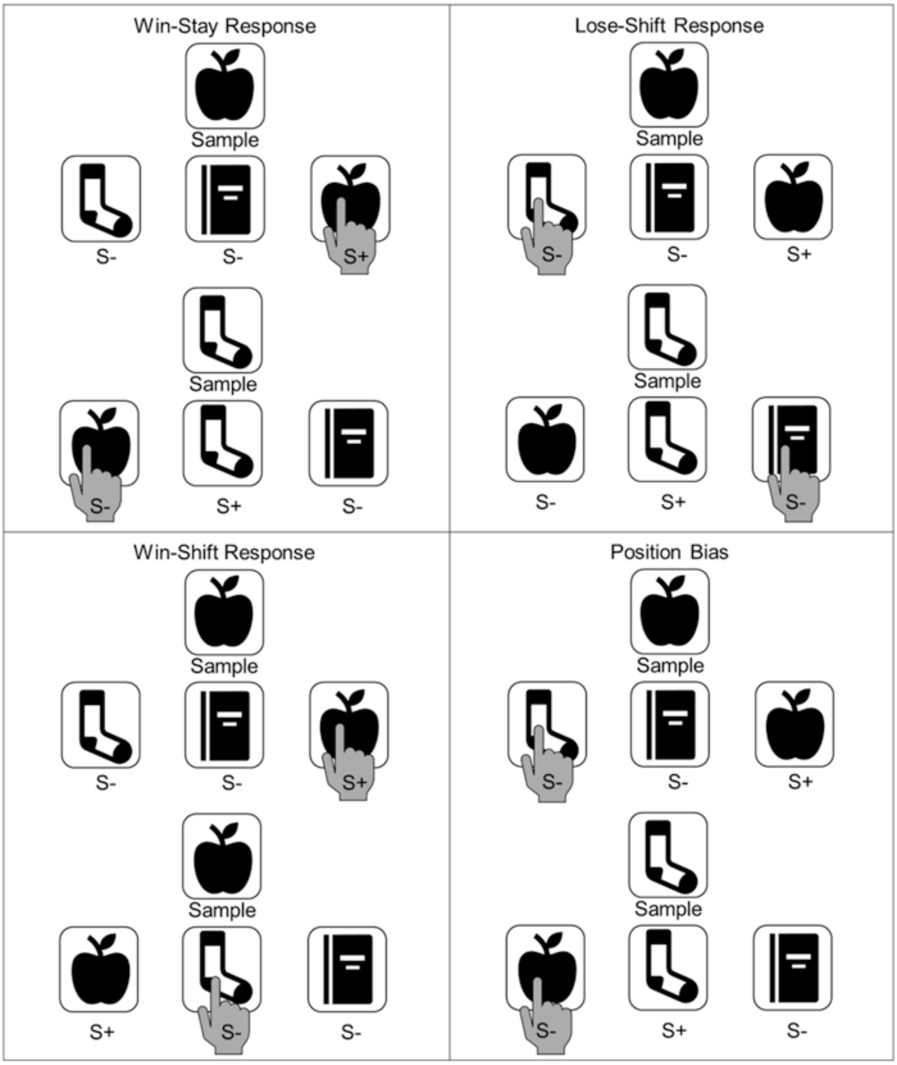

Fig. 13.3 Examples of potential problematic sources of control. *Note.* Each panel represents a possible series of trials showing molecular error patterns

Because stimulus control topography and error analyses require effortful data collection and expertise, it is recommended that instructors avoid using strategies that may promote faulty stimulus control from the outset (Grow et al., 2011; Table 13.1). Therefore, instructors should begin with conditional-only training, which is less likely to lead to problematic response patterns than simple-to-conditional training (Grow et al., 2011), after the learner can engage in skills like pointing to stimuli and scanning an array (Green, 2001).

Strategies to Mitigate Unwanted Sources of Stimulus Control

Differential Observing Responses (DOR) A DOR can reduce restricted stimulus control by ensuring the participant observes the relevant features of the sample stimulus. Dube and McIlvane (1999) resovled restricted stimulus control by arranging a DOR that required participants to match the compound sample (e.g., AB) to an identical compound sample in an array that also contained comparisons with an irrelevant form in each component (e.g., array contained AC, CB, AB). Only after participants correctly matched the compound sample to the identical comparison (i.e., matched AB to AB) were they permitted to advance to the second portion of the trial in which they matched one of the two components of the compound sample. Engaging in the DOR increased the salience of the second component of the compound stimulus, which resulted in highly accurate matching of each component in subsequent trials.

Blocking Some learners may not respond to conditional discrimination training procedures even when they incorporate the recommended components in Table 13.1. For example, Kodak et al. (2015) found 44% of children with ASD may not benefit from conditional discrimination training with common prompt-delay procedures. Individuals for whom conditional discrimination training is ineffective may benefit from a procedure called blocking. Blocking is a more intensive intervention that has demonstrated success in establishing conditional discrimination in learners with ASD and ID (e.g., Saunders & Spradlin, 1989).

Blocking involves training each sample-comparison relation in session blocks and then gradually reducing the number of consecutive trials in which each sample-comparison relation is targeted until samples are randomly rotated. For example, when conducting blocking of AVCDs, all training trials in a session (e.g., 16 trials) would include one auditory sample (e.g., the spoken word "apple") and responses to the S+ (e.g., picture of the apple) are reinforced in different positions in the two-comparison array. Once the child consistently responds to the picture of the apple in the presence of the sample "apple," the second sample-comparison relation is targeted by presenting "sock" on all 16 training trials and reinforcing responses to the picture of the sock. The targeted sample-comparison relation is alternated across blocks of sessions until learners respond correctly when reinforcement shifts to the other targeted comparison stimulus occurs on nearly all trials in the block (e.g., 90% or more of trials). Thereafter, the size of the trial blocks is reduced (Fig. 13.4). The goal of this reduction in block size is to produce a rapid shift in responding from one comparison to the other after a shift in the targeted sample-comparison relation. Trial blocks continue to decrease (e.g., blocks of 4 trials, blocks of 2 trials) as responding continues to shift rapidly from one sample-comparison relation to the other with each new block of trials. Blocking concludes with random alternation of the sample stimulus across trials and continued correct responding to both sample-comparison relations across several consecutive training sessions.

Researchers have successfully used blocking to teach targeted sample-comparison relations of visual–visual and auditory–visual conditional discriminations to individuals with ASD and ID (e.g., Kodak et al., 2011; Saunders & Spradlin, 1989). Nevertheless, blocking may take considerable time to conduct and should not be used with learners who might benefit from other conditional discrimination training methods.

Assessing and Teaching Prerequisite Skills for Discrimination Training Learners may be unlikely to benefit from discrimination training until they acquire putative prerequisite skills. Conducting discrimination training when learners cannot engage in the putative prerequisite skills could increase the likelihood that control by sources other than those defined by the instructor (e.g., instructor's eye gaze, the last stimulus touched when setting up) will develop. Green (2001) recommended teaching learners "learning to learn" skills like scanning materials, waiting for the sample stimulus before responding, and emitting observing responses. Researchers have examined putative prerequisite skills for conditional discrimination (e.g., Kodak et al., 2015; Saunders & Spradlin, 1989).

To engage in a correct discrimination during AVCD—arbitrary MTS—training, a learner must respond differentially to pictures associated with varying auditory stimuli; therefore, it is likely that they will need to acquire several skills before

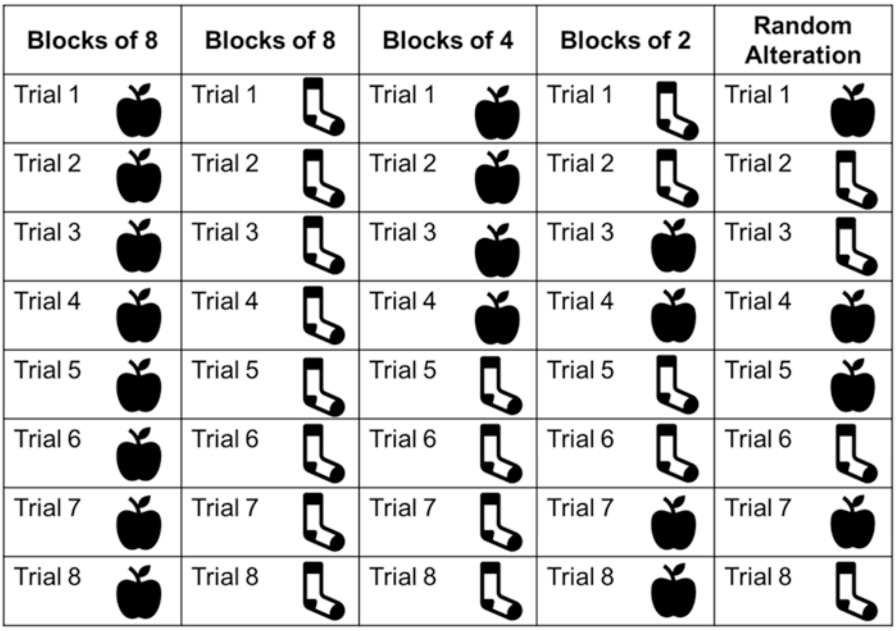

Fig. 13.4 Example distribution of S+ trials in blocking. *Note*. The order of each stimulus in the blocks can be randomized. That is, the sock might be the S+ for the first four trials in a blocks-of-four session. Both stimuli are present on each trial, but only one stimulus is the S+ for a specific number of trials in the block. The position of the S+ changes across trials within a block

AVCD training is successful. The skills include successive discrimination of auditory samples (e.g., discriminate the sound of a cow mooing from a baby crying), simultaneous discrimination of visual stimuli in the comparison array (e.g., touch the picture of the baby [S+] and do not touch the picture of the cow [S−]), matching identical stimuli (e.g., identical pictures of cows or identical sounds of mooing), and observing the visual comparisons in the array (e.g., looking at the pictures of the cow and baby).

Kodak et al. (2015) evaluated the correlation between an assessment of putative prerequisite skills for AVCD and the results of AVCD training. In addition to the skills described above, Kodak et al. measured how participants responded to a common extra-stimulus prompt (i.e., pointing). Kodak et al. showed four of nine participants with ASD did not display mastery-level responding to one or more skills included in the assessment. Subsequent outcomes of AVCD training were correlated with the assessment results for seven of the nine participants. Four participants who mastered all putative prerequisite skills also mastered AVCDs, and three of the four participants who did not master all putative prerequisite skills also failed to master AVCDs. Nevertheless, the skills assessment did not examine a functional relationship between mastery of prerequisite skills and successful AVCD training; future research should teach missing skills and evaluate whether subsequent AVCD training is successful.

Conclusion

Simple and conditional discriminations with auditory and visual stimuli are ubiquitous. Control of our behavior by stimuli in the environment promotes a more efficient and organized world (Skinner, 1953). When teaching auditory, visual, or auditory–visual discriminations, an instructor must consider the controlling relations, procedural arrangement, teaching strategies, and sources of stimulus control. Behavior analysis has amassed extensive literature on discrimination training parameters and procedures beyond the current chapter's scope. The interested reader is referred to several excellent chapters on basic, translational, and applied stimulus control (see Dinsmoor, 1995a, b; Harrison, 1991; Mackay, 1991; McIlvane, 2013; Pilgrim, 2015; Saunders & Williams, 1998; Spradlin & Simon, 2011).

Although the focus of this chapter was stimulus discrimination, we would be remiss if we did not acknowledge the importance of stimulus generalization. Stimulus discrimination and stimulus generalization are like opposite sides of a continuum of stimulus control, and both emerge from the same process—differential reinforcement (Dinsmoor, 1995a). Whereas stimulus discrimination training produces the highest levels of a previously reinforced response in the presence of the S+—thereby narrowing the effects of reinforcement—stimulus generalization can be observed when the behavior reinforced in the presence of the S+ occurs in the presence of stimuli similar to but different from the S+—thereby broadening the effects of reinforcement (Dinsmoor, 1995a; Saunders & Williams, 1998). Extending stimulus control outside the boundaries of the school, clinic, or home is essential for learners to navigate a world full of auditory, visual, and auditory–visual simple and conditional discriminations—many of which they will never contact directly in a formal training program.

Conflicts of Interest The authors have no conflicts of interest to disclose.

14 Instructive Feedback: Applications in Applied Behavior Analysis

Julia L. Ferguson, Shannon Arthur, Justin B. Leaf, and Joseph H. Cihon

Instructors, in general education and special education settings, are often required to teach a wide variety of skills and maximize instructional time. Effective and efficient teaching procedures not only produce positive outcomes but may do so in less time (Caldwell et al., 1996). The efficiency of a procedure can be assessed in a variety of ways, including, but not limited to, the number of trials to meet mastery, the number of learner errors, preparation time prior to implementation for a procedure, or the total amount of teaching time for a learner to reach a mastery criterion (Campbell & Mechling, 2009). A procedure for increasing the number of acquired responses in the same or less instructional time is instructive feedback. Instructive feedback is a procedure that involves providing supplemental non-target stimuli in the consequent or antecedent portion of trials (Werts et al., 2003). For example, when teaching a learner to expressively label pictures (e.g., Superman) using discrete trial teaching, the instructor may provide additional information during the consequence (e.g., the instructor saying, "Yeah! He can fly."). This instructional strategy has been shown to increase the efficiency of effective programming (Caroll & Kodak, 2015; Reichow & Wolery, 2011). Although instructive feedback requires the instructor to deliver extra stimuli during a teaching trial, the learner is not required to respond in any way, and the instructor does not provide programmed reinforcement if the learner does respond. Research spanning over 30 years has demonstrated the effectiveness of this instructional technique (Albarran & Sandbank, 2019; Werts et al., 1995). Researchers have found that learners acquire at least some of the non-target stimuli provided during the instructive feedback portion of the trial (Ross & Stevens, 2003; Tullis et al., 2017; Wall & Gast, 1999). Additionally, the acquisition of the non-target stimuli does not interfere with the learning rate of the target stimuli (Holcombe et al., 1993). This is an important finding as it suggests that adding extra information to the learning trial does not interrupt learning the target skill.

Instructive feedback can be used with a variety of learners and instructors. Studies have shown instructive feedback to be an effective procedure for learners diagnosed with autism spectrum disorder (ASD; Ledford et al., 2008; Werts et al., 2011), learners with intellectual disabilities (Caldwell et al., 1996; Colyer & Collins, 1996; Fetko et al., 2013; Werts et al. 2011), learners with speech and language impairments (Werts

et al., 2011), and typically developing learners (Griffen et al., 1998; Whalen et al., 1996). This has positive implications for use in behavioral intervention, special education, general education, and inclusive settings. Due to the fact that there is no requirement for the learner to respond to the instructive feedback and no requirement for the instructor to provide reinforcement for responding to the instructive feedback, it is a relatively simple procedure to implement. Instructive feedback can also be used in one-to-one or group teaching environments (Doyle et al., 1990a; Lane et al., 2015; Tullis et al., 2019). In a group environment, learners in the group may acquire additional targets through observational learning (e.g., Lane et al., 2015; Leaf et al., 2017). Instructive feedback has been used to teach skills related to daily living (e.g., Cromer et al. 1998; Griffen et al., 1998; Jones & Collins, 1997; Parrot et al., 2000), academic skills (e.g., Appleman et al., 2014; Fetko et al., 2013; Ross & Stevens, 2003), and social skills (e.g., Colozzi et al., 2008; Grow et al., 2017; Lane et al., 2015). Additionally, targets selected for instructive feedback can be related or unrelated to the target stimuli, which provides endless options for additional skills to be taught with minimal additional effort. The purpose of this chapter is to explore the use of instructive feedback in various treatment packages, highlight the benefits of using instructive feedback, and provide a review of the current literature on instructive feedback.

Variations of Procedure

Instructive feedback has been used to expose clients to non-target, or secondary, stimuli in a variety of ways. It can be provided as part of the antecedent or consequence portion of a trial. The secondary targets presented may or may not be related to the primary targets of an acquisition program. Additionally, the schedule of presentation of instructive feedback can be provided on a continuous schedule or on an intermittent schedule throughout teaching trials.

Antecedent Versus Consequence

When instructive feedback is provided as part of the antecedent portion of a trial, secondary target information is provided in addition to a discriminative stimulus or prompt and occurs prior to a response from the student (Haq et al., 2017; Jones & Collins, 1997; Nottingham et al., 2017; Vladescu & Kodak, 2013; Wolery et al., 2000). For example, Jones and Collins (1997) taught microwave skills to three adults with disabilities. The primary target skill was safely using a microwave and was taught using a task analysis. The secondary targets were nutritional information related to the cooking task. The secondary target information during this procedure was provided in the antecedent condition along with a prompt if the target skill was not performed. For example, when preparing food, if the participant did not initiate the step of adding water, the instructor provided the prompt, "You will need water" along with the instructive feedback "You should be drinking six cups of water each day to stay healthy." Instructors also provided instructive feedback in the consequent portion of each trial paired with praise if the participant performed the step correctly. Similarly, this consisted of nutritional information related to the task. Nottingham et al. (2017) also provided instructive feedback as part of the antecedent condition and consequence portion of learning trials to two children diagnosed with ASD. The instructor provided the secondary target information in the antecedent portion of the trial prior to presenting the antecedent stimuli relevant to the primary task. In another condition, two secondary targets were presented at the end of each trial. The participants in the study acquired the secondary targets that were presented in the antecedent and consequence condition. Nottingham and colleagues found that by providing the secondary feedback in both portions of the trial, the participants have more opportunities to be exposed to the non-target information and potentially leads to more efficient teaching. While these studies provided some evidence of the effectiveness of instructive feedback used in the antecedent portion of a trial, the majority of studies evaluating instructive feedback have used instructive feedback solely in the consequence portion of a teaching trial.

In a review of 54 studies using instructive feedback for people with disabilities, 49 used instructive feedback only in the consequence portion of a trial (Albarran & Sandbank, 2019). Instructive feedback delivered in the consequence portion of the trial presents somewhat differently in discrete learning trials versus task analysis procedures. During discrete trial teaching, instructive feedback is presented at the end of every trial in addition to programmed consequences of the primary target (e.g., Appelman et al., 2014; Gursel et al., 2006; Loughrey et al., 2014). When used in task analysis procedures, the instructive feedback is provided after each step is performed in the chain (e.g., Collins et al., 2017; Fiscus et al., 2002).

Appelman et al. (2014) targeted English sight words for four children with mild delays in a discrete trial format. For each trial, the instructors provided the child with an English written word. Following a prompted or unprompted response, the instructor provided praise and instructive feedback (e.g., "Great job saying padre. Padre is dad in Spanish.") after being presented with the English word (e.g., "Dad") on each trial. Similar procedures have been used while targeting letters of the alphabet and providing instructive feedback in the form of the corresponding letter sound in the consequent portion of the trial (Campbell & Mechling, 2009).

A common area of focus for adolescents and young adults with disabilities is vocational and job-related skills. It is often important for educational settings to teach these skills to prepare students for the future while adhering to a core academic curriculum. Research has used instructive feedback to target these skills when teaching using task analyses. Collins et al. (2017) embedded non-target information in the form of science content while learners performed the task of taking care of a plant. After the participants performed each step of the task, the researchers provided non-target information about photosynthesis as a rationale for the step being performed. In this way, instructive feedback facilitates acquisition of skills in more than one content area that increases instructional efficiency.

Classification of Targets

Information provided as instructive feedback can be classified into three different categories: parallel, expansion, and novel. Parallel stimuli refer to stimuli that target the same type of skill in a different form (e.g., target information is written numbers, parallel information is the roman numeral of that number). Werts et al. (1995) provided parallel information by targeting coin values as the primary target (e.g., $0.25) and the corresponding value as words as the secondary target (e.g., "twenty-five cents"). Expansion stimuli extend the concept of the primary target (Albarran & Sandbank, 2019). Ferguson et al. (2020) provided expansion targets by targeting superhero names as the primary target (e.g., Storm) and the corresponding superhero's power as the secondary target (e.g., "she can control the weather"). Novel stimuli are used in instructive feedback by providing information that is unrelated to the acquisition targets (Albarran & Sandbank, 2019). For example, Whalen et al. (1996) directly taught single-digit addition math facts (e.g., 3 + 2, 4 + 4) while targeting sight words (e.g., cheese, enter) using instructive feedback. When instructors use novel stimuli in instructive feedback, educators are able to target multiple goal areas and decrease time spent directly teaching each skill. While expansion targets are most commonly used in the instructive feedback research (Albarran & Sandbank, 2019), using novel targets in instructive feedback has been shown to be effective as well. Targeting different types of stimuli in instructive feedback procedures allows instructors flexibility when creating teaching programs because the information provided in the instructive feedback can be acquired regardless of its relationship to the targeted topic or skill (Fetko et al., 2013; Grow et al., 2017; Haq et al., 2017).

Schedule of Delivery

Another way that instructive feedback allows for flexibility in teaching is the schedule of delivery. Instructive feedback can be provided on every teaching trial or every few trials (e.g., Cromer et al., 1998; Griffen et al., 1998; Nottingham et al., 2020). For example, Griffen et al. (1998) compared two schedules of delivery to determine the efficiency of each schedule of instructive feedback. Two sets of target words were selected for acquisition. Two instructive feedback stimuli were selected for each target behavior, presented on two different schedules: (a) one on a continuous schedule (i.e., presented on every trial), and (b) the other on an intermittent schedule (i.e., presented every fourth trial). Acquisition of secondary targets provided during instructive feedback was assessed prior to teaching and following the participants reaching the mastery criterion for the primary targets. The researchers examined efficiency measures including the number of probe sessions required to meet the mastery criterion number of errors during probe sessions and the duration of instructional time. Griffen et al. found that, on average, there were fewer probe sessions per student required to meet the mastery criterion with a continuous schedule (i.e., 17.2) compared to the intermittent schedule (i.e., 18.8), more frequent errors with the continuous schedule (i.e., 25) compared to the intermittent schedule (i.e., 24.2), and more instructional time with the continuous schedule (i.e., 4 h 19 min) compared to the intermittent schedule (i.e., 3 h 33 min). Based on these results, there are no substantial differences in the efficiency of using a continuous schedule versus an intermittent schedule. In a replication and extension of Griffen et al. (1998), Nottingham et al. (2020) compared a continuous schedule of instructive feedback to two different intermittent schedules in which instructive feedback regarding the secondary targets was presented on every fourth trial or every other trial. The results of their evaluation found that the intermittent schedules of instructive feedback led to the lowest mean training time per target and to the more efficient acquisition of the secondary targets (Nottingham et al., 2020).

Taken together, the aforementioned studies suggest that instructors may choose a schedule for instructive feedback based on preference for the teaching procedures and other relevant variables in their educational setting, and learners are still likely to acquire the secondary targets at similar rates. For example, if an instructor would like to spend less instructional time teaching a skill, they could choose an intermittent schedule. This schedule may require more response effort on the part of the instructor. Their behavior would have to change throughout the session and between trials instead of a consistent presentation on every trial, so skill level and final educational objectives still need to be considered when choosing a schedule of presentation for instructive feedback.

Modalities

Instructive feedback can vary by modality as well. It can be provided vocally (e.g., Delmolino et al., 2013; Gursel et al., 2006; Jones & Collins, 1997), visually (e.g., Ledford et al., 2008; Wolery et al. 2000), through modeling (e.g., Grow et al., 2017; Parrott et al., 2000), or a combination of modalities (e.g., Falkenstine et al., 2009; Grow et al., 2017). Ledford et al. (2008) provided instructive feedback visually with community signs. In this study, expressive identification of words related to community signs was targeted for acquisition. The visual stimuli provided as instructive feedback was a picture of the community sign. Wolery et al. (2000) used sight words as a primary target and additional, unrelated sight words as the visual instructive feedback. Other studies have provided secondary targets vocally. For example, Delmolino et al. (2013) targeted labeling animals, school supplies, and kitchen utensils as the primary targets. Following the student's response, instructors provided praise and vocal instructive feedback by verbally providing a feature or function of the original target. These modalities of presentation have been used alone, in conjunction with each other, or in conjunction with modeling. When presented together, the visual stimulus is paired with a verbal label or description that can be related or unrelated to the primary targets. For example, Tullis et al. (2017) provided visual and vocal stimuli during instructive feedback. In their study, students were required to receptively identify a social dilemma as depicted in a picture when presented with the cue, “Where is the problem?” or something similar. Following the selection of a picture, the instructor held up the picture and described the problem that was represented (e.g., “This is a problem because her shoes are missing so she will get cold”). A few studies have presented instructive feedback by modeling a response, usually in conjunction with another modality. In one example of these studies, Grow et al. (2017) targeted labeling common features of animals, food, or objects as their primary response. Using instructive feedback, the instructor modeled a play behavior with a toy and measured play behaviors as their secondary targets. When the instructor modeled the play response, they also provided a verbal narrative or statement of the play behavior as the response was occurring (e.g., place a toy pizza on a tray, put the tray in the oven, and say, “I’m hungry”).

Populations

Instructive feedback has been shown to be effective with a variety of populations that span across diagnoses and age groups. Most commonly, the procedure is used with individuals diagnosed with ASD or intellectual disabilities (Albarran & Sandback, 2019). However, there is some research to support its use with disabilities such as attention deficit hyperactivity disorder (e.g., Caldwell et al., 1996; Fetko et al., 2013), Down syndrome (e.g., Fetko et al., 2013; Griffen et al. 1998; Singleton et al., 1995), emotional behavioral disorders (e.g., Fetko et al., 2013), as well as individuals with speech and language impairments (e.g., Colyer & Collins, 1996; Ledford et al., 2008). Instructive feedback has also been used with typically developing individuals in educational environments (e.g., Parker & Schuster 2002; Werts et al., 1996; Whalen et al., 1996).

Research has shown that using instructive feedback may be beneficial for teaching aspects of verbal behavior including tact relations and intraverbals, as well as play behavior for children diagnosed with ASD. Instructive feedback during skill acquisition programs related to tact training with children with ASD has led to the acquisition of secondary targets in the absence of direct teaching (e.g., Leaf et al., 2017) in which all participants in the study not only acquired the primary targets but also acquired the secondary targets through the use of instructive feedback. Individuals diagnosed with ASD often engage in rote responding and may be inflexible to adjust topics of conversation as necessary when engaging in social interactions with others (Lee et al., 2020). This can lead to a lack of variability when responding to others, unnatural interactions with others, and exclusion from peer groups (Stauch et al., 2017). Carrol and Kodak (2015) examined the use of instructive feedback to increase variability in intraverbal responses for two individuals diagnosed with ASD. When providing instructive feedback during the consequent event of a learning trial, the interventionist modeled response variability. For example, if the instructor asked, “Tell me three shapes,” and the participant responded with three shapes, the instructor provided praise for their response and said three additional shapes. This procedure resulted in increased response variability in the absence of programmed reinforcement. Another interesting use of instructive feedback for individuals diagnosed with ASD is the incorporation of unrelated targets when providing instructive feedback. As described previously, Grow et al. (2017) provided instructive feedback during tact training, but instead of providing instructive feedback in the form of a tact, they provided feedback in the form of play behavior. They found that tact training with instructive feedback resulted in fewer sessions for acquisition, and the play behavior provided during instructive feedback was acquired as well. These studies demonstrate the usefulness of instructive feedback to increase the efficiency of targeted skill acquisition as well as the acquisition of additional targets not directly reinforced for individuals diagnosed with ASD.

Similarly, this technique has been successful to teach aspects of functional life skills with individuals diagnosed with intellectual disabilities. Cromer et al. (1998) provided instructive feedback regarding prescription information in the consequence portion of teaching trials for middle school students diagnosed with an intellectual disability. Probe sessions were conducted prior to training trials and following training trials to determine the acquisition of instructive feedback stimuli. They found that the students' percentage of correct responses to questions about prescription details provided with instructive feedback was higher following the training trials. Many individuals with disabilities take daily medications, and using instructive feedback could increase efficiency in acquiring this type of life skill and lead to greater independence in adulthood. Taylor et al. (2002) used a task analysis to teach laundry skills to young adults with intellectual disabilities. They also presented words related to the laundry routine (e.g., delicates, temperature, cycle) on index cards throughout the task analysis as instructive feedback targets. Prior to instructive feedback, participants did not identify any of the related words. Following the intervention, the participants identified an average of 81.3% of the laundry-related words. Again, using instructive feedback was beneficial in teaching complex functional targets that contribute to a greater level of independence for individuals diagnosed with an intellectual disability.

Some studies have examined the use of instructive feedback for participants with varying diagnoses. For instance, Werts et al. (2011) included high school students diagnosed with ASD, Down syndrome, speech and language impairments, and seizure disorder. Three of the four participants acquired vocabulary related to civics information that was presented as instructive feedback. Parrott et al. (2000) also included participants with Down syndrome, ASD, Tuberous Sclerosis, and seizures. Instructive feedback was provided while the participants completed a hand-washing task. All participants increased the percentage of correct responses when responding to questions about the instructive feedback targets following training. The success of instructive feedback in acquisition with multiple disabilities provides a solid foundation for its use across varying populations.

Instructive feedback also has the potential to be used in inclusive settings with positive outcomes for students with disabilities and their typically developing peers. In a small group setting, Parker and Schuster (2002) examined the acquisition of instructive feedback and observational learning stimuli for two students with intellectual disabilities and two typically developing students between the ages of 15 and 19. Target stimuli and instructive feedback stimuli were presented to students in a group setting. Specific target stimuli were assigned to each student (e.g., cooking sight words, job-related sight words, prefixes, and chemical element abbreviations) and were presented on index cards. The instructor called the student's name, presented the index card with the target stimuli, and then provided the instructive feedback stimuli after the student's response. Instructive feedback information was related to the target stimuli (e.g., element abbreviations and type of element). The observational learning stimuli were the primary and secondary instructive feedback targets presented to other students in the group. Results showed that instructive feedback stimuli for target skills were acquired for three of the four students (range: 25–83%), observational learning of other student's target stimuli occurred for three of the four students (range: 9–38%), and some of the instructive feedback stimuli provided for other students' target stimuli were acquired for all participants (range: 13–59%). While there was some level of acquisition of instructive feedback for target stimuli, peers' target stimuli, and peers' instructive feedback stimuli, the complexity of the target skills and instructional feedback varied based on the cognitive functioning level of the participants. It is possible that some of the targets were more difficult to acquire because of the increased complexity, and this should be considered when choosing peer groups and future targets for observational learning stimuli.

Effects of instructive feedback have been demonstrated across multiple age groups as well. Research has demonstrated skill acquisition of primary targets and secondary information with participants as young as 3 years old and participants as old as 45 years old. Vladescu and Kodak (2013) provided secondary targets in the antecedent and consequence portion of the learning trials to teach tacting to four children with ASD. Their youngest participant was 3 years old and mastered all primary and secondary targets. Additionally, Vladescu and Kodak found that the conditions involving secondary targets for this participant required the least amount of training time per target. Jones and Collins (1997) evaluated the effectiveness of instructive feedback while teaching adults with intellectual disabilities microwave skills. Their oldest participant was 45 years old. This participant mastered all three microwave cooking skills and demonstrated acquisition of secondary targets (nutrition and safety facts) when assessed during post-tests. The participant also demonstrated maintenance and generalization of the primary targets.

Instructional Contexts

Instructive feedback has been demonstrated to be effective across many instructional contexts including one-to-one instructional formats and small and large group settings. Instructive feedback has also been successfully used in school, clinical, home, and telehealth settings. Across these varying instructional contexts, researchers, teachers, behavior interventionists, and peers have successfully implemented instructive feedback.

Groupings

Research on instructive feedback procedures has been commonly implemented in a one-to-one format in which there is one instructor and one learner (Albarran & Sandbank, 2019). One of the earliest studies published using instructive feedback occurred in a one-to-one format (i.e., Doyle et al., 1990b). Doyle et al. (1990b) used a constant time-delay procedure to teach sight words to three children diagnosed with developmental delays in a one-to-one format. Instructive feedback was provided regarding the action/function of the corresponding sight word (e.g., ball is something you throw). The results demonstrated the children learned the targeted sight words and the action/function of the targeted word provided as instructive feedback. In a more recent study, Tullis et al. (2017) used instructive feedback to teach a child diagnosed with ASD in a one-to-one format to identify a problem (e.g., batteries missing from a toy) and why it was a problem (e.g., the toy cannot work). Tullis and colleagues found that the use of instructive feedback resulted in the child learning nine out of ten of the secondary targets without direct teaching. This study was also unique in that the child participant used an augmentative or alternative communication device.

Research on instructive feedback has also been commonly implemented in small and large group settings. When instructive feedback is used in a group setting, there are additional opportunities for observational learning of primary and secondary targets for other members of the group. Research using instructive feedback in group settings has occurred with dyads (e.g., Appelman et al., 2014; Ferguson et al., 2020; Lane et al., 2015; Ledford et al., 2008; Singleton et al. 1995; Wall & Gast, 1999; Werts et al., 2003), groups as small as three (e.g., Campbell & Metchling, 2009; Falkenstine et al., 2009; Holcombe et al., 1993; Jones & Collins, 1997; Keel & Gast, 1992; Leaf et al., 2017; Ross & Stevens, 2003), and as large as an entire classroom of students (e.g., Werts et al., 1996). In a recent example, Leaf et al. (2017) evaluated the use of instructive feedback in a group of three learners diagnosed with ASD to teach superhero names (i.e., primary targets) and the corresponding superhero's power (i.e., secondary targets). The results demonstrated that all participants learned their designated primary and secondary targets and their peer's primary and secondary targets through observational learning. Leaf and colleagues demonstrated that when instructive feedback was used in a group setting, the participants acquired six targets in the same amount of time it took to master one target. This study is just one example of how targeted skills can be acquired effectively and efficiently when observational learning opportunities are coupled with the information acquired through instructive feedback.

Settings

Instructive feedback procedures have occurred in a variety of settings including special education classrooms (e.g., Anthony et al., 1996), self-contained or resource classrooms (e.g., Olszewski et al., 2017), general education classrooms (e.g., Whalen et al., 1996), clinical settings (e.g., Tekin-Iftar et al., 2008), community settings (e.g., Fiscus et al., 2002), preschool (e.g., Doyle et al. 1990b), and home settings (e.g., Ferguson et al., 2020). School classroom settings have been used most frequently in the instructive feedback literature, followed by clinic settings and then community and home settings (Albarran & Sandbank, 2019). No differences have been demonstrated in the acquisition of instructive feedback targets across settings, but some variables should be taken into account when considering the use of instructive feedback within various settings. One consideration is the selection of primary and secondary targets. For example, if the target skills are related to self-help or vocational skills, then a community setting may be more beneficial in which to teach the targeted skill. If the target skills are academic, a classroom or school setting may be more beneficial. If the target skills are social, teaching in a setting in which you have access to other learners would be beneficial. These examples of target skills and corresponding settings highlight the importance of teaching in settings that have the relevant stimuli desired to obtain control over responding. Another consideration is the desired number of targeted skills. A one-to-one setting may be sufficient when teaching a limited number of skills. However, a school setting, or settings in which multiple learners are present, may permit more observational learning opportunities without increasing instructional time when targeting a large number of skills. Another consideration is access to in-person settings. In-person behavioral intervention is not always accessible for individuals diagnosed with disabilities for a variety of reasons (e.g., rural locations, health guidelines). When this is the case, direct instruction via telehealth may be a viable option. Ferguson et al. (2020) evaluated the use of instructive feedback in dyads with instruction delivered directly via telehealth. This modality of instruction was found to be effective, and participants learned their respective primary targets, secondary targets, and their peer's targets through observational learning.

Instructors

Instructive feedback procedures have also been used by a variety of instructors, including researchers (e.g., Johnson et al., 1996), paraprofessionals (e.g., Colozzi et al., 2008), therapists (e.g., Vladescu & Kodak, 2013), special education teachers (e.g., Tekin-Iftar et al., 2003), speech-language pathologists (e.g., Shelton et al., 1991), and peers (e.g., Collins et al., 1995). In a recent review of the instructive feedback literature, Albarran and Sandbank (2019) found researchers to most commonly implement instructive feedback procedures, followed by teachers, paraprofessionals, behavior therapists, and then peers. This stands in contrast with an early review of the instructive feedback literature that found teachers to most commonly implement instructive feedback procedures (Werts et al., 1995). It is not surprising that so many different types of teaching professionals have implemented instructive feedback procedures due to the ease of their implementation. When peers have been used to implement instructive feedback procedures, the results have been similar (e.g., Collins et al., 1995; Fetko et al., 2013). For instance, Fetko et al. (2013) used peer tutors to provide science facts as instructive feedback while the participants learned to play UNO. Results showed that two out of the three participants acquired the secondary targets provided as instructive feedback by their typically developing peers. Notably, missing from the list of instructors that have implemented instructive feedback is parents and caregivers. The potential benefits of instructive feedback provided by parents outside of therapeutic and educational settings are currently unknown.

Future research evaluating instructive feedback procedures should evaluate parent and caregiver use of instructive feedback procedures. Future research should also evaluate methods of training parents and caregivers to implement instructive feedback procedures into teaching and learning opportunities that naturally occur in the child and parent's home and community settings.

Other General Research Findings

Skill Acquisition

The research evaluating instructive feedback has demonstrated the procedure to be effective and efficient to teach additional non-target stimuli, but the rates of acquisition for secondary targets have varied across studies. In a review of 23 studies using instructive feedback between the years of 1989 and 1994, Werts et al. (1995) found the net gain to be 58.2% of targets acquired through instructive feedback across all participants and studies reviewed. More recently, Albarran and Sandbank (2019) reviewed 54 studies that evaluated instructive feedback procedures and found that an average of 64% (range, 0–100%) of participants learned their instructive feedback targets. More research evaluating the conditions under which participants learn all instructive feedback targets, some instructional feedback targets, or none of the instructional feedback targets is warranted, but it is important to note that learner acquisition of the primary targets never affected the instructive feedback provided. Relevant prerequisite skills, such as attending and an echoic repertoire, should also be documented in future studies to assess which prerequisite skills are necessary for learners to acquire the instructive feedback targets.

Albarran and Sandbank (2019) also evaluated the overall participant gain of their peer's primary targets and secondary targets when instructive feedback procedures were evaluated in a group or dyad arrangement. Across 15 studies, Albarran and Sandbank found that acquisition of peer's primary targets averaged 59% (range, 16–95%) and acquisition of peer's instructive feedback targets averaged 55% (range, 19–99%). That is, the overall percentage of acquisition of observational learning targets was only 4% lower than the overall percentage of acquisition for participant's instructive feedback targets. This may be the case because learners in a dyad or group may already engage in behaviors that are likely to lead to successful learning in a group setting (e.g., attending for longer durations, active responding, generalized imitative repertoire). These prerequisite skills likely facilitate observational learning in the absence of direct teaching. Similar to the acquisition of instructive feedback targets, future research should focus on determining the conditions under which learners acquire their peer's primary and secondary targets and specific prerequisite skills that may increase the likelihood of target acquisition through observational learning.

Maintenance

Werts et al. (1995) found maintenance data to be reported in eight of the 23 studies (i.e., 34.8%) and Albarran and Sandbank (2019) found maintenance data to be reported in 13 out of 54 (i.e., 24.1%) studies reviewed. Taken together, maintenance data has rarely been reported in the instructive feedback research. When maintenance data has been reported, the results have varied with some participants maintaining their behavior from intervention to maintenance, some responding at lower rates compared to intervention, and some participants responding at higher rates compared to intervention (Albarran & Sandbank, 2019; Werts et al., 1995). More maintenance data is needed in the instructive feedback research. If instructive feedback targets are acquired by a learner but data on the maintenance of the targets learned is not collected, then the effectiveness of the instructive feedback procedure is unknown when it comes to maintaining the responses learned over time. It will also be important to assess the maintenance of the instructive feedback targets learned and targets acquired through observational learning in a group setting. It may be the case that targets learned through instructive feedback or observational learning do not maintain as long as targets learned through direct teaching. If this is the case, then more formal teaching may be required for the learned responses to maintain in a learner's repertoire.

Generalization

Albarran and Sandbank (2019) found generalization measures of instructive feedback targets to be reported in 9 out of 54 studies (i.e., 16.7%). When generalization measures were reported, they averaged 66% (range, 38–86%) across settings and instructors. This is another area in the instructive feedback literature that requires more research. The generality of behavior change is a hallmark of applied behavior analysis (Baer et al., 1968), and it is important to assess if the learned behaviors occur in other settings, with other people, with other related similar behaviors, and in the terminal environment. If reported generalization measures in the instructive feedback literature are consistently low, instructors would then need to develop generalization training procedures in order to ensure the learned behaviors generalize (Stokes & Baer, 1977).

Social Validity

Measures of social validity in the instructive feedback literature were not analyzed in the previous literature reviews (i.e., Albarran & Sandbank, 2019; Werts et al., 1995), but the assessment of social validity is present in some of the research on instructive feedback. Social validity is defined as the assessment of the social significance of a treatment's goals, outcomes, and procedures (Wolf, 1978) and is commonly underreported in behavior analytic journals (e.g., Carr et al., 1999; Ferguson et al., 2019; Kennedy, 1992). The percentage of instructive feedback studies including social validity measures remains unknown, but several research groups have reported measures of social validity. Appelman et al. (2014) assessed social validity by providing a questionnaire to teachers and students regarding the success of the instructional procedures. The results of the questionnaire were positive, indicating that teachers agreed that the goals of the study were important (i.e., teaching English and Spanish sight words), found the small group arrangement to be appropriate, and agreed that the children learned the target words. Students also responded positively to the questionnaire and indicated that they enjoyed learning new sight words and enjoyed working with their partner and the instructor. Collins et al. (2017) assessed social validity by asking three questions to the students participating in the study. Students' responses to the questions indicated that the students enjoyed the community setting of the study (i.e., greenhouse), agreed that they learned information about photosynthesis, and three out of four students found that learning about plant care would be useful in the future. Colozzi et al. (2008) also used a questionnaire to assess social validity. They asked parents, preschool teachers, and paraprofessionals questions regarding the effectiveness of the procedures and the importance of the targeted skills. The majority of parents rated the methods and goals to be moderately important, and the majority of staff found the methods and goals to be very important. Overall, when social validity has been assessed in the instructive feedback literature, surveys and questionnaires to parents, instructors, and student participants have been used most frequently. Other instructive feedback studies that have used questionnaires to assess social validity include Ledford et al. (2008), Pennington et al. (2014), and Shepley et al. (2016). Future instructive feedback research should continue to assess the social validity of the procedures to ensure instructors find the procedures to be helpful and easy to implement throughout their sessions. Future studies could also evaluate the learner's preference for this procedure compared to other teaching procedures using a concurrent chain arrangement (Hanley, 2010).

Behavioral Mechanisms

Although the research evaluating instructive feedback has demonstrated the procedure to be effective and efficient in teaching additional non-target stimuli, the behavioral mechanisms as to why instructive feedback works are still unknown since programmed reinforcement or prompting of the response(s) never occurs. Possible explanations and variables that could explain the effectiveness of instructive feedback include observational and incidental learning (e.g., Werts et al., 2003), the presence of a naming repertoire (e.g., Nottingham et al., 2020), echoic repertoire (e.g., Leaf et al., 2017), attending skills (e.g., Nottingham et al., 2020), motivating operations (e.g., Ferguson et al., 2020), indiscriminable contingencies in the instructional environment (e.g., Werts et al., 2003), and an association between the primary and secondary targets (e.g., Werts et al., 2003).

Some researchers have discussed the possibility of indiscriminable contingencies in the teaching and probe environments and the link between the primary and secondary targets (e.g., Werts et al., 2003; Wolery et al., 1993). This may come about due to the research designs implemented that continually probe and assess for the acquisition of the secondary responses throughout baseline and intervention. Since the participants in the studies are exposed to the secondary target stimuli in the baseline, this may function as a cue that the targets are important and increase attending when the stimuli are presented in future trials. When using instructive feedback procedures, the instructive feedback is assigned to a primary target or behavior and the instructive feedback is either presented on every trial or intermittently during trials when the primary target is being taught through reinforcement procedures. This may form an association between the primary target and the secondary targets due to the secondary stimuli being inadvertently paired with reinforcement that is delivered contingent on correct responses to primary targets (Werts et al., 1995, 2003). These potential variables explaining the effectiveness of instructive feedback have been evaluated, and Werts et al. (2003) found that participants still learned instructive feedback targets even when they were not directly assigned to primary target behavior. Werts et al. (2003) also evaluated the potential confounding effects of daily probes on the acquisition of instructive feedback targets and found that daily probes did not affect participants' acquisition of the instructive feedback targets. Overall, Werts et al. (2003) concluded that these factors did not explain the effectiveness of instructive feedback procedures.

More recently, researchers have noted participants emitting echoic behavior following the presentation of instructive feedback (e.g., Dass et al., 2018; Ferguson et al., 2020; Nottingham et al., 2017, 2020; Vladescu & Kodak, 2013). Attending behaviors such as orienting toward stimuli, looking at stimuli, and commenting have been shown to accompany echoic behaviors (e.g., Ferguson et al., 2020; Nottingham et al., 2020). These behaviors have led researchers to suggest that a naming repertoire (Horne & Lowe, 1996; Miguel, 2016) is relevant to the acquisition of targets through instructive feedback. A bidirectional naming repertoire is a higher-order operant in which there is a two-way relationship between listener and speaker behaviors, and teaching one of those behaviors (e.g., listener behavior) is enough to establish both repertoires (i.e., speaker and listener behaviors) in the absence of direct teaching (Horne & Lowe, 1996; Miguel, 2016). The demonstration of a naming repertoire could explain why some learners acquire the targets presented during instructive feedback without directly teaching the responses. Currently, no research has evaluated the aforementioned possible behavioral mechanisms responsible for the acquisition of secondary targets. Future research could help fill this gap by designing research to specifically evaluate the effects of the presence or absence of various repertoires (e.g., assessing participant's naming repertoire prior to intervention and evaluating if the demonstration of a naming repertoire correlates with the acquisition of secondary responses targeted through instructive feedback).

Future Directions

Clinical

Due to the flexibility of the types of learners, types of instructors, instructional arrangements, and target skills for which instructional feedback procedures can be used, the clinical implications are vast. Currently, it is unknown how frequently instructive feedback procedures are programmed into general education, special education, or clinical settings. It is possible that instructive feedback procedures are used incidentally by instructors in these settings without realizing the benefits of this instructional practice. Clinically, instructive feedback procedures could be implemented throughout almost all programming. Instructive feedback procedures are simple to implement and can be embedded into the consequence of any trial. Additionally, research has demonstrated that instructive feedback procedures do not need to be implemented on a continuous schedule, meaning that if instructors do not provide instructive feedback after every trial in a clinical setting, the learners will still acquire the secondary targets at similar rates.

By using instructive feedback procedures in clinical practice, instructors could cut down on instruction time by strategically planning the instructive feedback targets. For example, in a special education classroom, a teacher could be conducting a science lesson while providing instructive feedback on relevant math goals for the learners in the class. Similarly, general education classrooms could benefit from implementing this behavior analytic strategy by maximizing instructional time in the same way. Multiple subjects in general education settings can be taught together such as math and science targets or reading and vocabulary. This could help teachers and paraprofessionals cover multiple goals in the same amount of instructional time.

Research

Although the instructive feedback literature is substantial, there are still many areas for potential future research. First, to the authors' knowledge, there have been no training studies conducted on how to train instructors or caregivers on the implementation of instructive feedback. Since instructive feedback procedures can be embedded throughout and across programs, this is an important skill for instructors to be trained on that will lead to more efficient and effective teaching. Second, future research should evaluate instructive feedback procedures with parents or caregivers implementing the procedure. Social validity measures should be taken when parents or caregivers are implementing instructive procedures to ensure the procedures are acceptable to their family and are a procedure that can be easily implemented in their everyday lives.

Another area of future research for instructive feedback would be manipulating the treatment integrity of the procedure. Similar to other behavior analytic research that has evaluated errors of commission during discrete trial teaching (e.g., DiGennero Reed et al., 2011), conditions could be arranged in which instructors systematically engage in treatment fidelity errors when providing instructive feedback to assess how important following a particular schedule of instructive feedback is to learner acquisition of secondary targets. This type of research would be helpful for determining how important it is to adhere to a specific schedule of instructive feedback delivery. This information would be especially helpful when it comes to having teachers, behavior therapists, and parents use instructive feedback procedures in more natural settings in which they may not be able to adhere to strict schedules of when to provide instructive feedback.

Future research should also explicitly evaluate the role of naming repertoire in the acquisition of instructive feedback targets. The results of which may help shed light on possible behavioral mechanism(s) at work when learners acquire these targets in the absence of direct teaching. Another area of future research would be to evaluate for which participants and under what conditions instructive feedback is the most appropriate. Doing so would help inform instructors of the most and least optimal conditions to implement instructive feedback. Finally, future instructional feedback research should prioritize examining measures of maintenance, generalization, and social validity. As it stands currently, these additional measures are only appearing at low rates in the literature. More measures of maintenance, generalization, and social validity are needed so that clinicians and researchers have more information regarding the maintenance of targets acquired through instructive feedback, the generalization of those targets learned, and the social validity of the procedures used.

15 Generalization

Patricio Erhard and Terry S. Falcomata

Definitions and Historical Background

Generalization is a broad term that has been described as an individual's responding to novel stimuli, their novel responding topographies, or responding that is maintained across time. The concept of generalization was introduced by B.F. Skinner (1965) in *Science and Human Behavior*, in which he described generalization as (a) the effect that stimulus control has on responses to stimuli that share similar qualities (i.e., responding can come under stimulus control for directly trained stimuli and for stimuli that share similar qualities), and (b) the effect reinforcement has on directly trained responses and untrained responses (i.e., an increase of non-targeted responses can occur when reinforcement is provided for a specific behavior).

Baer et al. (1968) described generalization as part of the seven dimensions of applied behavior analysis as *generality*. When describing generality, Baer et al. noted that behavior change must be "durable over time… appear in a wide variety of possible environments, or… spreads to a wide variety of related behaviors" (p. 96) to be considered as generalized. That is, generalization describes the occurrence of behaviors that (a) are sustained across time (i.e., response maintenance); (b) occur across various untrained materials, places, people, and contexts (i.e., stimulus generalization); or (c) are emitted as untrained responses (i.e., response generalization). Stokes and Baer (1977) later expanded upon the definition of generalization by noting that for one to claim the occurrence of generalized behavior change, such behaviors must occur with no "extratraining changes" or when some "extra manipulations" are necessary, but less costly than direct training (p. 350). Stokes and Baer described seven strategies used to promote generalization of behaviors, including (a) train and hope, (b) sequential modification, (c) introduction of natural maintaining contingencies, (d) training sufficient exemplars, (e) training loosely, (f) use of indiscriminable contingencies, and (g) programming for common stimuli. Stokes and Osnes (1989) further refined the strategies presented by Stokes and Baer by focusing solely on programming tactics for generalization changes. Specifically, whereas Stokes and Baer presented a combination of assessment tactics (e.g., train and hope) and programming tactics (e.g., train loosely), Stokes and Osnes described 12 programming tactics organized in terms of 3 generalization principles, which will be discussed in greater detail later in this chapter.

Types of Generalization

Response Maintenance Response maintenance, often referred to simply as maintenance, is the term that describes sustained responding across time when training components are removed. For example, if an individual is taught to request water and the request continues to occur days, weeks, and/or months after the request was directly trained, such responding can be considered maintained. This is so because the response continued to occur without assistance following the initial training (i.e., maintenance is demonstrated). When efforts are made to produce behavior change, it is imperative to consider how environmental variables will maintain favorable behaviors (e.g., functional communication) or unfavorable behaviors (e.g., aggression) across time; because behavior change outcomes should be practical and applicable. Conversely, if one does not consider environmental variables, adaptive behaviors may not be sustained and maladaptive behaviors suppressed for long periods of time. Such considerations might require the identification of naturally occurring contingencies, creating necessary schedules of reinforcement, and/or determining how reinforcement will be recruited, among other potential strategies.

Stimulus Generalization Stimulus generalization is the term that describes responding to untrained stimuli that share similar characteristics (e.g., materials, places, people, contexts). For instance, if an individual is taught to request water at their home, and the individual emits the same request for water at his school, such an occurrence can be considered stimulus generalization because the previously taught response was emitted in a new, untrained setting. The same would be true if the request occurred with novel people or with novel examples of water. Stimulus generalization is important for a variety of reasons. For example, it is not feasible for one to directly teach an individual to respond in a particular way to every single potential stimulus with which responding is desired, but instead responding must be generated without direct training across a variety of places, peoples, and materials. When planning for stimulus generalization, some have emphasized the importance of focusing on (a) developing *stimulus classes* and (b) developing *stimulus discriminations* between stimuli (e.g., Cuvo, 2003).

Stimulus Class A stimulus class is a group of stimuli that share common physical, temporal, or functional characteristics. For instance, a bottle of Dasani® water, Aquafina® water, and Evian® water can all be grouped under the same stimulus class of water because they share common characteristics (e.g., bottled, clear, consumable, liquid, water). If an individual is taught to request a bottle of Dasani® water by pointing to it, and untrained requests via pointing for other brands of water are subsequently emitted, then it can be said that stimulus generalization has occurred. Thus, the emergence of stimulus generalization can also be described as the emergence of untrained responding across stimuli within the same stimulus class. Cuvo (2003) recommended that the development of stimulus classes is strongly considered when producing stimulus generalization, because it may result in the emergence of generalization across other stimuli within their respective classes.

Stimulus Discrimination It is also important to take into consideration teaching stimulus discriminations when producing generalized behavior change to ensure responding occurs in appropriate contexts (and does not occur in inappropriate contexts). That is, if stimulus discriminations are not taught, it is possible for stimuli to exert excessive control over a response (this is sometimes referred to as *stimulus overselectivity*; Lovaas et al., 1971). A study by Horner et al. (1986) demonstrated how one could program to avoid overselectivity. Four participants with intellectual disability diagnoses were taught to bus tables by teaching appropriate and inappropriate times to clean the tables at a university cafeteria. The participants had to attend to (a) whether people were present, (b) whether food was eaten, (c) whether the dishes were empty, (d) whether garbage was present, and (e) the position of the stimuli on the table. Generalization probes across novel cafeterias demonstrated that the four participants generalized their responses to new settings and maintained discriminations between tables that should and should not be bussed. This study by Horner et al. demonstrated how stimuli class membership (i.e., to-be-bussed tables and not-to-be-bussed tables) can be "appropriately expanded and delimited" (Cuvo, 2003, pg. 81) through the development of stimulus classes and by teaching stimulus discriminations.

Response Generalization Response generalization is the term that describes the occurrence of novel, untrained responses. For example, if a child is taught to request water by reaching their arm out and making a "grabbing" motion, and the child later emits requests by pointing, then such occurrence can be considered response generalization because the individual emitted a topographically different response relative to the original response. Many scholars have noted that topographically similar, but different responses (e.g., pointing instead of reaching/grabbing) can be considered a form of response generalization (e.g., Kazdin, 1994; Mayer et al., 2011), whereas others have noted that responses may be physically dissimilar (e.g., saying, "Wah" instead of reaching/grabbing; Partington & Sundberg, 1998).

Response Class Some have noted that functionally equivalent consequences are an important part of response generalization (e.g., Carr, 1988). Based on this classification, response generalization can also be considered as the emergence of novel responses within the same response class (i.e., within the same group of functionally equivalent responses). Let us consider the example of the child requesting water again. If a child engaged in novel requests (e.g., pointing) for the same consequence (e.g., water being provided), then both the previously taught response and the novel response would be members of the same response class (i.e., they both resulted in the same consequence whereby water was provided).

Other Generalization Outcomes

Several other generalization outcomes have been observed and described in behavior-analytic literature, that do not classify seamlessly within the concepts described in the preceding sections. We provide a brief overview of them for clarity's sake.

Generative Responding Generalization is referred to as generalized behavior change, generality, or even induction in some cases. Although similar, these terms should not be confused with *generative responding* (i.e., generative verbal behavior, language generativity), which is a term that is typically used to describe novel responses that are used for other functions. One way this term is used is for describing novel responses that operate under joint stimulus control (Holth, 2017), such as the emergence of untaught tacts during direct mand training (e.g., Greer & Ross, 2008; Nuzzolo-Gomez & Greer, 2004). That is, if an individual is taught to request an item by stating its name, and then the individual uses the name of the item for another purpose (e.g., label it spontaneously to engage in a social interaction), then such occurrence would be considered generative responding. This term has also been used to describe novel language, typically referring to the capacity one has to produce and understand sentences that have never been seen, spoken, or heard (Hayes et al., 2001; Stewart et al., 2013).

Recombinative Generalization This term is used to describe "differential responding to novel combinations of stimulus components that have been included previously in other stimulus contexts" (Goldstein, 1983, pg. 280). For example, if a student is directly taught to select a "blue car" or "red airplane" and the student then is able to select "red car" or "blue airplane" without direct training, then such an occurrence could be considered a form of recombinative generalization. This kind of generalization is favorable because responding in the natural environment often requires the capacity to "combine" stimuli in various ways to produce a desired consequence. One clear example of this is an individual's ability to combine letters to create words, phrases, and paragraphs with different meanings without direct instruction for each word-letter combination. This kind of generalization outcome can be programmed and produced through *matrix training* (Pauwels et al., 2015).

Response Variability Sometimes referred to as *behavioral variability* or *operant variability*, response variability describes the extent to which responses sequentially vary from one another within a response class (Neuringer, 2002). This skill is valuable because it may help individuals come in contact with reinforcement more effectively when any one topography from the same response class contacts extinction (e.g., Adami et al., 2017). For example, an individual traveling in a country where his/her language is not spoken may exhibit practical variable responding. After a long day of touring, the individual walks into a shop, approaches the clerk, and asks for water by saying, "water?" The clerk looks at the individual and shrugs his shoulders. The individual then walks to the fridge and points to the water. The clerk says, "oh!" and proceeds to sell the individual a bottle of water. In this scenario, it is clear that response variability (e.g., varying from vocally stating "water" to pointing) was beneficial in that it increased the likelihood of producing reinforcement when one response, within the same class, was not reinforced. Teaching response variability can also be useful for preventing the resurgence of problem behaviors; an individual who has been taught behavioral variability is more likely to refrain from engaging in problem behaviors (e.g., aggression), and vary between socially appropriate alternative behaviors (e.g., requesting), when any one response experiences extinction (e.g., Adami et al., 2017; Falcomata et al., 2018; Hoffman & Falcomata, 2014).

Emergent Relations Emergent relations, sometimes called *derived relations* or *emergence of stimulus relations*, originated from equivalence-based instruction (EBI) literature and are used to describe the emergence of untrained relationships between stimuli (Sidman, 1971). Essentially, a derived relation occurs when an individual shows that one class of stimuli (e.g., the written word CAR) is the same as another thematically similar class of stimuli (e.g., the image of a car) without direct training. If an individual is able to show further associations with three or more thematically similar stimuli (e.g., the vocalization "car"), then that is considered *stimulus equivalence* (i.e., if CAR = image of a car, and the image of a car = "car", then CAR = "car"). Although research has shown that EBI has the capacity to promote substantial generativity, further explanation of this intervention on derived relations is outside the scope of this chapter. For more information, see Pilgrim (2020) or Fienup and Brodsky (2020).

Programming Tactics for Generalized Behavior Change

Exploitation of Current Functional Contingencies

The term "natural communities of reinforcement" has been used to refer to the natural contingencies that exist in individuals' environments (Stokes & Baer, 1977). Stokes and Baer (1977) asserted that increasing the chances that individuals' communities of reinforcement will come to control target responding (i.e., adaptive; maladaptive) promotes generalization. Subsequently, Stokes and Osnes (1989) discussed the strategy of *Exploitation of Current Functional Contingencies* as one strategy for programming for generalization. Specifically, Stokes and Osnes described several tactics that rely on the exploitation of environment-based functional contingencies, including (a) *recruitment of natural consequences,* (b) *contacting natural consequences,* (c) *modification of maladaptive consequences*, and (d) *reinforcement of occurrences of generalization*. Each of the tactics that comprise the strategy of *Exploitation of Current Functional*

Contingencies is similar in that they incorporate the systematic promotion of contact by target behaviors with environmental sources of reinforcement or punishment through the reliance on pre-existing (i.e., *contacting natural consequences)* or actively programmed (i.e., *modification of natural consequences*; *reinforcement of occurrences of generalization)* contingencies in the environment; or the intentional designation of target behaviors that are more likely to be reinforced and maintained in the natural environment resulting in generalization (i.e., *recruitment of natural consequences*).

Recruit Natural Consequences Stokes and Osnes (1989) described situations in which target behaviors may not be occurring in such a way to allow for naturally occurring contingencies to develop control and produce generalization. Perhaps the behavior is occurring below rates that are necessary for existing naturally occurring contingencies that do not have an opportunity to effectively maintain it. Or, in some situations, the form of the target behavior itself may be a hindrance to the effects of natural contingencies. In such cases, the targeting and training of behaviors that actively access natural contingencies may be necessary to promote generalization. This tactic, referred to as *recruitment of natural consequences*, is intended to facilitate contact of the behavior with environment contingencies that exist in the individual's natural environment. Said another way, the tactic utilizes an approach in which the individual is provided with the means to actively solicit reinforcement in the natural environment through systematic teaching and training to facilitate generalization.

Numerous examples exist in the behavioral literature that demonstrate the effectiveness of the tactic of recruitment of natural consequences. For example, Chambers and Rehfeldt (2003) conducted a study in which they evaluated the relative effects of teaching manual signs and Picture Exchange Communication System (PECS; Bondy & Frost, 1994) in terms of generalization of mands (i.e., a verbal response that specifies its reinforcer; Catania, 1992) across settings exhibited by four individuals with diagnoses of severe/profound mental retardation and intellectual disability. The authors first trained the participants to utilize the respective mands to request reinforcers. The results of the training phase suggested that three of the participants acquired PECS-based mands; two of the participants who acquired PECS-based mands also acquired manual signs. Next, the authors conducted across-setting generalization probes of the respective mands with each of the participants. The results showed that (a) all three of the participants who had acquired the PECS-based mands via direct training demonstrated generalization with the PECS-based mands, (b) the two participants who had acquired the manual signs via direct training demonstrated generalization with the manual signs, and (c) the two participants who had acquired both mand modalities utilized the PECS-based mands more often than manual signs to request preferred items that were not present in the individuals' environment. The overall results of Chambers and Rehfeldt demonstrated that specific behaviors (i.e., mands) could be trained that would allow individuals with moderate/profound disabilities to recruit reinforcement in their respective environments which resulted in the generalization of the behaviors.

Functional Communication Training (FCT; Carr & Durand, 1985) is one of the most common reinforcement-based treatments for problem behavior (Tiger et al., 2008). FCT consists of the teaching of functional communicative responses (FCRs; mands) that are intended to replace problem behavior in an individual's repertoire. Specifically, following an antecedent (e.g., Carr & Durand, 1985) or functional (e.g., Iwata et al. 1982/1994; Northup et al., 1991) analysis that systematically demonstrates the function(s) of problem behavior, a functionally equivalent mand is targeted and trained that allows the individual to contact the reinforcers that previously maintained problem behavior. Thus, the tactic of recruiting natural consequences is a central aspect of FCT and is inherent to the treatment (Falcomata & Wacker, 2012). Several studies (e.g., Durand & Carr, 1992; Moes & Frea, 2002) have evaluated the effects of FCT in terms of generalization with a specific reliance on the recruitment of natural contingencies component (i.e., in the absence of other tactics for programming for generalization). For example, Durand and Carr (1992) conducted a three-study experiment in which they (a) identified the functions via functional analyses of problem behavior exhibited by 12 children with a variety of diagnoses (e.g., autism; attention deficit disorder; developmental language disorder; i.e., Study 1), (b) evaluated and compared the effects of FCT and a time-out procedure within and across two groups of children (i.e., Study 2), and (c) evaluated and compared the extent to which the positive treatment findings in the second experiment would maintain and generalize to trainers who were unaware of the participants' treatment history (i.e., Study 3). The results of Study 2 showed that both FCT and the time-out procedure were effective at decreasing problem behavior. In contrast, the results of Study 3 showed that the children in the FCT group demonstrated generalization by emitting functional communicative responses with novel individuals and their problem behavior remained low during the generalization evaluation. Thus, the tactic of recruiting natural consequence may be said to have been active within the procedures implemented by Durand and Carr as the children in the FCT group exhibited functional communicative responses with novel adults and the positive treatment effects generalized. The results of Durand and Carr also showed that the effects of the time-out procedure were not replicated with the novel trainers; thus, generalization was not demonstrated with the time-out procedure. The results of Durand and Carr are interesting in that the generalization comparison (i.e., Study 3) may be characterized as a comparison between the effects of recruiting natural consequences (i.e., FCT) and what was essentially a train and hope approach (i.e., the time-out procedure); with recruitment of natural consequences clearly shown to be the effective tactic in the study.

Contact Natural Consequences Natural consequences are those that exist in the environment that are not specifically programmed in an artificial way (Stokes & Osnes, 1989). When skills are taught that subsequently contact naturally occurring reinforcers that exist in the individual's environment, lasting generalization and maintenance is more likely. Stokes and Osnes (1989) described the tactic of "contacting natural consequences" as "the most fundamental guideline of behavior programming, as well as generalization programming" (p. 341). The power of this tactic lies in its economic and efficiency features (i.e., behavior change agents and/or therapists do not need to explicitly identify, program, and embed artificial reinforcers in the natural environment for desired behavior to be strengthened and maintained in the natural environment; instances of generalized behaviors may be more likely to be reinforced consistently when the reinforcement exists naturally in the participant's environment).

In addition to utilizing the recruitment of natural consequence tactic, Durand and Carr (1992) also provided an example of the systematic use of the tactic of contacting naturally occurring reinforcers. As described above, following functional analysis of problem behavior and the assignment of participants to two treatment groups (i.e., FCT and time-out), both FCT and time-out were demonstrated to be effective. However, only the group that received the FCT treatment demonstrated generalization and maintenance in the presence of novel and naïve therapists. As the novel therapists were naïve to the procedures, they represented naturally occurring sources of reinforcement. In addition to recruitment of natural consequences and contact with naturally occurring reinforcers, additional tactics for programming for generalization were implicit within the procedures used by Carr and Durand (e.g., use of sufficient stimulus exemplars; use of sufficient response exemplars). Thus, the study also provides an example of how tactics can be combined and enhance the probability that target skills and behaviors will contact naturally occurring reinforcement.

Modify Maladaptive Consequences Stokes and Osnes (1989) discussed situations in which problem behaviors are under the control of powerful consequences. Subsequently, Stokes and Osnes conceptualized and characterized those consequences that maintain inappropriate behaviors as "maladaptive." Therefore, they asserted, the modification of such maladaptive consequences may be a necessary tactic in some situations to promote generalization. Specifically, Stokes and Osnes discussed the "termination of reinforcer delivery" for maladaptive behavior so that "more appropriate behaviors can be developed and maintained through natural or temporarily artificial consequences" (p. 343). This tactic, referred to as *modify maladaptive consequence*, is intended to facilitate contact of appropriate/adaptive behaviors with naturally occurring environment contingencies by decreasing "maladaptive" behaviors that have been previously functioning to produce those same environmental contingencies. In such cases, if maladaptive consequences are not modified, the appropriate behaviors intended for generalization may not sufficiently contact naturally occurring environment contingencies to produce generalization because maladaptive behaviors are continuing to contact those environmentally based reinforcers. Thus, allocation of responding will favor the maladaptive behaviors rather than intended generalized appropriate behavior.

As with the recruitment of natural consequences tactic, the tactic of modification of maladaptive consequence is often implicit to FCT. Specifically, FCT often includes an extinction component and, in fact, previous studies have demonstrated that extinction is, at times, a necessary component of FCT (e.g., Fisher et al., 1993). For example, Moes and Frea (2002) evaluated the generalization of FCT treatment effects across routines, family members, and contexts with three families with children with autism diagnoses who engaged in multiply-maintained problem behavior. All phases of the study were conducted in the home by family members during routines that had been identified as common during the day. Specifically, Moes and Frea (a) conducted an antecedent analysis to assist in the generation of hypotheses regarding functions of problem behavior, (b) tested their hypotheses via brief functional analyses to confirm the functions of problem behavior, (c) conducted FCT during one target routine, and (d) evaluated the extent to which FCT was effective during other routines (identified via collaboration with the family) with multiple family members implementing the treatment. In addition to the reinforcement of FCRs, extinction was a primary component of FCT during the initial FCT condition, the "Contextualized FCT" condition in which multiple routines and family members were targeted during treatment, and the generalization probes (i.e., probes taken during routines in which no direct training occurred) conducted during the initial FCT and "Contextualized FCT" conditions. The treatment results showed that the treatment effects of FCT (i.e., rates of FCRs were high; rates of problem behavior were low) successfully generalized as evidenced by the results of the generalization probes across untrained routines.

Punishment procedures have also been shown to be, at times, a necessary component for the success of FCT (e.g., Wacker et al., 1990). Similar to extinction, the embedding of punishment within FCT treatment arrangements constitutes the inclusion of the tactic of modifying maladaptive consequences. Wacker et al. (2005) provided an example of the inclusion of punishment in the form of time-out as a component during FCT as part of a systematic evaluation of generalization. Specifically, Wacker et al. conducted FCT with 23 children who engaged in escape-maintained problem behavior. The authors first conducted pre-treatment probes across stimuli/contexts (i.e., people, tasks, settings) with the results showing high levels of problem behavior across stimuli/contexts demonstrated by 12 of the 23 participants. Subsequently, the authors implemented FCT which included a time-out procedure for a subset of the participants. Following FCT, which produced high levels of FCRs and low levels of problem behavior, the authors implemented generalization probes (i.e., across novel/untrained people, tasks, and settings) with the 12 children who had engaged in problem behaviors during the pre-treatment probes. Substantial reductions in problem behavior were observed during the generalization probes with each of the untrained stimulus conditions.

Reinforce Occurrences of Generalization Although Stokes and Osnes (1989) referred to the tactic of reinforcement of occurrences of generalization "probably the least of the current 12 tactics to be called a legitimate programming strategy" (p. 343), the authors also characterized the tactic as possibly "a most reliable and legitimate technique that facilitates generalization." The tactic of reinforcement of occurrences of generalization is one in which instances of generalization are identified and consequated with stimuli intended to reinforce those instances; thereby increasing the likelihood that generalized responding will continue to occur.

Silbaugh et al. (2018) provided an example of the use of the tactic of reinforcement of occurrences of generalization within the context of programming for variable responding exhibited by two individuals with autism diagnoses. Specifically, Silbaugh et al. implemented lag schedules of reinforcement in combination with progressive time delays (TD) to facilitate the variable mand responding. The authors first implemented a lag 0 (e.g., fixed-ratio [FR] 1 schedule) condition in which reinforcement was delivered for any mands. No novel mands (i.e., response generalization) occurred during the lag 0 condition. Next, the authors implemented a Lag 1 plus TD condition in which they prompted (following delays; i.e., the TD component) specific and variable mands and reinforced prompted and independent variable mands via a lag 1 schedule of reinforcement (i.e., for a mand to be reinforced it had to be different from the immediately preceding mand). The authors also reinforced novel (i.e., untrained) mands that emerged during the lag schedule procedure in addition to reinforcing specifically prompted variable mands. In addition to demonstrating variability in mand responding during the lag 1 plus TD arrangement, both individuals also demonstrated novel mands during the procedure which were reinforced within the lag schedule (if they varied from the preceding mand). These novel mands constituted response generalization and the reinforcement provided within the lag schedule represented reinforcement of occurrences of generalization.

Schindler and Horner (2005) provided an additional example of the implicit use of the tactic of reinforcing occurrences of generalization within the context of FCT; specifically, when generalization did not occur as a result of the implicit tactic of recruiting natural consequences. Schindler and Horner (2005) first conducted FCT with three individuals with histories of engagement in problem behavior. The authors implemented FCT in several settings including (a) a one-to-one and (b) a preschool setting. In addition, the authors evaluated generalization in two non-training settings including (c) a non-training room at the preschool and (d) in the individuals' homes. Schindler and Horner found that although FCRs increased and problem behavior decreased in the training settings, levels of FCRs and problem behavior did not change in the non-training settings; thus, generalization did not occur. Following the authors' incorporation of additional procedures (i.e., "low effort"), including the active encouragement of care providers to make FCR materials available and to prompt and reinforce FCRs, FCRs increased and problem behavior decreased in the generalization settings. In addition to providing an example of the systematic use of the tactic of reinforcement of occurrences of generalization, Schindler and Horner's procedures also illustrated the approach described by Stokes and Osnes (1989) to "set up conditions for generalization of responding" in the form of making FCR materials available and actively prompting the occurrence of FCRs; and, in turn, reinforcing the occurrence of the FCRs in the generalization settings.

Train Diversely

Behavior-analytic research has consistently demonstrated that diverse and varied programming generally results in diverse and varied behavioral outcomes. Diverse training, whether it be for increasing responding to novel stimuli or producing novel responses, can be promoted through a variety of ways. Stokes and Osnes (1989) identified four prominent tactics that are consistent with the concept of training diversely including (a) *use sufficient stimulus exemplars*, (b) *use sufficient response exemplars*, (c) *make antecedents less discriminable*, and (d) *make consequences less discriminable*. The former two are similar in that they highlight the importance of using the necessary number of examples of stimuli or responses to produce the desired stimulus or response generalization. The latter two stress the significance of making the antecedent-response or response-consequence contingencies less discernible to an individual, such that responding by the individual is not just controlled by narrowly contrived stimuli, but instead that stimulus control is broaden to a diverse universe of antecedents and consequences.

Use Sufficient Stimulus and Response Exemplars This tactic, which is also sometimes referred to as *multiple-exemplar training* (MET), involves the direct training of various examples of a stimulus or direct training of various examples of a response. The logic for using a variety of examples is so that an individual learns that the trained examples are not distinct from one another (i.e., they are part of the same "class" or "universe"), which then hopefully translates into learning that similar untrained examples are not distinct from the directly taught examples (Holth, 2017). Emphasis on using a *sufficient* number of examples is made primarily because a clear number of required examples needed to produce generalization has not been empirically demonstrated (Holth, 2017). Thus, it follows that setting an arbitrary number of examples across individuals may result in using too few or too many exemplars (i.e., it is possible that too many unnecessary exemplars may be wasteful if less are needed, because doing so would require an unnecessary amount of time and resources).

Schroeder and Baer (1972) distinguished that the number of exemplars that are presented during training can be introduced in different ways: either by sequentially adding one exemplar at a time (i.e., serial MET [S-MET]), or by adding two or more exemplars simultaneously (i.e., concurrent MET [C-MET]). For example, Eikeseth and Nesset (2003) followed an S-MET approach to teach participants with phonological disorders to blend letter sounds, wherein they introduced one letter sound blend at a time until generalization to untrained blends was observed. Conversely, a study by Reeve et al. (2007) followed a C-MET approach to teach four participants with ASD to provide help to other people by introducing four different examples of situations where helping behavior should be emitted, such as helping someone carry heavy objects or finding lost items. Both studies demonstrated that their specific MET approach can produce generalized responding, which has been confirmed by other studies as well (e.g., Panyan & Hall, 1978; Schroeder et al., 1998).

Although there is evidence that S-MET and C-MET tactics are effective, it is unclear which specific arrangement is most efficient. A study by Schnell et al. (2018) noted that the corpus of MET studies has suggested C-MET is most effective, but that idiosyncrasies exist that may potentially favor S-MET in some cases. For instance, Schnell et al. compared the efficiency of S-MET vs. C-MET on tact acquisition and generalization and found that S-MET was most efficient because it produced the lowest mean training time per mastered exemplar for two of three participants; a finding that was inconsistent with previous MET literature that examined other skill domains (e.g., Schroeder et al., 1998; Wunderlich et al., 2014). Thus, it is important that those who pursue generalized behavior change consider that the number of sufficient exemplars needed may vary across individuals and skills, such that efforts for generalization may involve weighing multiple factors prior to determining the number of exemplars to use.

Stimulus Exemplars Research over the past 50 years has shown that stimulus MET can result in generalization across a variety of skill domains. For example, early in the inception of applied behavior analysis, Baer et al. (1967) demonstrated that direct training of various imitation exemplars with people with intellectual disabilities resulted in the emergence of independent imitations of novel imitation models, which was then used to develop their verbal behavior. Likewise, Schnell et al. (2018) showed that using various examples of stimuli to teach tacts resulted in independent tacts to novel examples of those same stimuli.

When teaching various stimulus exemplars, it might also be useful to teach "don't do it" examples as well; that is, when a response should not occur or when a response will not come in contact with reinforcement. For instance, a study by Taylor-Santa et al. (2014) demonstrated how this could be accomplished with neutral stimuli by teaching three participants with ASD the difference between neutral stimuli that would signal the occurrence of reinforcement (i.e., discriminative stimuli [S^D]) and neutral stimuli that would signal nonoccurrence of reinforcement (i.e., stimulus delta; [S-delta]) through stimulus–stimulus pairing and discrimination training. First, the researchers paired preferred edibles with neutral stimuli when target responding occurred. Then, the researchers exposed the participants to trials involving S-delta stimuli, which were interspersed between S^D trials, in which no reinforcement was delivered even if an independent target response occurred. Their results showed that previously neutral stimuli acquired either an S^D or S-delta value based on the way reinforcement was delivered for one and not the other. One valuable implication from this study, as it relates to using sufficient exemplars, is that it may be useful for practitioners to consider how the use of various praise exemplars (while also embedding "don't do it" examples) could result in "a broader range of verbal stimuli that will have reinforcing effectiveness" (Taylor-Santa et al., 2014, pg. 173). Also, consistent with the "Stimulus Discrimination" section of this chapter, Taylor-Santa et al. highlighted the importance of delimiting the class or universe of stimuli so that accurate responding occurs.

Response Exemplars Previous studies have shown that response MET can be an effective tactic to promote generalization of a variety of skills. For instance, Rozenblat et al. (2019) taught four adolescents with ASD to initiate bids for joint attention using a variety of response exemplars in the form of textual and audio scripts. Rozenblat et al. found that the participants learned to initiate bids for joint attention using the scripts that were directly taught (e.g., "That's cool"; "look at that!"); and that they also learned to emit novel bids, sometimes by blending language from directly taught exemplars (e.g., "look at that cool thing!"). Another novel use of this tactic can be found in Silbaugh et al. (2018) described earlier in this chapter, where two participants with ASD were taught to emit various response exemplars of mands through progressive TD prompts and lag schedules of reinforcement. Using a multiple baseline design across behaviors with embedded reversals, Silbaugh et al. demonstrated that lag schedule conditions produced higher rates of mand variability per minute as well as more occurrences of novel mand responses (i.e., response exemplars). The results from these studies exemplified that not only can the use of various response exemplars produce generalization, but also that, when coupled with other interventions (e.g., lag schedules of reinforcement), other generalization outcomes can be achieved as well (in this case, response variability).

When teaching various examples of responses, it can be beneficial to also teach non-examples of responses (i.e., how a behavior should not be emitted). One way this can be accomplished is through the use of the Teaching Interaction procedure (TIP), which involves (1) identifying the response being taught, (2) providing the logic for learning said response, (3) instructing how to conduct the response, (4) modeling examples and non-examples of the response, (5) allowing the individual to role-play, and (6) giving feedback to the individual (Phillips et al., 1974). The effectiveness of this procedure for teaching examples and non-examples was illustrated by Leaf et al. (2010), who used TIP to teach a group of participants with autism how to emit social skills appropriately (e.g., showing appreciation, giving compliments, making empathetic statements), which resulted in generalization as well. Another way non-examples can be taught is through the "cool versus not cool" procedure (Leaf et al., 2016), in which individuals are taught to discriminate between "cool responses" (i.e., appropriate behaviors) and "not cool responses" (i.e., inappropriate behaviors). Leaf et al. (2016) embedded this strategy within TIP to teach eight participants with ASD how to engage in appropriate game play with others by asking the group of participants to label whether an example or non-example was either cool or not cool.

Make Antecedents Less Discriminable Also known as *loose training* or *teaching loosely*, this tactic involves manipulating the environment such that the individual is exposed to a broad array of stimuli that contains random, non-necessary qualities. This arrangement can reduce the likelihood that irrelevant characteristics of any one stimulus will exert excessive control over an individual's response, because exposure to a group of stimuli that bear non-necessary characteristics essentially teaches that individual that responding in the presence of those non-necessary qualities will still occasion reinforcement. For example, Pelios et al. (2003) showed how this tactic could be embedded in a multi-treatment package to establish independent academic work with participants with ASD. This was done by first teaching the students to engage in consistent on-task behavior when the instructor was present and then fading the presence of the instructor systematically by increasing the distance between the instructor and the participants until the instructor was able to exit the room and enter randomly 3–5 min after. By the end of the intervention, the three participants demonstrated independent academic work completion in the absence of the instructor with the materials and settings they were directly trained with, as well as with novel materials and in novel settings. By making antecedents less discriminable (e.g., varying the presence of the instructor), the researchers were able to promote higher rates of generalized responding (e.g., completion of academic work across materials and settings).

Make Consequences Less Discriminable Commonly referred to as *indiscriminable contingencies*, this tactic describes the deliberate arrangement of an environment after a response occurs such that the occurrence of reinforcement is less discernable or predictable by an individual. Generally, this is done to produce response maintenance. One way this can be accomplished is by shifting from continuous to intermittent schedules of reinforcement. For example, Andersen and Redd (1980) demonstrated this by teaching four participants to engage in academic work despite being told that the instructor would return and/or check the assignments. This was done by first teaching the participants to complete work using verbal prompts and praise, then fading the verbal prompts and presence of the instructor, and last making consequences indiscriminable by telling the participants that the work might be checked when the instructor returned.

Another method that can help produce response maintenance is delayed reinforcement (i.e., increasing the time between a target response and the occurrence of a reinforcer). For instance, Freeland and Noell (2002) used delayed reinforcement to increase correct single-digit math completion per minute by two third-grade participants. Initially, the researchers provided immediate reinforcement for each worksheet that met goal criteria from a box of possible reinforcers. Then, the researchers shifted to delayed reinforcement whereby only one of every two worksheets was selected for grading, followed by every one in four worksheets. Using a withdrawal design, the researchers showed that delayed reinforcement produced higher rates of digit completion per minute when compared to phases that replicated baseline conditions. In the end, the researchers concluded by fading the reinforcers altogether and showed that responding was maintained across numerous sessions.

Incorporate Functional Mediators

According to Stokes and Osnes (1989), functional mediators are stimuli that are present during training that, when also present during generalization conditions, facilitate generalization. Thus, the purpose of the tactics that comprise the incorporate functional mediators strategy is to use the discriminative control of specific stimulus (or set of stimuli) that were created during direct training conditions to produce responses under generalization conditions when the same discriminative stimulus/stimuli are present as well. This can be accomplished by using common and/or self-mediated stimuli.

Incorporate Common Salient Stimuli Incorporation of common salient stimuli involves the use of commonly occurring physical or social stimuli to facilitate generalization. An example of common physical stimuli was provided by Spohn et al. (1999), in which they taught three children with developmental disabilities to engage in social interactions during mealtimes by using modified placemats as a common salient physical stimuli. The researchers created 12 different placemats that contained collages of images of cartoon characters, food items, animals, and "something ridiculous or funny such as a cat dressed as a baby seated in a carriage" (pg. 6; Spohn et al., 1999), which were used as visual prompts for conversation topics during breakfast time. After the children were taught to engage in conversations with peers using the placemat during breakfast, the researchers then examined whether the placemats facilitated generalization by (a) removing the adult facilitator and (b) representing the placemats during lunch time. All three participants showed increased social interactions during lunch time when compared to baseline, which suggested that the placemats may have acted as functional mediators in that generalized responding emerged when common stimuli with discriminative properties were presented in a new context. A variety of physical stimuli can be used to produce this effect, such as commonly requested items (Charlop et al., 1985), or even academic materials (Marholin & Steinman, 1977). The use of common and salient stimuli is recommended during direct training because it is likely to promote more generalized responding given that it is highly likely that those stimuli will appear often in the environment where responding needs to occur. Conversely, using artificial stimuli may do very little for producing generalized responding, because those stimuli do not naturally appear in the targeted environments.

Social stimuli are another type of common stimuli that can be taken advantage of for their discriminative properties (i.e., common salient social stimuli; Stokes & Osnes, 1989). For example, parents, teachers, therapists, peers, and/or siblings can all produce stimulus control over responses, which can then be used to facilitate responding in generalization contexts (e.g., novel settings, novel materials). Schmidt and Stichter (2012) demonstrated this programming tactic by recruiting and training three typically developing peers as mediators (i.e., common social stimuli) to help produce generalized social interactions across two novel settings (e.g., lunch room, math class). The researchers first taught six adolescents with ASD to engage in social interactions (e.g., greeting, asking/answering questions, commenting) in a group format by holding 1-h lessons that incorporated modeling and rehearsal. Following training, the participants were then observed during lunch time and math class, during which peer mediators were instructed to initiate interactions with the participants during that time. Upon the introduction of the peers in these novel settings, social interactions increased when compared to baseline levels. The study by Schmidt and Stichter demonstrated that peers may take on discriminative stimulus properties that can result in generalized responses across environments.

Incorporate Salient Self-Mediated Stimuli In line with the concept that discriminative stimuli can be used to improve generalization outcomes, such stimuli can also be embedded within self-management strategies to produce generalized responses, typically through physical, verbal, and covert stimuli (Stokes & Osnes, 1989). An example of self-mediated physical stimuli was illustrated in a study by Prater et al. (1992) in which a participant with learning and behavioral issues showed generalized self-monitoring of on-task behavior across various classrooms when visual prompts (symbols in his notebook and on a poster) were present in those settings. The 14-year-old participant was first taught the meaning of visual prompts and how to self-monitor via modeling. Then, the participant was taught to self-monitor when studying 20 spelling words by (a) following an auditory prompt to ask himself "was I working?" and (b) scoring his on-task behavior on a self-monitoring sheet every 1–8 min. The auditory prompts were systematically faded until only the visual prompts remained. Using a multiple baseline design with reversals across settings, the researchers demonstrated the effects of the initial training and the presence of visual prompts on academic performance by (a) showing that academic performance increased across all settings and (b) that academic performance decreased during reversal phases in which visual prompts were removed. The results from the study suggested that self-mediated physical stimuli, such as self-monitoring checklists or posters, can result in effective stimulus control over generalized responses. Other physical stimuli that can be used for self-mediation include things such as bracelets with beads (Holman & Baer, 1979) strings (Stokes & Osnes, 1989), or even wearable technology (e.g., smart watch; O'Brien et al., 2016).

Self-mediated stimuli can also take the form of verbal or covert stimuli, which is commonly referred to as *self-instruction* in the self-management literature (Erhard et al., in press). This tactic involves teaching an individual to use their own verbal behavior to occasion target responses and, in some instances, produce generalized target responses. For instance, Swanson and Scarpati (1985) demonstrated generalization of academic performance across settings and tasks when they taught two participants in special education to engage in self-instruction. The researchers taught the participant to self-instruct themselves through (a) modeling, (b) instruction, (c) rehearsal involving self-instruction out loud, (d) rehearsal involving self-instruction through whispering, and (e) rehearsal involving self-instruction quietly. It is worth noting that this type of intervention shares characteristics that are grounded in cognitive behavioral theoretical frameworks (e.g., teaching someone to self-instruct silently).

Other Important Considerations

Baer's (1981) book, *How to Plan for Generalization*, highlighted many of the tactics presented in the current chapter. In addition, he also noted that when one is attempting to produce generalized behavior change, it is also imperative that one takes into consideration the application of said generalized behavior change with regards to the individual being taught and their current skill repertoire and where the stimuli the responses need to occur in. Finally, Baer recommended that one take into account response maintenance and how it will be planned for. In the following section, we have combined some of the recommendations from Baer with current behavioral practices as a guide for practitioners to use for programming for generalization.

Assessing the Individual and the Stimuli

The first recommendation Baer (1981) provided was for one to begin the process of generalization by closely examining the individual's skill repertoire so that one can list all behaviors that need change. For practitioners, this is similar to conducting an initial assessment or evaluation and establishing behavioral goals based on those observations. However, the purpose of this pre-assessment component is not to just understand the skill repertoire that an individual possesses so that we can determine what behaviors need to be taught and which need to be reduced, but so that one can determine what skills require systematic generalization programming. Further, pre-assessment allows for the subsequent measurement of the emergence of generalized responding based on the specific tactics implemented. One way this can be accomplished is through the use of a *generalization map* (Allen et al., 1991), a dichotomous assessment tool that groups generalization outcomes (e.g., time, settings, behaviors, people) into 16 different classes by whether those outcome combinations are present or absent. For example, if one could observe the presence of an individual's generalization across subject-behavior-setting-time, then the corresponding class (Class 16) would be marked as present for this individual.

Next, Baer (1981) recommended that one create a list of all the people, situations, and settings in which the target behavior needs to occur. This step is meaningful so that one can delineate the extent of programming needed to produce generalized responding. One way that this can be accomplished is by conducting a *general case analysis* or *general case programming*, where one (1) defines the instructional universe, (2) defines the range of relevant stimulus and response variations with that universe, (3) selects examples from the instructional universe for use in teaching and probe testing, (4) sequences teaching examples, (5) teaches the examples, and (6) tests with non-trained probe examples (Albin & Horner, 1988; Becker & Engelmann, 1978). Another way this can be accomplished is through *matrix training*, whereby practitioners create a grid or table that lists all the possible combinations desired between stimuli (e.g., red circle, red triangle, yellow circle, yellow triangle, and so on; Pauwels et al., 2015). Akin to conducting assessments and creating behavioral goals, general case analyses and matrix training allow practitioners to establish target stimuli for an individual to respond to.

Determining the Reinforcement Schedule

When an individual's repertoire has been assessed and generalization outcomes have been targeted, it is then useful to establish a reinforcement schedule, a reinforcer fading plan, and to follow the schedule/plan as precisely as possible. The importance of establishing a consistent schedule was underscored by Fragale et al. (2012), which showed how an abolishing operation (Langthorne & McGill, 2009) can result in less generalized responding. In their study, Fragale et al. demonstrated how three children with disabilities engaged in fewer mands across novel people and places when access to preferred stimuli was given prior to the "beginning" of their training session, when compared to sessions in which no *presession access* was scheduled. The results of Fragale et al. showed that individuals may emit less generalized responses if the motivating operation (MO) has been manipulated such that the value of a reinforcer is diminished. To the layman, it may seem as if generalization has not occurred (or may occur less than direct training), when in fact it is the value of the reinforcer which may "hide" the individual's capacity to generalize. Therefore, deliberate control and delivery of reinforcers is strongly recommended during training to ensure that one can assess generalized behavior change more accurately.

One of the main goals in producing behavior change is that such changes are durable and long-lasting (i.e., response maintenance). As indicated by Ferster and Skinner's *Schedules of Reinforcement* (1957), response maintenance effects are strongly influenced by the schedule of reinforcement that is used to train the occurrence of behaviors; denser schedules of reinforcement produce less persistent responses, whereas thinner schedules of reinforcement tend to produce more persistent responses. In line with this behavioral mechanism, then, one should consider how one will modify the response–reinforcer ratio and/or delay to reinforcement to produce more long-lasting responding (Baer, 1981). When doing this, it might be beneficial to determine the terminal ratio or delay that is most consistent with naturally occurring contingencies. For example, a child whose behavior is reinforced by a teacher's attention may not be able to gain her undivided attention repeatedly during class, so it is imperative that reinforcement is thinned to the point that the child may tolerate the delay of attention until it can be provided by the teacher at an appropriate time (e.g., unstructured learning time, lunch, recess, after class).

Establishing a Plan with Others

As it is true for any group effort, one should also consider the level of involvement and buy-in needed from stakeholders when attempting to produce generalized behavior change. It is imperative that one ensures stakeholders are aware of the effort needed to make these changes and willing to facilitate these efforts. In some cases, this may not be arduous if the individual in question has already begun producing generalized responding with minimal assistance. But in other cases, deliberate and systematic efforts may be warranted. As such, one should ask when beginning services: Is it possible to collaborate with others effectively given their level of training and availability? How much training will be required of each stakeholder? Can time be allocated sufficiently among all parties to attain the desired behavioral change? What barriers can be expected, and how can those barriers be overcome?

Finally, practitioners should be parsimonious when programming for generalized behavior change. One must allocate resources at their disposal judiciously: the more manipulatives one adds to an intervention (e.g., visual supports, token systems, measurement systems), the more opportunities there may be for any one of those stimuli to create excessive or restricted stimulus control over responding (and measurement reliability may be reduced as well). As such, consider that less may be more. For instance, when determining how many stimulus and response exemplars are enough, consider whether one exemplar is sufficient or if multiple exemplars are needed, and evaluate generalization as necessary (cf. Schnell et al., 2018).

16 Response Interruption and Redirection

Haley M. K. Steinhauser and William H. Ahearn

Redirection Procedures of Automatically Reinforced Behavior

Unlike behavior maintained by social consequences, behavior maintained by automatic reinforcement poses treatment challenges due to the inaccessibility of maintaining sensory consequences (Vollmer, 1994). Several procedures have approached the treatment of automatically reinforced behavior by enriching the environment with competing stimuli (e.g., Hagopian et al., 2020; Piazza et al., 2000) and/or by contingently prompting alternative responses, including overcorrection (Foxx & Azrin, 1973), contingent demands (e.g., Fisher et al., 1994a, b), and response interruption and redirection (RIRD; Ahearn et al., 2007). Competing stimuli alone have not been found to be consistently effective (e.g., Hagopian et al., 2017, 2020; Piazza et al., 1998, 2000). Redirection in isolation or especially when combined with other procedures has been found to be generally effective. For the purposes of this chapter, *redirection* is defined as the contingent prompting of appropriate alternative responses.

RIRD is the most common redirection procedure in recent publications, and it has been identified as an evidence-based practice for automatically reinforced behavior (Tomaszewski et al., 2017). The Ahearn et al. (2007) evaluation of RIRD in the treatment of automatically maintained vocal stereotypy is often cited as a seminal reference for RIRD. The procedure involved the contingent interruption of stereotypy, followed by prompts to emit appropriate vocalizations until the individual complied with these demands in the absence of stereotypy. In the years following the Ahearn et al. study, there have been numerous evaluations and variations of the RIRD procedure.

Martinez and Betz (2013) provided a brief review of early RIRD studies published in the *Journal of Applied Behavior Analysis* from 2007 to 2012. The authors outlined areas for future research to improve the practicality of the procedure, including treatment evaluations during naturally occurring activities and component analyses of procedural variations. In the past 20 years, redirection has been evaluated with automatically reinforced behavior extensively (e.g., Ahearn et al., 2007; Ahrens et al., 2011; Hagopian & Adelinis, 2001; Hagopian et al., 2011). In order to summarize the redirection literature, we conducted a 20-year systematic review of empirical evaluations of redirection procedures with automatically reinforced behavior.

Literature Review Method

Peer-reviewed papers were collected through a search of relevant databases and behavior-analytic journals, including APA PsycInfo, Academic Search Premier, JSTOR, ERIC, *Journal of Applied Behavior Analysis*, *Behavioral Interventions*, and *Behavior Modification*. All databases and journals were searched by combining the terms "automatic reinforcement," "pica," and "stereotypy," with the terms, "redirection," "response redirection," "response interruption and redirection," "RIRD," "contingent demands," and "overcorrection" to conduct advanced searches. Articles were also identified by reviewing the references of papers obtained from the database and journal searches. We used the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) method recommended by Liberati et al. (2009) for obtaining and including papers in our review. The database and journal searches were last conducted in September 2020.

Inclusion Criteria

Studies were included if they (1) were published in a peer-reviewed, English-language journal, (2) were published between the years of 2000 and 2020, (3) involved an empirical evaluation of redirection, (4) were conducted with individuals with autism or other related developmental disability, and (5) targeted behavior presumably maintained by automatic reinforcement. As noted above, for the purposes of this chapter, *redirection* was defined as the contingent prompting of an appropriate alternative response following the occurrence of a target response for decrease. The target behavior was considered to be maintained by automatic reinforcement if (1) the authors reported an assessment of function (e.g., functional analysis, persistence in a no-interaction condition) or (2) the target behavior was stereotypy based on the conclusion of Rapp and Vollmer (2005) that stereotypy is most often automatically reinforced.

Exclusion Criteria

Titles and abstracts were reviewed, and studies were excluded if (1) they were duplicates of other obtained studies, (2) they were review or discussion papers, (3) they did not evaluate a redirection procedure, (4) they did not involve participants with autism or other developmental disabilities, and (5) they targeted behavior maintained by socially mediated consequences (i.e., not automatic reinforcement). The full-text articles of all remaining studies were then reviewed for the same criteria. Given the current definition of redirection, any studies that involved the redirection of hands down, or similar response, rather than the prompting of active engagement in appropriate alternative behavior were also excluded from the current review.

Summary of Redirection Literature

In reviewing the redirection literature, we have identified three main takeaway points with respect to redirection procedures in the treatment of automatically reinforced behavior. Firstly, redirection can be an effective strategy for automatically reinforced behavior. Additionally, there is evidence to support that promoting appropriate behavior likely improves the efficacy of redirection. Lastly, there are procedural variations of redirection and treatment components to consider when developing a redirection treatment package. These variations and components present methods for individualizing and contextualizing redirection treatment packages to improve the efficacy and social acceptability of the procedure. Table 16.1 lists the redirection studies that we identified from 2000 to 2020, procedural details, and redirection efficacy.

Redirection Efficacy

Redirection procedures have most often been evaluated with stereotypy. Of the 48 studies that we reviewed from 2000 to 2020, redirection was

*progressed to natural setting, **natural setting, *AV* appropriate vocalization, *CS* competing stimuli, *DRA* differential reinforcement of alternative behavior, *DRO* differential reinforcement of other behavior, *HV* hyperventilation, *MS* motor stereotypy, *NCA* noncontingent attention, *NCE* noncontingent edible, *RB* response blocking, *RC* response cost, *VR* verbal reprimand, VS vocal stereotypy also evaluated with automatically reinforced pica, public masturbation, daytime sleep, body tensing, and hyperventilation. Across all studies, the authors concluded that redirection decreased the target behavior or there was a clear level change during redirection for 107 of 117 participants (91.5%). This includes redirection evaluations with modest decreases in the target behavior, but a clear change in the level of behavior was obtained.

Although we limited our literature search to behavior maintained by automatic reinforcement, the persistence of the target behavior in no-interaction conditions or automatic reinforcement screens (Querim et al., 2013) was used to suggest the behavior was at least partially maintained by automatic reinforcement in several studies. Automatic reinforcement screens, however, do not assess if behavior is maintained by both automatic and social reinforcement. Multiple studies reported this as a limitation affecting redirection efficacy, noting that redirection might involve attention that reinforces the target behavior. This possibility should be considered when reviewing published and clinical evaluations of redirection. When developing redirection packages for behavior possibly maintained by both automatic reinforcement and attention, practitioners might consider conducting a variation of the Cividini-Motta et al. (2020) brief attention screen.

With *redirection* defined as the contingent prompting of an alternative response, there were considerable variations across the reviewed studies that likely impacted the observed redirection efficacy. Numerous studies evaluated the additive effects of treatment components paired with redirection, and some evaluated the relative efficacy of redirection compared to other interventions. Other treatment components and interventions included medication prescribed for the target behavior, noncontingent competing stimuli, reinforcement of alternative behavior, verbal reprimands, response blocking, and response cost.

Measures and Interpretations of Efficacy

Target Behavior Measurement

Response measurement and the interpretations of redirection efficacy have been an area of discussion and study in the redirection literature. Methods of measurement and data analysis directly affect interpretations of functional relations. In the Meany-Daboul et al. (2007) comparison of momentary time sampling (MTS) and partial interval recording (PIR) to continuous duration recording (CDR), the MTS method most closely aligned with the CDR method. These results suggest that MTS should be used when the target behavior is best measured using duration recording, but CDR is impractical, which is likely the case in clinical or classroom settings.

Some redirection studies measured the target behavior using *interrupted measurement* that involved pausing the session timer during redirection (redirection may prevent targeted behavior from occurring thus creating unequal opportunity for targeted behavior to occur between baseline and treatment) continuing the session until a set duration outside of redirection or maximum total duration, and only recording occurrences of the target behavior outside of redirection. Several studies that compared this practice to *uninterrupted measurement* (i.e., total session recording) were among studies that concluded redirection was ineffective or resulted in modest reductions (e.g., Carroll & Kodak, 2014; DeRosa et al., 2019; Wunderlich & Vollmer, 2015). Carroll and Kodak suggested that interrupted measurement overestimates the efficacy of redirection, and Wunderlich and Vollmer replicated these results with four of seven participants. Subsequent research has resulted in inconsistent conclusions in this area, with several studies demonstrating significant redirection treatment effects using uninterrupted measurement methods (e.g., Martinez et al., 2016; McNamara & Cividini-Motta, 2019; Toper-Korkmaz et al., 2018). Given that interrupted measurement has been demonstrated to overestimate redirection efficacy, at least in some cases, future evaluations should (1) use uninterrupted measures and/or (2) provide supplemental measures with respect to redirection implementation. Although uninterrupted measures are more stringent with respect to the redirected behavior, uninterrupted measures might inflate measures of appropriate behavior.

Supplemental Measures

In addition to measuring the automatically reinforced target behavior, several redirection studies have included supplemental measures to evaluate redirection. These supplemental measures have often included redirection implementation, appropriate behavior, and untargeted challenging behavior. As noted in the *Target Behavior Measurement* section (Sect. 3.1.1), measures of redirection implementation (e.g., frequency, duration) might serve as supplemental measures to interpret redirection efficacy or treatment practicality when implementing redirection in natural settings.

Lanovaz et al. (2013) concluded that reducing stereotypy often results in response reallocation and, therefore, suggested that measures of untargeted behavior might be relevant when treating behavior maintained by automatic reinforcement. Response reallocation might be to other forms of automatically maintained behavior or appropriate behavior. Cook and Rapp (2020) and Pastrana et al. (2013) specifically evaluated the effect of stereotypy redirection on untargeted forms of stereotypy. Researchers and practitioners should monitor the levels of other forms of presumably automatically reinforced behavior during redirection procedures.

As for supplemental measures of appropriate behavior, numerous redirection studies have measured topographies of adaptive behavior. Measures of appropriate vocalizations are common in redirection evaluations targeting stereotypy, but other measures of adaptive responses during redirection include leisure engagement and academic responding (Cook & Rapp, 2020; Gibbs et al., 2018). Some studies with supplemental measures of appropriate behavior arranged reinforcement to promote reallocation to appropriate alternatives, and other studies simply measured the indirect effects of redirection. Supplemental measures of contextually appropriate behavior should be used to evaluate if the target behavior is interfering with functional engagement and the effects of redirection (e.g., Steinhauser et al., 2021).

With the objective of identifying socially acceptable punishers, Verriden and Roscoe (2019) measured the indirect effects of putative punishers on *emotional responses*, defined as whining, crying, screaming, aggression, self-injury, attempts to escape from the procedure, or physical resistance. Similarly, Hagopian and colleagues (Hagopian & Adelinis, 2001; Hagopian & Toole, 2009) evaluated redirection procedures with participants who engaged in aggression when the target behavior was blocked and measured the effects on aggression. Supplemental measures of untargeted challenging behavior might also be useful measures to interpret the social validity or acceptability of redirection.

There are various supplemental measures that might guide interpretations of redirection efficacy. We recommend that practitioners and researchers include measures relevant to the individual and context. That is, supplemental measures of appropriate behavior should be informed by the behavior that constitutes functional engagement in the treatment context or activity (e.g., social, vocational, academic). In addition to supplemental measures of appropriate behavior, future research and clinical applications of redirection should include supplemental measures of challenging behavior as a measure of social validity (e.g., Verriden & Roscoe, 2019). Therefore, future evaluations of redirection should include at least three key areas of measurement to interpret the efficacy of redirection, including measures of (1) the automatically reinforced challenging behavior, (2) contextually appropriate behavior, and (3) emotional responses or other forms of challenging behavior.

Mechanism of Behavior Change

The mechanism of behavior change responsible for redirection efficacy is a recurring discussion in the redirection literature. The results of Ahrens et al. (2011) Experiment 3 support the assertion that redirection functioned as positive punishment with one participant. The same can be said about the Colón and Ahearn (2019) systematic analysis of redirection treatment integrity, with low levels of stereotypy during phases of diminished treatment consistency. This interpretation of positive punishment as the mechanism of behavior change needs to be considered in context. Redirection has interdependent components (e.g., prompting, alternative responses) that vary considerably across redirection procedures, and redirection is often packaged with other treatments. Reinforcement-based treatment components often involve sources of reinforcement either provided noncontingently or contingent on appropriate alternative responses. Other consequence-based treatment components (e.g., verbal reprimands, response blocking, response cost) might also function as punishment (see also Lerman and Iwata (1996) and Smith et al. (1999) for evaluations of response blocking). In most cases, response cost likely functions as negative punishment. Therefore, the mechanism of behavior change may be idiosyncratic, and there is likely not a single mechanism of behavior change.

Comparative Studies and Relative Efficacy

Numerous studies have evaluated the relative efficacy of redirection compared to other interventions. Several reviewed studies, including Carroll and Kodak (2014), Gibney et al. (2020), Love et al. (2012), and Shawler et al. (2020), suggested that noncontingent competing stimuli can effectively decrease automatically reinforced behavior without redirection in some cases. Noncontingent competing stimuli might be a practical alternative to redirection when resources are limited. Similarly, the reinforcement of appropriate alternative behavior might mitigate the need to redirect behavior. Colón et al. (2012) and Cividini-Motta et al. (2019) produced preliminary results that suggested differential reinforcement of alternative behavior (DRA) without redirection can effectively decrease automatically reinforced behavior in some individuals.

Relatedly, Hagopian et al. (2015, 2017) proposed a model for subtyping automatically reinforced self-injurious behavior (SIB) based on functional analysis response patterns and treatment outcomes. Subtype 1 is characterized by the differentiation between the alone and play conditions and corresponds to the effectiveness of reinforcement-based intervention. This can be conceptualized as other sources of reinforcement competing with the automatic reinforcement of the target behavior. Contrarily, Subtype 2 with high and undifferentiated levels in functional analyses might be indicative of the need to include redirection as well as reinforcing appropriate behavior to observe sufficient treatment effects. Although published applications of this model have been specific to SIB, the level of differentiation obtained during functional analysis may be a general indicator of the likelihood of effective intervention with reinforcement-based intervention alone. That is, if there is differentiation in the FA, competing stimuli or other reinforcement-based intervention may be effective, but if there is no differentiation, redirection may be a necessary component of the intervention.

Although we recommend that practitioners first consider reinforcement-based interventions when designing treatments for automatically reinforced behavior, practitioners are often selecting between punishment-based procedures. Several reviewed studies evaluated the relative efficacy of redirection compared to response blocking and response cost. The reviewed studies include conflicting conclusions with respect to the relative efficacy of redirection and response blocking. Giles et al. (2012) concluded that redirection was both more effective and preferred by participants. More recently, DeRosa et al. (2019) suggested that response blocking was more effective with all three participants and attributed these conflicting results to measurement methods. Similar to redirection, response blocking procedures vary with respect to numerous dimensions, lasting only several seconds to longer durations up to 30 s. Therefore, the relative efficacy of the two procedures needs to be interpreted in the context of the specific procedures compared in each study and not generalized to the procedures more broadly. Toper-Korkmaz et al. (2018) and McNamara and Cividini-Motta (2019) concluded that response cost alone can sufficiently decrease automatically reinforced behavior with some participants, but redirection effectively decreased behavior with all participants. The results of the Verriden and Roscoe (2019) punisher assessment, however, suggest that perhaps the most effective and socially valid punisher is idiosyncratic across individuals and relevant stakeholders. Therefore, future research should emphasize refining methods for identifying the most appropriate consequences in particular cases rather than asking generalized relative efficacy questions.

Redirection and Promoting Appropriate Behavior

Similar to the Lanovaz et al. (2013) conclusion that decreasing automatically reinforced behavior often results in response reallocation, both Vollmer (1994) and Rapp and Vollmer (2005) suggested that treatment packages might promote response reallocation to appropriate alternatives and improve the reductions of automatically reinforced behavior. Many reviewed studies evaluated redirection packaged with other treatment components, including reinforcement or interventions implemented contingent on the target behavior. Reinforcement components packaged with redirection have included noncontingent sources of reinforcement (e.g., competing stimuli) and reinforcement delivered contingent on alternative behavior (i.e., DRA).

Redirection and Noncontingent Competing Stimuli

Several redirection studies have evaluated redirection combined with noncontingent access to competing stimuli, which has also been referred to as *matched stimulation*, *enriched environment*, or *noncontingent reinforcement* in the behavior-analytic literature (see Gover et al., 2019, for a review). For the purposes of this chapter, we refer to all treatment components involving response-independent stimulation as *competing stimuli*. Noncontingent access to competing stimuli, in the form of free access to leisure items and/or sound-producing items, was a treatment component packaged with redirection in nearly half of the reviewed studies. Additionally, other studies were conducted during classroom activities or academic instruction. Classroom settings involve various contingencies, demands, and stimuli that can potentially compete with the automatic reinforcement of the target behavior. In one redirection study, Gibbs et al. (2018) prompted engagement in an ongoing task independent of the target stereotypy. However, we did not identify any studies that evaluated the effect of noncontingent prompting of contextually appropriate behavior on the efficacy of redirection.

Two studies have experimentally evaluated the additive effects of competing stimuli with redirection. Love et al. (2012) compared redirection, competing stimuli that produced presumably matched stimulation, and redirection plus competing stimuli. All three procedures decreased stereotypy for both participants, but the redirection plus competing stimuli was slightly more effective for one participant and resulted in higher levels of appropriate vocalizations and less time implementing redirection. With these results, the authors posited that noncontingent competing stimuli could mitigate the need for redirection by competing with the target behavior. Similarly, Gibbs et al. (2018) replicated Love et al. and concluded that redirection with competing stimuli resulted in lower levels of stereotypy than redirection alone.

Redirection and Differential Reinforcement of Appropriate Behavior

Redirection is often combined with DRA arrangements in treatment packages for automatically reinforced behavior. Over half of the redirection studies that we reviewed discussed differential reinforcement of appropriate behavior, including appropriate vocalizations, engagement with leisure items, academic responses, and appropriate discard responses of pica items. The reinforcement of appropriate vocalizations, involving praise and requested items, was the most common reinforcement procedure in the reviewed studies. Other studies noted that appropriate vocalizations were acknowledged but did not describe specific reinforcement procedures. As noted in the *Redirection and Noncontingent Competing Stimuli* section (Sect. 3.2.1), several studies were conducted in natural settings that likely included other sources of reinforcement, including naturally occurring reinforcement contingencies for appropriate behavior.

Several redirection studies have systematically trained appropriate alternative responses prior to redirecting automatically reinforced challenging behavior, including Colón et al. (2012), Hagopian et al. (2011), Schmidt et al. (2017), and Taylor (2020). Colón et al. approached the treatment of vocal stereotypy by building upon the participants' verbal repertoires in the form of tact training and one participant also received mand training. Following verbal operant training, stereotypy and appropriate vocalizations were measured outside of the training sessions. Verbal operant training sufficiently decreased the vocal stereotypy of one participant and redirection was added for the other participants. The Colón et al. results suggest that the training and reinforcement of appropriate alternative responses can obviate the need to implement redirection in some cases. Similar to the Colón et al. procedures, Hagopian et al., Schmidt et al., and Taylor systematically trained alternative discard responses in treatment packages targeting pica. Once discard responses were established, redirection with a DRA for discard responses maintained clinically significant treatment effects.

Dickman et al. (2012) evaluated the role of reinforcement contingent on appropriate alternative behavior paired with redirection in a treatment package for vocal stereotypy. The study involved a comparison of redirection with two different reinforcement procedures contingent on appropriate vocalizations. Although both procedures decreased stereotypy, the procedure involving additional token reinforcement resulted in consistently higher levels of appropriate vocalizations and lower levels of vocal stereotypy. Dickman et al. posited that the additional reinforcement better competed with the automatic reinforcement of stereotypy and/or the appropriate vocalizations were incompatible with the target vocal stereotypy.

More recently, Cividini-Motta et al. (2019) conducted a similar comparison of redirection, DRA, and redirection plus DRA in the treatment of stereotypy. The DRA involved praise contingent on appropriate vocalizations, requested items when possible contingent on mands, and a tangible reinforcer delivered contingent on engagement with leisure items. The results suggest that DRA can sufficiently decrease automatically reinforced behavior in some cases, but redirection might be a necessary treatment component to observe treatment effects. Notably, Cividini-Motta et al. did not observe sustained increases in appropriate vocalizations or item engagement during any of the procedures. The tangible reinforcer delivered contingent on toy engagement likely affected these results by competing with appropriate behavior. Given this limitation and few evaluations in this area, further investigations are warranted to evaluate the additive effects of DRA packaged with redirection on levels of the automatically reinforced target behavior and contextually appropriate behavior.

Recommendations for Promoting Appropriate Behavior

In addition to improved treatment efficacy, evaluating redirection with reinforcement available for appropriate behavior is in accordance with behavior-analytic ethical standards (Behavior Analyst Certification Board® [BACB], 2020; Pokorski & Barton, 2021). Although other sources of reinforcement might significantly decrease automatically reinforced behavior, redirection might be warranted depending on the severity of behavior and treatment goals (e.g., Hagopian et al., 2011). As we mentioned in the *Supplemental Measures* section (Sect. 3.1.1), some redirection studies have specifically programmed for appropriate behavior by arranging reinforcement and others measured the indirect effects of redirection on appropriate behavior.

We recommend that practitioners arrange other sources of reinforcement, including noncontingent sources of reinforcement and reinforcement contingent on contextually appropriate

Initial Considerations	**Reinforcement Considerations**	**Redirection Considerations**	**Treatment Components**

Consider the target behavior and context to inform treatment package development
 	
Target Behavior
• Function
  ○ Automatic reinforcement?
  ○ Sensitive to attention?
• Topography
  ○ Inherently harmful? SIB?
  ○ Can it safely occur?
 	
Context
• Identify problematic context(s)
• What constitutes functional engagement?
• Measure baseline levels of target behavior and contextually appropriate behavior
	Assess available reinforcement promoting appropriate behavior before implementing redirection
	
	Context Reinforcement
	• Noncontingent Competing Stimuli
	  ○ What stimuli are present? (e.g., leisure, social, academic)
	• Differential Reinforcement of Appropriate Behavior
	  ○ Is there reinforcement contingent on functional engagement?
	
	Individual Repertoire
	• Do they have the skills to contact reinforcement?
	• Do new functional skills need to be trained?
	• Would prompting functional engagement promote response reallocation?
		Add redirection component to reinforcement procedures if target behavior warrants intervention
		
		Contingent Component
		• Likely redirecting all or most occurrences of target behavior initially
		
		Prompting Component
		• Redirection topography
		  ○ Verbal or physical redirection?
		  ○ Consider listener repertoire
		• Do they readily comply with demands?
		  ○ Consider prompt hierarchy
		
		Alternative Response Component
		• Redirect back to contextually appropriate behavior
			Consider other treatment components to improve treatment package efficacy
			
			Differential Reinforcement of Other Behavior (DRO)
			• Consider contingent access to periods without redirection
			
			Verbal Reprimands
			• Low responding in functional analysis attention condition?
			
			Response Blocking
			• Dangerous topography? Response blocking might be necessary
			• Can target behavior be blocked?
			
			Response Cost
			• Redirection during preferred activity?

Fig. 16.1 Redirection treatment package development considerations for practitioners

behavior, when developing redirection treatment packages. (See Fig. 16.1 for practitioner considerations during the development of a redirection treatment package.) Similar to the Colón et al. (2012), Hagopian et al. (2011), Schmidt et al. (2017), and Taylor (2020) procedures, practitioners should consider building upon individuals' existing behavioral repertoires by systematically training new appropriate behavior and maintaining it with a DRA to promote response reallocation to contextually appropriate behavior. Considering the limitation of the Cividini-Motta et al. (2020) study, the reinforcer contingent on appropriate behavior should be easy to deliver and not compete with contextually appropriate behavior (e.g., praise, token delivery). Ultimately, functional engagement in contextually relevant behavior should be the end goal of intervention. Producing independent functioning will presumably bring the individual's behavior into contact with the natural consequences for responding in the community at large.

Individualizing and Contextualizing Redirection Treatment Packages

The procedural variations in the redirection literature can inform individualized redirection treatment packages for automatically reinforced challenging behavior. With the individual's safety and wellbeing as a priority, socially valid redirection procedures and outcomes for automatically reinforced SIB differ from those of stereotypic behavior. Unlike SIB, stereotypy is not inherently harmful. Therefore, it is not always necessary, or socially acceptable, to intervene. In the subsequent procedural variations, this distinction must be applied when considering how to best individualize and contextualize redirection procedures.

Treatment Package Components to Improve Redirection Efficacy

Earlier in this chapter, we highlighted that reinforcement procedures can obviate or mitigate the need to implement redirection procedures. In addition to noncontingent sources of reinforcement and differential reinforcement of appropriate behavior, other treatment components can be packaged with redirection to improve treatment efficacy. These procedures include differential reinforcement of other behavior (DRO), verbal reprimands, response blocking, and response cost.

Redirection and Differential Reinforcement of Other Behavior (DRO)

For target responses that are not inherently harmful, such as stereotypy, it is possible to provide contingent access to the target response without redirection. Brusa and Richman (2008) arranged a DRO that involved presenting a stimulus paired with no redirection following intervals without stereotypy. With discrimination training and contingent access to stereotypy, stereotypy occurred at high levels in the presence of the discriminative stimulus and low levels in the presence of the inhibitory stimulus paired with intervention. However, the practicality of the procedure was limited by the brief interval requirements without stereotypy and stereotypy was permitted half of the session duration. These results provide preliminary support suggesting that periods without redirection might be a viable reinforcer that can be arranged in a DRO with non-harmful target behavior in some cases.

Redirection and Verbal Reprimands

In our literature review, we identified several studies that reported general verbal reprimands (e.g., "Stop") or specific reprimands (e.g., "Don't X") paired with redirection. For example, the Hagopian and Adelinis (2001) evaluation involved a contingent verbal prompt to stop engaging in pica followed by either response blocking or response blocking plus redirection. Other redirection procedures involved similar verbal directives, or reprimands, but none of the reviewed studies specifically evaluated the effects of redirection with and without reprimands.

In a treatment analysis for public masturbation, Cividini-Motta et al. (2020) compared redirection to response interruption. Redirection involved 1 min of physical activity and response interruption procedure involved a verbal reprimand (e.g., "stop doing that") paired with brief physical interruption (i.e., response blocking). Both procedures effectively decreased public masturbation, but the response interruption procedure required significantly less time and fewer resources to implement. These results suggest that similar brief interventions might prove to be equally effective as more resource-intensive interventions, such as physical and/or time-based redirection procedures.

Redirection and Response Blocking

Response blocking is another consequent intervention combined with redirection. We identified seven studies that reported combining redirection with a response-blocking component. Notably, multiple redirection evaluations targeting pica (Hagopian & Adelinis, 2001; Hagopian et al., 2011; Schmidt et al., 2017; Taylor, 2020) described response-blocking components combined with redirection. Some redirection procedures involving physical prompts during redirection have the potential to block opportunities to engage in motor target responses, but other redirection procedures have programmed blocking components.

Frewing et al. (2015) described different consequent interventions for vocal stereotypy and motor stereotypy. Vocal stereotypy was followed by redirection to appropriate vocal responses, but motor stereotypy was followed by physically prompting hands-in-pockets. The consequence for vocal stereotypy met our definition of redirection by prompting an active response but the consequence for motor stereotypy is an example of response blocking. Brusa and Richman (2008) noted a response-blocking component in the treatment of stereotypic string play. Contingent to string play, the therapist presented verbal redirection to play with leisure items followed by response blocking in the form of string removal. Similarly, Gould et al. (2019) evaluated a redirection treatment package that involved response blocking prior to presenting redirection demands.

Although we identified numerous studies that combined redirection and response blocking, none of the studies systematically evaluated the additive effects of response blocking. However, Hagopian and Adelinis (2001) demonstrated that redirection can be a useful component to package with response blocking when response blocking alone evokes aggression. In a comparison of response blocking alone and response blocking packaged with redirection, the procedure with redirection effectively treated pica with minimal aggression. Similarly, Hagopian and Toole (2009) demonstrated that verbal redirection might be another alternative to response blocking when it evokes aggression. As previously discussed, Cividini-Motta et al. (2020) compared redirection and a response interruption procedure, involving a reprimand and brief physical blocking. Response interruption effectively decreased the target behavior and required less time to implement the procedure, suggesting brief response blocking can be a useful treatment component that requires few resources to implement. However, it is unclear to what degree the reprimand or blocking was each responsible for the efficacy of the Cividini-Motta et al. procedure.

Redirection and Response Cost

A response cost component has been packaged with redirection in various studies. In several redirection evaluations, the authors did not report a *response cost* component but the redirection procedure involved blocking or removing leisure items during redirection. Procedural components like this, involving the contingent removal of putative reinforcers, can be conceptualized as examples of response cost procedures. Response cost treatment components have the potential to improve the efficacy of redirection treatment packages.

The Brusa and Richman (2008) study, involving a DRO with periods without redirection following intervals without stereotypy, arguably involved a response cost component. Following 10 s without stereotypy in the presence of the red card paired with intervention, the green card was presented, and stereotypy was free to occur. If stereotypy occurred in the presence of the red card, redirection or response blocking was implemented, and the interval was restarted with the latency to reinforcement extended. When redirecting non-harmful target behavior, a DRO combined with a similar response cost component might add to the efficacy of a redirection treatment package.

In recent years, Toper-Korkmaz et al. (2018) and McNamara and Cividini-Motta (2019) evaluated the additive and relative efficacy of redirection and response cost in the form of contingent toy removal. The most effective intervention and the relative efficacy were idiosyncratic across the participants, which is in line with the Verriden and Roscoe (2019) punisher assessment conclusions. In some cases, however, redirection packaged with response cost was more effective than redirection alone. These results suggest that response cost treatment components can add to the efficacy of redirection with some individuals. Additionally, Toper-Korkmaz et al. posited that other published reports of redirection efficacy might have been affected by the inclusion of a response cost component.

Recommendations for Treatment Package Components

When incorporating empirically supported redirection procedures into practice, the goal should be to develop efficient and effective treatment packages that (1) promote appropriate behavior and (2) decrease interfering or dangerous automatically reinforced behavior. In addition to the reinforcement-based treatment components outlined in the *Recommendations for Promoting Appropriate Behavior* section (Sect. 3.2.3), practitioners can consider packaging DRO, verbal reprimands, response blocking, and/or response cost with redirection. Firstly, it is important to consider if the target behavior can safely be permitted to occur. If so, it might be feasible to arrange a DRO with contingent access to intervals without redirection following intervals without the target behavior (e.g., Brusa & Richman, 2008).

Although there is limited research evaluating the additive effects of verbal reprimands paired with redirection, verbal reprimands might be a useful treatment component in some cases. In addition to functional analyses informing whether or not reinforcement-based procedures will decrease automatically reinforced behavior, low levels of responding in an attention condition may be indicative of reprimands functioning as a positive punisher. The social acceptability of verbal reprimands might also be improved when paired with redirection by promoting appropriate behavior with redirection. Verbal reprimands that provide a precise description of contextually-relevant behavior should be considered.

Considering the Verriden and Roscoe (2019) punisher assessment conclusions that the most effective and socially valid intervention is likely idiosyncratic, we recommend that practitioners consider the individual and context when developing treatment packages. For topographies of automatically reinforced SIB, response blocking might be a necessary treatment component to package with redirection to prevent occurrences of the target behavior (e.g., Hagopian & Adelinis, 2001; Hagopian et al., 2011; Schmidt et al., 2017; Taylor, 2020). Additional contingent intervention components (e.g., verbal reprimands, response blocking, response cost) paired with redirection have the potential to improve treatment effects, but they also may require more resources to implement in some cases. Notably, response cost may not be necessary, and if not, the intervention will likely be more socially acceptable. Similar to what was noted in the *Redirection and Promoting Appropriate Behavior* section (Sect. 3.2), we reiterate the Pokorski and Barton (2021) recommendation to pair all consequence-based interventions with reinforcement available for appropriate behavior to promote response reallocation to appropriate alternatives.

Contextualize Redirection Treatment Packages

In a review of RIRD studies, Martinez and Betz (2013) noted that the efficacy and practicality of redirection in natural settings were unknown. Our review of redirection studies involved broader inclusion criteria and more evaluations conducted in natural settings in recent years. Although recent studies have been conducted in naturalistic settings, few studies have informed redirection procedures and supplemental measures based on the treatment context. Naturally occurring contexts and activities dictate what responses constitute functional engagement and the contingencies of reinforcement at play. Therefore, we recommend that practitioners consider the treatment context when developing redirection treatment packages.

Identify Problematic Contexts

The consideration of "Is the target behavior inherently harmful?" is of particular importance when identifying the contexts in which the target behavior is problematic. As mentioned, it is not always appropriate or necessary to intervene with stereotypic behavior. Therefore, it is important to identify contexts in which the target behavior warrants intervention. Supplemental measures of contextually appropriate behavior can inform if the automatically reinforced challenging behavior is interfering with functional engagement in particular contexts.

In the redirection studies that we reviewed, over half of the studies measured appropriate vocalizations during redirection and only several studies measured other topographies of appropriate behavior. With the aim of implementing redirection during naturally occurring activities, supplemental measures of contextually appropriate behavior (e.g., social, vocational, academic) should be informed by the contexts in which redirection is being considered. Therefore, we recommend measuring baseline levels of the target behavior and contextually appropriate behavior to (1) determine if redirection of non-harmful behavior is warranted in a particular context and (2) measure the effects of redirection on contextually appropriate behavior. If the target behavior is both not harmful and not interfering with functional engagement in the context, redirection of the behavior may not be warranted or socially valid. When targeting automatically reinforced SIB, it is likely irrelevant to identify problematic contexts because intervention will likely be necessary in all contexts in which the target behavior occurs.

Promote Contextually Appropriate Behavior

As noted, more recent redirection studies have been conducted in natural settings. Natural settings lend to noncontingent competing stimuli and natural reinforcement contingencies for contextually appropriate behavior. Pokorski and Barton (2021) asserted that behavior-analytic research must evaluate less-intrusive reinforcement-based interventions prior to implementing punishment-based procedures. Therefore, prior to implementing redirection, researchers and practitioners should consider if there are other sources of reinforcement to promote and maintain contextually appropriate behavior. In addition to including measures of contextually appropriate behavior, we recommend that redirection evaluations need to promote appropriate behavior by prompting functional engagement in ongoing activities (e.g., Gibbs et al., 2018), training new adaptive skills (e.g., Colón et al., 2012; Hagopian et al., 2011; Schmidt et al., 2017; Taylor, 2020), and/or arranging reinforcement contingencies.

Redirection to Contextually Appropriate Behavior

Most of the redirection studies that we identified evaluated redirection demands unrelated to an ongoing activity (e.g., social questions, vocal imitation), and few studies redirected the target behavior by prompting contextually appropriate behavior. Some studies redirected the target behavior by prompting item engagement with leisure items (e.g., Brusa & Richman, 2008; Peters & Thompson, 2013; Verriden & Roscoe, 2019). The redirection demands described by Karmali et al. (2005), Guzinski et al. (2012), and Wells et al. (2016) involved vocal demands related to the ongoing activity. Karmali et al. and Guzinski et al. redirected by prompting tacts related to the ongoing activity. Whereas Wells et al. implemented redirection during group instruction in a classroom and the redirection demands were questions related to the ongoing instruction. Similarly, Cook and Rapp (2020) evaluated contingent physical redirection to engage in an ongoing academic task (e.g., puzzle, pegboard, sorting) that required motor responses.

Multiple redirection procedures targeting pica involved redirection to discard possible pica items. During redirection in naturalistic settings, Hagopian et al. (2011) programmed for generalization by only redirecting to discard items when the item was suitable to discard, but otherwise redirecting to functionally engage with the item. We suggest that practitioners program for generalization across settings by redirecting the target behavior by prompting functional engagement in the ongoing activity.

Several studies, including Ahrens et al. (2011), Shawler and Miguel (2015), and Wunderlich and Vollmer (2015), have compared redirection demands requiring motor responses with those requiring vocal responses on the efficacy of redirection. To date, these comparisons have concluded that redirection efficacy does not correspond to the topography of redirection demands. In addition to supporting the use of motor redirection contingent on automatically reinforced vocalizations with individuals without vocal verbal repertoires, these results provide flexibility to practitioners to redirect automatically reinforced behavior back to the ongoing activity irrespective of topography. Although additional research is warranted to evaluate the possible additive effects of redirection to contextually appropriate behavior, it has the potential to increase contextually appropriate behavior (e.g., academic, social, vocational) in addition to decreasing interfering automatically reinforced behavior. Redirection back to contextually appropriate behavior might also prove to be more socially valid in natural settings.

Social Acceptability Considerations

Similar to what was outlined in the seminal paper by Wolf (1978), redirection treatment package development and treatment goals should be informed by input from relevant stakeholders. Verriden and Roscoe (2019) provided a model for identifying socially valid interventions by incorporating clinician input throughout the assessment and evaluating putative punishers in the context of reinforcement for appropriate behavior (i.e., competing stimuli, DRA). According to Pokorski and Barton (2021), evaluations of consequence-based procedures should adopt a variation of the Verriden and Roscoe model to evaluate consequent interventions with reinforcement simultaneously available. Following the Verriden and Roscoe assessment, the researchers reviewed the results and videos with the participants' clinicians to evaluate the acceptability of the procedures, outcomes, and goals, and the feasibility of implementation. Similarly, Athens et al. (2008) used caregiver input to inform the treatment thinning goal to systematically program for socially significant outcomes. In addition to these methods for developing socially acceptable redirection treatment packages, researchers and practitioners need to consider the practicality of the procedure in natural settings.

Several redirection studies that progressed to naturalistic contexts evaluated treatment package variations to improve implementation practicality and treatment effect durability. The reviewed studies conducted in natural settings provide empirical support for redirection during naturally occurring activities. However, evaluations of redirection in natural settings need further development, but practitioners can incorporate existing empirical research to develop socially acceptable redirection treatment packages.

Redirection Procedural Variations

Several reviewed studies conducted in controlled settings evaluated procedural variations to reduce redirection implementation. Saini et al. (2015) and Toper-Korkmaz et al. (2018) concluded that one-demand redirection produced significant treatment effects, and the redirection implementation was significantly less or equal to that of three-demand redirection. These results suggest that reduced redirection requirements might result in equally effective treatments and require less time to implement redirection. The Cividini-Motta et al. (2020) treatment comparison of brief response interruption and 1-min physical redirection produced similar results, with the brief interruption being equally effective but requiring considerably fewer resources. However, similar systematic evaluations with time-based redirection procedures (e.g., 30 s of physical guidance) are lacking in the current literature. Future investigations need to evaluate more practical time-based redirection procedures to maintain treatment efficacy and improve practicality for implementation in natural settings. These evaluations are especially relevant to redirection treatment packages in natural settings when redirection often interrupts ongoing activities and requires effort on the part of an implementer.

Redirection procedures have also varied with respect to prompt topography, including both verbal and physical prompts to engage in appropriate alternative responses. Practitioners should consider listener repertoires (i.e., following verbal directives), compliance with demands, challenging behavior that might be evoked by physical prompting, and the practicality and social acceptability of the form of prompting. For example, redirection involving physical prompts might be most effective and feasible for small children with limited verbal repertoires who do not engage in challenging behavior when physically prompted. Some redirection procedures have involved prompt hierarchies to prompt compliance with redirection demands after initial redirection, but Ahrens et al. (2011) also suggested that redirection can be effective without requiring compliance. Hagopian and Toole (2009) elected to evaluate a verbal redirection procedure because the participant engaged in aggression when stereotypic behavior was blocked. More research is needed with respect to the relative efficacy and social validity of redirection prompts and prompt hierarchies, but we recommend that practitioners consider client-specific characteristics and repertoires. Similarly, repertoires of appropriate behavior should inform the alternative responses of redirection. As noted in the *Redirection to Contextually Appropriate Behavior* section (Sect. 3.3.2), comparisons of redirection to motor and vocal responses (e.g., Ahrens et al., 2011; Shawler & Miguel, 2015; Wunderlich & Vollmer, 2015) all suggest that the redirection alternative responses do not need to match the target behavior topography. This finding allows practitioners to develop redirection procedures informed by individuals' repertoires, including redirection procedures similar to those described by Steinhauser et al. (2021) that involve teaching contextually relevant functional engagement that are likely more socially acceptable than arbitrary redirection demands.

Treatment Integrity and Redirection Thinning

With concerns about the practicality of redirection implementation in natural settings, Giles et al. (2018), Colón and Ahearn (2019), and Gauthier et al. (2020) evaluated redirection treatment integrity. Experiment 1 of Colón and Ahearn suggested that the most common treatment integrity error in classroom settings was the failure to implement redirection contingent on the target behavior. However, the procedure was implemented with accuracy when it was implemented. The results from Experiment 2 replicated the Ahrens et al. (2011) Experiment 3 results, suggesting that redirection remains effective at as low as 50% integrity (i.e., treatment consistency). Additionally, the level of stereotypy during the phase alternating 100% integrity booster sessions and 25% integrity sessions suggests that redirection just needs to be implemented with high treatment integrity at least some of the time. Unlike the Colón and Ahearn arrangement, Gauthier et al. compared 33% and 100% integrity in an alternating treatment component within an ABAB design. The 33% condition was evaluated prior to obtaining treatment effects with a full integrity condition and decreased stereotypy in some cases. The results suggest that exposure to full or integrity redirection might be necessary before thinning treatment consistency. Given the outcomes of Colón and Ahearn and Gauthier et al., scheduling occasional booster sessions might maintain redirection treatment effects when implementing redirection in natural settings with uncertain integrity. The Sivaraman and Rapp (2020) findings are also informative for clinical applications, suggesting that longer exposure to redirection procedures can have longer lasting effects on the target behavior when the intervention is no longer in place.

Similar to the Colón and Ahearn (2019) findings and the Martinez et al. (2016) and Sloman et al. (2017) redirection thinning, we suggest that practitioners consider thinning the redirection procedure after the treatment package effectively decreases the automatically reinforced target behavior. After repeated exposure to five-demand redirection, Martinez et al. improved the redirection practicality by reducing the redirection requirement to one-demand redirection. With the aim of improving the practicality of redirection during academic and vocational activities, Sloman et al. approached redirection thinning by fading the consistency of redirection in an intermittent redirection phase following an initial redirection evaluation. The intermittent redirection procedure involved consistent redirection implementation for the first minute of the condition and then on a fixed interval (FI) 1-min schedule, and the target behavior remained at low levels during intermittent redirection. With no redirection as the desired end point, we recommend that practitioners arrange systematic redirection thinning based on available resources in the natural environment and empirically supported procedural variations.

With redirection often evaluated with socially significant topographies of challenging behavior, the maintenance over time and generality of treatment effects across naturalistic settings, activities, and implementers are particularly important. We identified numerous studies that paired a stimulus (e.g., colored card, wristband) with contingent redirection with the aim of establishing inhibitory stimulus control, but the reviewed studies provide minimal support for the establishment of inhibitory control (e.g., Martinez et al., 2016). Multiple studies involved datasets with delays to recapture original baseline levels, suggesting that there is more evidence to support the assertion that the implementer of redirection or treatment setting acquired inhibitory stimulus control (e.g., Cividini-Motta et al., 2020; Wunderlich & Vollmer, 2015). Therefore, we recommend that future applied evaluations systematically evaluate redirection across settings, activities, and implementers similar to the

Hagopian et al. (2011) treatment application in naturalistic settings.

Although studies have evaluated procedural variations to improve the clinical practicality of redirection, Vorndran and Lerman (2006) was the only study that we identified that paired redirection with a less-intrusive procedure that did not involve redirection. After pairing the less-intrusive procedure with redirection, the less-intrusive procedure without redirection maintained the treatment effects. We suggest that future investigations further evaluate methods for pairing redirection with less-intrusive alternatives and thinning interventions.

Error-Correction Procedures

17

and Delanie F. Platt

Discrimination Training and Error Correction

Discrimination is defined based on differential responding in the presence of a target (i.e., discriminative) stimulus and not its absence (Catania, 2013; McIlvane, 2013). Differential reinforcement of responding in the presence of a given stimulus, and extinction of responding in its absence, has been shown to establish discriminated responding in some (Petursdottir & Aguilar, 2016; Schilmoeller et al., 1979), but not all cases (Saunders & Spradlin, 1990, 1993). Further, a history of this training arrangement may be detrimental to the acquisition of future discriminations (Schilmoeller et al., 1979; Stoddard & Sidman, 1967). This arrangement has historically been referred to as *trial-and-error learning*, although reference to *differential reinforcement* may be preferred (Skinner, 1984). Regardless of the terminology used, a major limitation of these arrangements is the considerable number of errors that may be emitted during training.

Establishing differential responding in the presence of a stimulus with few to no errors is a prominent goal of discrimination training in educational or therapeutic interventions (Mueller et al., 2007; Sidman, 2010; Wolery & Gast, 1984). Doing so may require a variety of antecedent manipulations commonly referred to as *errorless* strategies (Moore & Goldiamond, 1964; Terrace 1963a, b; Touchette & Howard, 1984). Reference to these strategies as *errorless* can be misleading as these procedures commonly produce discriminated responding in fewer errors than differential reinforcement procedures, although errors are still emitted (Mueller et al., 2007). Indeed, initial discrimination training that includes errorless strategies may be associated with a considerable number of errors, particularly for individuals with intellectual disabilities (Graff & Green, 2004; McIlvane et al., 2016; Stoddard & Sidman, 1967). As a result, additional error-contingent consequences may be programmed in concert with antecedent manipulations (e.g., errorless strategies) to facilitate the efficient transfer of stimulus control.

Error-correction procedures include a range of consequence strategies presented following an error that increase the probability that a correct response will occur in the future (Cariveau et al., 2019; McGhan & Lerman, 2013). Although procedural variations are common, the function of error correction is often twofold: (a) to decrease the likelihood that an incorrect response will be emitted under similar conditions and (b) to prompt the target response. As such, the primary

goal of error correction is to arrange disparate consequences for correct and incorrect responding and to facilitate the transfer of stimulus control within and across learning trials.

To date, limited research on error-correction procedures has considered the nature (i.e., controlling relations) of incorrect responding. The fine-grain stimulus control analyses offered by McIlvane (2013) may not be incorporated into typical clinical programming and are similarly absent from the extant literature on error-correction procedures. Instead, a single strategy may be applied to all learners' programming in a given clinical or educational setting. It is unsurprising, then, that research in this area has predominantly included comparative studies in which the efficiency of discrimination training is examined across two or more error-correction procedures. This body of comparative research serves to illustrate the various components of error-correction procedures that may contribute to the efficient transfer of stimulus control. Nevertheless, considering an operational definition of errors and the conditions that produce errors is critical to arranging effective instructional practices.

What Are Errors?

In educational and therapeutic settings, errors may commonly be defined based on some cultural, social, or normative criterion. This point was already made by Skinner:

> I do not believe that organisms ever misbehave. I long ago adopted the basic rule in animal research that the organism is always right. It does what it is induced to do by its genetic endowment or the prevailing conditions. If anyone misbehaves, it is the experimenter in making a bad prediction (Skinner, 1977, p. 1007).

> The term 'error' does not describe behavior, it passes judgement on it (Skinner, 1984; p. 583).

As such, the characterization of an organism's responding as incorrect or as misbehavior may suggest that (a) the perceived controlling relations and those actually controlling responding are incongruent (McIlvane & Dube, 2003) or (b) our understanding of the many effects of the arranged contingencies is inadequate (Skinner, 1977). Further complicating the matter, patterns of responding may be affected by selection at the phylogenic level (Breland & Breland, 1961), referenced as the organism's genetic endowment in the Skinner (1977) quote above.

Errors may commonly be defined as instances in which the target response is not emitted under the target conditions (i.e., errors of omission) or when a target response is emitted under nontarget conditions (i.e., errors of commission; Bergmann et al. (2017), Fisher et al. (2014), Leon et al. (2014)). This categorization is limited, however, as it does not include further consideration of the controlling relations of the incorrect response. McIlvane and Dube's (2003) concept of *stimulus control topography (SCT) coherence* may provide instructors with a greater understanding of the conditions producing incorrect responding. In short, SCT coherence is said to occur when the controlling relations specified by the instructor and those actually controlling the learner's response are concordant (McIlvane & Dube, 2003; McIlvane, 2013). The level of stimulus control analysis offered in descriptions of *SCT coherence* allows for a more robust determination of controlling relations. This is critical to understanding errors as conditions that may initially appear to produce accurate responding may later be shown to have contributed to faulty stimulus control (e.g., Grow et al., 2011; McIlvane, 2013).

In one exceptionally pertinent example, instructional programs may commonly attempt to establish discriminations under *select* control. That is, selection of the target stimulus (S+) is made regardless of what nontarget stimuli (S−) are presented. This may be assumed under situations in which the learner selects the picture of a mouse when the instructor says "mouse"; however, it is also possible that the learner is responding away from the other comparison stimuli, termed *reject* control (Sidman, 2009). A number of conditions may contribute to the development of reject control (McIlvane et al., 1987, 1988; Wilkinson & McIlvane, 1997; Sidman, 1987; Wilkinson et al., 2009), and the instructor may be completely unaware of this faulty stimulus control until incorrect responding is observed when minor changes to the instructional procedure (e.g., the comparison stimuli) are made (Sidman, 1987, 2009).

In the above-example, selection of the mouse in the presence of the auditory stimulus "mouse" may occur through select or reject control (or a combination of select and reject control; McIlvane, 2013). Regardless, the learner's response would be considered correct until future conditions were arranged in which the controlling relations were not present (e.g., when the S− are also unknown). This may illustrate the complexity of error analysis as even correct responding (e.g., selecting the mouse) may be incorrect (i.e., under faulty stimulus control; Sidman, 1987). Further contributing to this complexity are pervasive patterns of responding that may develop before or during discrimination training, referred to as *response* or *stimulus biases*. Although a thorough description of this literature is beyond the scope of this chapter, some pertinent domains for instructors to consider are described below.

Bias as Errors

Responding may be said to exhibit *bias* when it occurs in the presence of some stimulus condition despite no differential consequences being arranged (Irwin, 1958). Differentiated responding to some dimension of a discrimination paradigm (e.g., position or stimulus) is commonly reported (Lander, 1968; Kieffer, 1965) and may persist in the early stages of acquisition. Stimulus bias is most evident under concurrent schedules of reinforcement in which two or more response alternatives, and corresponding stimuli, are presented simultaneously (Biederman et al., 1988), although other schedule arrangements have been used (e.g., multiple schedules; Kieffer, 1965; Starr & Staddon, 1982). Biased responding is said to occur when differentiated response rates are observed even though the schedule on each alternative is identical. This finding was previously termed *sensory superstition* and believed to arise from adventitious reinforcement (Morse & Skinner, 1957; Starr & Staddon, 1982). Nevertheless, the relations controlling these biased patterns of responding are often unclear, although they may be related to variables such as the interfood interval and stimulus duration (Starr & Staddon, 1982), stimulus onset (McIlvane et al., 2002), stimulus modality (Kieffer, 1965), or stimulus intensity (Biederman et al., 1988; Blue et al., 1971; Raslear, 1981).

Biased responding may commonly be endorsed as adhering to win-stay or win-shift patterns. These response patterns may be most apparent in an example of a red/green color discrimination. Following reinforcement of a response to the green stimulus, win-stay responding would be characterized by persistent responding to the green stimulus. In contrast, win-shift responding would be characterized by responding immediately shifting to the red stimulus after reinforcement on the green. Some authors have suggested that these response patterns are species-specific, with pigeons and rats exhibiting more durable stay (Shimp, 1966; Zeiler, 1987) and shift (Timberlake & White, 1990) patterns of responding, respectively (Randall & Zentall, 1997). Nevertheless, other features of the environment may affect the durability of these response patterns (Hearst, 1962; Randall & Zentall, 1997; Shimp, 1976).

Additional response biases have been reported in human populations and may be most prevalent in individuals with autism spectrum disorder (ASD) or intellectual disabilities (Dickson et al., 2006; Koegel & Schreibman, 1977; Lovaas et al., 1979; Schreibman et al., 1982). In these populations, responding may be controlled by specific components of a compound stimulus instead of all relevant features, termed *stimulus overselectivity* (Schreibman et al., 1982), *overselective stimulus control* (Dickson et al., 2006; Farber et al., 2017), or *restricted stimulus control* (Dube & McIlvane, 1997; Dube et al., 2010). Overselective responding may have considerable implications for learning under a variety of conditions (Lovaas et al., 1979) and has accordingly received substantial attention in the extant literature (see review by Ploog, 2010). An additional concern in overselective or biased responding by individuals with intellectual or developmental disabilities is control by irrelevant features of an instructional arrangement, such as biased responding to a stimulus position.

Position bias is a significant concern in discrimination training programs that include a stimulus array (i.e., simultaneous discriminations; Grow et al., 2011; Mackay, 1991; Sidman, 1980). Stimulus position is often a nonfunctional feature of discrimination paradigms, yet numerous studies have reported responding that is controlled by position (e.g., responding exclusively to one side of an array; Berryman et al., 1963; Bourret et al., 2012; Grow et al., 2011; Kangas et al., 2011; Kangas & Branch, 2008; Schneider et al., 2018). Position biases may be evident early in discrimination training and resolved quickly through contact with reinforcement on alternatives (Berryman et al., 1963; Schneider et al., 2018); yet they have also been shown to inadvertently arise as a direct result of discrimination training (Grow et al., 2011). A number of variables may contribute to the development of position biases (Bourret et al., 2012); although a prominent concern is the schedule of reinforcement available for responding exclusively to one position (MacKay, 1991; Skinner, 1950). This schedule is functionally related to the number of comparison stimuli in the arrangement, such that more comparisons would be associated with a reduced reinforcement schedule for position-exclusive responding. Further, alternating the position of the discriminative stimulus across trials, a commonly recommended practice (Green, 2001), may produce a variable schedule of reinforcement for biased responding. As a result, interventions that directly affect the reinforcement available for responding to a single position may be particularly effective (e.g., Bourret et al., 2012), including certain error-correction procedures. For example, error-contingent trial re-presentations until a response to the correct stimulus is emitted require (a) a shift in responding to the other comparison stimulus to produce reinforcement and (b) a reduction in the schedule of reinforcement as durable responding to a side will result in greater extinction (Kangas & Branch, 2008; Mackay, 1991). As a result, error-correction procedures may play a critical role in the reduction of response biases during discrimination training.

Evaluating Error-Correction Procedures

Error-correction procedures in the extant literature have included a considerable number of procedural variations. Evaluating these procedures requires consideration of at least four domains: (a) effectiveness, (b) efficiency, (c) intrusiveness, and (d) the learner's preference for a particular procedure.

Effectiveness

A procedure is effective if it produces responding at the mastery criterion. Effectiveness serves as a necessary condition for all other evaluative domains. Specifically, efficiency, intrusiveness, and learner's preference would not be considered if the procedure is ineffective. As described below, a number of error-correction procedures have been shown to be effective, which has allowed for researchers to consider other evaluative measures, such as efficiency.

Efficiency

Efficiency is relationally defined, such that a procedure may only be considered efficient relative to another condition (e.g., typical instruction). As such, studies of efficiency require the use of comparative research designs (see Ledford & Gast, 2018). Wolery et al. (1991) describe five conceptualizations of efficiency, although research on error-correction procedures has generally only considered rapidity of acquisition. Specifically, a procedure may be endorsed as efficient when it produces responding at the mastery criterion in fewer trials/exposures, sessions, or time than another procedure (Cariveau et al., 2016; Kodak et al., 2016; Wolery et al., 1991). Efficiency may often take precedence over the intrusiveness of, or a learner's preference for, a procedure; although this should certainly not always be the case (Van Houten et al., 1988).

Intrusiveness

Intrusiveness has been defined as the amount or duration of responding required by the instructor or learner (McGhan & Lerman, 2013). Less-intrusive or less-restrictive interventions are commonly recommended in the behavior analytic literature (Bailey & Burch, 2016; BACB, 2014; Foxx, 2008; Van Houten et al., 1988). McGhan and Lerman (2013) have similarly recommended that the intrusiveness of error-correction procedures be considered. Interestingly, it may be commonly assumed that more-intrusive strategies are less efficient; yet, the description of error-correction procedures below will show this is not always the case. Nevertheless, instructors may select interventions that are more intrusive if they are more efficient, although some behavior analysts have argued for refining less-intrusive interventions to be more effective or efficient (Lerman & Vorndran, 2002). Finally, it is commonly assumed that the intrusiveness and aversiveness of a given procedure are positively correlated (McGhan & Lerman, 2013), yet some research has shown that learners may prefer more-intrusive interventions (Hanley et al., 2005; Kodak et al., 2016; Markham et al., 2020).

Learner Preference

Learner preference for error-correction procedures should also be considered. Preference for an instructional intervention is commonly assessed using a concurrent-chains assessment (Hanley et al., 1997; Kodak et al., 2016). In this arrangement, a learner is allowed to select a condition and then receives instruction using the selected procedures. To date, only two studies examined learners' preference for error-correction strategies (Jessel et al., 2020; Kodak et al., 2016). Findings of preference are often idiosyncratic and may not be related to intrusiveness or efficiency. For example, of the five participants included in the study by Kodak et al. (2016), four exhibited a preference for a condition. For three of these participants, the least-intrusive intervention was also the most efficient; yet this condition was preferred by only a single participant. As a result, selecting an error-correction procedure may require instructors to consider efficiency, intrusiveness, and preference, although the extant literature would suggest that concordance among these variables should not be expected.

Error-Correction Procedures

An abundance of error-correction procedures has been described to date. Instructors may face challenges in navigating this literature as a result of the (a) number of procedures described, (b) prevalence of minor procedural differences across studies, and (c) use of similar or identical names to describe unique procedures (see review by Cariveau et al. (2019)). In this section, error-correction procedures are grouped based on methodological similarities and presented from least-to-most intrusiveness.

Extinction

Extinction following an incorrect response is consistent with procedures described previously as trial-and-error learning or differential reinforcement. In comparative research on error-correction procedures, extinction-only conditions predominate as control conditions. Vast amounts of experimental data suggest the efficacy of these differential reinforcement arrangements (see above). Notably, these procedures have not been shown to be similarly efficacious in applied research (Carroll et al., 2018; Kodak et al., 2016), likely due to the inclusion of topography-based response requirements (Michael, 1985). Nevertheless, when the response modality is selection-based, applied research has found differential reinforcement procedures to be effective, but often less efficient, than other error-correction procedures (Harris & Tramontana, 1973; Rodgers & Iwata, 1991; Smith et al., 2006).

Punishment Alone

Additional research has arranged for error-contingent consequences that do not include demonstrating or prompting the target response. We have referred to these conditions as *punishment alone* procedures as increases in correct responding would still occur only through contacting the prevailing contingencies (i.e., differential reinforcement). Common arrangements in this literature include timeout from positive reinforcement, negative punishment, and error statements.

Timeout

Research on the punishment of incorrect responding in discrimination training received attention from prominent scholars in behavior analysis in the 1960s. In this work, timeout from reinforcement following incorrect responses was often studied (Ferster & Appel, 1961; Miller & Zimmerman, 1966; Zimmerman & Baydan, 1963; Zimmerman & Ferster, 1963). This literature has generally found that the duration of timeout is functionally related to the suppression of incorrect responding (Ferster & Appel, 1961). As the duration of timeout increases, however, this effect has been shown to diminish past some optimal value (Chelonis et al., 2007), potentially due to complete suppression of responding (Miller & Zimmerman, 1966; Zimmerman & Baydan, 1963). Although the duration of timeout has received prominent attention, the schedule of timeout is also implicated in the effectiveness of a given procedure. In one example, Zimmerman and Baydan (1963) evaluated the effects of intermittent schedules of timeout on discrimination accuracy in undergraduate students and found that continuous schedules produced greater accuracy than intermittent schedules. Similarly, Zimmerman and Ferster (1963) examined different schedules and durations of timeout on the accuracy of performance on a matching-to-sample task with two pigeons and observed optimal performance when S- responding produced a continuous schedule of "timeout of intermediate duration" (p. 355). The findings of this experimental research would suggest that timeout is an important variable to be considered in error-correction procedures.

Negative Punishment

Negative punishment is the error-contingent removal of a reinforcer or conditions discriminative for reinforcement (Catania, 2013). Negative punishment contingencies have not received substantial attention in the error-correction literature, although prominent examples exist. In one such example, Harris and Tramontana (1973) evaluated the effects of response-contingent removal (negative punishment) or addition (positive reinforcement) of candy on simple discrimination task performance with 24 children with intellectual disabilities. The authors also included a third condition that combined both contingencies. Participants exhibited significantly fewer trials to criterion in negative punishment and combined conditions compared to the positive reinforcement-only condition. Similar outcomes have been shown across numerous studies on discrimination learning (Hemry, 1973; Munson & Crosbie, 1998; Witte & Grossman, 1971). These findings suggest that error-contingent removal of reinforcers or conditions discriminative for reinforcement facilitates discrimination learning.

Error Statements

In the applied literature, error statements, such as saying "no" following an incorrect response, have also been evaluated. These arrangements may be conceptualized as a positive punishment procedure, which have been shown to be efficacious in a number of error-correction studies (McGhan & Lerman, 2013; Rodgers & Iwata, 1991; Smith et al., 2006). Smith et al. (2006) compared the effects of no feedback, error statement, and a demonstration condition on the acquisition of two-choice word-to-picture matching tasks for six children with ASD. During all conditions, correct responding produced reinforcement and errors produced either (a) no differential consequences (no feedback), (b) the instructor saying "no" (error statement), or (c) the instructor demonstrating the target response (demonstration condition). Across 33 comparisons, responding met the mastery criterion in the fewest number of trials in the demonstration condition for eight comparisons, the error statement condition for six comparisons, and the no feedback condition for three comparisons. For the remaining 16 comparisons, trials to mastery were similar in at least two conditions with five target sets being acquired in the same number of trials across all three conditions. These results suggest that the error statement and demonstration conditions are superior to no feedback following incorrect responding. Nevertheless, the similar efficiency outcomes in the error statement and demonstration conditions may be surprising, although this finding may not be generalizable to tasks beyond two-choice discrimination procedures. Specifically, using identical conditions and larger stimulus arrays, McGhan and Lerman (2013) found the demonstration condition to be superior to an error-statement condition across all comparisons. These findings suggest that error-statement procedures may be effective under limited conditions. Nevertheless, this research has also shown that other minimally intrusive procedures may also be effective (e.g., demonstration procedures).

Demonstration and Active Student Response

Demonstration and active student response error-correction procedures are commonly included in comparative studies and differ only in the response requirement of the learner. In a typical demonstration error-correction procedure, errors result in the instructor demonstrating the correct response and removing the discriminative stimulus (Cariveau et al., 2019). The term *demonstration* is preferred over *modeling* as the learner is not required to emit the target response. In contrast, active student response procedures involve the therapist modeling the target response and requiring the student to echo or imitate the prompt (Cariveau et al., 2019). Barbetta and Heward (1993) compared the effects of demonstration and active student response procedures on the acquisition of state and country capitals for three students with learning disabilities. Following an error in the demonstration condition, the instructor provided an error statement and demonstration (i.e., "No, it's ____. Look at it.") and gave the learner 2 s to look at the card. The instructor then praised the learner for looking at the stimulus and presented the next trial. The learner was not required to emit the correct response and doing so did not produce any differential consequences. In the active student response condition, the same corrective statement was presented (i.e., "No, it's _____.) followed by a model prompt. The learner was required to emit a prompted correct response, which produced verbal praise and the next trial. The authors found that the learners acquired more targets under the active student response condition, although both procedures were effective.

The findings of Barbetta and Heward (1993) are generally consistent with other comparative studies suggesting that active student response procedures may produce more efficient learning (Barbetta et al., 1993; Drevno et al., 1994). Interestingly, the demonstration procedure was shown to be effective in producing mastery levels of responding in the majority of comparisons (Barbetta et al., 1993; Drevno et al., 1994). More recently, research with individuals with developmental disabilities has found the opposite finding, suggesting that demonstration conditions may be more efficient than active student response procedures (Isenhower et al., 2018; Kodak et al., 2016; McGhan & Lerman, 2013).

Kodak et al. (2016) compared five different error-correction procedures on the acquisition of sight words and prepositions for five children with ASD. The authors found that the demonstration condition was the most efficient form of error correction for four out of five participants when assessing sessions, exposures, and minutes to mastery. Isenhower et al. (2018) also evaluated the effectiveness of a demonstration and active student response error-correction procedure on the acquisition of auditory-visual conditional discriminations (e.g., pointing to a dog from an array when instructed to "point to the dog"). In a subsequent phase, the authors modified the demonstration condition to minimize the learner's ability to emit the target response following the demonstration by moving the card out of the learner's reach. Similar to the findings of Kodak et al., the demonstration condition with and without blocking were more efficient at producing mastery level responding relative to the active student response procedure.

The findings of both Kodak et al. (2016) and Isenhower et al. (2018) are particularly interesting as they do not replicate the findings of earlier research on these procedures (Barbetta & Heward, 1993; Barbetta et al., 1993; Drevno et al., 1994). In an attempt to account for these differences, Kodak et al. measured the emission of echoic responses in the demonstration condition, even when they were not required or produced any differential consequences. The authors found that the learners who acquired targets more rapidly in the demonstration condition emitted the echoic following the instructor's demonstration during an average of 79% of trials. Isenhower et al. also found that the learners in the demonstration condition emitted the correct response following the instructor's demonstration during all presentations. Participants even did so when the instructor attempted to remove the target stimuli to prevent these responses in a subsequent modification to the demonstration condition. Although earlier research also reported responses during the demonstration condition (e.g., Barbetta & Heward, 1993), responding reportedly occurred in only a small portion of trials. As a result, it is unclear whether participants' overt responses, even when not required, affected the efficiency of the demonstration condition.

The emission of the target responses in the demonstration condition would seemingly equate the demonstration and active student response procedures in the studies by Kodak et al. (2016) and Isenhower et al. (2018). Indeed, the only apparent difference between these two conditions would be the instructor's expectations for the learner to emit the response. The instructor's expectations certainly would not have an effect on responding by the learner, so additional characteristics of the procedures must be considered. Demand characteristics of the prompting procedure in active student response conditions are of interest as they may function as aversive conditions; yet other procedural variations may be responsible for some of these unique findings, particularly those by Kodak et al. Specifically, differential reinforcement of unprompted correct responses differed in the demonstration and active student response conditions.

Criteria for arranging a greater magnitude, schedule, or quality of reinforcement for unprompted, relative to prompted, correct responses have been shown to affect the efficiency of instructional procedures (Johnson et al., 2017; Karsten & Carr, 2009; Olenick & Pear, 1980). The onset of these differential reinforcement procedures, however, has only been evaluated in a single study to date (Campanaro et al., 2019). Campanaro et al. (2019) found that the immediate onset of differential reinforcement of unprompted correct responding produced more efficient acquisition for three children diagnosed with ASD compared to early onset (i.e., two consecutive sessions with unprompted correct responding at or above 33%), late onset (i.e., two consecutive sessions with unprompted correct responding at or above 55%), and nondifferential conditions. These findings suggest that the onset of differential reinforcement procedures is functionally related to acquisition and should be controlled in studies comparing error-correction procedures. Interestingly, Kodak et al. (2016) introduced differential reinforcement of unprompted correct responses at the outset of instruction in the demonstration condition and after a set criterion in the active student response condition (i.e., two consecutive sessions with 40% or higher unprompted correct responses). Considering the results of Campanaro et al., the greater efficiency observed in the demonstration condition may be related to differences in the onset of differential reinforcement between the two conditions.

A final procedural variation included in the active student response condition includes the error-contingent presentation of a brief timeout (e.g., 2 s) followed by the re-presentation of the discriminative stimulus (S^D) and an immediate prompt (Carroll et al., 2015; Turan et al., 2012). Although infrequently studied, this procedure has been shown to be effective for the vast majority of participants. Further, this variation, termed *remove and re-present* (Cariveau et al., 2019; Carroll et al., 2015), was the most efficient procedure in teaching sight word reading for one child with ASD in the study by Carroll et al. (2015). This finding is promising, although this condition was not compared to a traditional active student response or demonstration condition, so conclusions regarding relative efficiency are not known.

Both demonstration and active student response error-correction procedures have been shown to be effective; yet findings of efficiency have differed across studies. In addition, both procedures require a similar number of responses by the instructor. Nevertheless, the response requirement in the active student response procedure would make this condition slightly more intrusive. Slight variations of this procedure (e.g., brief timeout or onset of differential reinforcement) may contribute to greater efficiency without drastically increasing their intrusiveness. Nevertheless, further research comparing these conditions is needed. Additional research should seek to (a) further elucidate the variables responsible for the efficacy of these procedures, (b) describe the behavioral repertoires needed to benefit from either condition (e.g., imitative or echoic repertoires), and (c) consider procedural modifications that may increase the efficiency of discrimination learning without increasing the intrusiveness of these strategies.

Re-present Until Correct

In this procedure, the instructor presents a prompt and requires the learner to echo or imitate the target response before the S^D is re-presented and the learner is required to emit the target response a second time (Cariveau et al., 2019). Typically, an error during the re-presentation results in the procedure being repeated until a correct response is emitted. The re-present until correct procedure provides the learner with additional opportunities to emit the target response, which has been hypothesized to facilitate acquisition (Plaisance et al., 2016). Three variations of the re-present until correct procedure have been described in the literature. These variations include (a) trial re-presentations with an unprompted response opportunity (Carroll et al., 2015), (b) trial re-presentations with a prompted response opportunity (Kodak et al., 2016), or (c) embedding mastered targets before trial re-presentations (Plaisance et al., 2016; Turan et al., 2012).

Unprompted

Some procedures require the emission of an unprompted response on the trial re-presentation. This procedure may be commonly used in experimental research, although rarely studied (Kangas & Branch, 2008). In their work, Kangas and Branch (2008) used a re-present until correct procedure to eliminate position and stimulus biases of pigeons in a two-choice color discrimination task. Following an incorrect response, the trial was repeated until a correct response was emitted. The authors compared the onset of error-correction and found that birds exposed to the re-presentation procedure from the outset of training exhibited more rapid acquisition of the target task. Further, two birds in the control group who did not acquire the target discrimination were subsequently exposed to the error-correction procedure and performance increased immediately.

In an applied example, Carroll et al. (2015) evaluated the effectiveness of the re-present until correct procedure on the acquisition of sight words and tacts of item functions or features. Following an error, the instructor prompted the target response, and the learner was given 2 s to echo the prompt. After the learner emitted a prompted correct response or 2 s passed, the instructor re-presented the trial. This procedure was repeated until the learner emitted an unprompted correct response or 20 re-presentations. If the learner emitted the correct response during error correction, the instructor provided verbal praise and the next trial was presented. The authors found that the re-present until correct procedure was the first or second most efficient procedure for all participants.

In a subsequent study, Carroll et al. (2018) found that the re-present until correct condition produced acquisition in the fewest number of minutes to mastery in two out of nine comparisons across four children with ASD or global developmental delay. This finding suggests that including unprompted opportunities during re-presentations may be an efficient error-correction strategy for some participants. To note, a cursory review of participant characteristics from the Carroll et al. (2015, 2018) studies seems to suggest that greater verbal repertoires may be correlated with the efficacy of this procedure.

Interestingly, Rodgers and Iwata (1991) included a procedure similar to the Carroll et al. (2015, 2018) studies and found that the re-presentation of the target relation was not necessary to produce acquisition. In their study, Rodgers and Iwata (1991) evaluated the effects of (a) error-statement, (b) practice, and (c) avoidance procedures on the cumulative number of correct identity or arbitrary matching responses by seven adults with intellectual disabilities. During all conditions, correct responses produced praise and food or pennies. In the practice condition, incorrect responses resulted in an error-statement and the repeated presentation of the target stimulus until a correct response was emitted. The avoidance condition was similar to the practice condition; however, instead of re-presenting the target stimulus, the participant was required to complete a color-matching (irrelevant) task. The number of color matching trials was yoked to the number of re-presentations in the practice condition. The authors observed the greatest number of targets being mastered in the avoidance condition for three participants, the practice condition for two participants, and a similar number across all conditions for the remaining two participants. This finding may suggest that re-presentation of the target relation may not facilitate discrimination. Instead, the negative reinforcement contingency arranged in both the practice and avoidance conditions may be responsible for the observed effects. Additional research is needed to further determine the role that unprompted response opportunities may have on acquisition, particularly relative to prompted re-presentations.

Prompted

Another variation of the re-present until correct procedure involves re-presenting the S^D with an immediate prompt (Cariveau et al., 2019; Kodak et al., 2016). Kodak et al. (2016) evaluated the effectiveness of this procedure on the acquisition of sight words and prepositions for five participants with ASD. Following an error, the instructor prompted the correct response and immediately re-presented the trial using a 0-s prompt delay. After the learner emitted the second prompted correct response, the instructor provided verbal praise and presented the next trial. This procedure was effective for all participants; however, it was also consistently one of the least efficient. This may suggest that including an additional prompted correct response may be an effective, but inefficient error-correction procedure.

Embedded Mastered Targets

The last variation of the re-present until correct procedure includes the presentation of a mastered demand before the re-presentation of the trial. Embedding mastered demands between the prompted and unprompted response opportunities is suggested to facilitate stimulus control by requiring discrimination between targets when the target relation is repeatedly presented (Plaisance et al., 2016). Plaisance et al. (2016) examined the effectiveness of inserting mastered targets in their re-present until correct procedure when training a variety of targets (i.e., intraverbals, auditory-visual conditional discriminations, and motor imitation) to four children with ASD. In the no-insertion condition, after the learner emitted an error, the instructor modeled the correct response and re-presented the discriminative stimulus and allowed an independent opportunity. In the insertion condition, a mastered target trial was presented before the re-presentation of the discriminative stimulus. These procedures were repeated until the learner emitted an unprompted correct response during the re-presentation. The findings of Plaisance et al. suggest that the no-insertion condition was effective for all four participants and the insertion condition was effective for three participants. When both procedures were effective, they were also similarly efficient. Although these findings may suggest that the insertion procedure is unnecessary, this may not be the case under all conditions. For example, win-stay response patterns, characterized by the repeated emission of the last prompted or reinforced response, may be more responsive to the inclusion of a mastered demand as this arrangement may require that responding is controlled by the relevant stimulus. Further, although the insertion condition does not appear to influence rapidity of acquisition, additional research is needed to determine whether this procedure is associated with greater maintenance or generalization.

Multiple Response Repetition

The final error-correction procedure described in the extant literature is multiple response repetition (MRR). In MRR procedures, the learner is required to emit multiple responses following an error (Rodgers & Iwata, 1991), sometimes likened to positive-practice overcorrection procedures (see review by Axelrod et al., 1978). This procedure is the most-intrusive error-correction procedure in the literature and commonly includes the therapist prompting the learner to repeat the correct response either three (Kodak et al., 2016; McGhan & Lerman, 2013) or five times (Carroll et al., 2015; Drevon & Reynolds, 2018; Marvin et al., 2010; Rapp et al., 2012; Worsdell et al., 2005). Multiple response repetition procedures have been shown to be efficacious across numerous skills and populations. For example, Marvin et al. (2010) evaluated the effects of MRR on sight-word reading for four children between the ages of 7 and 12 years old. The introduction of the MRR procedure produced mastery level responding across all target sets and participants. In a subsequent study from the same lab, Rapp et al. (2012) demonstrated the effectiveness of an MRR procedure on correct responding to single-digit addition, subtraction, and multiplication problems for three out of four boys with intellectual disabilities. For one participant, responding met the mastery criterion for a single target set and the intervention was terminated when no change in responding was observed after 10 sessions for the subsequent set. These findings suggest that MRR error-correction procedures are effective in teaching math and reading skills to children and adolescents with and without developmental disabilities.

Additional research has compared the efficiency of the MRR procedure to other, less-intrusive, error-correction strategies. Multiple studies have found the MRR procedure to be superior to differential reinforcement (Carroll et al., 2018; Drevon & Reynolds, 2018; Kodak et al., 2016) and active student responding (Kodak et al., 2016; Worsdell et al., 2005) conditions across various measures of efficiency. In one direct comparison, Worsdell et al. (2005) examined the effects of active student response and MRR error-correction procedures on sight-word acquisition for six adults with developmental disabilities (Study 1). The results showed that all six participants mastered more sight words in the MRR condition relative to the active student response condition. This finding may suggest that the number of repeated trials may be positively correlated with instructional efficiency.

The MRR arrangement is among the most-studied error-correction procedures. As a result, some work has attempted to elucidate the role that response repetition may serve in the effectiveness of these procedures. In a similar arrangement to Rodgers and Iwata (1991), Worsdell et al. (2005; Study 3) compared the effects of relevant and irrelevant responses during MRR procedures on the acquisition of sight words for nine adults with developmental disabilities. The authors found that a similar number of words were acquired in both conditions for five participants, although the relevant condition was the most effective for three of the participants. The finding of similar acquisition across conditions in the study by Worsdell et al. is similar to those of Rodgers and Iwata, suggesting that the effects of repetitive error-correction procedures may result from the arranged negative reinforcement contingency and not the repeated emission of the target response.

The combined results of these studies suggest that MRR is efficacious in teaching new skills to children and adults with and without developmental disabilities. Moreover, MRR procedures may be more efficient than other commonly used strategies (Carroll et al., 2015, 2018; Kodak et al., 2016; Worsdell et al., 2005). Notably, MRR is also the most-intrusive error-correction procedure included in this literature. Although problem behavior is often assumed to be correlated with intrusiveness, studies that have recorded problem behavior have not consistently reported higher rates in MRR conditions. Carroll et al. (2015) noted increased rates of problem behavior during training using MRR for a single participant; however, the authors did not provide a definition or interobserver agreement calculations for problem behavior, so additional research is warranted. Researchers might also consider procedural modifications designed to reduce intrusiveness or increase the efficiency of MRR procedures. Doing so may capitalize on an effective method for remediating discrimination errors, while increasing the acceptability of the procedure.

Learner-Based Assessments

The need for highly individualized instructional procedures has become increasingly evident with the common finding of idiosyncratic results in comparative studies (Carroll et al., 2015; Delfs & Frampton, 2014; Kodak et al., 2016). Recently, comparative research designs have been presented as a method to identify an optimal error-correction procedure for individual learners (Carroll et al., 2018; Frampton et al., 2017; Johnson et al., 2017; McGhan & Lerman, 2013; Slocum & Tiger, 2011). Additional within-subject replications often referred to as a *validation* phase (e.g., Carroll et al., 2018; McGhan & Lerman, 2013) allow for an analysis of the predictive validity of the initial assessment on future discrimination learning. Two studies have evaluated the potential utility of such an assessment.

McGhan and Lerman (2013) compared the acquisition of listener responses by five children with ASD across four error-correction procedures: (a) error-statement, (b) demonstration, (c) active student response, and (d) MRR. Following the initial assessment, the procedure that produced mastery in the fewest number of trials was compared to a more- and less-intrusive procedure. This validation phase included three additional comparisons for each learner. The demonstration condition was the most efficient procedure for four out of five participants during the initial assessment. During the validation phase, the demonstration condition was also the most efficient procedure in 11 of the 12 comparisons. For the remaining participant, active student response was identified as the most efficient procedure during the initial assessment; however, this finding was replicated in only one of three comparisons in the validation phase. Interestingly, the demonstration condition was not included in the validation phase for this learner. As a result, the findings of McGhan and Lerman may suggest that either (a) an initial assessment may predict the future efficiency of error-correction procedures or (b) the demonstration error-correction procedure may be the most efficient and least-intrusive procedure, so an assessment is unnecessary.

In an extension of McGhan and Lerman (2013), Carroll et al. (2018) conducted an abbreviated assessment that compared (a) extinction, (b) demonstration, (c) active student response, (d) re-present until correct, and (e) MRR error-correction procedures on the acquisition of target skills for four children with developmental disabilities. The abbreviated assessment included between 36 and 60 trials in each condition. Following this assessment, the authors ranked each procedure based on the number of correct responses, errors, and error-correction trials. The authors then conducted at least two additional within-subject comparisons during a replication phase. The abbreviated assessment suggested that the most efficient error-correction procedure varied across participants, which was predictive of the most efficient procedure in four out of nine validation comparisons. The findings of McGhan and Lerman and Carroll et al. may suggest that an individualized assessment of error-correction procedures may aid instructors in identifying appropriate instructional techniques for individual learners. Nevertheless, additional research is needed to determine optimal assessment conditions and systems of measurement that may allow for more precise prediction of performance on subsequent discrimination tasks.

Future Research

Research on error-correction procedures may continue in several domains. Among the most fruitful areas may be those that identify functional relations between the efficacy of a given procedure and (a) particular patterns of responding (e.g., position biases or overselective responding), (b) participant characteristics (e.g., prerequisite repertoires), or (c) other related variables. Doing so will allow for greater individualization of instructional programs without requiring extensive assessment procedures. Of these three domains, identifying prerequisite repertoires that may facilitate acquisition under a given procedure may be particularly meaningful to current practice and research. Prerequisite skills necessary for learners to acquire targets in the demonstration procedure may be of particular interest as the literature reviewed above might seem to suggest that a universal endorsement of this procedure for all learners' programming would be appropriate. Nevertheless, it is likely that certain repertoires and even a particular instructional history may be needed for a learner to acquire novel discriminations using this procedure. Additional research might include participants with less-developed repertoires or particular barriers to learning (e.g., prompt dependence) to determine the extent of the effects previously reported in demonstration and related procedures.

Additional research should also consider current practices in applied settings. Surveys or descriptive studies of error-correction procedures in educational and therapeutic programs may guide future research and training initiatives. It is currently unclear whether the procedures commonly included in comparative studies align with those used in applied settings. In fact, based on the numerous modifications to standard procedures (described above), it may be presumed that additional modifications would be present in applied work. Describing these practices might further elucidate those variables influencing the instructors' selection of instructional practices, and subsequent research might evaluate methods to reduce the intrusiveness or increase the efficiency of those procedures. As one example, embedding mastered demands during error correction (e.g., Plaisance et al., 2016) or active student response procedures may be commonly used in applied settings despite a growing body of research suggesting that these may not be optimal strategies. Nevertheless, minor modifications to these procedures may have robust effects on instructional efficiency while maintaining or even reducing their intrusiveness (e.g., procedures more closely aligned with demonstration conditions).

Finally, future research should consider the findings of extensive experimental and translational research on stimulus control in an effort to develop or refine error-correction procedures that produce more robust instructional outcomes. Although rapidity of acquisition is certainly of interest, components that produce greater generalization to untrained conditions (Stokes & Baer, 1977) or emergence of untrained relations (Wolery et al., 1991) might also be explicitly arranged during error correction.

Conclusion

A number of error-correction procedures have been shown to be effective in facilitating the transfer of stimulus control. These procedures have been found to differ in efficiency, intrusiveness, and learner preference, which may require individualized assessments to identify optimal procedures. Finally, although error-correction procedures are ubiquitous in instructional arrangements, discrimination learning with minimal errors should endure as the most desirable training outcome. As a result, error-correction procedures should constitute a small but consequential component of effective instruction.

Mand and Tact Training for Children with Language Impairment

18

Tiffany Kodak, Mary Halbur, and Maria Clara Cordeiro

In his text *Verbal Behavior*, Skinner (1957) described a behavioral approach to language in terms of the role of environmental variables on the occurrence of language. Skinner identified a taxonomy of language that classified responses, which he called verbal operants, based on the variables that preceded and followed these operants. That taxonomy has served as a guide for the successful practice of verbal behavior instruction for individuals with language impairment (e.g., children and adults with intellectual and developmental disabilities).

Skinner's taxonomy (1957) includes seven elementary verbal operants, two of which serve as the focus of this chapter. The mand is a verbal operant that occurs under motivating conditions (e.g., deprivation, satiation) and specifies the consequence that will reinforce the response. Mands can be colloquially referred to as requests, and this operant occurs when another person is present to respond to a mand for certain objects (e.g., a ball), activities (e.g., pushing a swing), or information (e.g., the name of an unfamiliar object). For example, a child who has not had anything to eat for a few hours (i.e., the motivating condition of food deprivation) may mand for a peanut butter and jelly sandwich when his mom enters the kitchen. If this mand produces the outcome specified by the response (i.e., the child receives a peanut butter and jelly sandwich), this response will be more likely to occur again under similar conditions. The tact is a second verbal operant that occurs in the presence of a nonverbal stimulus (e.g., objects in the environment, private events like thoughts and feelings) and produces a conditioned reinforcer (e.g., praise, attention). For example, a girl walking with her father says, "an orange cat" while pointing at a cat under a bush by a house. Her father says, "I see it, too! It looks like our cat," which is the social consequence that increases the likelihood that the tact will occur again in the future under similar circumstances.

Mand and Tact Assessments

There are several assessments that assist behavior analysts in measuring an individual's mand and tact repertoires. These assessments are beneficial to conduct prior to verbal behavior instruction to identify types of mands and tacts should be the focus of intervention, to assist in selecting an intervention, or to identify the function(s) of the child's current vocalizations.

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_18

Standardized Verbal Behavior Assessment Tools

The Verbal Behavior Milestones Assessment and Placement Program (VB-MAPP) measures the level of a child's language skills to guide verbal behavior intervention (Sundberg, 2008). It was developed based on Skinner's conceptualization of verbal behavior and in consideration of a child's developmental milestones. The VB-MAPP is comprised of three assessments including the Milestones Assessment, Transition Assessment, and Barriers Assessment. The Milestones Assessment serves as the core assessment, which evaluates 16 domains of behavior (e.g., mands, tacts, social behavior, and social play) that are divided into three developmental levels (0–18 months, 18–30 months, and 30–48 months). Assessment data are collected during tests of specific skills and through naturalistic observations. Based on the results of the Milestones Assessment, behavior-analytic intervention focuses on teaching domains with the lowest scores until all domains are at a similar developmental level (e.g., all scores fall within the 18- to 30-month level). Thereafter, all domains within a level are targeted for instruction. The Milestones Assessment is repeated at scheduled intervals (e.g., every 6 months) to track a child's progress toward meetings important developmental milestones.

The Assessment of Basic Learning and Language Skills–Revised (ABLLS-R) is an assessment that identifies skill domains that require intervention for children with language impairment and developmental disabilities (Partington, 2006). The ABLLS-R includes skills grouped into 25 domains (e.g., self-help, motor skills) that most children acquire before entering kindergarten and is based on Skinner's (1957) account of verbal behavior. Assessment data are gathered during interviews with caregivers and other familiar individuals, tests of specific skills, and naturalistic observations. The ABLLS-R also is repeated at scheduled intervals to track a child's progress on learning skills across domains included in the assessment.

Assessments to Identify Functions and Interventions

The importance of assessing mands and tact for children with developmental disabilities (DD) led to the publication of assessment strategies that link assessment outcomes to specific interventions. Researchers have developed several assessments to evaluate environmental variables that affect the occurrence of mands and/or tacts (e.g., Bourret et al., 2004; Lerman et al., 2005). For example, Bourret et al. (2004) developed a mand assessment to measure potential barriers to mand training (e.g., only engaging in partial responses such as saying "t" rather than "tunes," waiting for prompts to mand). Three participants with deficient mand repertoires completed a mand assessment that included 10-trial sessions. Each trial began with the presentation of a preferred item (e.g., candy) and a 10-s opportunity to mand for the item, and the intrusiveness of prompts increased within the trial (e.g., nonspecific prompt, vocal model of response). The authors evaluated patterns of responding during the assessment to guide their selection of an intervention. For example, one participant consistently waited for a prompt to mand before engaging in the targeted vocalization. That participant's pattern of responding resulted in an intervention that addressed prompt dependence and included fading of prompts. All three participants in Bourret et al. acquired mands as a result of intervention that addressed their specific pattern of responding in the assessment. Nevertheless, the clinical utility of the assessment may be reduced due to the assessment duration; assessment of a single mand requires 1–2 h.

When children are referred for verbal behavior intervention, it can be helpful to assess the function (i.e., reinforcing consequences) of existing vocalizations. For example, a child may frequently say, "ball" yet refuse to play with a ball given to him. In these situations, the function of the child's vocalization may be unknown, thereby making it difficult for adults to identify how they should respond to the child's vocalization. Lerman et al. (2005) developed a functional analysis to assess functions of emerging speech in children with DD. Similar to functional analyses used to identify the function of problem behavior (e.g., Beavers et al., 2013), a functional analysis of verbal behavior includes specific conditions that isolate and manipulate common consequences that follow behavior. For example, the mand condition was conducted after the participant did not have access to the item for 60 min (i.e., arranged a period of deprivation as a motivating condition). Following the target response (e.g., the child said, "ball"), the participant was given the ball for 20 s. Thereafter, the ball was removed and only returned following another occurrence of the target response.

The results of the functional analysis were analyzed to determine which condition(s) resulted in high rates of responding compared to the control condition. One or more functions were identified for at least one of the assessed responses for their four participants (Lerman et al., 2005). Nevertheless, the functional analysis required considerable time to assess the function(s) of one targeted vocalization, which may limit its feasibility in practice. Thereafter, Kelley et al. (2007) modified the functional analysis conditions to reduce the overall duration of the assessment and improve its practical utility.

Mand Training

Verbal behavior intervention often includes, and frequently begins with, mand training. Skinner (1957) described the mand as the verbal operant that has a direct benefit to the speaker, because mands allow people to gain access to objects, assistance, and information in their environment under conditions of deprivation or aversive stimulation. All people experience some form of deprivation throughout the day (e.g., long intervals of time between meals, engaging in activities when it is hot outside without drinking water) that will serve as motivating conditions to engage in behavior and produce outcomes that can reduce deprivation. However, children who have deficits in verbal behavior may learn inappropriate or problematic ways to obtain these outcomes. Prevalence estimates indicate as few as 8% to as high as 94% of children with autism spectrum disorder (ASD) engage in problem behavior (Jang et al., 2010; Matson et al., 2009). For example, a child with ASD who has not eaten for a while may tantrum (i.e., cry loudly and pound on the floor with her fists), which results in her parents approaching her and guessing the reason for her tantrum. If her parents hypothesize that she might be hungry, they may give her a snack to stop the tantrum. Thereafter, future tantrums may function as a mand that occurs during conditions of food deprivation and produces access to food. If tantrums continue to produce food for extended periods, the child may not learn more appropriate ways to mand for food without targeted intervention.

A well-supported and common behavioral intervention for problem behavior is Functional Communication Training (FCT; Tiger et al., 2008). Children are taught to engage in an appropriate communicative response (i.e., mand) to obtain the consequences that used to follow problem behavior. For example, if a child engages in problem behavior to obtain a preferred toy (e.g., a tablet), FCT involves teaching the child to mand for the preferred toy, such as saying, "Tablet, please." FCT is more likely to be effective if extinction for problem behavior is included in the intervention, meaning that the consequence for problem behavior (e.g., the tablet in the example above) does not follow an occurrence of problem behavior (Hagopian et al., 1998). FCT is frequently conducted as an initial intervention to address problem behavior that may interfere with acquisition of other skills. Furthermore, the inclusion of mand training in early behavioral intervention is recommended to help prevent the development of problem behavior (Sundberg & Michael, 2001).

Mand training also is conducted at the start of intervention because mand acquisition may lead to the emergence of other untrained repertoires. For example, research suggests that mand training may result in the emergence of tacts without any additional training (e.g., Egan & Barnes-Holmes, 2009). Finn et al. (2012) taught four children with ASD to build a four-part construction task. Each piece of the construction was assigned an arbitrary name, and participants were either taught to mand for pieces needed to complete the construction task or tact (i.e., label) the parts. Following training, researchers measured whether mand training led to the emergence of tacts without additional training. All four participants engaged in correct tacts following mand training, showing the transfer of training across verbal operants. From the perspective of training efficiency, the identification of strategies for training one skill that result in learning of other untrained skills will decrease the overall amount of time needed to develop and strengthen the verbal behavior repertoires of children with language impairment. Therefore, early and ongoing mand training that results in learning of novel skills should be emphasized during verbal behavior instruction.

Mand Modalities

Vocal verbal behavior is often a goal of many parents of children with language impairment. Although vocal mands are likely the most socially acceptable mand form, there are circumstances under which training of alternative mand modalities should be considered. For example, a portion of children with DD may not be able to echo (i.e., a vocalization that has point-to-point correspondence and formal similarity to a preceding auditory stimulus; Skinner, 1957; colloquially referred to as vocal imitation) another person's vocalization. Vocal mand training is unlikely to be effective for children who are unable to echo at least two syllables (Valentino et al., 2019).

Alternative mand modalities such as sign or exchange-based communication systems have been successfully established in children with language impairment. A variety of augmentative communication systems exist for teaching exchanged-based and sign modalities, although there is considerable empirical support for training with lower cost, low-tech options (e.g., sign, paper-based Picture Exchange Communication System [PECS]; Bondy & Frost, 1994). The PECS is a paper- and app-based communication program to teach mands and other verbal operants to children with language impairment. The PECS program includes six training phases; it begins with single picture exchanges to mand for preferred items and activities and progresses to full-sentence mands (e.g., "I want chips"), answering questions, and tact training.

Some researchers advocate for sign training, whereas other researchers advocate for training with an exchange-based system. Those who advocate for sign suggest it is easier to acquire than exchange-based systems (e.g., PECS) because a different response topography (motor movements associated with the sign) is required for every mand, whereas an exchange-based system has the same response topography (e.g., pointing at or exchanging a picture) for every mand (Sundberg & Michael, 2001). In addition, sign does not require physical materials so it can occur in any setting, and there is a community of people who engage in sign and can provide this training (i.e., the hearing-impaired community). Researchers who advocate for exchange-based systems suggest training can be efficient, training does not require children to engage in complex motor responses and have well-developed motor imitation skills, and the community does not require any specialized training to respond to picture-based communication (e.g., Bondy, 2001; Mirenda, 2003).

Several assessments have been developed to investigate the efficacy of teaching different mand modalities based on a child's putative prerequisite skills. It is hypothesized that motor imitation may be a prerequisite for successful sign mand training, whereas identity matching (i.e., matching identical pictures) may be a prerequisite for exchange-based mand training. Valentino et al. (2019) measured matching and motor imitation as well as vocal imitation of one- and two-syllable words taken from the Early Echoic Skills Assessment (EESA; Esch, 2008). Thirteen participants completed the prerequisite assessment and then received sign, exchange-based, and vocal mand training. Their results showed weak correlations between motor imitation assessment scores and successful sign training and weak correlations between matching assessment scores and exchange-based mand training. In contrast, the vocal imitation assessment (specifically, the two-syllable words) was strongly correlated with successful vocal mand training. Overall, the authors concluded that individuals who do not correctly imitate two-syllable words are unlikely to benefit from vocal mand training, and an alternative format of training (either sign or exchange-based training) should occur.

When a child's matching and motor imitation repertoires are strong, it is often the case that the format of training will be decided by the intervention team comprised of professionals and the child's parent(s). The team might consider variables such as the supports in place for the selected format of training (e.g., a community of individuals who sign, participation in an intervention model that uses exchange-based communication), parent's preference as to the type of training they would like their child to receive, among others. Although vocal mand training is typically preferred by many parents, the results of Valentino et al. (2019) suggest that either sign or exchange-based mand training should occur first for children who cannot echo two-syllable words. If vocal mand training remains a priority of the intervention team, vocal imitation training could occur to strengthen the child's vocal imitation repertoire (i.e., echoic training) while simultaneously establishing mands in an alternative format.

If the treatment team selects exchange-based mand training, there are many augmentative and alternative communication (AAC) devices and applications that can be included in this training. For example, Proloquo2go® is an app-based program for the iPad® that functions as a speech-generating device. Children select picture icons in Proloquo2go®, which then emits the vocalizations that accompany the selected icons. The community may be able to respond more effectively to an exchange-based system when paired with a speech-generating device, because the device produces a vocal output of the mand through the iPad® speaker, such as saying, "I want to play tag" (Still et al., 2014). Research shows children with DD acquire mands taught with Proloquo2go® (e.g., Lorah et al., 2013).

Mand Training Formats

There are several common formats of training for the mand including naturalistic environmental training and trial-based instruction. Depending on the intervention program provider selected by parents, one or both formats of mand training are likely to occur.

Trial-Based Instruction

Researchers have successfully taught mands using trial-based instructional arrangements (e.g., Brodhead et al., 2016; Shillingsburg et al., 2019). Mand training that occurs within a trial-based format includes highly structured and repeated learning opportunities within instructional training sessions. This training often begins with the therapist identifying one or more highly preferred items that will be included in an instructional session, which occurs during periods of item deprivation (i.e., when there is an establishing operation [EO]). During trials, the therapist and child often sit close together either on the floor or at a table, and the therapist retains access to all items included in training trials. The therapist first assesses whether the child is motivated to access the item by presenting it in front of the child and measuring whether the child reaches for, points at, or engages in some other approach behavior to the item. If a child does not frequently engage in approach behavior, the therapist could measure attending behavior as an alternative indicator of a putative EO.

Following the occurrence of an approach or attending response, the therapist might remove the item and place it out of sight (e.g., in a paper bag) so that the child engages in the targeted mand in the absence of the item. This step is beneficial to include in mand trials so that the child learns to mand under motivating conditions (i.e., item deprivation) rather than only when the item is visually present, otherwise the child will not likely mand for items under natural conditions (e.g., when in a different room than the item, when items are in opaque containers, when items must first be purchased from another setting).

Once the item is out of sight, the therapist waits for the child to independently mand during a pre-established response interval (e.g., 5 s). Following an independent mand, the therapist removes the item from the bag and gives it to the child. If the child does not mand or makes an error during the response interval, the therapist models the target response (e.g., says, "cookie"; signs cookie; exchanges the cookie icon) and waits for the child to imitate the modeled response. Responses following the model also result in the therapist giving the child the item, although the duration of access may be shorter to increase the likelihood that the child will respond independently on the next trial to receive a longer period of item access (referred to as arranging differential reinforcement for independent correct responses; Vladescu & Kodak, 2010).

The therapist may conduct repeated trials with the target item for a predetermined number of trials (e.g., 10) or until the child no longer engages in an approach or attending response. If the latter occurs, the therapist could either initiate mand training with another preferred item for the remainder of the scheduled training trials, or the training session could be discontinued until item deprivation can again be contrived (e.g., by restricting access to the item or providing access to another item that might rapidly establish the value of the restricted item) or until the next day or training.

Although mands are successfully taught with trial-based instructional arrangements, there are some limitations to this format. For example, it may be difficult to contrive motivation for an item across repeated trials. If the child has access to the item for multiple trials in a row, it is possible that the child will become satiated on the item. Under conditions of satiation, an individual should not be taught to mand for access to that specific item, or it is likely that mands will come under faulty sources of control (e.g., the mand occurs to avoid prompts rather than to access the item). In addition, it is possible that a child will mand for different items than those programmed during training trials. If this occurs, the targeted mand is not likely to be taught until the child is satiated on items that may compete with the motivating conditions necessary for training other mands. Finally, trial-based mand training that repeatedly occurs in one setting may not result in generalization of the mand to novel settings or conditions (e.g., the child only mands for food at the table in a clinic setting but not when food deprived at home or at school). Due to potential limitations associated with trial-based instruction, a combination of trial-based and naturalistic environmental training could be conducted.

Natural Environmental Training

Naturalistic teaching consists of methods that have been recommended to establish mands and increase generalization to the natural environment. Natural environmental training (NET) focuses on capturing the child's motivation in the context of play or other events, rather than through structured teaching or work at a table. A teaching opportunity begins with the child pointing, gesturing, or approaching an item. At this point, the therapist or caregiver withholds the item and waits for an independent mand or prompts a response. For example, a child reaches for a green train while playing, and the therapist picks up the green train in her hand and holds it up to the child. The child mands, so the therapist immediately gives the child the green train to play with for a specified time. Rogers-Warren and Warren (1980) taught three children to mand for items during play. When the child approached an item, the teacher said, "Tell me what you want" and provided the item (e.g., red ball) and praise (e.g., "Terrific; you asked for the red ball") following a mand. This training increased mands.

Unlike trial-based instructions, NET relies on child initiation of learning opportunities often within the context of play. NET can be implemented across a variety of environments such as in the home with caregivers and in classrooms with teachers. An additional advantage to NET is that the therapist or caregiver is paired with positive interactions and access to preferred items, which may decrease problem behavior (Sundberg & Partington, 1999). Nevertheless, it may be difficult to determine what a child is motivated to interact with if the child does not frequently approach items or has few toys with which s/he plays. Under these circumstances, the therapist may attempt to contrive learning opportunities that may not be relevant to the child's motivation and result in less positive interactions. Furthermore, it may not be possible to always deliver the preferred item due to competing demands or other activities which are not necessarily associated with the child's interests (e.g., social studies). Thus, a combination of trial-based instruction and NET is recommended under most training conditions.

Sequence of Mand Training

Mands are one of the first verbal operants that children acquire because they directly benefit the speaker (Sundberg & Michael, 2001). Additionally, mand training often occurs in a sequential order to ensure appropriate motivational and stimulus control. Through a shaping process early, simple mands become more sophisticated. As mands progress from simple to complex, the items or information requested may also become more abstract.

Early mands may consist of partial or single words which result in access to tangible items. For example, a child says, "bah" or exchanges a picture icon of a ball, and the parent gives the child his favorite ball. It is beneficial to reinforce early mands that are less complex so that the child's verbal behavior consistently results in preferred outcomes rather than other behavior (e.g., problem behavior) producing reinforcers. Thereafter, the complexity of the response may be shaped toward a developmentally appropriate response that is more socially valid across environments (see Table 18.1).

In the example shown in Table 18.1, the most effective mand is when the child includes a mand frame (i.e., "May I have"), because the verbal community is more likely to reinforce this response with access to a ball. If the response "ball" is not accompanied by the mand frame, the verbal community may be unsure of how to respond to the vocalization. Some people might respond as if the child is labeling an object s/he sees in the environment and provide general praise (e.g., "Yes; it's a ball"), whereas others may provide access to the ball. Inconsistency in consequences provided by the verbal community may weaken or prevent acquisition of the mand, and the child may engage in other behavior (e.g., problem behavior) that more consistently produces access to the ball. Furthermore, mand frames may result in generalization of the response across operants (e.g., Finn et al., 2012). Thus, establishing a mand frame early can produce several beneficial outcomes for the child.

Mand frames can be taught through several methods of instruction. For example, practitioners could vocally model a response with the mand frame (e.g., "may I have a ball") and permit an opportunity for the child to echo. This is an efficient method of training for children who have the prerequisite echoic behavior of imitating longer utterances. Mand frames could also be taught via the PECS. For example, a child can be taught to place a picture icon for "I want" on a sentence strip before placing a picture of a preferred item on the strip. After the child exchanges the sentence strip, the therapist points to each icon while demonstrating the vocal response (e.g., says, "I want crackers"), and then gives the child crackers.

Regardless of the method of training, it is beneficial to use procedures that increase variability of mand frames (e.g., Brodhead et al., 2016). Lag schedules result in reinforcement of a response that is different from a predetermined number of previous responses. For example, a lag 2 schedule requires a response that differs from the previous two responses to produce a reinforcer. Thus, if a child emits the mand frames "I want" and "can I have," the third mand frame must be different from the previous two to result in the consequence. Variation in mand frames may prevent stereotypic or invariant mands that are not socially valid. However, research on natural variation in mand frames in populations of typically developing children can guide the extent of variability that should be targeted in treatment for individuals with language impairment.

Table 18.1 Example shaping steps of mand response topography[a]

Step	Functional communication response
1	A vocal mand in a sentence fragment (e.g., "Ball")
2	A polite vocal mand in a sentence fragment (e.g., "Ball please")
3	A polite vocal mand with a mand frame (e.g., "May I have a ball please?")
4	A mand for attention plus a polite vocal mand with a mand frame (e.g., "Excuse me. May I have a ball please?")
5	A mand for attention with a pause for acknowledgement plus a polite vocal mand with a mand frame (e.g., "Excuse me." [pause; adult looks at child], "May I have a ball please?")

[a]Adapted from Ghaemmaghami et al. (2018)

Mands for Information

A mand for information is evoked by an EO and reinforced by access to some type of information rather than specific items (e.g., "where is the cookie" results in information about the location of a cookie). Nevertheless, the information obtained may lead to access to preferred items (e.g., the location of a puzzle piece), which can condition the information as a reinforcer. For example, if Jamie asks her parent, "where is the air pump" in order to inflate an old basketball, the information about the location of the pump leads to Jaime locating the pump, filling the deflated basketball, and then playing a game of basketball with her siblings. Thus, the information is paired with increased access to a preferred activity, and this pairing will likely increase the value of information in the future.

Children with ASD often display deficits in their question-asking repertoires (Charlop & Milstein, 1989). Yet, mands for information are critical for children to acquire, because they play a large role in language development (McNeil, 1970). Mands should be taught when the information is valuable (i.e., an EO is present) and not when the information is already available (i.e., AO conditions). For example, Shillingsburg et al. (2014) taught three children with ASD the mands "who" and "which" to access information. During EO trials, an array of different opaque colored cups was presented on the table ("which" trials) or three therapists stood by the table ("who" trials). Independent and prompted mands for information ("which cup" or "who has it") were reinforced by access to relevant information (i.e., the color of the correct cup or person who had the item), which the participant then used to access a preferred item. During AO trials, the therapist provided information on how to access the item at the start of the trial (i.e., the location of the preferred item), thereby eliminating the value of engaging in behavior that produces information that is already available. The AO trials served as a type of control that reduced the probability of these mands coming under other sources of control (e.g., the presence of cups) during trials. Procedures like this can be valuable to ensure that the child is able to engage in mands for information under the correct stimulus and motivating conditions.

Mands to Terminate Aversive Stimuli

It is common to encounter stimuli in the environment that one finds aversive or unpleasant. For example, a very loud noise, a non-preferred type of music, or the persistent smell of tuna-fish lingering in the office fridge may be aversive stimuli to some individuals. Termination of unpleasant or aversive stimuli can function as a reinforcer (Skinner, 1953). As such, mands for termination can consist of requests for removal and termination of non-preferred or low-preference items (e.g., Groskreutz et al., 2014) as well as requests for the removal of obstructing stimuli that block access to a preferred activity (e.g., Shillingsburg et al., 2013). If children do not learn to mand for termination, they may experience prolonged or intense exposure to aversive stimulation, which may evoke problem behavior.

Caregivers and stakeholders (e.g., teachers) indicate they find it important for children to appropriately communicate about non-preferred events or items (Groskreutz et al., 2014). There are several, socially appropriate ways to mand for termination of unpleasant events and stimuli. For example, a child could ask someone to "please stop" doing something or say, "move, please" if someone is obstructing access to preferred items. However, for children with ASD, mands for termination are not acquired though naturalistic interactions with the environment and may need to be directly taught (Sundberg & Michael, 2001).

Groskreutz et al. (2014) taught two children with ASD to mand for termination in the presence of aversive stimuli using a prompting procedure. Results showed training with two exemplars was necessary to observe generalization of mands for termination to untrained stimuli. Furthermore, results suggested that the mand was under the control of relevant Eos, because the participants rarely engaged in mands for termination when they were exposed to trials with preferred items and when programmed aversive stimuli were not present. Also, the mand generalized to untrained contexts.

After training mands for termination, it is important that practitioners consider procedures that may need to be implemented to prepare the child for when these mands cannot be honored on a consistent (i.e., fixed-ratio [FR] 1) schedule. For example, if a loud noise cannot be turned down (e.g., siding on a house is being replaced) or if a peer engages in vocal stereotypy (i.e., repetitive sounds) that has not been treated, children will need to tolerate some exposure to these aversive stimuli. Tolerance training procedures may consist of thinning the schedule of reinforcement, increasing delays to reinforcement, teaching mands for items that may reduce or block the aversive stimulus (e.g., mand for noise-canceling headphones), or teaching social skills such as compromising or negotiating with the person associated with the aversive event.

Generalization of Mands

It is critical that mands occur across settings, with novel people, and with materials that are not included in training. Baer et al. (1968) described generality as one of the seven dimensions of applied behavior analysis, suggesting that practitioners consider and specifically program for behavior change across contexts. There are at least three types of generalization that should be considered when conducting mand training, including generalization across SDs, generalization across MOs, and response generalization. Mands may generalize across SDs, such as when a mand to use the restroom that is taught at school also occurs when the child is at the grocery store. The MO for this mand is the same (e.g., deprivation of access to a toilet when one has a full bladder), but the stimulus conditions paired with the MO (e.g., the setting, the people present when the mand occurs) differ. In contrast, mands may generalize across MOs, such as when a child mands "play" following periods of deprivation from watching a preferred video and also mands "play" when it has been several hours since recess. Researchers have investigated the generalization of mands across SDs, such as people (e.g., Greenberg et al., 2012) and settings (e.g., Wacker et al., 2005). Fewer studies have assessed generalization of mands across MOs (e.g., Lechago et al., 2010). In one example, Lechago et al. (2010) taught a participant to mand "spoon" while making a volcano and probed for generalization across MOs by evaluating whether the participant would mand "spoon" to complete the behavior chains for making chocolate milk and setting the table. Results showed mands generalized across MOs.

A third type of mand generalization involves engaging in a novel response form based "on the analogy of old ones" (p. 48, Skinner, 1957). Skinner referred to these responses as magical mands, because they have never occurred before and have not previously contacted reinforcement. For example, a child who has learned to mand "where" to obtain information about the location of items may mand, "where is God" when she and her parents are at church. The deprivation of information on the whereabouts of people (MO) and aspects of the church environment (e.g., a cross, prayer) may collectively evoke this mand, although it has never occurred before.

Nevertheless, this mand will likely produce some information (e.g., "God is in our hearts") that may function as reinforcement.

Tact Training

Most children who receive verbal behavior intervention have a deficient tact repertoire; children may not yet know how to label or describe items in the world around them. The tact is occasioned by nonverbal stimuli and produces generalized conditioned reinforcers (Skinner, 1957). For instance, a child who plays outside in her backyard sees a plane fly overhead. She points up at the airplane and says, "I see a huge plane, Mommy!" Her mother responds, "Wow! It is big. You went on a plane like that last year." As can be seen in this example, the daughter's tact of the airplane resulted in attention and a vocal exchange with her mother (i.e., generalized conditioned reinforcement).

According to Skinner (1957), the nonverbal stimuli for the tact include (1) the audience and (2) "nothing less than the whole of the physical environment—the world of things and events" (p. 81). When one considers the vast number of stimuli in the whole of the physical environment, there are many stimuli that must acquire control over an individual's responding. Thus, tact training may account for a portion of a child's intervention services for several years to establish many relevant stimuli as tacts. Children are also taught to tact private stimuli, which are stimuli that are not available to the general public (e.g., feelings, pain). For example, a child who has a stomach ache and feels as if she might vomit can inform a parent of this private event so that her parent can behave more effectively, such as offering her a bowl or bringing her to the bathroom. As such, the tact allows the speaker to bring others into contact with many aspects of the environment that can help the listener (the person to whom the tact is directed) respond more effectively.

An extensive tact repertoire is necessary to establish other verbal operants. For example, if a child can talk about items that are present (e.g., a thick blanket), then he may quickly learn to mand for the item when he is cold, answer questions about the blanket (i.e., engage in intraverbal behavior, which is another elementary verbal operant that is critical to conversational and social skills development), and can learn to talk about the blanket when it is no longer present (i.e., the nonverbal stimulus that evokes the tact might include visual imagery).

Tact training can lead to the emergence of other, untrained behavior (Matter et al., 2020). For example, research suggests tact training may result in the emergence of listener behavior (i.e., identifying a stimulus in an array; Petursdottir & Carr, 2011). Delfs et al. (2014) compared tact and listener training with four participants with ASD. The authors conducted both tact and listener training with each participant and examined the emergence of listener responding following tact training and tacts following listener training. Consistent with previous research, the results showed tact training produced untrained listener relations for all participants, whereas listener training only produced some emergence of tacts for two participants.

The outcomes of studies showing the emergence of listener relations following tact training are important for several reasons. First, any verbal behavior instruction that results in the emergence of untrained relations will increase the efficiency of intervention and reduce time that must be spent directly teaching those relations. Second, the results support a framework, known as bidirectional naming (BiN; Miguel, 2016), through which verbal behavior instruction can be designed. Originally referred to as naming (Horne & Lowe, 1996), this framework describes the point in a child's development when speaker and listener behavior are interrelated, and training of one of these repertoires produces mediating verbal behavior that leads to the emergence of the other repertoire. For example, when an adult asks a child to "get the balloon," the child might echo the adult's vocalization (i.e., repeat the response "balloon") while looking around at items, respond to oneself as a listener by self-echoing the response (i.e., saying "balloon" to oneself several times) while picking up the balloon, and hand the balloon to the adult who provides praise (e.g., "Thanks for getting the balloon!"). This praise reinforces the verbal mediating behavior (i.e., echoic and self-echoic behavior) as well as the listener response of handing the balloon to the adult, and the reinforcer provided for those behaviors facilitates the emergence of the tact in the future. Thus, when an adult asks, "what is this" while holding out a balloon later that day, the child may say, "It's a balloon." If these repertoires become interrelated, and training of one repertoire (tacts) results in the emergence of the other repertoire (listener responses), then verbal behavior instruction can primarily focus on tact training and omit most or all listener training. Therefore, practitioners who provide verbal behavior instruction should assess the presence of a BiN repertoire prior to designing this training to evaluate the necessity of teaching both listener and tact relations versus tact relations only.

Tact training may also lead to the emergence of untrained mands. When tacts of highly preferred items are taught, research suggests tact training results in transfer across operants; mands for these items may emerge following tact training (Wallace et al., 2006). For example, Wallace et al. taught tacts of items ranked highest or lowest in a preference assessment to three participants with DD. Following tact training, the authors assessed whether participants engaged in untrained mands. Results showed all participants engaged in mands for items that were highly preferred, but they did not consistently mand for low-preference items. Because the mand specifies its reinforcer and occurs under the control of a MO, it is no surprise that participants would not engage in a mand for low-preference items. That is, being deprived of an item that one does not prefer to consume (e.g., broccoli) is not likely going to result in a mand for this item. In contrast, deprivation of a highly preferred item (e.g., popcorn) that one has recently learned to tact is likely to evoke the mand for that item so that it can be consumed. Therefore, practitioners should consider including tacts of highly preferred items in verbal behavior instruction to facilitate the transfer of control from the tact to the mand without any additional training; doing so will increase the efficiency of intervention.

Tact Training Formats

Similar to mand training, tacts are often taught through naturalistic environmental training and trial-based instruction. However, trial-based instruction is the predominant format of tact training, because tacts are under the control of nonverbal stimuli that can be precisely arranged by a therapist during trials and produce generalized conditioned reinforcement (e.g., praise). Trials of pictures or objects of common stimuli are presented in rapid succession to efficiently teach children to tact stimuli in the world around them.

There are instructional strategies frequently included in trial-based tact training to further increase the efficiency of instruction. For example, instructive feedback (IF) may be embedded in tact training trials in either the antecedent or consequence portion of the learning trial (e.g., Vladescu & Kodak, 2013). During IF, the therapist presents a secondary target to which the child is not required to respond, nor are reinforcers provided for responding. A learning trial that includes antecedent IF begins with the presentation and model of a response to the secondary target immediately followed by the presentation of the primary target that is being taught in the learning trial and to which the child is required to respond. Following a correct response to the primary target, the therapist provides a reinforcer. In comparison, a learning trial that includes consequence-based IF begins with the presentation of the primary target. Following a correct response to the primary target, the therapist provides praise and then immediately presents and models the response to the secondary target. After instructional sessions that include either type of IF, probes are conducted to measure whether the child learned the secondary targets.

Previous studies demonstrate the benefits of IF embedded in tact training for children with language impairment (e.g., Vladescu & Kodak, 2013). Interestingly, some studies show that secondary targets may be acquired before primary targets (e.g., Leaf et al., 2017), and other studies demonstrate that IF presented alone, rather than being embedded in a learning trial with a primary target, also results in acquisition of secondary targets (e.g., Vladescu & Kodak, 2013). Taken together, these studies support the inclusion of IF in tact training to increase the efficiency of instruction.

Error correction is another method of increasing the efficiency of trial-based tact training for children with language impairment. Following an error, the therapist models the correct response and provides either one or multiple opportunities for the client to practice responding correctly (e.g., Carroll et al., 2015). Although there are many types of error correction to select from when conducting tact training, consideration should be given to the procedure that will result in the most efficient instruction. Studies show that the most efficient error correction is often learner specific; thus, an assessment of error-correction procedures could be conducted prior to tact training to identify the most efficient procedure for each client to include in subsequent tact training (e.g., Carroll et al., 2015).

Tacts as a Prerequisite for Other Skills

More complex verbal behavior, such as intraverbals (e.g., answering questions), are often under multiple sources of control (Michael et al., 2011). Researchers have suggested that tacts of stimuli should be trained prior to using such targets within intraverbal training procedures (e.g., Sundberg & Sundberg, 2011). For example, if the question, "what is a red vehicle" will be targeted during instruction, a child should first have tacts for the individual components (e.g., red, vehicle) and be able to tact relevant exemplars from categories (e.g., firetruck, sports car). May et al. (2013) evaluated the emergence of intraverbals following tact training and found untrained intraverbals emerged for three adolescences with ASD. However, other researchers have found that the training of component tacts does not increase all related intraverbals (e.g., Miguel, 2017).

Complex verbal behavior also may emerge following specific sequences of prerequisite skills training that include tacts. For example, DeSouza et al. (2019) investigated tact training as part of a prerequisite skills training sequence for intraverbals. Intraverbals (e.g., "A bird from the rain forest is a…") emerged at the end of the training sequence that included several types of tact training, suggesting that component and category tacts (e.g., tacts of locations such as the rain forest, categories of animals such as birds, and exemplars of bird such as Toucan) were likely prerequisites. Nevertheless, continued research is required to identify the sequence of prerequisite skills, including types of tact training, that leads to more advanced and complex verbal behavior.

Tact Modalities

Vocal verbal behavior, sign, PECS, and AAC are all relevant modalities for tact training. For example, Lorah et al. (2014) used Proloqu2Go® on an AAC device to teach object tacts and tact frames (I have, I see) to children with DD. Researchers taught the tact frame "I see" with four items (i.e., dog, ball, crayon, book), followed by training of the tact frame "I have" and the same items. Following mastery of each tact frame in isolation, discrimination training was conducted in which the stimulus arrangements were randomized. Results suggested rapid acquisition of tacts and tact frames in isolation and when combined during discrimination training. However, it should be noted that tacts with AAC devices involve non-identical matching (selecting a picture on a device that is similar to an item in the physical environment) and may also be characterized as listener behavior in some contexts.

Similar to mand training, each modality has benefits or limitations for different learners (e.g., Tincani, 2004). At the present time, there is limited research on tact training across non-vocal modalities (e.g., Lorah & Parnell, 2017); however, it is likely that many of the assessments used to identify a mand-training modality would be applicable for tact training, along with client, caregiver, and stakeholder preference for a modality.

Sequence of Tact Training

Systematic tact training occurs early and often during comprehensive behavioral intervention for children with language impairment (e.g., Leaf & McEachin, 1999), because there are many nonverbal stimuli that a child must learn to tact in order to benefit from later pre-academic instruction (e.g., caregiver's names, household items). After one-to-two-word tacts of common items are taught, categorical tacts (e.g., animals, clothing) as well as tacts of features and functions of items are taught. In addition, practitioners should consider conducting training of tact frames, multiple-tact training, and training of multiply controlled tacts.

Tact Frames

Tact frames consist of the inclusion of autoclitics in addition to a tact. An autoclitic is verbal behavior "which is based upon or depends upon other verbal behavior" (Skinner, 1957, p. 315). As such, autoclitics accompany other verbal operants to help the listener respond more effectively to the speaker's verbal behavior. A descriptive autoclitic has been referred to as an autoclitic tact because it indicates the conditions of the speaker (MOs) and specifies the source(s) of control for the tact (i.e., describes the controlling variables). Tact frames including, "I see," "I hear," and "I have" specify the environmental stimuli controlling the tact and affect how the listener responds to the speaker's tact. For example, if a child says, "I hear a dog," the listener may be quiet for a moment to observe the environment for the sounds of a dog before responding to the speaker. In comparison, if a child says, "I see a dog," the listener may look around for the dog before responding with some observation about the dog (e.g., "It's really cute and fluffy").

There are benefits of teaching children with language impairment to use tact frames. First, the inclusion of autoclitic frames during training may lead to the emergence of other types of verbal operants (e.g., mands) by facilitating the transfer of control between verbal operants (Finn et al., 2012). For example, Finn et al. (2012) taught participants to emit the frame, "that's a…" during tact training and "I need a…" during mand training. Training resulted in the transfer of control from one verbal operant to another for three of the four participants. It is possible that these autoclitic frames can function as additional intraverbal prompts therefore assisting with the acquisition of other verbal operants.

Also, the use of autoclitic frames increases the child's length of utterance as well as the social acceptability of the tact for the verbal community. Researchers have suggested longer mand frames are more socially appropriate and equip learners with more advanced communication skills to converse with their community (Yosick et al., 2016). Relatedly, autoclitics frames can be useful for the speaker's verbal community as they may lead to more detailed discussions and potentially more specific tacts (Skinner, 1957).

Multiple-Tact Training

Most individuals will engage in varied tacts of stimuli in their environment, which indicates that children with language impairment should be exposed to multiple-tact training. Multiple-tact training commonly consists of teaching a tact of an object as well as the category to which the object belongs (Partington & Bailey, 1993). For example, multiple tacts can be established in the presence of pictures by teaching, "this is a carrot, and it is a vegetable" or "a piano is an instrument." An intraverbal relation (e.g., between carrot and vegetable or between piano and instrument) may be established when tacts are taught in this manner (Partington & Bailey, 1993). Nevertheless, the efficacy of multiple-tact training on the emergence of other verbal operants has been variable in the literature. For example, Miguel et al. (2005) found limited impact on intraverbal acquisition following multiple-tact training, and direct training of their intraverbal targets was necessary. In comparison, Ribeiro and Miguel (2020) used a slightly different procedure to teach multiple tacts of stimuli, which consisted of teaching object tacts prior to categorization tacts, rather than teaching both tacts simultaneously. For both participants, visual categorization (i.e., sorting by category) and listener responding emerged following multiple-tact training. Due to variable findings across studies, it is possible that learner characteristics, histories of reinforcement, and specific teaching procedures may impact the emergence of verbal operants following multiple-tact training. Additional research on the benefits of multiple-tact training is needed.

Multiply Controlled Tacts

Tacts assist children in responding to questions that are under multiple sources of control throughout their lives (Michael et al., 2011). For example, a father may hold up a block from part of a shape sorter toy and ask his son to tact the color of the block. Later, he may ask his son to tact the shape of the block. Different questions in the presence of the same object require children to attend to and respond differentially to aspects of the visual stimulus (the color and shape of the block) and the question that is asked about it (e.g., "what color" or "what shape"). Multiply controlled tacts are often impaired in children with ASD (Sundberg & Sundberg, 2011) due to delayed or limited vocal verbal repertoires. Furthermore, children with ASD may have difficulty acquiring this skill because it requires attending to multiple antecedents at the same time (or in close proximity) when learning multiply controlled tacts.

Few studies have evaluated ways to teach multiply controlled tacts. However, some researchers have evaluated training of similar and related skills such as teaching intraverbals about the feature, function, and class of stimuli (e.g., DeSouza et al., 2019), responding to complex questions about visual stimuli during training of one type of question at a time (i.e., instruction to respond to "what," then "why," and then "how"; Krantz et al., 1981), and teaching multiply controlled intraverbals (e.g., Kisamore et al. 2016). For example, Kisamore et al. (2016) taught children with ASD to answer questions containing multiple components such as "what is an animal that is yellow, "what is an animal that is green," "what is a fruit that is yellow," and "what is a fruit that is green" The responses to these questions are multiply controlled because both the category of the item in the question (animal or fruit) as well as the color specified in the question (yellow or green) must converge to occasion a specific response. Results suggested that repeating portions of the antecedent during training (e.g., repeating "fruit, yellow") assisted with acquisition. Due to the limited body of research on teaching multiply-controlled tacts, researchers should continue to evaluate effective teaching procedures in addition to examining the sequence of training of related skills.

Multiple Exemplar Training

Tact training for children with language impairment typically includes multiple examples of the same item. For example, a child is taught to tact "flower" in the presence of a dandelion, sunflower, rose, orchid, and daffodil. Practitioners teach multiple exemplars to establish members of a stimulus class (e.g., the stimulus class "flower") and so the tact comes under the control of relevant features that define members of the stimulus class (LaFrance & Tarbox, 2020). Thus, careful consideration should be given to the exemplars that are included in instruction. Exemplars should include critical (must have) features that help distinguish the exemplars in one stimulus class from another stimulus class (Layng, 2019). Exemplars also should include variable (can have) features that occur within members of the stimulus class but do not define the members. For example, several exemplars of flowers may share the variable feature of color (e.g., yellow), although that feature is not what defines membership in the stimulus class of flower.

Research suggests it may be more efficient to teach tacts of one exemplar of a stimulus at a time rather than teaching multiple exemplars simultaneously to establish a stimulus class (e.g., Schnell et al., 2018). The efficiency of single versus multiple exemplar training (MET) is evaluated by teaching one exemplar of a stimulus and evaluating generalization of correct responding to other exemplars in the stimulus class (Speckman et al., 2012). Training of exemplars continues until a child can respond correctly to all selected members of a stimulus class. The purpose of MET is to produce stimulus generalization and establish many stimulus classes for children with language impairment (LaFrance & Tarbox, 2020).

Evaluating Emergence Across Verbal Operants Following Training

Skinner (1957) suggested verbal operants are functionally independent, which means a response that is learned as one verbal operant (under one set of antecedent stimuli and with the specific consequences as defined within the operant) may not generalize to other operants. For example, if a child learns to mand "cookie," this does not mean that she will be able to tact the cookie nor answer questions about a cookie. Instead, a response that is learned as one verbal operant may require additional training to transfer control to other verbal operants. Shillingsburg et al. (2009) described how the response of yes and no can occur under a variety of environmental conditions, even though the topography of the response stays the same. For example, a child may say, "yes" if offered a dessert to consume after a long period without food (mand), but that response may not occur when the child is asked if the item she is eating is a dessert (tact), nor will the child say, "yes" when asked if cake is a type of dessert (intraverbal). Shillingsburg et al. taught three children with ASD to mand yes and no. They found mand training did not result in the emergence of yes and no as a tact nor intraverbal. Participants required direct training to also acquire yes and no as a tact and intraverbal.

In the natural environment, verbal behavior is usually under the control of variety of antecedent stimuli (i.e., multiply controlled). Thus, it is ideal to conduct training that can establish multiple verbal operants. One method to teach a response as multiple operants is called multiple exemplar instruction (MEI), which involves random rotation of trials targeting the same response (e.g., bubbles) as different verbal operants (LaFrance & Tarbox, 2020). For example, the child may say, "bubbles" so the adult blows bubbles (mand). The child also may say, "bubbles" when watching a video of bubbles blowing in the wind (tact). In addition, the child may point to a picture of bubbles in a book when the adult asks, "Where are the bubbles?" MEI is often introduced to establish the bidirectional relation between speaker and listener repertoires (i.e., BiN; Miguel, 2016). Research suggests that conducting MEI may lead to BiN, which is described as a prerequisite for complex verbal behavior such as categorization and problem solving. Therefore, implementing MEI promotes functional interdependence of operants as well as generative language.

Conclusion

Mand and tact training are necessary components of verbal behavior intervention for children with language impairment. Intervention should be carefully structured to teach mands and tacts under the proper motivating and stimulus conditions. Furthermore, training should be sequenced to promote the emergence of untrained exemplars and transfer across verbal operants. Successful mand and tact training, in combination with training of other verbal operants, can produce socially significant improvements in the verbal behavior of children with language impairment.

Basic Assessment Methods

19 Essentials of Observing Behavior

Art Dowdy, Kenneth W. Jacobs, Jennifer Quigley, Joshua Jessel, and Corey Peltier

Essentials of Observing Behavior

Art Dowdy et al.

> The radical behaviorist is further characterized by the heavy value he places on the consequences of direct observation. In his view, the more he can bring his own verbal behavior under the control of what he has actually observed, the more productive and useful it is likely to be. (Day, 1969, p. 320)

The behavioral worldview is self-inclusive (Hineline, 1992), which is to say that the observer does not stand outside of the causal stream (Skinner, 1974). Contingencies of reinforcement operate on the observer just as much as they operate on the target of observation. In Skinner's (1956) words, "The organism whose behavior is most extensively modified and most completely controlled in research of the sort I have described is the experimenter himself" (p. 232). Applied behavior analysts, like the experimenter, are susceptible to the same contingencies of reinforcement influencing the behavior of their clients. Observing is behaving—the cornerstone of applied behavior analysis—and it must be taken into account.

Behavioral Observation

Observation is traditionally identified with sensation. The observer is said to use the sensations of sight, hearing, touch, etc. If the observer cannot sense the target of their observation, then instrumentalities are used to clarify and amplify such as when the physiologist uses a microscope or when the astronomer uses a telescope. The identification of observation with sensation is also a defining feature of empiricism, whereby evidence from the senses is said to be the basis of our conclusions (Morling, 2018). The stimulation of the senses, however, is not the only feature of observation or empirical science more generally. The senses may be necessary, but they are not sufficient. The senses are a part of the observer's behavior, which has consequences of its own.

Who Observes?

Observation entails an observer. In some cases, we are our own observers. We can *self-monitor* our own behavior by recording its occurrence.

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_19

Self-monitoring can provide a baseline measure of one's own behavior or serve as an intervention itself (see Nelson & Hayes, 1981). In other cases, the observer is a parent, teacher, or school aide to the client whose behavior is being referred. Parents and educators may be considered *casual observers* when they do not use formal, behavioral science methods to monitor the behavior of concern. "If our casual observer spent enough time, he might discover some of the contingencies, but he would do so only if he knew what to look for" (Skinner, 1971, p. 149). This is to say that the casual observer does not know to look for behavior in terms of its antecedents and consequences. Compared to the casual observer, the applied behavior analyst is a *formal observer* because of his/her principled and methodical approach to measuring behavior.

What Do We Observe?

We observe *behavior* for its functional effects—from seemingly innocuous movements like a thumb twitch to writing a book (Hayes et al., 1988). Importantly, though, behavior analysts do not observe a thumb twitch to understand its mechanics. Rather, behavior analysts observe a thumb twitch for its effect on the environment. Similarly, behavior analysts do not observe the permanent products of the book to understand the rules of grammar. Rather, behavior analysts observe the permanent products of a book for its effect on the social environment. This is to say that the target of the behavior analyst's observations is *operant* (Skinner, 1935).

The emphasis on *operant* is important because it guides our formal observations. *Operant* is an open-ended, class-concept defined by the effect of behavior on the environment (Hackenberg, 1988). The open-ended nature of the operant means that the target of observation could have one or more effects under different circumstances. Therefore, the target of observation, otherwise known as the *target behavior*, is operant behavior under the differential control of antecedents and consequences in the environment. Additionally, operant behavior may be public or private, as there is no requirement for an operant to be publicly observable (Skinner, 1945). What is felt or introspectively observed is one's own body (Skinner, 1974), which can serve as an antecedent for operant behavior (Lubinski & Thompson, 1987; Rajagopal et al., 2021). Further, the thinking, feeling, and emotions that influence our behavior can be linked to the classes of motivating operations we observe in the environment (Killeen & Jacobs, 2017a, b).

Why Do We Observe?

Applied behavior analysts are inundated with verbal descriptions of things seen by parents, physicians, psychiatrists, social workers, support staff, teachers, and more. For example, we are told the client is "not listening" or is "defiant." Moreover, we are told that the client is "not listening because he is defiant." Such descriptions lack the specificity needed to identify a target behavior *and* its controlling variables. The purpose of observing, then, is to bring one's own verbal behavior under the control of relevant organism-environment interactions (Bijou et al., 1968; Day, 1969). After one or more observation periods, an applied behavior analyst might come to describe "not listening" as "screaming to escape from demands." When the cause for what we say is what we see, we can begin to work more effectively with the behavior of concern. *Screaming* becomes the target behavior, *demands* the antecedent, and *escape* the consequence. There are organism–environment interactions we can change in service of our ultimate aim to predict and influence behavior (Hayes et al., 2012).

Where Do We Observe?

Observational settings range from the highly contrived laboratory setting to the various contexts in the field. Applied behavior analysts may find themselves in clinics, homes, schools, places of work, or the community. Dependent upon the target behavior, we may observe in one or more settings and across stimuli and people in those settings. For instance, property destruction may occur at school but not at home. Furthermore, that same behavior might occur in the presence of one teacher but not another, or in the presence of one academic task but not another. In addition, parents may report a behavior of concern that occurs at home, with the mother but not the father, at a certain time of day (e.g., bedtime). In any case, the observational setting is chosen and described for its effect on behavior. Observational settings include the things, events, and people relevant to the behavior of concern. Importantly, the observer's choice of observational setting is not arbitrary and is not chosen for the sake of one's own convenience.

What Is Observing?

Observing is behavior under the control of things seen. The effect of observing is verbal descriptions under the control of relevant organism–environment interactions. Things seen and said, however, can be distorted by the colloquialisms that creep into our observations (Hineline, 1980). For example, when the observer goes looking for the "obsession," "aggression," or "defiance" described by a parent. That is, as "events taking place somewhere else, at some other level of observation, described in different terms, and measured, if at all, in different dimensions" (Skinner, 1950). Formal behavioral observations rely on what we know about the principles of *behavior*; not some mental or mediational events taking place somewhere else. Formal behavioral observations involve methods for identifying, defining, and measuring our behaviors of concern. The remainder of this chapter covers the behavioral observation methods used to predict and influence socially significant behavior.

Target Behaviors

Applied behavior analysts aim to select target behaviors that possess social relevance and select target behaviors that are significant to the individual whose behavior is of interest. The target behavior selected should (a) lead to the access of new reinforcers, contingencies, and/or environments; (b) be socially valid (Bosch & Fuqua, 2001); (c) be generalized across contexts, behaviors, and individuals; (d) have the ability to compete with inappropriate behaviors; and (e) be important to those that the behavior change effects (Rosales-Ruiz & Baer, 1997). With these criteria in mind, the applied behavior analyst is better equipped to select behaviors most appropriate for targeted change.

Defining Target Behaviors

When defining a target behavior, the response must first be identified. A response is a single instance of behavior and multiple responses comprise a response class (Catania, 2013). A response class is a collection of individual responses that have common sources of influence in the environment. The importance of accurately identifying and defining the target behavior directly impacts the design of the intervention and measurement system. Without a well-defined response class, behaviors may be erroneously clustered together without sharing common environmental features.

When applied behavior analysts define a target behavior, they should consider the definition with respect to both specificity and sensitivity (Johnston & Pennypacker, 2010). Specificity refers to clear inclusion and exclusion criteria that will separate responses that are included in the class from those that are not. Sensitivity refers to the ability of the target behavior's definition to capture its range of variability. Ongoing evaluation of the specificity and sensitivity of the target behavior should ensure accurate measurement during all stages of data collection (i.e., both assessment and treatment).

A six-step sequence can be used to guide the process to identify and define a target behavior (Johnston & Pennypacker, 2010). First, the characteristics of the response class should be considered. Second, the type of definition used to define the target behavior should be decided. Namely, whether the behavior will be defined functionally or topographically. Third, a draft of the target behavior definition should be written that captures the topographical range of the target behavior. The target behavior definition assists the observer with discriminating between those behavior(s) that should be measured among those behavior(s) that should not be measured. Fourth, observations of the target behavior should be carried out before formal data collection to present an opportunity to test and refine the definition. Fifth, the dimension of measurement is selected for measures (e.g., frequency, latency, etc.). Last, an assessment or intervention is implemented that includes the target behavior along with the selected system of measurement.

Even during times when the applied behavior analyst follows the six-step sequence to identify and define a target behavior, adjustments to the definition may be needed. For example, during behavior measurement, the applied behavior analyst might notice that an aspect of the target behavior is not captured by the current definition or that the measurement system is not accurately representing the behavior as it occurs. In this case, changes must take place and the definition should be updated prior to continuing with data collection. Once the definition is updated, only those data collected that are based upon the updated definition and measurement system are analyzed (cf. data collected from the previous definition).

Types of Definitions

As mentioned during the six-step sequence, the two primary approaches to define a target behavior are either a function-based definition or a topography-based definition. A function-based definition is an approach for defining behavior to include responses whose occurrence depends on (is a function of) a particular class of stimuli that precede or follow the response(s). The function-based definition may include behaviors that vary significantly in form and topography, yet share the same function given that all behaviors within a function-based response class do share the same function. For example, a function-based response class might include aggression in the form of hitting others and disruption in the form of throwing items yet are defined functionally in that both are maintained by access to peer's attention. A common reason for using function-based definitions is to interpret the effectiveness of the intervention on the selected target behavior.

A second approach to define a target behavior is to do so using a topography-based definition. Topography-based definitions capture the three-dimensional form of the response. However, not all responses that are defined topographically will serve the same function. Furthermore, given its emphasis on the *form* of behavior, topography-based definitions often disregard the influence of antecedents and consequences that might impact behavior change. Defining a target behavior using a topography-based definition is advantageous when the form of the behavior is of critical importance. To illustrate why topography-based definitions might be useful, suppose a child exhibits head hitting (self-injurious behavior) from a distance of 12 inches or more with a closed fist. The behavior analyst defines this behavior topographically to contrast it with the occurrence of those instances when the same child exhibits head hitting from a 1-inch distance with an open palm. Differences between the defined topographies of behavior may offer crucial information about the child's health (i.e., the greater distance will likely result in more harm). Thus, topographically defining both behaviors offers vital data about the safety and health of the child.

The Importance of Precise Definitions

Precise behavioral definitions directly impact both the validity and reliability of an intervention. Data are valid if they represent what the behavior analyst observes and can subsequently draw conclusions from (Johnston & Pennypacker, 2010). Reliability is the agreement between observers who independently score the same behavior of a subject (Kazdin, 1977). If there is agreement between observers who are collecting data and both observers record the same behavior given its occurrence in that moment in time, this results in increased confidence of data collection. Reliability can be compromised by several factors that include observer awareness, observer drift, the complexity of the behavior/coding system, and observer expectancy (Kazdin, 1977).

Several studies have specifically evaluated the validity of research findings with respect to behavior observation. Hay et al. (1977) recruited teachers and parents and asked them to observe and collect behavior data. Hay et al. found that teachers' and parents' observer reactivity and history with participants impacted data collection agreement between the observers. Despite these factors that influenced agreement, it is important to note that observation agreement is directly related to the interpretation of the target behavior definition. The definition prescribed to the target behavior may be iterative, optimized, and changed over time. Thus, the observers can improve data collection with training if the definition has been updated or if there appear to be other factors impacting poor reliability (reactivity and history with participants). Related to this point, Alvero and Austin (2004) found that an employee who was asked to collect data on a co-worker's behavior had demonstrated poor data collection. The employee was provided with feedback on their data collection and the results showed that the delivery of feedback substantially improved their data collection performance. We encourage observers to take steps aimed to support precise data collection. These steps are for the observer to: (a) identify and describe the target behavior and the events that relate to it; (b) observe the behavior in a setting in which the targeted behavior is most likely to occur; and (c) record when the behavior is observed based on the definition within the context of the occurrence (Baer et al., 2005).

Dimensions of Measurement

Seeing an individual holding a baseball may be a relatively undaunting image for many individuals but if I were to ask you to measure what you see, the task becomes infinitely more difficult. That is because how we measure and what we measure is dependent on the scientific field of interest that is coupled with our specific training. A physicist may ask to weigh the baseball to calculate a mass. A chemist may take apart the ball to analyze the percentage of different materials that create its makeup. The behavior analyst, on the other hand, will be interested in measuring the behavior of the individual in relation to that ball. For example, the behavior analyst may want to know how many times the individual throws the ball or how long it takes them to throw the ball. The behavior analyst may even calculate the accuracy of catching the ball. Therefore, the environment is only important to the extent that it contributes to what we do, and our task as behavior analysts is to quantify what we do as any natural scientist would.

Establishing measurable dimensions of behavior is important for a number of reasons. First, science cannot exist without a quantifiable measure of your dependent variable. Without this, we are left subjectively describing behavioral events based on our own experiences. That may be well and good for the snake oil salesman but we, as scientists, hold ourselves up to a higher standard. The results of a study must be objective and replicable for behavior analysts to come to a confident consensus of an identifiable functional relation. Second, our language lacks precision and accuracy when describing the behavioral change. Of course, our words can convince someone that a change occurred but they cannot visually display the behavioral events in a way that allows an individual to analyze the outcomes for themselves and come to their own conclusions. In other words, the quantifiable measures are an objective translation of the events as they occurred in time. If a behavior analyst assigns a unit value to observed behavior, that value does not change or vary depending on appeals by the untrained observer. Third, measures of behavior are required for clinicians to make treatment decisions, such as when to (a) introduce an intervention, (b) continue an effective intervention, (c) modify a partially effective intervention, and (d) discontinue an ineffective intervention. Conjecture is not enough, especially when the stakes are as high as behavioral interventions developed for vulnerable populations in need of help.

Although recognizing justifications for using measurable dimensions of behavior may be simple enough, identifying *how* to now measure the behavior of interest raises the bar and adds new challenges for the behavior analyst. That is because behavior isn't an object that can be picked up, put down, or inspected with a magnifying glass. Behavior exists within time and we must measure it relative to the moments in which it occurs. Furthermore, the interpretations of a particular outcome are dependent on how you measure the target behavior of interest. For example, a behavior analyst may count how many times a child cries each day and point to fewer instances after the introduction of the intervention as an indication of effective action on their part. However, an astute assistant may notice that the child now cries once a day but the bout is much longer. Thus, for applied behavior analysts, the measure of choice must be representative of a socially meaningful outcome. Below are some of the fundamental dimensions that behavior analysts can use to measure behavior (see also Fig. 19.1). This is not meant to be an exhaustive list, rather the dimensions mentioned are common because they have repeatedly been determined to have particular utility.

Dimension #1: Count

When a response occurs, a behavior analyst can attribute a singular unit to that response and sum up each instance within an observation to establish a count. In order to properly use count to measure behavior, the response must be repeatable. That is, the behavior analyst is interested in identifying how often a response occurs given an environmental change. For example, an observer may count how many problems a student completes on a math homework sheet. Or a driving instructor may count how many times a trainee uses the blinker in a drive around the block. Although a measure of behavior is in its simplest form, count is limited to observational periods that do not vary or if the observation period is irrelevant. Therefore, the count is only really relevant when the issue is the target behavior occurring in the absolute sense (e.g., self-injury so severe it should not be occurring at all regardless of how brief or extended the observation period is). This is rarely the case because the expectation of the behavior analyst is that the target behavior is repeated within a certain period of time. How we interpret the outcomes of interventions is often impacted by the duration of the observation. A child who does 10 jumping jacks during the first observation, 20 jumping jacks during the second observation, and 40 during the third may start to impress the coach who is seeing her data increase with every data point. However, any interpretations of improvements may soon be disregarded by the coach when she finds out that the observation periods have also been progressively increasing from 5–10, to 20 min, providing the student with more time to exhibit more behavior.

Dimension #2: Rate

Rate is the solution to count that reduces the limitation of a measure lacking any relative value. The rate takes into consideration the period of time in which the behavior is occurring. Repeatability is therefore supplemented with properties of temporal locus to define how many times a response occurs given a specified period. To calculate the rate, the count is divided by the duration of the observation. The cycle of choice exists on a continuum from those that are brief (e.g., responses per sec) to those that are extended in time (e.g., responses per month). For example, Jessel et al. (2020) measured problem behavior on the order of minutes and the order of seconds to determine the correspondence between the two evaluations and the fruitfulness of conducting within-session analyses. The authors found that, in some cases, problem behavior can be analyzed on the order of seconds, which can reduce the necessity of extensive assessment periods. This holds practical value for clinicians working with individuals who exhibit dangerous behavior because the rapid assessment period allows the

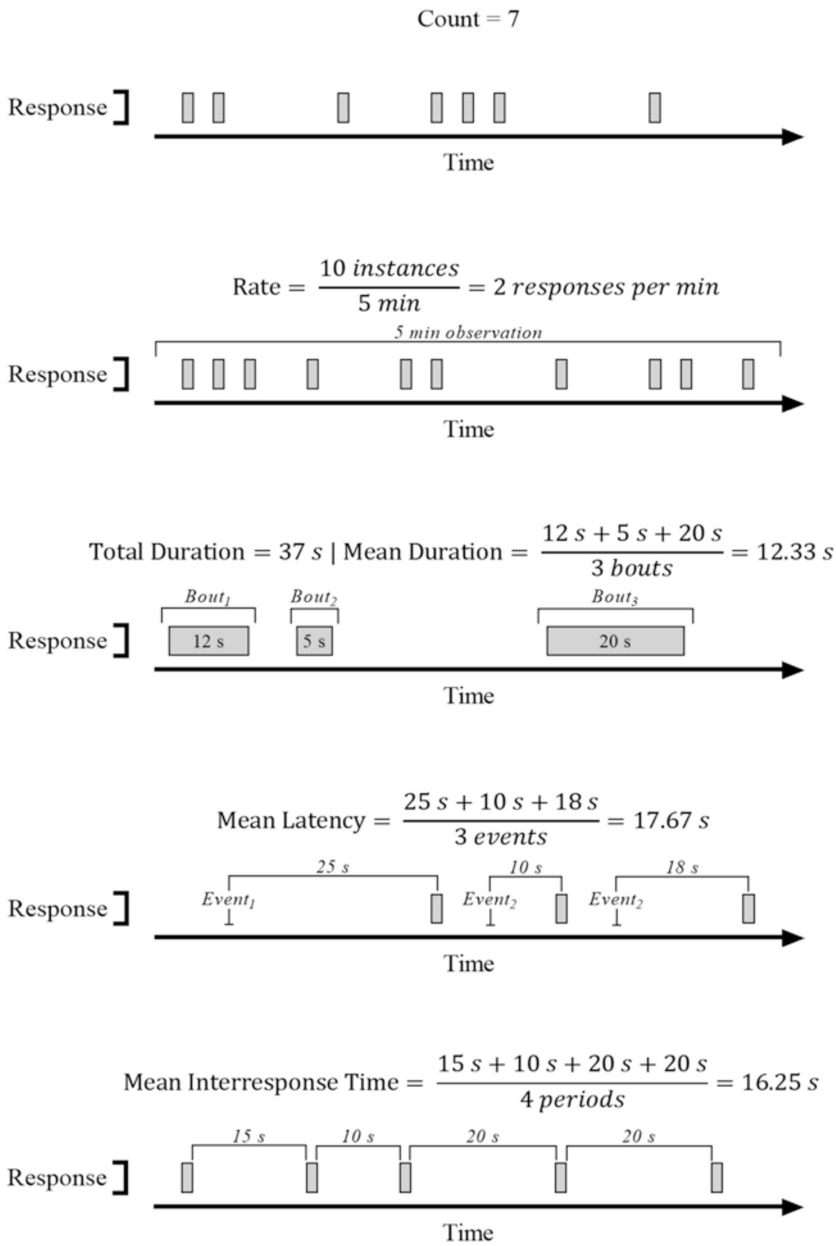

Fig. 19.1 Examples of each dimension of measurement

clinician to move quickly to implement an effective intervention. Other responses may occur across a larger window of time, making using smaller units of measurement inappropriate. For example, the behavior of smoking cigarettes is often measured as responses per day because it is highly unlikely for an individual to smoke multiple cigarettes in a minute, let alone a second (e.g., Garrison et al., 2020; McClure et al., 2018). Therefore, units of time can vary but are dependent on the behavior of interest. The behavior could be physically impossible to exhibit within certain windows of time or the measurement doesn't depict a socially acceptable form of change the intervention is intended to address. To put it another way, you wouldn't use a ruler to measure a room or a yard stick to measure the point of a pencil. The behavior analyst's job is to understand the unit of time that fits the target behavior in the same manner.

Dimension #3: Duration

In some cases, the behavior of interest does not have the properties of repeatability and the behavior analyst is more concerned with temporal extent, or how long the behavior occurs across time. More often this is the case when there are no discrete indicators of the behavior's beginning or end. Duration coalesces behavior into bouts of occurrence and the behavior analyst times how long the bout of behavior occurs. For example, a behavior analyst may try to measure each instance of a hand flick or body rock but the definition of each movement that fits the description of stereotypy may be difficult to reliably measure. Using duration with behaviors such as stereotypy has the benefit of reducing the grey area of every single instance and creates a simplified definition of the behavior being "on" and "off" for a period of time, so to speak. In addition, a soccer coach may be more concerned with how long a player remains active in a game rather than the number of times they kick the ball. Whether an artifact of the difficulty with using measures of repeatability or concerns of social relevance, the duration can be a useful dimension to consider.

How you measure duration can vary in multiple ways. A behavior analyst may be interested in the duration of each bout. That is, the behavior analyst starts and ends the timer with each occurrence and records the bouts separately, potentially calculating the mean duration of bouts per session: $\frac{t\,\text{bout}_1 + t\,\text{bout}_2 + \ldots t\,\text{bout}_n}{n}$. The duration can also be measured cumulatively across the entire session. This would involve starting the same timer with each bout to create one continuous duration of time that can be divided by the session duration to get a percentage of behavior that is occurring across the entirety of the session. Once again, the choice of measure is dependent on the social relevance of the situation. For example, a music instructor may be interested in a percussionist's ability to consistently maintain a drum roll on a snare drum for around 15 s. In such a case, the instructor would want a mean of 15 s across bouts. On the other hand, the trombone player often has to hold notes for extended periods of time and the instructor is more likely to be interested in the total percentage of time across a particular observation.

Dimension #4: Latency

In some cases, it may be important for a behavior analyst to understand when a response occurs relative to some other discrete stimulus. That interval of time between the stimulus being presented and the response occurring refers to latency and can be indicative of response strength, similar to elevated rates of responding. That is to say, if I were to press a button to answer a question on a game show reliably within 5 s that is likely to mean I am confident I have the answer, whereas waiting for 30–60 s would be a clear indication of my inability to answer. An individual may even find a particular event aversive and the latency can be measured to an escape response. For example, Call et al. (2016) presented various instructions to individuals who engaged in problem behavior and measured the latency to problem behavior given each instruction. The authors were able to take the mean latency for each discrete instruction and create a hierarchy of aversiveness depending on how quickly problem behavior occurred in the presence of the selected evocative events. Instructions that evoked problem behavior quicker were determined to be more aversive than those instructions that evoked problem behavior after extended periods of time.

Latency can be quite an efficient measure of behavior because it only requires a single, brief instance of a response to occur. Rate and count both require repeated instances across time and duration requires the response to occur over extended periods of time. This strength can reduce the necessary time required to conduct a session. For example, Thomason-Sassi et al. (2011) compared the use of latency and rate for measuring problem behavior during functional analyses. Using the measure of latency allowed the therapist to discontinue sessions after the first instance because repeated measures were not necessary. However, to calculate the rate, the therapist had to allow problem behavior to continuously occur across a period of time. The difference created a mean of 11 instances of problem behavior observed during the functional analyses using latency and 193 instances when using rate. The time required to collect measures of rate or duration can be problematic when considering severe problem behavior if repeated instances or long exposure could be physically harmful to those involved.

Dimension #5: Interresponse Time (IRT)

The dimension of interresponse time (IRT) shares many similarities with latency. The behavior analyst is measuring a period of time between two events. Where they differ is in what those events are: The distance between a stimulus and a response refers to latency; the distance between a response and a repeated instance of that response refers to IRT. Therefore, IRT is a measure of behavior as it occurs repeatedly in time in relation to itself. This is often referred to as pacing behaviors and is evident when an individual finds themselves stepping to the beat of their favorite song.

In some cases, a fast pace with brief IRTs is expected, such as when a child must repeatedly press a button in an arcade game to beat a boss. In other cases, a slower pace is desired. For example, Wright and Vollmer (2002) attempted to reduce the pace of eating for an adolescent girl diagnosed with developmental disabilities. Initially, the IRTs between each bite were so brief that it could result in dangerous complications during meals (e.g., choking). The authors developed a treatment package that involved response blocking and reinforcement on a differential-reinforcement-of-late-rate (DRL) schedule whereby access to the food was only allowed after a certain period of time had passed since the last bite. The intervention was intended to extend IRTs to a point that allowed the individual to appropriately chew and swallow the food before initiating another bite. The measure of IRT is also commonly used in models of attention-deficit/hyperactivity disorder (ADHD) as an indication of impulsivity. That is, the faster the pace (i.e., briefer IRTs) the more impulsive the individual is, and the slower the pace (i.e., extended IRTs) the more self-control the individual has. Studies measuring IRT often employ response inhibition tasks to determine the level of relative impulsivity among those with ADHD (van Den Broek et al., 1987) or animal models with rats (Orduna et al., 2009).

Combining Dimensions

We identified multiple dimensions that can be used to measure a single response but this does not necessarily infer that the behavior analyst is restricted to measuring behavior in such a limited and regulated manner. Multiple dimensions could be combined to, for example, measure the rate and duration of a tantrum. The behavior of interest may not be easily simplified to a single measure and providing multiple quantifications of behavior change may improve interpretations of intervention outcomes. In addition, a comprehensive treatment package that is intended to produce meaningful change in the behavioral repertoire of an individual is likely to involve the measurement of multiple responses, each utilizing a specific dimension. For example, Hanley et al. (2014) may have been particularly interested in reducing the problem behavior of three individuals diagnosed with autism; however, the authors used multiple measures when evaluating the comprehensive treatment to ensure a more impactful outcome in the child's environment. Hanley et al. taught multiple and increasingly complex communication skills and measured those responses as a rate. In addition, the authors were interested in cooperation with instructions and measured a percentage of compliance within a session. Finally, to ensure the majority of the participants' time was spent engaging in appropriate alternative behavior, Hanley et al. used the duration of reinforcement to measure the total percentage for each session. The combined measures and behaviors painted a quantitative mural of children who were now using developmentally appropriate language to ask for their wants and needs while accepting denials to reinforcers and following adult instructions when those reinforcers are not available. Without the combination of these dimensions, the picture would be incomplete.

Derivative Measures

Derivative measures are graphical representations of data that are transformed from direct measures of dimensional qualities of behavior. Derivative measures are often used to display data in a manner that highlights the salient features of the behavior. Two derivative measures commonly used in applied behavior analysis consist of trials-to-criterion and percentage. Both derivative measures serve distinct purposes when used to interpret behavioral data.

Trials-to-Criterion

Trials-to criterion is a derivative measure used to determine the number of occurrences of behavior required to reach a pre-set level of behavioral performance. The parameters of the pre-set level are often determined using a normative sample and offer insight into the efficiency of interventions for the respective participant. To illustrate this, suppose that a teacher plans to compare the effectiveness of two academic-based interventions on one student who is struggling to read sight words, the teacher chooses to set a criterion based on the performance of other students in the class who had already mastered identifying the sight words, and thus are considered to be the normative sample. The teacher is interested in the child's sight word identification performance (number of trials required) given both interventions with respect to the set criterion determined from the normative sample. The intervention considered to be most *efficient* is the intervention that had met the set performance criterion (often based upon the normative sample) in the least number of trials.

Roncati et al. (2019) evaluated the efficiency of prompt topographies that included both visual and auditory prompts in teaching intraverbals to three children diagnosed with Autism Spectrum Disorder (ASD). Using a trials-to-criterion measure, two types of prompt topographies (echoic and tact) were evaluated to determine which one transferred control to the verbal stimulus in the fewest number of trials. For two participants there was little difference in efficiency between topographies as shown when comparing the number of trials required to meet the set criterion (i.e., trials-to-criterion). For the third participant, the tact prompt appeared to be more efficient requiring less trials as compared to the echoic prompt for the learner to achieve the set criterion.

Trials-to-criterion is an appropriate derivative measure to use to capture the number of opportunities required to achieve a set criterion of a chained skill that requires several responses. For example, suppose, using a behavior chain a child is taught how to turn on a computer and how to navigate to a website. Trials-to-criterion is suitable to use to measure the number of trials needed for the child to independently achieve the chained skill. Additionally, the trials-to-criterion can be used to measure the number of trials needed to demonstrate independence during discrete trial instruction. To illustrate this, suppose a child is learning to identify shapes using discrete trial instruction. Each presentation of a shape is likely to be displayed a set number of times (e.g., 10 times) to promote learning. The set number of times is often referred to as a *block* and the number of trials (or blocks in this case) required to meet the set criterion is measured using trials-to-criterion.

Percentage

Another measure that is considered a derivative is percentage. Percentage is often used when the response of interest is dependent on the number of opportunities presented to respond. Behavior analysts often use percentage as a derivative measure when they are interested in the proportion of responding as it relates to a target response. For example, in discrete trial teaching the teacher may identify a specific target for the learner, run a set number of identical blocks of trials (e.g., 10 trials per block), and calculate the percentage based on correct responses within the block. Percentage is flexible in that it can be calculated for a range of behavior dimensions including frequency or count, duration, and discontinuous measures (see next section in this chapter). The formula used to calculate a percentage is:

$$\text{Response Occurrence} \div \text{Total Opportunities to Respond} \times 100$$

When using percentages, behavior analysts should be aware that upper and lower limit restrictions are placed on the data. For example, drawing on the previous discrete trial instruction example suppose that 10 trials equate to a block. The learner may accurately respond 10 out of 10 times resulting in a percentage of 100%, considered the upper limit. This percentage outcome suggests that optimal learning has occurred, and no further improvement can be made. However, if one, two, three, or more trials were conducted in addition to the initial 10 and the learner responded incorrectly, it would no longer appear that optimal learning had occurred. Rather than reflecting *true learning,* these outcomes are simply an artifact of the upper and lower bounds placed on the percentage derivative. These bounds, both upper and lower, can potentially distort behavior analysts' interpretation of the student's learning outcomes.

Quigley et al. (2018) used percentage to measure the independent play skills of three children diagnosed with ASD. The three teaching strategies that were evaluated included prompting, modeling, and a multi-component approach and all three strategies were compared to determine both the most effective and the most efficient strategy for teaching. The authors used the percentage derivative to show that all teaching strategies were equally effective; namely, all three participants showed an increased percentage of independence with the play response compared to the baseline.

Interval Recording

Interval recording, also referred to as discontinuous recording systems, are data collection methods often used during times when continuous data recording (count, duration, latency, etc.) may be arduous or impractical for the data collector. Interval data recording methods are often selected to record data when the response of interest is not discrete, or there is not a clear beginning and end. Examples of behaviors considered to be non-discrete and suitable to measure using interval recording may include playing with friends, on-task behavior during designated work times, or sleeping. Common types of interval recording include whole-interval recording (WIR), partial interval recording (PIR), and momentary time sampling (MTS). Although differences exist between the three, generally the observation period is divided into time intervals and the responses' occurrence or nonoccurrence is recorded at a designated time indicated by the interval recording method selected. Recently researchers have investigated interval recording accuracy; namely, Falligant and Vetter (2020) assessed the likelihood of false positive outcomes using types of structured visual criteria on two interval recording methods (i.e., momentary time sampling and partial interval recording). Although additional research is needed, findings showed that both interval recording methods likely control for false positive outcomes.

Whole-Interval Recording

Whole-interval recording (WIR) is appropriate to use when the behavior of interest continuously occurs and occurs at such a high rate that makes it is difficult for the data recorder to distinguish between instances. To collect data using WIR, a series of brief time intervals (5–10 s) is partitioned within the observation period. The data recorder pays special attention to whether the target behavior occurs or doesn't occur throughout the *whole* interval. If the behavior had occurred during the entire interval, this is indicated on the datasheet (+), and if the behavior had not occurred during the entire interval, this is too indicated on the data sheet (−). These data are then reported as a percentage of the total, temporally contiguous, intervals in which the target response had occurred during the observation period. Given that the defining feature of WIR is that the behavior must occur throughout the entire interval, WIR is known to underestimate the overall percentage of the behavior's occurrence.

Drawing from a recent study that included WIR, Lichtblau et al. (2018) implemented a biobehavioral treatment that consisted of melatonin and standardizing sleep and wake times aimed to decrease head and mouth touches related to sleep-related trichotillomania and trichophagia. Using a DropCam Pro video camera, 1-min WIR data were recorded on whether the participant's head was visible which indicated that she was sleeping and partial-interval recording (see below) was used to collect data on head and mouth touches. Results showed that the biobehavioral treatment increased the participant's sleep as measured by the percentage of (whole) intervals the participant was asleep per night.

Partial-Interval Recording

Partial-interval data (PIR) is commonly used for behaviors in which there is a clear beginning and end (i.e., discrete). To collect data using PIR, a series of brief time intervals (e.g., 10 s) is partitioned within the observation period (Schmidt et al., 2013). Yoder et al. (2018) found that Poisson-corrected estimates with short PIR intervals were optimal when using PIR recording. At the end of each interval, the data recorder marks if target behavior occurred at *any* point during the interval. If the behavior had occurred at any point during the interval (even briefly) this is recorded on the datasheet (+), and if the behavior had not occurred at all during the interval, this is too recorded on the data sheet (−). These data are reported as a percentage of the total, temporally contiguous, intervals in which the target response had occurred. Since PIR requires that the behavior occurs at least once during the interval, PIR is known to overestimate the overall percentage of the behavior's occurrence but underestimates instantaneous behavior (Bailey & Burch, 2002). A benefit to using PIR is that multiple behaviors can be tracked simultaneously since the data recorder only needs to track if the behavior(s) had or had not occurred.

Pisacreta et al. (2011) used partial-interval recording when they evaluated the 1:1 ratio of praise-to-behavior correction delivered by teachers on students' disruptive behaviors. If an instance of disruption was demonstrated by any student in the class during the designated interval, data were marked indicating its occurrence, and the percentage of intervals with disruption were graphed. Results showed that when teachers delivered praise-to-correction statements on a 1:1 ratio the percentage of disruptions had decreased compared to when teachers delivered praise-to-correction statements on a 1:2, 1:3, and 1:4 ratio.

Momentary Time Sampling

Like other interval recording methods, momentary time sampling (MTS) requires that brief (10 s), temporally equal, and contiguous intervals are partitioned (Schmidt et al., 2013). At the end of the interval, the observer *samples* the participant's behavior and if the target response occurs at that moment it is indicated on the datasheet (+); likewise, if the behavior is not occurring at that moment (the end of the interval) it is also marked accordingly on the datasheet (−) and this process is repeated for the duration of the observation period. Once the observation period is over, percentage data are calculated by the total number of intervals the target behavior had occurred divided by the total number of intervals multiplied by 100. A primary advantage of MTS is that the observer does not have to continuously observe the target behavior throughout the observation period which allows the observer to complete additional tasks while collecting data. This might be beneficial for someone tasked with multiple, simultaneous responsibilities such as an educator who teaches and supervises many students in their classroom. However, because the behavior is sampled at the end of the interval, instances of the behavior might be missed that occurred during the interval. Given this, it is recommended that this method is used for continuous activity behaviors, rather than behaviors that infrequently occur or those with short durations.

In a recent example of a study that used MTS to record instances of the dependent variable, Mendres-Smith et al. (2020) investigated the impact of two individual and combined interventions (i.e., play mat and interaction) along with a modified intervention on negative vocalizations and head elevations. Participants included infants who were experiencing tummy time. Throughout the study the MTS interval was set for 10 s. At the end of the 10 s interval the observer glanced at the mother and infant and recorded whether or not a negative vocalization or head elevation had occurred. Results showed that the modified intervention wherein mothers interacted with their infants using a toy and lying chest-to-chest was most effective.

Permeant Product Recording

In some instances, it is only feasible to measure behavior after it has occurred in the form of a *behavioral product*; however, we recommend when possible to collect data in vivo. Permanent product recording is when a behavior is measured after it has occurred with respect to the behavior's impact on the environment. Though, to record the behavior the observer must ensure that the behavior's effect on the environment lasts long enough for data recording to occur. This type of measurement is in reference to the time the measurement took place and its effect on the environment; for this reason other types of measurement can be coupled with permeant product recording (e.g., count, duration, etc.) to measure the dimensions of the permanent product. Benefits of permanent product recoding include limiting disturbances surrounding other required responsibilities, such as not diverting attention from students when teaching benefiting the one collecting data. There are also instances in which data recording is not accessible. For example, if a behavior analyst were scheduled to provide treatment to one patient and another patient in a different location exhibited a target behavior that had an effect on the environment. The behavior analyst could resort to permanent product recording if there were no other methods available to collect the data. When selecting to use permanent product recording, the behavior analyst should ensure that each instance of the target response always results in the same effect on the environment and that the effect on the environment can only be produced by the target response.

In an effort to foster parent's treatment fidelity with behavioral intervention implementation, Fallon et al. (2016) used an Implementation Planning strategy which was coupled with a Conjoint Behavioral Consultation model and data were collected using permanent product recording. The behavioral intervention parents had implemented was aimed at increasing compliance and decreasing aggression for two children diagnosed with ASD in a home setting. Results showed that following the training model parents' treatment fidelity had increased. However, the authors acknowledged a limitation with using permanent product recording for interpreting study outcomes; specifically, that research observations were not conducted to confirm the accuracy of the data—a primary drawback of using permeant product recording.

Elements of Optimal Behavior Measurement

A humorous tweet illustrates a critical issue commonly faced with those who conduct single-case research and observe behavior data when starting a new research project or clinical treatment (Masson-Forsythe, 2020). Namely, the ability to operationally define and then measure the phenomenon of interest, considered the bedrock of any empirical investigation. The onus is on researchers or clinicians to demonstrate the credibility, or believability, of their data (Johnston & Pennypacker, 2010). Single-case research designs and group designs share a similar concern, the *true* score is never known—rather we are always estimating the *true* score. One way to conceptualize this challenge is by viewing the formula:

$$\text{Obtained Score} = \text{True Score} + \text{Error}$$

This formula highlights that as error is added to the behavior measurement process the obtained score and true score become more disparate, thus resulting is less credible, or believable data. In essence, the obtained score, or datum point, that behavior analysts plot on their time series graph is only believable, or credible, if a justification and data are provided to suggest the error of measurement is minimized.

Two constructs relevant to the current conversation are *reliability* and *validity*. Reliability is often defined as the consistency of the data collected. High reliability in the data collection process for an individual study increases the likelihood the obtained score will closely resemble the true score and will allow the behavior analyst to have greater confidence that changes in the data are due to true changes in the behavior rather than error in the behavior measurement process (Barlow et al., 2009). Validity is often defined as the accuracy of the data collected in measuring, or representing, the phenomenon of interest. High validity in the data collection process for an individual study occurs when other measures of the same phenomenon align with the data collected. A common misconception often held is believing an instrument, or in the case of single-case research a behavior measurement procedure, is reliable or valid. However, the properties of reliability and validity are not inherent to an instrument or behavior measurement procedure but rather are properties of the data, or scores, collected (Wilkinson & APA Task Force, 1999). To unpack this further, this would mean the behavior analyst would need to demonstrate the validity and reliability of the data collected as part of the behavior measurement process for their treatment or experiment, across all included participants. For example, when constructing an operational definition of a target behavior, related literature may be consulted but it needs to be refined for the individual participant(s) participating in the study or treatment to increase the validity in measuring the phenomenon of interest. Another example, when creating the behavior measurement procedures prior literature should be consulted that will increase the likelihood of collecting reliable data, however, reliability data must be provided for the individual experiment across all included participants.

Pertaining to reliability, it is important for behavior analysts to consider multiple aspects. Because direct observation of behavior is the most commonly used behavior measurement approach, researchers demonstrate evidence of reliability by using multiple observers to collect data and results are compared. This demonstrates data collected through the behavior measurement system for the study are consistent across multiple individuals—thus demonstrating evidence of reliability. To maximize the evidence for reliability researchers can include several components. Using observers who are naive to the purpose of the study and which "phase" of the study participants are in (i.e., baseline and intervention) increases the credibility of the data collected and reduces the impact of observer reactivity. Observer reactivity occurs when observer knowledge of study purpose or condition impacts their data collection. Another element that behavior analysts should incorporate is collecting reliability data using two observers throughout the entire length of the study and across all conditions. Observer drift is a term used to describe situations in which observers using the behavior measurement system drift away from the original operational definitions or procedures resulting in data that were not representative of the original purpose.

The relationship between reliability and validity is also important to consider (see Fig. 19.2). As the figure highlights you can collect reliable data that are not valid. For example, two naïve observers may demonstrate high levels of agreement on their measurement of behavior (i.e., reliability), yet if they drifted from the original operational definition, or if the original

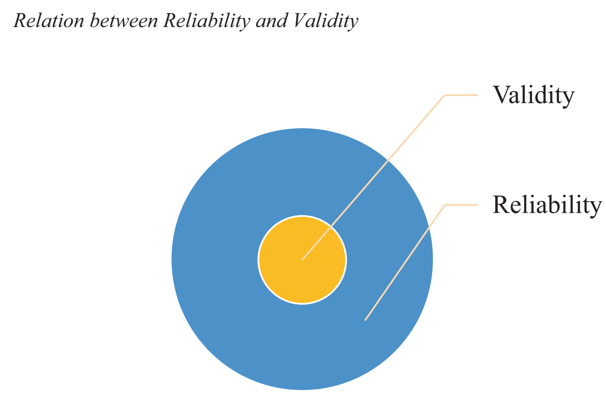

Fig. 19.2 Relation between reliability and validity. (*Note*. This figure highlights the relationship between validity and reliability. The first step is to evaluate whether reliability in behavior measurement is established across all participants, settings, behaviors, etc. The second step is to determine whether the measurement of the behavior validly represents the phenomenon of interest)

operational definition is flawed, these data may not be a valid representation of the phenomenon of interest. Yet, the inverse cannot be true.

Measuring Reliability

The primary method for providing data related to the reliability of the data collected as part of behavior measurement process is through interobserver agreement (IOA). IOA is important to provide evidence that naïve observers used the behavior measurement system yielding high agreement on the occurrence of the operationally defined behavior. However, this evidence is only convincing if researchers select an appropriate method to compute interobserver agreement and provide a justification for this decision. For example, a researcher selecting interval by interval agreement to evaluate IOA should provide a firm reason for why this method is appropriate if scored and unscored interval agreement were not also evaluated (see below).

Methods for Computing Interobserver Agreement

Total Agreement Total agreement can be used for count, duration, or latency behavior measurement systems. To compute total agreement the following steps will be followed:

1. Sum of the count, duration, or latency behavior across the observation intervals for each observer.
2. Use following formula to compute IOA for session: (smaller value/larger value) × 100.
3. Compute mean and standard deviation of observation sessions within phase (i.e., baseline or intervention) per participant.

The primary benefit of total agreement is the ease in computing and conceptualizing the estimated IOA. An important limitation to total agreement is it does not provide any evidence on whether both observers ever agreed when the behavior occurred, or did not occur. See Table 19.1 below for an example. The total agreement IOA would be (5/5) × 100 = 100%. However, a closer look at the data sheet highlights the two observers disagreed on 6 of 10 intervals whether the behavior occurred.

Table 19.1 Frequency count for callouts

	15 s intervals									
	1	2	3	4	5	6	7	8	9	10
Observer 1	1	0	1	0	1	0	1	0	1	0
Observer 2	0	1	1	1	0	0	0	1	1	0

Interval by Interval Agreement Interval by interval agreement can only be used for interval behavior measurement systems. To compute interval by interval agreement the following steps will be followed:

1. Score each interval as agreement (i.e., both observers say behavior occurred or both observers say behavior did not occur) or disagreement (i.e., one observer says behavior occurred and one observer says it did not occur).
2. Sum number of intervals coded as agreement.
3. Sum number of intervals coded as disagreement.
4. Use the formula: [agreements/(agreements + disagreements)] × 100.

A primary benefit of interval by interval agreement is increased precision over total agreement (i.e., described above). If we use data presented in Table 19.2, there were four intervals scored as agreements (i.e., intervals 3, 6, 9, and 10) and six intervals scored as disagreements (i.e., intervals 1, 2, 4, 5, 7, and 8). The interval by interval agreement IOA is [4/(4 + 6)] × 100 = 40%. We can see this differs drastically from the total agreement estimate of 100%. An important consideration to interval by interval agreement is high or low occurrences of behavior may inflate IOA of behavior. See Tables 19.2 and 19.3 for examples. Table 19.2 presents data for a behavior occurring at high frequency and the interval agreement is [8/(8 + 2)] × 100 = 80%. However, a closer look at the data shows the observers never agreed on when the behavior did not occur, they merely agreed on eight intervals that the behavior did occur. Table 19.3 presents data for a behavior occurring at a low frequency and the interval agreement is [8/(8 + 2)] × 100 = 80%. Though a closer look at the data shows the observers never agreed on when the behavior did occur, they merely agreed on eight intervals that the behavior did not occur.

Scored Interval and Unscored Interval Agreement Scored interval agreement focuses specifically on the agreement between observers on when the behavior occurred. Unscored interval agreement focuses specifically on the agreement between observers on when the behavior did not occur. To compute scored interval IOA the following steps will be followed:

1. Identify all intervals where both observed scored the behavior as not occurring, and then "remove" these intervals from your data sheet.
2. Sum all intervals scored as agreement (i.e., both observers scored behavior as occurring).
3. Sum all intervals scored as disagreement (i.e., one observer scored as behavior occurring and one observer scored as behavior not occurring).
4. Use the following formula: [agreements/(agreements + disagreements)] × 100.

To compute unscored interval IOA the following steps will be followed:

1. Identify all intervals where both observed scored the behavior as occurring, and then "remove" these intervals from your data sheet.
2. Sum all intervals scored as agreement (i.e., both observers scored behavior as not occurring).
3. Sum all intervals scored as disagreement (i.e., one observer scored as behavior occurring and one observer scored as behavior not occurring).
4. Use the following formula: [agreements/(agreements + disagreements)] × 100.

Table 19.2 Interval data for talking with peers

	10 s intervals									
	1	2	3	4	5	6	7	8	9	10
Observer 1	X	X	O	O	X	X	X	X	X	X
Observer 2	X	X	X	X	X	X	X	X	X	X

Table 19.3 Interval data for aggressive behavior

	10 s intervals									
	1	2	3	4	5	6	7	8	9	10
Observer 1	O	O	O	O	O	O	O	O	O	O
Observer 2	O	O	X	X	O	O	O	O	O	O

Table 19.4 Desirable and less desirable IOA collection

	Baseline										Intervention									
Sessions	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
Participant1	X	X	X								X	X	X							
Participant 2	X				X					X	X				X					X

Note. X denotes IOA collected

Scored and unscored interval agreement is ideal to report alongside interval by interval agreement to provide a more precise estimate of the agreement between observers for observing the occurrence and nonoccurrence of the behavior. If we use the data from Table 19.2, the scored interval IOA would be [8/(8 + 2)] × 100 = 80% and the unscored interval IOA would be [0/(0 + 2)] × 100 = 0%. If we use the data from Table 19.3, the scored interval IOA would be [0/(0 + 2)] × 100 = 0% and the unscored interval IOA would be [8/(8 + 2)] × 100 = 80%.

Standards for Acceptable Levels of Collection and Agreement

Similar to other decisions researchers make as part of the scientific process, context matters. We will provide general guidelines for the collection of IOA and thresholds deemed acceptable. If I redirect our attention back to the discussion surrounding reliability, remember that this construct is *not portable*. This means reliability must be established for the data collected as part of the experiment across all participants, conditions, settings, and dependent variables.

It has been recommended to collect IOA on a minimum of 20% across sessions in single-case research (What Works Clearinghouse, 2020) with preference for collecting IOA between 25% and 33% of sessions (Barlow et al., 2009; Kennedy, 2005). However, we do want to emphasize the IOA collected on 50%, 75%, or 100% of sessions is more desirable, though, this may not be feasible because of the required personnel. An additional consideration is to ensure IOA is collected between 25% and 33% of sessions within each phase and across participants. For example, a research team would ensure IOA data were collected across 33% of baseline sessions for participants 1, 2, 3, and 4 and across 33% of intervention sessions for participants 1, 2, 3, and 4. Last, it is important to sample IOA throughout the entire phase of the design to check for observer drift. See Table 19.4 for desirable and less desirable IOA collection. IOA data were collected for 30% of sessions for both participants 1 and 2. However, for Participant 1 IOA data collection was stacked at the beginning of each phase with the last seven sessions not including IOA collection whereas for participant 2 IOA data collection is spread out throughout the length of the phase (i.e., beginning, middle, and end).

Conclusion

Observation is a paramount component to allow for efficient examination and description of behavior, thus found at the core of applied behavior analysis. Keen observation offers applied behavior analysts the capacity to ensure sustained behavior change in their effort to improve the conditions of humanity. In this chapter, the relationship between observation—radical behaviorism—and applied behavior analysis is delineated and explored. Moreover, to provide the reader with the *essentials* of behavior analytic observation, we describe the importance of precisely defining target behaviors, dimensions of measurement, and elements to establish optimal behavior measurement.

Single-Case Designs

20

Lodi Lipien, Megan Kirby, and John M. Ferron

Introduction

Single-case design (SCD), also known as single-subject design, single-case experimental design, or N-of-1 trials, refers to a research methodology that involves examining the effect of an intervention on an individual or on each of multiple individuals. Unlike case studies, SCDs involve the systematic manipulation of an independent variable (IV) (i.e., the intervention) along with repeated measurements of a dependent variable (e.g., a behavior). These designs are especially useful for examining the impact of treatment on an individual's performance of a measurable target behavior over time (McDougall et al., 2006). As such, SCDs are considered an adaptation of interrupted time-series designs and can provide strong evidence for establishing causal inference (Kratochwill et al., 2010). Moreover, each participant serves as his or her own comparison, which allows researchers to control for a variety of confounding variables.

Single-case studies have become increasingly popular in behavioral, educational, and psychological research to examine the effects of interventions among individuals with specific disorders, such as autism and learning disabilities.

Often, disorders with low prevalence are difficult to study with traditional group designs that require large sample sizes to achieve adequate statistical power (Odom et al., 2005). The goal of a single-case study is usually to determine whether a particular intervention is more effective in changing behavior as compared to a baseline or business-as-usual condition (Kratochwill et al., 2010). Repeated observation in the business-as-usual condition creates a baseline phase, whereas repeated observation in the intervention condition creates a treatment phase (Lobo et al., 2017). Contrasting baseline and treatment phases may result in suggestions of effect, but stronger assumptions require stronger experimental designs. A variety of experimental methods discussed within this chapter can be used to enhance experimental control (Horner et al., 2005), in turn allowing researchers and practitioners to make conclusions about the existence of functional relations.

Research questions should drive the selection of experimental designs. Behavior analysts rely heavily on the trustworthiness of their data to make informed decisions about continuing, adjusting, or stopping interventions. Their research question typically determines which particular method or approach is most appropriate (Kratochwill et al., 2010), although practical and ethical considerations also contribute to design methodology. After a research question or aim has been identified, knowledge of the participants,

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_20

environment, and response classes being measured must be considered. Although experimental design is a process, the purpose of this chapter is to provide enough information to allow for the consideration of the most experimentally sound, appropriate, and feasible research design selection.

In this chapter, we will discuss four of the most common SCDs in applied behavior analysis: reversal (e.g., ABAB), multiple baseline, alternating treatments, and changing criterion designs (CCD). For each design, we present information about its development and applications, defining features, analytic approaches, and limitations. As we are limited to space, we must acknowledge that the scope and depth of this content are not intended to be fully representative of the experimental design and the measurement literature and practices available. However, we hope that the information presented will generate curiosity and motivate the reader to seek further information and/or comprehensive training needed to further advance the science and practice of applied behavior analysis.

History of SCD

Single-case research methodology has been used in the behavioral sciences since the nineteenth century (Onghena, 2005). For example, Hermann Ebbinghaus's classic experiments on memory relied on observations of a single participant (the investigator) over multiple trials and under a variety of conditions. In the early twentieth century, B. F. Skinner (1938) observed the effects of operant conditioning on behavior in experimental studies using nonhuman subjects under highly controlled conditions. Skinner clearly recognized the individuality of organisms and made the following observation: "…instead of studying a thousand rats for one hour each, or a hundred rats for ten hours each, the investigator is likely to study one rat for a thousand hours" (Skinner, 1966, p. 21).

Two decades later, Sidman's (1960) *Tactics of Scientific Research* articulated the necessary elements of single-case methodology for studies of behavior and provided guidelines for researchers. Another influential text was Johnston and Pennypacker Jr.'s (1980) book entitled *Strategies and Tactics of Behavioral Research*, which provided a comprehensive description of behavioral research methods.

For behavior analysts, SCD is foundational to the systematic study of how environmental manipulations influence changes in a living organism's behavior. Experimental research in behavior analysis relies heavily on the use of single cases to determine the relationships between interventions and behavior change, and SCDs continue to be utilized by researchers who are interested in applying behavioral, educational, or psychological interventions at the individual level.

Advantages of SCDs (vs. Group Designs)

In applied research, group designs are often used to obtain a measure of the average overall effect of an intervention on a large sample, such as all first-grade students within a school district or at the classroom level (Alberto & Troutman, 2009). Traditionally, the sample of participants is divided into an experimental group and a control group. Members of the experimental group receive the intervention while members of the control group do not. Measurements of the behavior are made before and after the intervention is implemented, and average changes in the behavior of the two groups are compared. Statistical procedures can determine whether the differences in average scores between the two groups are greater than can be explained by the random assignment of participants to different groups.

In contrast to group designs, SCDs provide a way to evaluate the effect of an intervention on the performance of a single individual or case. Each individual or case is compared to themselves, although the experiment may be replicated with other individuals. SCDs are most noticeably different from group designs in their reliance on baseline logic (Ledford et al., 2019), in which participants serve as their own control to compare differences in responding across conditions. Whereas researchers using group designs primarily rely on statistical procedures to evaluate the effect of an intervention, researchers who utilize single-case designs primarily rely on visual inspection of graphed data.

Single-case designs offer several advantages over group designs for behavior analysts. SCDs reduce or eliminate (a) the need for large numbers of participants with a particular behavior disorder, (b) the ethical problem of withholding treatment from a control group, and (c) the likelihood of obscuring individual responses to treatment by grouping data (Barlow & Hersen, 1984; Poling & Grossett, 1986). Another key advantage of SCDs is their flexibility because the intervention can be adjusted over the course of the experiment in response to the pattern of results (Ledford et al., 2019; Perone & Hursh, 2013). This can be important when "the research topic is novel, when the investigator's ability to exert experimental control is limited by ethical or logistical considerations, and when the goal is to produce an empirically validated therapeutic result for an individual" (Perone & Hursh, 2013, p. 118).

Defining Features of SCDs

Basic Elements

SCDs include at least three main ingredients: a case, an independent variable (IV), and at least one dependent variable (DV). A case refers to the subject of the experiment, such as a single living entity (Critchfield & Shue, 2018) or a group of participants. The IV is a single intervention or set of treatments under investigation systematically manipulated in some way by the researcher to demonstrate experimental control (Horner et al., 2005). The DV is a socially significant, observable, and measurable outcome used to demonstrate causal relations (change in the IV results in a change in the DV). As a simple illustration, suppose a researcher is interested in implementing an intervention to increase the amount of time a young child stays in his seat during a lesson. The intervention involves rewarding the child with stickers for remaining seated. In this scenario, the DV is the amount of time the child remains seated, and the IV is the distribution of stickers as a reward.

In order to quantify, analyze, and infer causal effects, the DV should be operationalized so that measurement is both reliable and accurate. Across time, the effects of repeated systematic manipulation of the IV (conditions over which the researcher has control) are measured by evaluating changes to the DV. In addition, measures are conducted to ensure consistency in intervention implementation (fidelity) and measurement of the DV (inter-observer agreement). Evidence of an effect is confirmed via replication.

Social Validity

One of the seven dimensions of applied behavior analysis is the study of socially significant behavior: "In behavioral application, the behavior, stimuli, and/or organism under study are chosen because of their importance to man and society…" (Baer et al., 1968, p. 92). The acceptability of intervention components, methods of measurement, and experimental outcomes can be equally as relevant to interventionists as a measure of effectiveness, answering "For whom does it work?" and "Will it continue in use when I'm gone?" Behavior scientists can use surveys and choice measures to gather information about the social significance of the research before and after a study (Fuqua & Schwade, 1986). Structured interviews with participants and stakeholders can supplement measures of treatment adherence, attrition (i.e., participant drop-out), and follow-up interviews with participants and primary stakeholders and can supplement information to ensure research methods and designs are aligned with the applied dimension of applied behavior analysis (Baer et al., 1968; Kazdin, 1977; Wolf, 1978).

Internal Validity

Once the research question, IVs, and DVs are identified and defined, the next step is to consider the possible threats to the experiment and plan to prevent or reduce their effects on reliable and valid outcomes. The internal validity of a study is high when we can attribute the effect seen in the data to the intervention, whereas the internal validity is low when there are other plausible explanations for the changes that were observed. Threats to internal validity can be conceptualized as factors that influence the case (i.e., add variability to the data stream) while having nothing to do with the intervention itself. Threats to internal validity that can result in the loss of experimental control include history (e.g., medication changes or illnesses), maturation (e.g., changes in behavior due to developmental growth or learning), instrumentation (e.g., revisions to data collection tools or the use of different observers), and practice effects (e.g., improvement resulting from repeated exposure to test content and procedures). Because of the applied nature of the research, threats to internal validity cannot be completely eliminated, however, the judicious use of SCD features can control these threats and enable single-case researchers to make valid effect inferences, as will be elaborated in the rest of this chapter.

External Validity

External validity considers the extent to which the procedures and results of a study can be generalized across circumstances and individuals. In order to enhance external validity, researchers should describe their participants, interventionists, and research contexts to the extent the results can contribute to answering the question, "For whom and in what context does this treatment work?" External validity can be increased when researchers report participants' socioeconomic status (Fontenot et al., 2019), disability status, and cultural and linguistic background (Li et al., 2017; Wang et al., 2019). In addition, researchers should include as much information about the interventionists, context, and setting of the observations as possible to allow for future replication and meta-analytic research. In addition, planning for maintenance and generalization phases can provide information about the extent to which behavior change persists in other contexts and over time.

Example

If a teacher is interested in studying the effects of a small group vocabulary intervention for dual-language learners, it is important they consider the factors other than their intervention that may affect the child's vocabulary learning. When they design the study to control these factors and limit their effect on the intervention effect inferences, they are enhancing the internal validity of the study. If the intervention was effective, the ability to generalize the suggestion (i.e., external validity) would be enhanced if the teacher included several students, instead of one, and the intervention had similar effects across participants. By conducting a post-study survey of the teacher and/or participants' experience, social validity outcomes such as likeability and feasibility of the intervention can be assessed (e.g., students found the materials to be outdated, teacher reported that the students had difficulty sitting for long periods during administration). When considered together, measures of social, internal, and external validity can enhance data-informed decision making.

Baseline Logic/Experimental Control

Single-case research methodology is founded on baseline logic (Sidman, 1960), which relies on the assumption that a single case under study can serve as its own control. During the baseline phase, repeated measurements of the DV are taken to determine the status of the individual prior to implementing the intervention. As such, the baseline phase is analogous to a control group in group designs. Without intervention, researchers assume that the baseline pattern would remain relatively stable (Engel & Schutt, 2013). This temporal stability assumption is critical because effect inferences are based on comparing what is observed during the intervention to what would have been expected had the baseline continued.

To illustrate, consider the simplest SCD, which is the AB design, or interrupted time-series design. This design consists of repeated measurement of an outcome across two measurement periods: baseline (A) and intervention (B). During the baseline phase, observation and data collection occur prior to treatment or intervention. Dimensions of behavior such as rate, duration, or latency are recorded systematically at specific points in time. These dimensions are measured repeatedly during the A phase until a consistent pattern of responses or stable level of performance is observed. At that point, the intervention is introduced, and the behavior is again measured repeatedly during the B phase. Researchers must ensure that there is treatment integrity so that the intervention is delivered in a fashion consistent with its intent (Morgan & Morgan, 2009). Researchers have recommended a minimum of five data points in each phase (Kratochwill et al., 2010).

Figure 20.1 provides an illustration of hypothetical data from an AB design. Recall the example in which a young child was rewarded with stickers for remaining seated during a lesson. The child was observed at nine time points during the A phase and was not able to stay seated for more than 1 minute at a time. After the intervention was introduced, the child consistently remained in his seat anywhere from 20 to 25 minutes during the B phase.

The primary tool for analysis in SCDs is the visual inspection of data. Graphs, such as the example in Fig. 20.1, enable researchers to detect fluctuations that may be attributable to the intervention. These visual illustrations allow researchers to view the entire process in order to evaluate the treatment effect. Baseline logic is essential in interpreting the graphs. The researcher uses the baseline observations to project what would have happened had they not intervened and then compare intervention phase observations to this projection. When the baseline is stable, as in Fig. 20.1, it is possible to visualize, at least approximately, what would have been observed had there been no intervention, but if there is a lack of experimental control as evidenced by excessive variability and trend in the baseline, any projection becomes so questionable that effect inferences cannot be made. Thus, the design of SCDs hinges on the use of methods that ensure the establishment of stable baselines.

Although adopting methods to establish stable baselines is a necessary step in designing single-case studies, it is not sufficient for making causal inferences. We also need opportunities to see the replication of the effect. Consider the results of the AB design shown in Fig. 20.1. We see a shift in the number of minutes the child stays in their

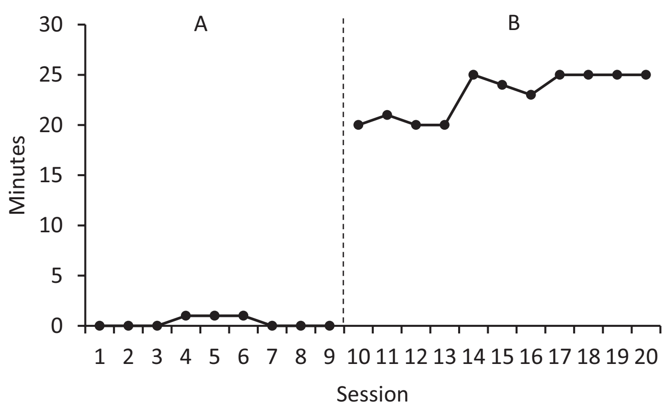

Fig. 20.1 Illustration of an AB design

seat, but it is difficult to know if the intervention caused the change in behavior. Similar to pre-test/post-test group designs, without randomization or replication of the phases, one cannot rule out alternative explanations for the change (or lack thereof). The child could have remained in his seat because he was interested in the lesson or for a variety of other reasons. Thus, the AB design is known to have poor internal validity because changes in the DV could be attributed to extraneous variables rather than changes in the IV (Poling & Grossett, 1986).

Using Single-Case Designs

Given the limitations of the AB design that restrict the ability to make causal inferences, there are many SCDs to consider in response to specific research questions. There are a variety of options to choose from based on the outcome of interest and what the researcher is trying to accomplish. The most common designs are described in detail in the following sections: withdrawal and reversal, multiple baseline, alternating treatments, and changing criterion designs.

Withdrawal and Reversal Designs (ABA and ABAB)

Withdrawal and reversal design[1] methodology was formally introduced in behavior analytic literature in the 1960s (Baer et al., 1968; Sidman, 1960). Traditionally, with both ABA and ABAB designs, treatment is introduced and withdrawn or reversed in a sequence that allows for within-subject comparisons.

An ABA reversal design consists of three measurement periods: baseline (A), intervention (B), and removal of the intervention (A). The difference between this design and an AB design is that measurement of the behavior continues after the intervention ends. The rationale for returning to baseline is to ensure that the behavior change occurring during treatment was attributable to the treatment and not some other variable (Morgan & Morgan, 2009). However, ABA design limitations include only two potential demonstrations of effect as well as ethical concerns about ending a study during a withdrawal phase when an intervention showed desirable effects.

Alternatively, with the addition of another treatment phase, ABAB designs increase the number of potential demonstrations of effect. An ABAB design consists of two baseline phases and two intervention phases and is the most frequently used reversal design. Reversal designs can be used to examine increases in desirable behaviors with intervention (see Fig. 20.2 for an example) or to examine decreases in problem behavior with intervention. As an example of the latter, consider a researcher who wants to reduce the number of times a student calls out in the classroom. During the baseline condition (A), the researcher counts the number of times the student calls out during five 10-minute sessions. The researcher introduces an intervention in which the child receives verbal praise for not calling out. During the intervention phase (B), the child is praised whenever he has not called out at the end of each 10-minute observation period. After this phase, the researcher returns to the baseline condition (A) and the child no longer receives praise for not calling out. When the intervention is reintroduced (B), the child again receives praise at the end of each observation period. If the reintroduction of the intervention results in a significant reduction in calling out, the researcher can feel confident that the intervention was responsible for changing the child's behavior.

ABAB designs are typically dynamic designs, where researchers are responsive to the data they

[1]Reversal designs, first described by Leitenberg (1973) and later reviewed by Wine et al. (2015), originally referred to a type of design in which the effects of one IV on two topographically distinct DVs (DV 1, DV 2) were repeatedly measured across time. The intervention, such as reinforcement, was presented in each phase but was in effect for either DV 1 or DV 2. The purpose of the use is to show changes in rates of responding when an IV is introduced to DV 1 and withdrawn from DV 2, as the rate of responding for each would change across phases when in the presence or absence of the IV. However, the reversal design as described is rarely used in contemporary behavior analytic literature and is often used interchangeably with *withdrawal design*.

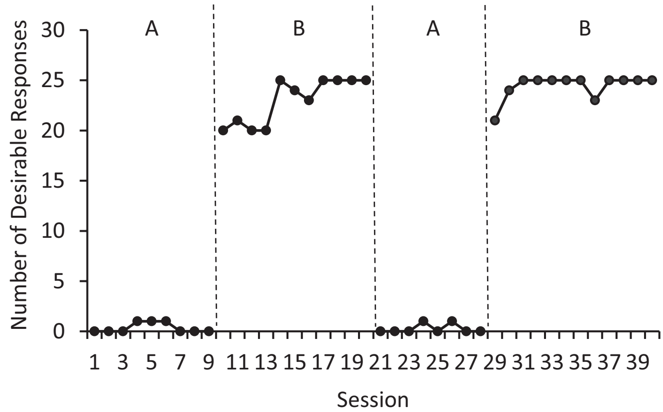

Fig. 20.2 Illustration of an ABAB design

observe and make choices during the conduct of the study that enhances their ability to make effect inferences. For example, suppose that the initial baseline phase (A1) was showing an unexpected therapeutic trend, creating questions about why the behavior was improving, and whether the uncontrolled factors responsible for the change would continue to operate and the behavior would continue to improve or whether the behavior would stabilize at a still problematic level. Given these questions, the researcher would extend the baseline until the behavior stabilized. As a second example, consider a researcher who was conducting an ABAB design where there were clear and immediate shifts in the behavior as the participant transitioned from A1 to B1, and from B1 to A2, but not an immediate shift when the participant transitioned from A2 to B2. In such cases, the researcher would ask why the effect was not immediate and perhaps conclude that some other factor besides the independent variable affected the behavior around the third transition. Because this third opportunity to demonstrate an effect was compromised, there are only two demonstrations of the effect (A1 to B1 and B1 to A2), which is generally not sufficient to demonstrate experimental control. To increase the internal validity of the design and strengthen the argument that the IV is impacting the DV, the researcher could extend the study to include additional phases (e.g., A3 and B3), and if effects were immediate with the transitions from B2 to A3 and from A3 to B3, the intervention effect argument would be bolstered.

Although ABAB designs are typically dynamic as just described, there are contexts where practical circumstances prevent researchers from being able to extend phases or studies. For example, the school year may be ending, or a participant or clinic may limit the number of observations to be collected. In such circumstances, baseline stability cannot be ensured. However, probabilistic control over threats to internal validity can be obtained by randomizing aspects of the design. For example, the time of the transition points could be randomly selected from the fixed study length with some constraints to ensure that phases had some minimum number of observations (Onghena, 1992).

The purpose of reversal designs is to investigate the effect of an intervention for an individual where the target behavior of interest is a reversible behavior. Relative to AB designs, withdrawal designs allow researchers to make stronger assumptions about the effects of an introduced or withdrawn intervention on a reversible outcome of interest. For example, a teacher hypothesizes that listening to classical music makes their students more productive writers. To test whether listening to classical music results in increased writing productivity, the teacher would systematically present or withdraw classical music and measure the number of sentences written by students across time. Reversal designs are not used when target behaviors are irreversible, such as in studies of academic skill acquisition.

With these designs, the outcome of interest is measured consistently across phases to examine differences in responding between conditions. Within each phase (baseline or intervention), the level, trend, and variability of the data are compared to their corresponding conditions (A1 to A2, B1 to B2) and to the alternate conditions (A1 to B1, A2 to B2, etc.). Experimental control is demonstrated by examining the trend, level, and variability of data in each phase and comparing them to each other. In Fig. 20.2, the baseline phases are stable, showing a low level of desirable responding, with no trends, and little variability, with response values ranging from 0 to 1. In contrast, the intervention phases show a much higher level of desirable responses with values ranging from 20 to 25. The immediate shift in response level between adjacent phases, the lack of overlap in data between adjacent phases, and the similarity of patterns (level, variability, and trend) in common phases (i.e., A1 is similar to A2, and B1 is similar to B2), all suggest experimental control. Furthermore, because the effect was replicated in each of the three opportunities provided (i.e., A1 to B1, B1 to A2, and A2 to B2) there is convincing evidence that the intervention impacted the DV. The stability of the data and replication of effects helps to rule out alternative explanations. Put another way, the internal validity is high because there are no plausible rival explanations for the observed effects (e.g., it is not reasonable to attribute the data pattern to maturation, practicing, or some event that happened during the study).

Although visual analysis is the primary tool used to analyze reversal designs, there are other methods that can be used to complement visual analysis. For example, researchers recognize that it takes multiple studies to accrue enough evidence for an intervention to be categorized as an evidence-based practice and that the synthesizing of evidence across studies relies on quantitative summaries of the size of the intervention effect, and thus a variety of effect size measures have been developed for single-case studies. Some effect sizes index the degree of non-overlap between adjacent phases (Parker et al., 2011), others standardize the mean difference between intervention conditions (Shadish et al., 2014), and others index progress toward a goal (Ferron et al., 2020). Furthermore, when designs incorporate randomization to control threats to internal validity probabilistically, randomization tests can be used (Onghena, 1992).

Limitations

Practicality, feasibility, and ethical concerns present limitations to the use of the withdrawal design. In terms of practicality, withdrawal designs are unsuitable for studying behaviors that cannot be unlearned. For example, in measuring the effect of an intervention on alphabet knowledge, withdrawal of the intervention should not result in a student's loss of alphabet knowledge previously acquired. Additionally, this design requires enough data within each phase to evaluate level, trend, and variability, in addition to at least three phase changes to provide sufficient data to assess replications of effect. If barriers such as scheduling difficulties or low-rate behaviors exist, the design may not be feasible for consistent measurement and introduction/withdrawal of intervention. Last, as with any experimental design, a researcher must consider the ethical implications of withdrawing treatment that significantly improves a participant's health and/or quality of life. For example, if a participant engaged in self-injurious behaviors requiring medical attention, it would be inappropriate to remove a successful intervention and return to a condition that resulted in harm to the participant. Instead, other designs should be considered.

Multiple Baseline Design

The multiple baseline design (MBD) is one of the most frequently used designs in the field of applied behavior analysis (Baer et al., 1968). With the aim of investigating the effect of an intervention on a behavior of interest, the MBD involves the sequential introduction of an intervention across two or more behaviors, settings, or individuals in a staggered fashion. As implied by *multiple*, the design typically involves a minimum of three baselines, with graphed data pre-

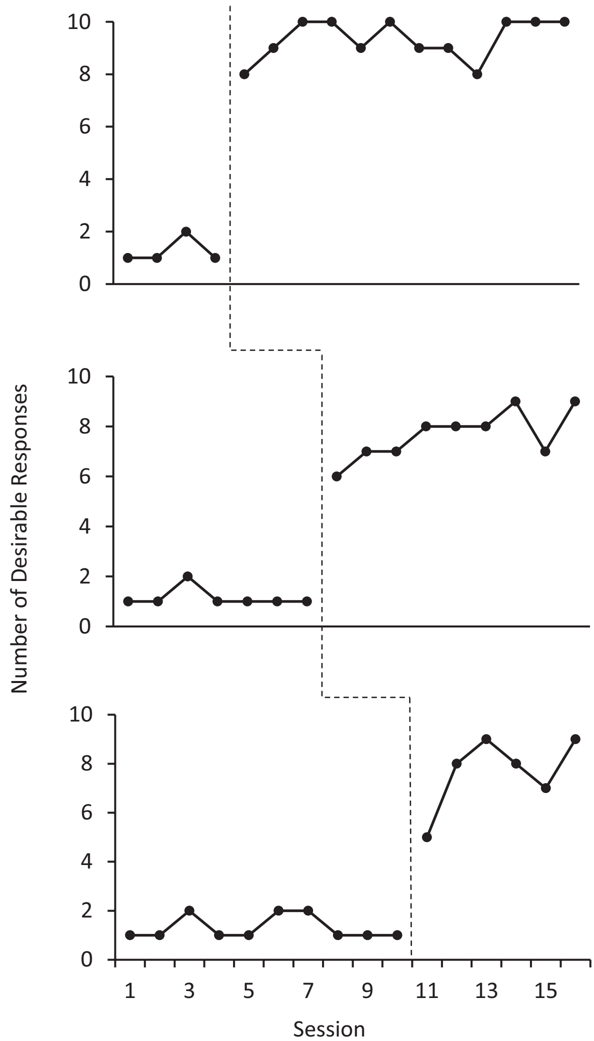

Fig. 20.3 Illustration of a multiple baseline design

sented in stacked graphs, one for each behavior, setting, or individual. Baseline lengths are purposefully varied across cases, so the introduction of the intervention occurs at different times for different cases, as illustrated in Fig. 20.3.

In order to achieve experimental control with the MBD, the baseline phase for each case should be stable. In addition, the baseline for the second case lasts until the intervention phase data for the first case becomes relatively stable. Likewise, the intervention for the third case does not begin until the intervention phase data for the second case has stabilized. The second and third cases act as controls for the first case, and the third case acts as a control for the second case (Engel & Schutt, 2013). This staggered approach allows the researcher to determine if changes in behavior coincide with the intervention for each participant, which makes explanation through history or maturational effects less plausible.

As with the previously discussed reversal designs, MBDs tend to be dynamic, where decisions about when to intervene are made based on an ongoing visual analysis of the data to ensure there is stability in the phases. When practical constraints make response-guided decision-making untenable, probabilistic control over threats to the internal validity of the study can be obtained by specifying baseline phase lengths a priori (e.g., staggered lengths of 3, 5, 7, and 9 data points), and randomly assigning cases to the different baseline lengths. Both probabilistic control over threats to internal validity and control through baseline logic can be obtained by coupling the use of a dynamic response-guided design (i.e., where interventions occur only after baseline stability has been obtained) with random assignment of participants (or behaviors or settings) to tiers of the MBD (e.g., randomly selecting which participant is intervened with first; Ferron & Jones, 2006). The MBD can also have additional features, such as a reversal/withdrawal phase, generalization, or maintenance phase.

The MBD is useful for practitioners and researchers interested in studying the effects of an intervention on more than one case (i.e., participant, setting, or behavior). By removing the requirement to withdraw intervention, the MBD is particularly useful when it is not appropriate to use a reversal design; for example, when the outcome is not reversible (e.g., a learning task) or when reversing an outcome would not be ethical. MBDs can be ideal for the study of intervention effects in very specific populations in a wide range of diverse contexts, such as substance abuse treatment for adults with an intellectual disability (Gosens et al., 2020) or to teaching young children to recycle or compost items (Bolanos et al., 2020).

The observed change in the outcome data are evaluated through visual inspection within and across the MBD graphs. Starting with the examination of within-case responding, researchers look for patterns of stable responding during baseline and a marked change in level, trend, and/or variability once an intervention is introduced. For example, in Fig. 20.3 we see for each case an immediate shift in the number of desirable responses with the initiation of the intervention. In addition to this horizontal within-case analysis, we conduct a vertical across-case analysis to see at the time of intervention if there is a shift in behavior only for the case starting the intervention. For example, at the time of the first intervention in Fig. 20.3, we see that while case 1 responds to the intervention, both cases 2 and 3 show no appreciable change. Similarly, when case 2 begins intervention, there is no change in the behavior of case 3. The magnitude and immediacy of change in the DV after the introduction of the IV, and the number of replications of a similar effect across cases, greatly enhance causal assumptions from visual inspection of the MBD graphs.

The visual analysis of MBDs can be complimented with statistical analyses to index the size of effects (e.g., Ferron et al., 2020; Parker et al., 2011; Shadish et al., 2014), or to model the variation in effects over time and across cases (Moeyaert et al., 2014). Furthermore, if the design is both dynamic and randomized, masked visual analysis methods can be used to make probability-based inferences (Ferron & Jones, 2006). If the design is randomized and fixed (not dynamic), randomization tests can be used to make probability-based inferences (Koehler & Levin, 1998).

Limitations

Intervention effect inferences for a specific individual (or behavior or setting) are weaker in MBDs than in ABAB reversal designs, because there are not multiple demonstrations of within-case effects. Rather the causal relations must be inferred through the replication across participants (behaviors or settings) coupled with the comparisons of data patterns across tiers in the MBD. Additional limits to using the MBD involve practical considerations, such as time and resources needed to plan and implement the design in an applied setting. In addition, staggered baselines introduce ethical concerns related to withholding a potentially effective treatment from some participants for an extended time.

Variations

There are variations in the MBD, which include multiple probe and delayed multiple baseline designs. In multiple probe designs, the observations are made intermittently, as opposed to continuously, and thus multiple probe designs are MBDs with planned missing data. Delayed multiple baseline designs are MBDs in which baselines do not start concurrently for all cases. Both designs purposefully address known barriers to consistent and continuous measurement across cases for the duration of a study. Having knowledge of the behavior, participant, and/or research context, a researcher may select a multiple probe design because of ethical concerns about repeated measurements in extended baseline or practical concerns (e.g., barriers to scheduling observations in an applied research setting). In applied research contexts where there are limited resources (e.g., public-school classroom) or when an additional setting, subject, or behavior becomes available after the study has begun, a delayed multiple baseline design may be most appropriate. However, due to the non-concurrent method of at least some of the data collection, these two MBD variations may lead to weaker effect inferences, particularly when measuring a highly variable behavior.

Alternating Treatments Design

An alternating treatments or multi-element design requires the systematic and rapid alternation of two or more interventions over time while consistently measuring their effects on a DV. Introduced only one at a time, the interventions must be different enough from one another to ensure that the changes in the DV are related to the presentation of the specific levels of the IV. The decision to include specific features within an alternating treatments design (ATD) is driven by the study research questions. When designing a study to examine the extent to which different treatments result in different DV responses, compared to no treatment at all, the research aims necessitate the inclusion of a baseline condition. When theory and prior research support the assumption that compared treatments will affect the DV, researchers may forgo a baseline phase and focus on comparing outcomes across different intervention phases. Similarly, the presentation sequence of treatments is driven by research questions. In some alternating treatments designs, the alternation between conditions is systematic, such that the B phase always follows the A phase yielding a sequence of ABABABABABABAB; however, it is better to randomize the order of treatment for each pair of observations, which could lead to a series of ABBABAABBABAAB or BABAABBABA ABAB.

Different treatments have different symbols or markers to allow for visual inspection of their unique impacts on the DV. Lines connect only those data points representing the same treatment condition over time.

Alternating treatments designs are ideal for situations in which there are multiple treatment options available, but a researcher wants to select the treatment having the largest effect on the measured behavior or outcome. Thus, unlike reversal and multiple baseline designs that address the question of whether an intervention is effective, ATDs address the question of which intervention is most effective. For example, Blair et al. (2018) used an alternating treatments design to examine the differential effects of two different prompt fading techniques (most-to-least verbal versus most-to-least physical) on learned behaviors for two participants. The comparison of the different prompt fading procedures was achieved by studying interventions that were topographically distinct, to rule out participants' failure to discriminate between the two interventions and reduce the risk of multiple treatment interference. ATDs are typically used for the study of reversible behaviors and have been used in the study of variable behavior when phase extension to achieve stable responding is untenable (e.g., setting or time constraints unpermitting). The ATD can also be used for component analyses. Component analyses involve testing the effects of individual ingredients of a treatment package and exploring their impact on efficacy. A component analysis can help interventionists design more parsimonious treatments as necessary to ensure the intervention package includes only the necessary components.

Similar to outcome analyses of a withdrawal design, visual analysis of an ATD looks for consistent differential responses between conditions

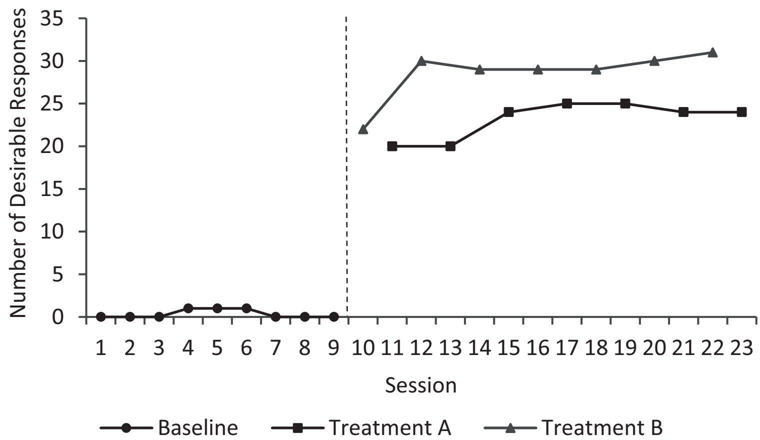

Fig. 20.4 Illustration of an alternating treatments design

in order to make inferences about functional relations. However, inferences about causation are stronger in ATDs than withdrawal designs because they offer more demonstrations of differences in treatment effects over time. By experimentally and systematically alternating quickly between different treatments, the rate, level, and variability of observations for each treatment can be compared over time and to one another. As seen in Fig. 20.4, observations corresponding to each treatment are connected to create a data path, thus allowing one to examine the within-condition level, trend, and variability (pattern of responding) for treatments A and B, as well as comparing each data path to the other.

In addition, the ATD works well with both visual and supplemental statistical analyses. For example, when researchers randomize the presentation of each treatment over time, which serves to further reduce threats to internal validity, randomization tests can supplement the visual analyses (see Craig & Fisher, 2019; Kratochwill & Levin, 2010; and Weaver & Lloyd, 2019 for methodological procedures using randomization in ATD).

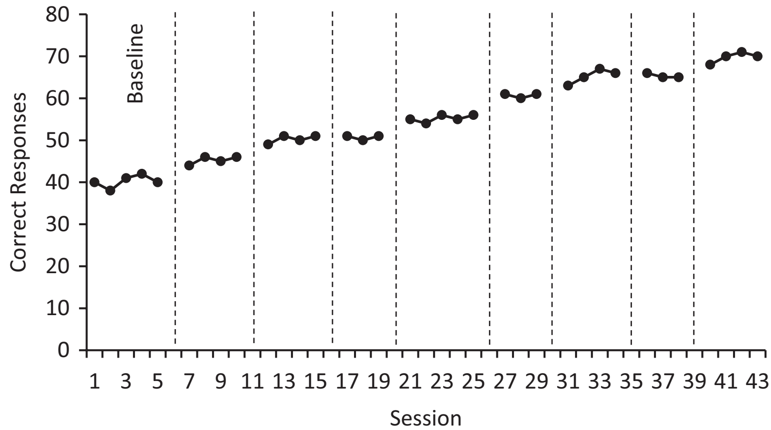
Limitations

The lack of a baseline in the comparison of two different treatments can be a limitation of this design, unless the research question is to compare those treatments only to one another. The potential for carry-over effects must be considered when selecting an ATD. If the treatments are not distinctly different from one another, experimental control is threatened by a responder's failure to discriminate between interventions and/or the influence of multiple treatment interference. The result can be a carry-over of treatment A effects to the next observation in the treatment B condition.

Changing Criterion Design

Starting with a pre-specified and socially significant outcome, changing criterion designs (CCDs) allow for the measurement of stepwise changes in the rate, duration, or accuracy of a specific response as it moves toward the intended outcome or goal. CCDs begin with an initial baseline phase, and when stable responding is present, additional phases are introduced over time to shape the outcome toward a predetermined goal. In many applications of CCDs, each phase is only as long as necessary for responding to stabilize at a criterion before a new phase with a new criterion is introduced. Researchers have recommended three to four changes in the criterion level (Gast & Ledford, 2014; Klein et al., 2015). The design can be used to explore a gradual shift or shaping of a DV over time and across different criterion-based conditions. Graphically, the data cluster around a criterion set by the researchers and modeled on the y-axis, as illustrated in Fig. 20.5. As the magni-

Fig. 20.5 Illustration of a changing criterion design



tude of the criterion changes over time, the intended result is an incremental change in the DV yoked to the set criterion.

Unlike MBDs, individual participants move through phases based on their individual response to treatment—staggered baselines are unnecessary. Unlike withdrawal designs, there is no requirement to return to previous criteria/phases to provide replications of effect. However, internal validity may be strengthened with the addition of baseline or reversal conditions over time presented in a stepwise manner. For example, a researcher may introduce a phase with a previously met criterion to examine persistence or maintenance effects, whether or not the DV returns to response levels corresponding to the former criterion. Additional methods to increase the internal validity of CCDs include changing the distance between criterion levels, varying the lengths of phases, and including randomization (Ferron et al., 2019; Onghena et al., 2019).

Changing criterion designs (CCDs) have been used for the study of interventions to shape specific behaviors and to evaluate performance management outcomes. They have been described as a variant of the MBD "in which different criterion levels are introduced in a time-lagged fashion" (Ledford et al., 2019, p. 42). CCDs are often used when a "target behavior requires considerable skill or has not previously existed at all in the client's repertoire" (Morgan & Morgan, 2009, p. 161). In other words, this design can be especially useful when stepwise changes are more reasonable because the behavior is not expected to change quickly. In the measurement of academic behaviors, CCDs are compatible with fluency training for discrete skills like spelling, decoding, and math facts. They can be used to increase the frequency of behaviors (e.g., amount of time spent exercising) or reduce the frequency of behavior (e.g., number of cigarettes smoked). In order to reach a criterion level of performance, gradual stepwise changes in these behaviors (exercise or smoking) would be expected and desirable. The advantages of this design are that it requires only one participant, behavior, and setting; the treatment does not have to be withdrawn; all participants receive treatment after a brief baseline period; and treatment efficacy is clearly demonstrated when performance closely matches the criterion (Byiers et al., 2012; Poling & Grossett, 1986).

Primary analyses, like with other SCDs, are visual, where researchers examine level, trend, and variability within phases, and look for changes across phases that correspond to the changing criterion. To supplement visual analysis, non-overlap indices have been proposed as a way to quantify the change in behavior, and the percentage of conforming data (PCD) is often utilized to index the percentage of data points within each intervention phase that fall within a specified range (McDougall, 2005). In addition, randomization tests are available if randomization is included in a fixed-length CCD (Onghena et al., 2019), and masked visual analysis procedures can be used when randomization is included in a dynamic CCD (Ferron et al., 2019).

Limitations

A limitation of this design is that the intervention must address a performance deficit, not a skill deficit, as the CCD requires the response to be within one's preexisting behavioral repertoire. When the behavior does not closely parallel the criterion levels, interpretation can be difficult. Because the behavior changes slowly over time, brief reversals to a prior criterion are advised to ensure that the intervention caused the changes rather than maturation (Ledford et al., 2019). Additionally, Hartmann and Hall (1976) have recommended that subphases should differ in length but be long enough to ensure that changes are not naturally occurring.

Summary

Single-case design is a useful approach for studies of behavior in which there is interest in the individual effects of the intervention. In addition, SCDs are well-suited for behavioral, educational, and psychological research contexts, where obtaining large samples is not feasible. With its focus on individual change over time, SCDs can provide important information about the effectiveness of interventions on behavior. This chapter provides an introduction to the most common SCDs by describing their purpose, analytic approaches, and limitations. Examples of each SCD are illustrated to give the reader an idea of research questions that may be appropriate when considering each approach. While there are many variations and adaptations of the designs presented in this chapter, this overview does not allow for more thorough descriptions of additional SCDs such as the repeated acquisition design (Spencer et al., 2012) and SCDs that combine design elements (e.g., combined MBD and ATD elements within a single study). Readers who are interested in detailed coverage of these designs are encouraged to review more comprehensive texts (e.g., Gast & Ledford, 2014).

Stimulus Preference Assessments

21

Cammarie Johnson and Richard B. Graff

The use of effective reinforcers is paramount to the effective treatment for individuals with intellectual or developmental disabilities (IDD) and is critical to both increase new skills and decrease interfering or dangerous behavior (Fisher et al., 1996; Karsten & Carr, 2009). Reinforcers, however, are both idiosyncratic and potentially ephemeral, which can make their identification challenging.

Reinforcement is a process defined by the effect of specific consequences that follow specific responses: If the probability of a specific response increases when specific consequences follow that response, a positive reinforcement effect is demonstrated, and that specific consequence is shown to be a reinforcer. A basic building block to developing effective treatment, therefore, is to identify stimuli and events that when incorporated strategically into programming efforts (i.e., delivered contingent on target behavior or noncontingently) will function as reinforcers and produce meaningful behavior change.

Over the past few decades, much behavior analytic research has focused on how to identify reinforcers effectively and efficiently for individuals. Because reinforcers cannot be identified a priori (i.e., before they are delivered contingently and their effect on behavior is observed), behavior analysts have focused on methods that may predict which stimuli and events will function as reinforcers. Methods have focused on identifying individually preferred stimuli as probable reinforcers. Preference for specific stimuli or events is demonstrated by an individual's behavior to obtain access to or maintain access to that stimulus or event. The identification of preferred stimuli, therefore, can be observed directly and separately from the reinforcing effect those stimuli have on a particular response. In subsequent evaluations, preferred stimuli have been reliably shown to function as reinforcers.

The research on stimulus preference assessments (SPA) has led to a robust technology for individually delivered assessments to (1) identify preferred stimuli that will function as reinforcers for individuals, and in particular for individuals with severe and profound disabilities who may be unable to communicate their preferences, and (2) validate that preferred stimuli function as positive reinforcers.

In this chapter, we review research on stimulus preference assessments in four sections.

In the first section, we start by reviewing the different methodological arrangements by which preference has been assessed, placing special emphasis on four of the most researched methods: single-stimulus (Pace et al., 1985), paired-stimulus (Fisher et al., 1992), multiple stimuli without replacement (MSWO; DeLeon & Iwata, 1996), and free-operant (FO; Roane et al., 1998) preference assessments. Next, we report on the types of stimuli that have been evaluated for preference and how these stimuli and other variables may affect outcomes. Then, we review the research on criterion validity (using different reinforcer assessments) of different preference assessment methods; test–retest reliability and preference stability when the preference assessment is repeated; and social validity of the preference assessment outcomes. We end this section with recent research on more efficient stimulus preference assessment methods. In the second section, we review reinforcer assessments. We start by reviewing their purpose to validate the predictions of the stimulus preference assessment. Then we discuss the different arrangements used in reinforcer assessments and how, based on the arrangement used, the assessment results indicate the assessed stimuli's absolute or relative reinforcer effects. In the third section, we review the research on different methods of training non-behavior analysts, such as therapists and parents, to use stimulus preference assessments. Specifically, we review behavioral skills training (BST), pyramidal training, self-instruction, video modeling, and telehealth methods. In the last section, we end with recommendations and considerations related to best practices in using stimulus preference assessments.

Stimulus Preference Assessment Methods

Behavioral researchers have developed numerous methods of identifying potential reinforcers. These methods can be categorized as either indirect or direct assessments.

Indirect Assessments

Early attempts to identify preferred stimuli (i.e., an item that an individual chooses to engage with that *may* function as a reinforcer) involved indirect assessments, such as the use of staff or parent report or checklists. For example, Cautela and Kastenbaum (1967) developed a reinforcer survey that asked respondents to rate how pleasurable the client found various stimuli (e.g., from "not at all" to "very much"). Stimuli that received the highest ratings were hypothesized to function as reinforcers (although no direct test of reinforcer effectiveness was conducted). In a similar study, Atkinson et al. (1984) developed a reinforcer checklist to identify potential reinforcers for children with autism. Parents and staff members were asked to develop a list of potential reinforcers, and respondents rated each potential reinforcer on a 4-point scale; this process was repeated 1 month later. The researchers found that the checklist had acceptable test–retest reliability. A high correlation between staff and parent opinion was also observed. No attempt was made, however, to determine if any of the items functioned as reinforcers.

Indirect preference assessments are relatively quick and easy to implement, but their results typically correspond poorly with the outcomes of more systematic assessments (e.g., Cote et al., 2007; Green et al., 1988). More recently, indirect preference assessments have been used in concert with direct assessments, as a way to determine the stimuli to be directly assessed (e.g., Fisher et al., 1996).

Fisher et al. (1996) sought to determine if adult opinion had beneficial effects when attempting to identify preferences. Six parents of children with IDD were given an experimenter-generated list of items and asked to predict preference rankings (from most preferred to least preferred). Parents were also provided with an interview form called the Reinforcer Assessment for Individuals with Severe Disabilities (RAISD). The adults were asked to generate a list of items that they thought their child preferred and rank those items from most to least preferred. The predicted rankings based upon the experimenter-generated list and the parent-generated list were compared, and direct preference assessments and reinforcer assessments were conducted. The authors found that the parent predictions based upon the RAISD were more accurate than those based upon the experiment-generated list of items. Thus, although caregiver report alone may not necessarily identify an individual's most preferred items, using caregiver opinion to generate the array of items to be used on a direct preference assessment can be an important aspect of the assessment process.

Direct Assessments

Prior to 1985, most researchers and clinicians relied on indirect assessments; however, there were some early attempts to use more systematic methods to identify potential reinforcers. Witryol and Fischer (1960) identified potential reinforcers by the method of paired comparisons. A pool of stimuli was identified, and then objects were presented two at a time, with the order of pairings presented to minimize position bias and order effects. The authors found that some stimuli were selected more often than other items. Another early attempt to systematically identify potential reinforcers was conducted by Rynders and Friedlander (1972). Preference for three different visual stimuli was assessed by placing three touch-sensitive panels in front of each participant. When a panel was pressed, the corresponding visual stimulus was presented. The researchers recorded the total number of panel presses for each stimulus, as well as the total duration that each panel was pressed. Although only a small number of stimuli could be simultaneously evaluated, the direct measurement of differential responding and total duration of engagement per stimulus represented a significant improvement over indirect methods of preference assessment. Other researchers also measured the duration of engagement with stimuli that were directly presented to individuals to identify potential reinforcers (e.g., Favell & Cannon, 1977).

Despite the earliest attempts by researchers to systematically identify reinforcers, it was not until 1985 that Gary Pace and his colleagues developed what is now considered by many behavior analysts to be the first systematic stimulus preference assessment (Pace et al., 1985; see Box 21.1). Prior to the start of the single stimulus (SS) preference assessment, Pace et al. selected items thought to produce various forms of sensory stimulation. Across a series of trials, stimuli were presented one at a time to participants with IDD. Approach responses (e.g., moving hand or body toward the item) were recorded, and preference hierarchies were established by calculating the percentage of approach responses for stimuli. Stimuli were considered high preference (HP) if they were selected on 80% or greater of trials, and stimuli were considered to be nonpreferred (sometimes referred to as low-preference, or LP) if they were selected on 50% or less of the trials. The authors found that different preference hierarchies were established across participants. Subsequent reinforcer assessments (to be discussed later in this chapter) demonstrated that, in general, the contingent presentation of HP stimuli was associated with higher response rates than the contingent presentation of nonpreferred items. Thus, HP stimuli were more likely to function as reinforcers than nonpreferred stimuli. One potential drawback to the SS assessment was that some participants approached most of the stimuli as they were presented, suggesting that some participants preferred all stimuli equally.

To address the issue of potentially approaching all stimuli equally using the SS assessment, Fisher et al. (1992) developed a paired-stimulus (PS) assessment (see Box 21.2). On each trial, two items were placed in front of the participant, who could only approach one item. Across a series of trials, each stimulus was paired with every other stimulus an equal number of times, and each item was placed on the participant's left- and right-hand side an equal number of times. The mean percentage of approach responses to each stimulus was calculated and preference hierarchies were established. Fisher et al. compared preference hierarchies generated from an SS assessment (Pace et al., 1985) to hierarchies generated from a PS assessment, and

Box 21.1

Pace, G. M., Ivancic, M. T., Edwards, G. L., Iwata, B. A., & Page, T. J. (1985). Assessment of stimulus preference and reinforcer value with profoundly retarded individuals. *Journal of Applied Behavior Analysis*, *18* (3), 249-255. https://doi.org/10.1901/jaba.1985.18-249

Purpose: To determine if a paired stimulus arrangement will better predict reinforcing stimuli than the Pace et al. (1985) single-stimulus arrangement.

Participants: 4 children (2-10 years old) with moderate to profound intellectual disabilities.

Design: Nonexperimental design (Phase 1).

Dependent measure: Percentage of trials each stimulus was approached.

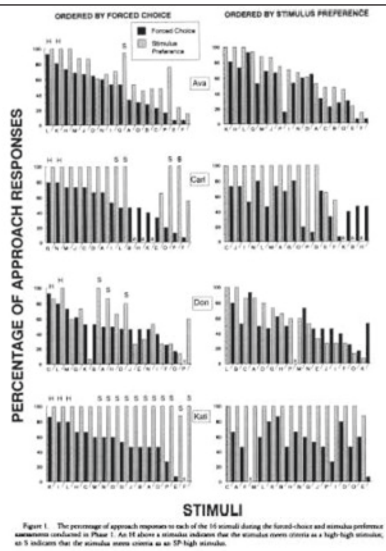
Stimuli assessed: Same as Pace et al., 1985, except swivel rocker replaced swing.

Procedures (Phase 1): Preference Assessment
Single stimulus (SS): Similar to Pace et al. (1985) except each session had 5 trials with each of 4 stimuli presented 0.7 m in front of participant (in a counterbalanced order).

Paired stimulus (PS): Same general procedures as SS (Pace et al., 1995) except two stimuli presented 0.7 m apart in each of 120 trials; each stimulus was paired once with every other stimulus.

Approach to stimulus → 5 s access and removal of other stimulus

Approach to both stimuli → blocked
Nonapproach within 5 s → prompted to sample each stimulus for 5 s, then represented both stimuli



Copyright 1992 by the Society for the Experimental Analysis of Behavior Inc. Reprinted by permission of John Wiley & Sons Inc

Interpretation of results:
PS arrangement shows rank order (black bars); SS does not (gray bars). Both assessments identified the same 9 preferred stimuli (H or High-High); the SS arrangement identified 19 additional stimuli as preferred that were not similarly identified in the PS arrangement (S or Sp-High).
Used ≥ 80% approach as an index of preference (same as Pace et al., 1985) and ≤ 60% as an index of nonpreference (Pace et al., 1985, used 50%).

Procedures (Phase 2): Reinforcer Assessment

Participants: same as Experiment 1.

Design: ABA reversal design with baseline, concurrent operants, baseline phases.

Dependent measure: Percentage of time spent in-chair (or in-square) with the chair (or square) associated with the different stimuli.

Stimuli assessed: 2 High-High stimuli (next to one chair, or in one square) and 2 Sp-High stimuli (next to another chair, or in another square).

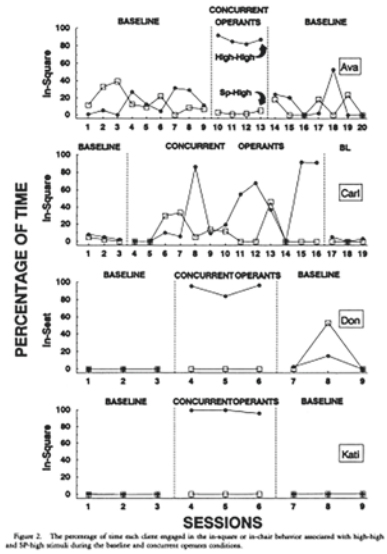
Procedures:

Consequences for in-chair (or in-square) behavior:

<u>Baseline</u>: Therapist present, but no interaction with participant; no stimuli present.

<u>Training trials</u> (no data): 10 trials per session. Criteria to move to next phase = 8/10 trials without prompts for 3 consecutive sessions. Not in-chair (or square) for 5 s → sequential prompts (verbal, gestural, physical) every 5 s. In-chair (or square) → either High-High or Sp-High stimuli (randomly alternated across trials) available for 10 s.

<u>Concurrent operants</u>: Therapist present, but no interaction. When participant is in Chair (or Square) 1 → access to 2 High-High stimuli; when in Chair (or Square) 2 → access to 2 Sp-High stimuli. When participant leaves chair (or square) for 3 s → stimuli returned.



Copyright 1992 by the Society for the Experimental Analysis of Behavior Inc. Reprinted by permission of John Wiley & Sons Inc

Interpretation of results:

Longer durations of time in-chair (or in-square) associated with High-High stimuli than with in-chair (or square) with Sp-High stimuli when these two sets of stimuli were concurrently available, or with either chair (or square) in baseline when no stimuli were available. PS assessment showed better predictive validity than the SS assessment and can identify more (relatively) preferred stimuli that function as more (relatively) potent reinforcers.

Box 21.2

Fisher, W., Piazza, C. C., Bowman, L. G., Hagopian, L. P., Owens, J. C., & Slevin, I. (1992). A comparison of two approaches for identifying reinforcers for persons with severe and profound disabilities. *Journal of Applied Behavior Analysis*, *25* (2), 491-498. https://doi.org/10.1901/jaba.1992.25-491

Experiment 1 Purpose: To assess approach responses as an index of stimulus preference.

Participants: 6 children (3-18 years old) with profound intellectual disabilities.

Design: Nonexperimental design.

Dependent measure: Percentage of trials each stimulus was approached.

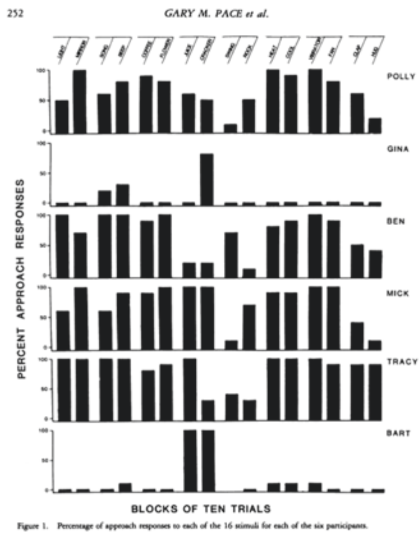
Stimuli assessed: visual: mirror, light; auditory: song, beep; olfactory: coffee grounds, flower; gustatory: juice, graham cracker; tactile: vibrator, fan, heat pad, cool block; vestibular: swing, rock; social: clap, hug.

Procedures:

Each of 16 stimuli was presented singly for 5 s and typically 20 cm from participant (i.e., a trial, 1-2 trials/stimulus per 20-trial session, and a total of 8 sessions).

Approach to stimulus → another 5 s access

Nonapproach → stimulus was removed and presented again for 5 s with prompts to look at stimulus and then presented again (without prompts) for 5 s



Copyright 1985 by the Society for the Experimental Analysis of Behavior Inc. Reprinted by permission of John Wiley & Sons Inc

Interpretation of results:

Differential approach behavior across stimuli that was idiosyncratic to each participant.

Used ≥ 80% approach as an index of preference and ≤ 50% as an index of nonpreference.

Experiment 2 Purpose: To assess the reinforcement value of preferred and nonpreferred stimuli.

Participants: same as Experiment 1.

Design: Reversal design with baseline, preferred, nonpreferred conditions.

Dependent measure: Percentage of correct responses to vocal requests. Responses were identified for each participant (e.g., Look, raise hand) that occurred at low rates.

Stimuli assessed: For each participant as identified in Experiment 1: preferred stimulus, nonpreferred stimulus.

Procedures:
Vocal requests (paired with a motoric gesture of the response) were provided in 10 trials/session. Incorrect or no response within 5 s were followed by a 10-s intertrial interval (ITI). Consequences for correct responses differed across conditions:

Baseline: Correct response → 10-s ITI

Preferred stimulus: Correct response → preferred stimulus provided for 5 s

Nonpreferred stimulus: Correct response → nonpreferred stimulus provided for 5 s

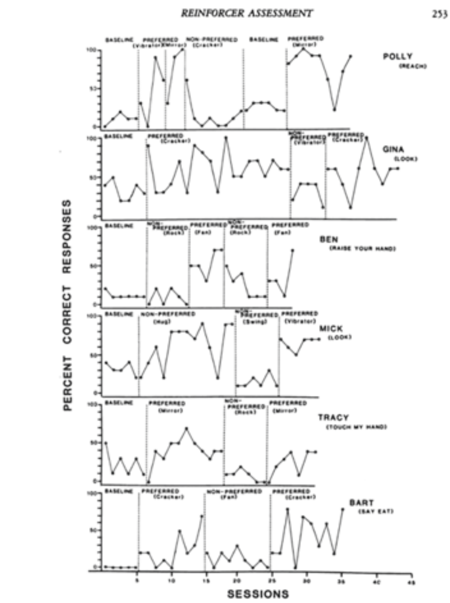


Figure 2. Percentage of trials each child engaged in the target response during baseline, preferred, and nonprefe conditions. Specific stimuli and target responses are indicated for each child.

Interpretation of results:
Preferred stimuli functioned as reinforcers as evidenced by increased correct responses when preferred stimuli were made contingent (preferred condition) than when no consequences (baseline) or nonpreferred stimuli (nonpreferred) were available.

found that all items classified as HP (selected on 80% or greater of trials) on the PS assessment were also classified as HP on the SS assessment. However, stimuli judged to be moderate to low preference (60% or below) on the PS assessment were frequently classified as HP on the SS assessment. Subsequent reinforcer assessments demonstrated that stimuli identified as HP on both assessments (high-high stimuli) were associated with higher response rates on a simple task than items ranked as HP on the SS assessment but moderate or low preference (SP-high stimuli) on the PS assessment. These findings suggest that the PS assessment may measure preference more precisely than the SS assessment. Although the PS assessment may be an effective method to identify preferences, the authors noted that the PS assessment took more time to implement than the SS assessment.

In an attempt to develop assessment methods that required less time to implement than a PS assessment, researchers began to develop procedures to assess multiple stimuli simultaneously (e.g., DeLeon & Iwata, 1996; Windsor et al., 1994). DeLeon and Iwata (1996) developed the multiple stimuli without replacement (MSWO) assessment (see Box 21.3). At the start of each session, multiple stimuli were placed in front of the individual, who was instructed to select one, and the individual was given that item for a short period of time. Then, the selected item was not replaced in the stimulus array, and the positions of the remaining stimuli were changed. The individual then selected from the remaining items until all items had been selected or the individual stopped selecting items. Each individual participated in several assessment sessions, and preference hierarchies were established by calculating the percentage of approach responses per stimulus across all sessions. These preference hierarchies were directly compared to hierarchies generated by a PS assessment. The authors found that both methods generated similar preference hierarchies, but the MSWO assessment was completed in approximately half the time that it took to complete the PS assessment.

Whereas many stimulus preference assessment (SPA) procedures measure approach responses to stimuli presented across a series of trials, several researchers have measured preference for stimuli by measuring the duration of engagement with stimuli. Roane et al. (1998) developed a brief, duration-based, free-operant (FO) preference assessment, in which multiple stimuli are placed on a tabletop, participants are free to engage with any of the items for a specified period of time (e.g., 5 min), and duration of engagement with each object is measured (see Box 21.4). Preference hierarchies are established by ranking items according to the duration of object manipulation for each stimulus. The authors found that items engaged with for the longest durations were more likely to function as reinforcers than items that were manipulated at shorter durations. The authors suggested that the brief FO assessment potentially had advantages over the traditional approach-based assessments: (a) it was quicker to administer, which potentially allowed for more frequent assessments; (b) stimuli were never withheld or withdrawn, which might evoke problem behavior in some individuals; and (c) although not specifically acknowledged by the authors, the FO assessment allows for the assessment of larger items that cannot be easily presented and removed in tabletop assessment trials (e.g., television and computer). One potential limitation to the FO assessment is that an individual may engage with only one item during the 5-min assessment, and thus, fewer potential reinforcers might be identified. Subsequent researchers attempted to overcome this potential limitation by restricting access to items once a clear preference had been identified, which can potentially yield a more distinct preference hierarchy (response-restriction analysis; e.g., Hanley et al., 2003).

DeLeon, I. G., & Iwata, B. A. (1996). Evaluation of a multiple-stimulus presentation format for assessing reinforcer preferences. *Journal of Applied Behavior Analysis*, *29* (4), 519-533. https://doi.org/10.1901/jaba.1996.29-519

Experiment 1: Preference Assessment

Purpose: To compare multiple-stimulus-without-replacement (MSWO) and multiple-stimulus (MS) arrangements (Windsor et al., 1994) to the paired stimulus (PS; Fisher et al., 1992) arrangement.

Participants: 7 adults (25-45 years old) with profound developmental disabilities.

Design: Nonexperimental design.

Dependent measures: (1) Percentage of trials each stimulus was selected (physical contact with item); (2) duration of each assessment type.

Stimuli assessed: 7 items per participant (a few of which were based on observation or caregiver report; most were arbitrarily selected).

Procedures

Prior to the assessment, participants had access to all stimuli assessed. Across all assessment types, the first stimulus touched within 30 s was made available for 30 s (leisure item) or until consumed (edible item). There were 5 consecutive sessions of each assessment type, with the order counterbalanced across participants.

MSWO: 7 stimuli in a straight line 5 cm apart; Participant told to select one. Selected stimuli were not replaced in subsequent trials and remaining items were rotated (left item moved to right-most position and equally spacing all items). Session continued until all stimuli selected or no selection in 30 s.

MS: Same as MSWO, except selected stimuli were returned or replaced.

PS: 2 stimuli per trial in a predetermined order such that every stimulus was paired once with every other stimulus for a total of 21 trials/session. No selection within a trial was followed by the next trial.

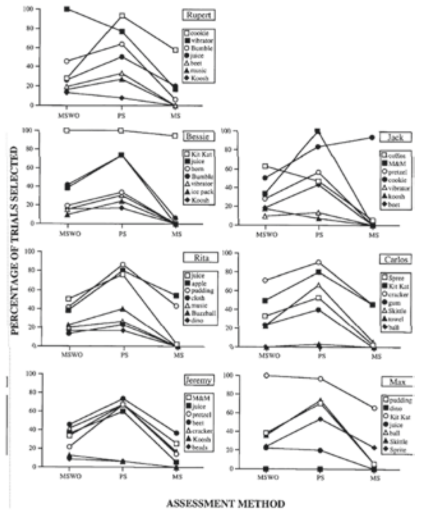

Figure 1. Percentage of trials on which stimuli were selected, when available, by 7 participants for all three assessment methods: multiple stimulus without replacement (MSWO), paired stimulus (PS), and multiple-stimulus with replacement (MS).

Copyright 1996 by the Society for the Experimental Analysis of Behavior Inc. Reprinted by permission of John Wiley & Sons Inc

Interpretation of results:

Good correspondence across assessments for top-ranked stimuli: (1) The same stimulus was identified as the most highly preferred across all 3 assessment types; (2) The MSWO and MS both matched the PS assessment by identifying the 2 or 3 of the 3 most selected stimuli for all participants; (3) Kendall rank-order correlation coefficients means were .61 for MS/PS and .72 for MSWO/PS; (4) Kendall's correlation of concordance was higher for MSWO and PS (.81 and .83) than MS (.56).

Difference in mean duration of assessment administration: MS and MSWO required less time (16.5 and 21.8 min) than PS (53.3 min).
Fewer total items selected in MS than MSWO or PS. Continuous availability of most-preferred stimuli in MS may have masked preference for other items and resulted in false negatives with the MS. Alternatively, the PS/MSWO may have resulted in false positives by providing more opportunities for selections of all stimuli (purpose of Experiment 2).

Experiment 2: Reinforcer Assessment

Purpose: To determine if stimuli never selected in the MS but selected in the MSWO and PS assessments would function as reinforcers.

Participants: 4 participants from Experiment 1.

Design: Reversal design with baseline and reinforcement phases (3 participants).

Dependent measure: Responses per minute (responses varied by participant such as putting blocks in a can, pressing a switch that activated a light, etc.).

Stimuli assessed: 2 High-High stimuli (next to one chair, or in one square) and 2 Sp-High stimuli (next to another chair, or in another square).

Procedures: 10-min sessions. Responses were in participants' repertoires or shaped (i.e., Carlos, Phase 1). Phase changes occurred after stable responding was shown.

Baseline: Experimenter prompted response (if necessary); provided no consequence for responses.
Reinforcement (fixed ratio, FR, 1): Experimenter delivered 1 stimulus contingent on each response.

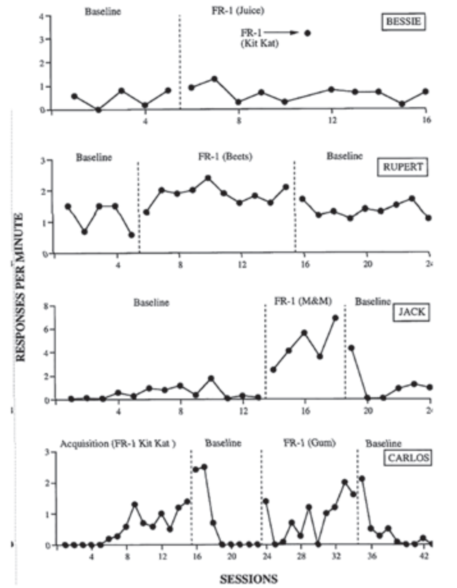

Figure 2. Results of reinforcer potency evaluations for four stimuli selected by participants during the PS and MSWO assessments but not during the MS assessment.

Copyright 1996 by the Society for the Experimental Analysis of Behavior Inc. Reprinted by permission of John Wiley & Sons Inc

Interpretation of results:
The MSWO produced the same beneficial outcome of the PS: it identified a hierarchy of stimulus preferences, including some that were not identified by the MS that functioned as reinforcers (3 of 4 stimuli assessed). In addition, the MSWO took much less time to complete.

Box 21.4

Roane, H. S., Vollmer, T. R., Ringdahl, J. E., & Marcus, B. A. (1998). Evaluation of a Brief Stimulus Preference Assessment. *Journal of Applied Behavior Analysis*, *31* (4), 605-620. https://10.1901/jaba.1998.31-605

Experiment 1 Purpose: To evaluate the utility of a brief, free-operant multiple stimulus assessment in identifying differentially preferred stimuli that functioned as reinforcers.

Participants: Free-operant (FO) stimulus preference assessment: 10 individuals (3-37 years old) with severe intellectual or developmental disabilities. Reinforcer assessment (RA) A: 6 of the individuals; B: 4 of the individuals.

Design: FO assessment: Nonexperimental; RAs: concurrent operants.

Dependent measure: Percentage of 10-s (partial) intervals. FO assessment: manipulation of each stimulus RAs: time in-square (or in-workstation, RA-B).

Stimuli assessed:
FO assessment: 10-11 caregiver- or staff-nominated stimuli across the following categories: food, drink, leisure/play, auditory, tactile, social attention (therapist present).

RA-A: preferred stimulus (most intervals of manipulation in SPA) vs no stimuli (control).

RA-B: preferred stimulus vs. nonpreferred stimulus (never or rarely manipulated in FO assessment).

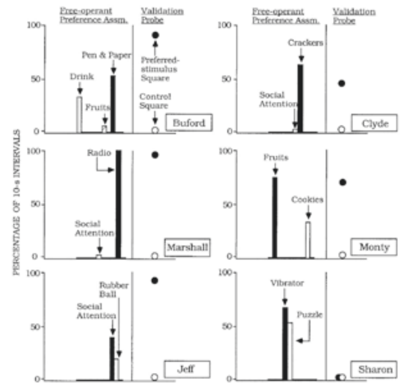

Figure 1. The percentages of 10-s intervals of item manipulation and in-square behavior during the free-operant preference assessments and validation probes of Reinforcer Assessment A of Experiment 1.

Interpretation of FO assessment and RA-A results:
At least one preferred stimulus was identified for each participant (Figures 1 and 2). 5 participants spent more time in the square with the preferred stimulus than no stimulus; 1 participant spent no time in either square.

Procedures:

<u>FO assessment</u>: Stimuli arranged in a circle on a table. Pre-session exposure to each stimulus (participant manipulated or therapist modeled). During FO assessment, participant could manipulate some, all, or no stimuli during 5-min session. (Food/drink was replenished as needed.)

<u>RAs</u>: Two equal areas (squares or stations) were demarcated, and each contained one stimulus (or no stimulus in RA-A). Sessions lasted 10 min. Pre-RA-A training provided instructions and exposure to contingencies.

At start of <u>RA-A</u>, participant stood equidistant from each area, was given instructions, and had access to areas/items. Mid-session, the stimuli were switched to the other workstation (to control for position) and the procedures were repeated. 1 FO assessment and 1 RA session.

During <u>RA-B</u>, the same task was available at each workstation, therapist provided 3-step prompting hierarchy, and the station-designated stimulus (placement randomized across sessions) was provided for 15 s upon each prompted or unprompted task completion. 1-2 FO assessments and 2 RA sessions/ day for up to 5 days.

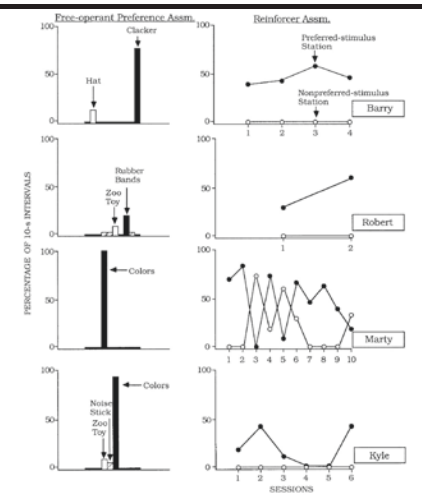

Figure 2. The percentages of 10-s intervals of item manipulation in each participant's initial free-operant preference assessment and the percentage of 10-s intervals spent at the preferred or nonpreferred station in Reinforcer Assessment B of Experiment 1.

Interpretation of RA-B results:

3 participants allocated all responding to workstation with preferred stimulus; 1 participant shifted responding between workstations but completed more tasks in station with preferred stimulus.

Stimulus Selection for Direct Assessments

Determining the stimuli to be assessed is an important part of the assessment process. It is important to recognize that preference measures do not provide information regarding absolute preference levels, but rather relative preference levels (e.g., Graff & Larsen, 2011; Roscoe et al., 1999). The most and least preferred stimuli identified in a preference assessment, therefore, are bound by the actual stimuli assessed. For example, an item may be ranked as most preferred on one preference assessment, and then ranked as least preferred on another assessment that included different stimuli.

The main goal of a SPA is to identify stimuli that will function as reinforcers, thus, careful consideration should be given in the selection of stimuli to assess. Whereas some SPA procedures have used a standardized pool of stimuli for all participants (e.g., Fisher et al., 1992; Pace et al., 1985), or a combination of standardized stimuli and participant-specific stimuli based on caregiver reports of preferred stimuli (e.g., DeLeon & Iwata, 1996), the most effective way to meet the assessment purpose is to assess only stimuli that are likely to be preferred for an individual participant. This can be accomplished by conducting an indirect assessment, such as RAISD (Fisher et al., 1996), and then including the caregiver-nominated stimuli in the direct assessment.

Although many SPA procedures involve presenting tangible stimuli on the tabletop and measuring approach responses or duration of engagement with items, some items are difficult to present (e.g., large leisure items, community locations, or social stimuli). Alternative procedures have been developed to address this issue. A verbal PS preference assessment (e.g., Cohen-Almeida et al., 2000; Kuhn et al., 2006; Tessing et al., 2006) is an alternative method that is similar to the PS assessment (Fisher et al., 1992). On each trial of a verbal PS assessment, the clinician asks, “Do you want X or Y?” and the participant selects the preferred stimulus by vocally stating the name of one of the items or activities. Preference hierarchies are established by calculating the percentage of vocal selection responses for stimuli. Verbal preference assessments can identify effective reinforcers if participants have auditory-visual conditional discrimination skills (e.g., Conyers et al., 2002), and have been effectively used to identify preferences for tangible stimuli (e.g., Tessing et al., 2006), social stimuli (e.g., Kuhn et al., 2006), and preferred and non-preferred staff (Jerome & Sturmey, 2008). Pictorial preference assessments can also be useful to assess preferences for items that are difficult to present. On a pictorial PS preference assessment (e.g., Graff & Gibson, 2003; Heinicke et al., 2016), across a series of trials, pictorial representations of stimuli are presented two at a time; individuals can approach (i.e., select) only one picture on a trial. Approach responses are recorded. Preference hierarchies are established by calculating the percentage of approach responses per stimulus. Certain visual conditional discrimination and matching skills are likely necessary to identify reinforcers using pictorial preference assessments (e.g., Clevenger & Graff, 2005; Conyers et al., 2002). Pictorial preference assessments have been used to identify preferences for a variety of stimuli such as recreational activities such as riding a bike or playing basketball (e.g., Hanley et al., 1999), social stimuli (e.g., Kelly et al., 2014; Morris & Vollmer, 2019), preferred break environments (Castelluccio & Johnson, 2019), and preferred content on electronic devices (e.g., Hoffmann et al., 2019).

Preference assessments using video stimuli have become more prevalent in preference assessment literature recently. Video SPAs are similar to pictorial preference assessments, but instead of placing two or more pictures in front of a participant, two or more video clips of individuals engaging with a stimulus are displayed on tablets or laptops, and the individual selects the video clip of the item with which they would like to engage. Snyder et al. (2012) conducted tangible PS assessments and video PS assessments with six children with autism. A comparison of preference hierarchies showed that the highest and lowest preference leisure items were the same for most participants. Other studies have examined the use of video stimuli in multiple stimulus without replacement (MSWO) preference assessments. Brodhead et al. (2016) compared tangible and video MSWO preference assessment hierarchies for four individuals with special needs. The authors found that preference hierarchies were similar for three of four participants.

Variables that May Affect Direct Assessment Outcomes

There are several variables that may affect selection responses and preference hierarchies, including the magnitude of stimuli assessed (duration of access to leisure stimuli and social attention, amount of edibles), number and types of stimulus classes assessed, and whether or not the stimulus selected can be accessed immediately or after a delay.

Several researchers have evaluated the effects of magnitude on preference assessment outcomes. Steinhilber and Johnson (2007) conducted MSWO assessments and subsequent reinforcer assessments with two individuals with autism spectrum disorder (ASD) under two conditions. In one preference assessment condition, selection responses resulted in 15-s access to a leisure item; in the other condition, selection responses resulted in 15-min access to that item. Different preference hierarchies were established across the two conditions. In other words, stimuli that were most highly preferred with brief access were less preferred with extended access and stimuli that were most highly preferred with extended access were less preferred with brief access. The researchers concluded that the duration of access to items influences preference for those items. Researchers have also demonstrated that children with IDD displayed preferences for longer durations of social interactions versus shorter durations of social interactions (e.g., Trosclair-Lasserre et al., 2008). Paden and Kodak (2015) evaluated the effects of magnitude on preference with four individuals with autism spectrum disorders. During preference assessments using edible items, participants could choose between a larger magnitude of edible items or a smaller magnitude of edibles. All participants preferred the larger magnitude of edibles.

Early preference assessment research included multiple categories of potential reinforcers such as edibles and nonedibles that provided different sensory consequences (e.g., Fisher et al., 1992; Pace et al., 1985). DeLeon et al. (1997) evaluated the effect of combining stimuli from edible and nonedible categories in preference assessments. They conducted one SPA with only edible items, and another with only leisure items, with 14 individuals with IDD. Then, the most preferred items on each assessment were combined on a third assessment. For 12 of 14 participants (86%), an edible item ranked first on the combined assessment, and for 11 of 14 participants (79%), edible items ranked first and second. Although some leisure items were judged to be highly preferred when presented alone, the food items displaced the leisure items when combined, resulting in the leisure items appearing to be less preferred. The finding that edible items may displace nonedible items in preference assessments has been replicated by a number of researchers. Bojak and Carr (1999) conducted separate edible and leisure assessments with four individuals with severe intellectual disabilities, and then conducted a combined assessment, using the top 4 ranked items from the edible and leisure assessments. For all participants, the edible items were ranked first through fourth, while the leisure items were ranked fifth to eighth. Fahmie et al. (2015) found that for eight of 12 individuals with IDD, edibles ranked first to fourth and leisure items ranked fifth to eighth on a combined edible/leisure preference assessment; for two additional participants, edibles held three of the top four ranks. On the other hand, some researchers have found lesser degrees of displacement of leisure items by edible items (e.g., Conine & Vollmer, 2019; Sipila-Thomas et al., 2021), particularly when the duration of access to leisure items was increased (e.g., Clark et al., 2020). Although less frequent, the displacement of edible items by leisure items has also been noted for some individuals (Sipila-Thomas et al., 2021). Displacement effects can also occur when using only one category of stimuli. For example, when conducting a preference assessment with only edible items, the inclusion of sweet items such as candy may displace preference for fruits and vegetables for some individuals (e.g., Livingston & Graff, 2018).

Studies demonstrating displacement effects may have clear implications for clinicians. After clinicians classify items as moderate or low preference, they may fail to use these items in behavior programs. After demonstrating that displacement effects can occur when different categories of stimuli are included on a SPA, DeLeon et al. (1997) conducted reinforcer assessments in a second experiment and found that the leisure items identified as less preferred on the combined assessment functioned as reinforcers. One question raised by the findings of DeLeon et al. (1997) was whether or not items ranked low on a SPA would function as reinforcers if all items came from the same stimulus modality (e.g., all leisure items or all edible items). Several studies evaluated this possibility. Taravella et al. (2000) conducted PS assessments with two individuals with disabilities. Nine or 10 nonfood items identified for each participant were assessed in a "complete array" PS assessment, which used the procedures described by Fisher et al. (1992). Preference hierarchies were established, and the five items ranked as least preferred were assessed in a "partial-array" PS assessment. For both participants, at least one item classified as moderately preferred or low preference on the complete array was now classified as HP based upon the results of the partial array; thus, the relative preference value of stimuli changed, based upon the composition of the preference assessment array. Subsequent reinforcer assessments demonstrated that for both individuals, the top-ranked item from the partial array assessment, which was initially classified as a moderate or low preference on the complete array assessment, functioned as a reinforcer. Other researchers have also demonstrated that stimuli classified as LP on one assessment were then classified as HP on another assessment, and stimuli initially classified as LP were found to function as reinforcers (e.g., Graff & Larsen, 2011). Thus, it seems clear that SPAs generate a relative preference hierarchy in which the value of one item can only be judged as HP or LP in the context of the alternative items, and that in some cases, LP items may be effective reinforcers.

The fact that LP items can function as reinforcers may be an important finding for clinicians, as it suggests those items may still be used effectively in behavioral programming. However, it is likely that not all stimuli classified as LP will function as reinforcers, and it is not clear from previous research whether the contingent presentation of LP stimuli consistently results in levels of responding similar to those generated by HP items. Nonetheless, the possibility of "low-preference" stimuli functioning as reinforcers may be of particular interest to (a) clinicians who require access to multiple effective reinforcers at a time, (b) clinicians who work with individuals who exhibit restricted preferences, and (c) clinicians who encounter ethical concerns with delivering HP stimuli on a continuous basis (e.g., weight gain, age-appropriateness of materials, problem behavior occasioned by the presentation of stimuli, problem behavior occasioned by the removal of stimuli).

Another variable that can influence preference hierarchies involves delayed access to an item following a selection response, or when access to an item following a selection response is not possible. For example, if a pictorial preference assessment were to be used to assess preference for community-based activities (e.g., different restaurants), it would not be practical to provide access to the selected community activity on every trial of the assessment. Researchers have found that delayed access to selected items or no access to selected items can influence the results of preference assessments (e.g., Groskreutz & Graff, 2009; Heinicke et al., 2016). For example, Hanley et al. (1999) conducted pictorial preference assessments under two conditions. In one condition, making a selection response led to access to the selected item; in the other condition, selection responses resulted in no programmed response. The researchers found that in most cases, distinct preference hierarchies were established when selection responses resulted in access to the item; when selections resulted in no consequence, preference hierarchies were typically not differentiated.

Concurrent Validity, Test–Retest Reliability and Stability of Preference, and Social Validity

The outcomes of many SPA methods have been evaluated for concurrent validity and reliability. Concurrent validity is the extent to which the outcomes obtained from one assessment protocol are similar to the outcomes obtained from another assessment protocol that is considered valid (Brown et al., 2011). Reliability is a measure of consistency or the extent to which the results can be reproduced given the same conditions (Sidman, 1960). Concurrent validity increases our confidence that a new method is effective, and reliability is essential if we are to have confidence that our assessment results will be informative in the future and not just at the moment of the assessment.

Concurrent Validity

When new preference assessment methodologies are first researched their results are almost always compared to the results of a more researched method. For instance, when the PS was first developed, Fisher et al. (1992, see Box 21.2) used the same stimuli that were used by Pace et al. (1985, see Box 21.1) and compared the results with the PS to those obtained with the SS method for four participants. The SS arrangement identified 28 HP stimuli whereas the PS arrangement only identified nine HP stimuli across participants. Importantly, those nine stimuli were also identified as HP with the SS arrangement. This finding provided support that PS preference assessment outcomes had concurrent validity (and subsequent reinforcer assessments confirmed that these nine stimuli were more efficacious as reinforcers than the other 19 identified by the SS assessment). A similar tactic was used when the MSWO (DeLeon & Iwata, 1996) and FO (Roane et al., 1998) were first developed, and when verbal, pictorial, and video stimuli were first used in SPAs (e.g., Cohen-Almeida et al., 2000, Graff & Gibson, 2003; Morris & Vollmer, 2019; Snyder et al., 2012). Concurrent validity with previous assessments was shown with each of these newer assessment methods.

Test–Retest Reliability and Stability of Preference

The reliability of a direct SPA method is assessed through test–retest measures in which the results from one administration are typically compared with the results from another administration of the same method with the same individual (Brown et al., 2011). Two different outcome measures have been evaluated for reliability: HP stimuli and the ranks of all assessed stimuli.

When an assessment identifies HP stimuli, that assessment can be repeated to see if the same stimuli will be identified as preferred (either the same most highly preferred stimulus, or the same stimuli that meet an established criterion of selection responses or duration of interaction). When the assessment yields a hierarchy of preference, the assessment can be repeated and reliability is measured by the extent to which the obtained ranks for all assessed stimuli are comparable and is typically analyzed using statistical tests, such as the Spearman rank-order correlation coefficient. This statistic yields a coefficient value, r_s, which represents the magnitude of correlation between two variables. Coefficient values range from −1 to +1, whereby −1 represents a perfect negative correlation, 0 represents no correlation, and + 1 represents a perfect positive correlation between ranks. We are usually interested in positive correlations between administrations, and the closer the score is to 1, the more stable the results are and this stability is also used as a reliability measure of the data. Generally, an r_s score of 0.5–0.7 is indicative of a moderate positive correlation, a score of 0.7–0.9 is indicative of a high positive correlation, and a score of 0.9–1.0 is indicative of a very high positive correlation (Mukaka, 2012).

A potential problem with measuring the test–retest reliability of SPA data is that preferences are not always static, but instead may vary depending on the context and are influenced by motivating operations such as deprivation and satiation (Gottschalk et al., 2000; Hanley et al., 2006). When test–retest reliability is not shown, we are usually unable to parse out whether these incongruent results are a direct result of a less reliable assessment, or if they are a direct result of naturally occurring preference shifts. All SPA results are influenced by the current motivational status of the individual, and when a SPA is repeated there is always the potential for a shift in preference due to a change in the current motivational status, and shifts in preference can confound the test–retest reliability measure. Because of this inherent threat to internal validity, the best way to determine if one SPA method is more likely to provide reliable outcomes would be to control all variables—subject, motivational, and stimuli—except the assessment methods. Verriden and Roscoe (2016) did just this; they compared the correspondence of assessment results for six individuals with autism spectrum disorders (ASD) or traumatic brain injury across six administrations of each of four major assessment methods and found that PS and MSWO had higher correspondence across administrations (as measured by the Spearman rank-order correlation coefficient and Kendall rank coefficient of concordance) as compared to RR and FO methods. The finding of increased consistency across administrations of the PS and MSWO as compared to other methods was also reported by Kang et al. (2013) in their review of SPAs.

Test–retest measures are also used to evaluate the stability or instability of preferences across different time spans for specific stimuli and stimulus categories, and for ranked hierarchies of stimuli. From a practical perspective, preference stability can inform clinicians how often preference should be assessed (Butler & Graff, 2021). The stability of preferences has been assessed across as few as 2 or as many as 16 assessments (Hanley et al., 2006), ranging from daily administrations (Kelley et al., 2016) to 20 months between administrations (Zhou et al., 2001).

The stability of preferences has been evaluated across different time spans. Ciccone et al. (2007) compared the stability of preferences for edible stimuli in eight individuals with IDD. They found greater stability in the outcomes from assessments that were conducted 6 months apart than those conducted 12 months apart, suggesting that the amount of time between SPA administrations (or between SPA administration and programmatic applications of the SPA outcomes) is a critical variable. In a recent study, Butler and Graff (2021) conducted monthly PS assessments for edible, leisure, and social attention stimuli over a one-year period with four individuals with autism. Short-term stability was assessed by comparing the results of month-to-month assessments, and long-term stability was assessed by comparing the results of the first and last preference assessments, conducted 12 months apart. The average short-term stability score across participants was greatest with edible items ($r = 0.79$), then leisure items ($r = 0.66$), and finally social attention stimuli ($r = 0.50$). Average long-term stability scores across participants were 0.63 for edibles, 0.19 for leisure items, and 0.33 for social stimuli. These findings suggest that, for some participants, stability of preference decreases over time and most notably with leisure items.

The stability of preference has also been evaluated for HP stimuli and for stimuli assigned to all ranks (i.e., preference hierarchy). Zhou et al. (2001) evaluated the stability of preferences for leisure stimuli in 22 individuals with IDD given two administrations of a single-stimulus variation of a duration-based SPA (DeLeon et al., 1999) 12–20 months apart. Whereas the median rank-order correlation coefficient for the 15 stimuli was only 0.11, greater stability was shown among the five top-ranked stimuli. Other studies have also reported increased stability with the highest-ranked stimuli (e.g., DeLeon & Iwata, 1996; Lee et al., 2010).

Social Validity

Despite the prevalent use of SPAs in behavior-analytic, peer-reviewed research, the use and acceptability of SPAs in clinical settings are less common. In a survey of professionals working with individuals with IDD, Graff and Karsten (2012b) found that SPAs were less likely to be implemented in public schools than in other treatment settings and attributed these findings at least in part to the lack of "buy in" by teachers and school administrators. Surprisingly, there are very few published social validity measures on the outcomes generated by SPAs by "the specific consumer or representatives of the relevant community" (Wolf, 1978, p. 209). In a notable exception, Castelluccio and Johnson (2019) found in a post-experimental survey that clinical staff, who were not involved in the research, either somewhat or strongly agreed that the preference assessment outcomes were beneficial to the programming for the participants. Further, the clinical teams elected to incorporate the identified HP break environments into participants' programming.

Efficiency Measures

Preference assessments can be time-consuming, particularly when one considers all of the component responses: gathering a pool of stimuli, conducting the preference assessment, summarizing and analyzing the data, communicating the results, and incorporating these results into ongoing education or treatment. In a survey, 81% of behavior analysts reported that time was an obstacle to their routine use of SPAs (Graff & Karsten, 2012b).

Of the direct SPAs reviewed in this chapter, the FO takes the least amount of time to administer. A defining characteristic of this duration-based procedure is that each session is 5 min. The session duration of selection-based assessments such as the SS, PS, MSW, and MSWO is not similarly defined; instead, session duration is influenced by the number of stimuli assessed, the number of times each stimulus is presented and the arrangements of those presentations, and the prescribed post-selection stimulus access time. DeLeon and Iwata (1996) completed a PS, MSW, and MSWO assessment for seven adults with IDD using the same seven edible and leisure items. They found that the MS and MSWO took considerably less time (16.5 and 21.8 min, respectively) as compared to the PS assessment (53.3 min[1]). Conducting one of the direct assessments, therefore, can take between 5 and 60 min.

Recent research efforts have focused on how valid preference assessment outcomes can be achieved in fewer trials by reducing the number of stimuli assessed or the number of times each stimulus (or stimulus arrangement) is presented. Reducing the number of trials will reduce the amount of time a SPA takes to complete.

The PS assessment is arranged such that each stimulus is paired once with every other stimulus and the validity of this assessment might be compromised if this was not done; therefore, the best way to decrease the time of a PS assessment is to reduce the number of stimuli assessed. Reducing the number of stimuli will reduce the number of trials necessary to pair each stimulus with every other stimulus and therefore take less time. For instance, it takes 240 trials to conduct the assessment with 16 stimuli (Fisher et al., 1992), but only 42 trials with seven stimuli (DeLeon & Iwata, 1996). At face value one might have some concerns including fewer stimuli in a preference assessment; however, when the assessed stimuli are individualized and based on indirect assessments, the literature supports that SPAs can identify HP stimuli that serve as efficacious reinforcers.

The MSWO uses only seven stimuli and is arranged with five sessions of seven trials each. Each session starts with the full stimulus array (but presented in different orders). The use of five sessions appears to be arbitrary as it would take seven sessions to have each stimulus in each position once in an effort to control for position biases. Researchers have evaluated if fewer than seven trials per session or fewer than five MSWO sessions would yield valid outcomes (e.g., Carr et al., 2000; Graff & Ciccone, 2002; Higbee et al., 2000; Richman et al., 2016).

In post hoc analyses of MSWO assessments with 15 individuals with IDD, Graff and Ciccone (2002) found that the same HP stimulus was identified in the first three trials as in a full seven-trial session 93% of the time (25 of 27 cases) and that when the first three trials were evaluated across all five sessions, the same HP stimulus was identified 81% of the time (22 of 27 cases). In post hoc analyses by Richman et al. (2016), outcomes derived from three sessions of an MSWO were significantly and positively correlated with the outcomes derived from full, five-session assessments for nine adults with intellectual disabilities.

[1]Other reported estimates of PS assessment administration time have been under 22 min (Roane et al., 1998).

Other researchers have directly evaluated a brief MSWO, comprised of three sessions. Carr et al. (2000) conducted a three-session MSWO assessment with three young children with ASD using eight stimuli and evaluated the brief MSWO's predictive validity of lower, moderately, and higher-ranked stimuli in a multielement design. Subsequent reinforcer assessments confirmed that the three-session MSWO accurately predicted efficacious reinforcers for all three participants. Higbee et al. (2000) also conducted three-session MSWO assessments using seven stimuli and found in subsequent multielement reinforcer assessments with the top-ranked stimulus (or one of the stimuli tied for top rank) that the brief MSWO predicted effective reinforcers for seven of nine adults with intellectual disabilities.

Most recently, Conine et al. (2021) conducted post hoc analyses on 147 MSWO assessments across 49 participants to determine the correspondence on the outcomes based on the first or first two sessions to those obtained in three sessions (i.e., brief MSWO). The results showed a strong correlation between the hierarchies obtained given one, two, and three sessions, but not on the HP stimulus. The authors suggest that the predictive validity of the one-session MSWO, therefore, depends on the intended purpose and use of the results. If the purpose is to identify a relatively more and relatively less preferred stimulus to use in differential reinforcement procedures, then a one-session MSWO may be appropriate, but if the purpose of the MSWO is to identify the most highly preferred stimulus to use in a particular contingency, then a three-session MSWO will likely be more appropriate.

Based on the data currently available, the brief (three-session) MSWO appears to be a valid and more efficient preference assessment method than the five-session MSWO. Both Carr et al. (2000) and Richman et al. (2016) report that the brief MSWO takes about 5 min, which represents a considerable time saving from the more than 20 min administration time reported for the full MSWO (DeLeon & Iwata, 1996), and makes the brief MSWO as efficient as the FO assessment.

Reinforcer Assessments

Reinforcer assessments serve one main purpose: they provide evidence for the predictive validity of the preference assessment. Predictive validity is a measure of the extent to which the outcomes of a method predict future behavior (Brown et al., 2011). The predictive validity of SPAs has been measured largely through reinforcer assessments. Reinforcer assessments measure the effect of an assessed stimulus on behavior.

A reinforcer effect is shown when the level of behavior increases as a function of a particular contingent stimulus on that behavior, and this is often demonstrated with replicability in an experimental design so that we have confidence that the contingent stimulus is responsible for the behavior change. Reinforcer assessments can measure either an absolute or a relative reinforcer effect of particular contingent stimuli.

Absolute Reinforcer Effect

In a single-operant reinforcer assessment, a single reinforcement schedule is arranged for emitting a specific response, and frequently, the response is a simple one that is already in an individual's repertoire (e.g., Roscoe et al., 1999). Responding is first measured in a baseline phase (A), where no stimulus is delivered for responding. Then, during the reinforcement phase (B), the stimulus is provided when the response requirement is met. If the frequency of responding is higher during reinforcement phases than during baseline phases, the stimulus is considered a reinforcer, and the higher the frequency or rate of responding, the more potent the reinforcer is judged to be. One consideration in evaluating reinforcer strength is that, because phases in single-operant reinforcer assessments are often relatively short (e.g., 5 min), ceiling effects may occur. Nonetheless, single-operant reinforcer assessments can provide a measure of absolute reinforcer strength. Single-operant reinforcement assessments have typically shown that HP stimuli almost always function as reinforcers and LP stimuli sometimes will (e.g., Roscoe et al., 1999). Lee et al. (2010) evaluated each assessed stimulus in a single-operant ABAB reinforcer assessment and calculated the percentage change between reinforcement and baseline. They found concordance of reinforcer effects and preference ranks for one individual with IDD, and partial concordance for the other, with disagreements shown with less preferred stimuli.

Multielement (sometimes referred to as multiple-schedule) reinforcer assessments have also been used to evaluate absolute reinforcer effects. In these arrangements, baseline sessions (no contingent stimulus) and sessions with one (i.e., most preferred) or more (i.e., moderately or lowest preferred stimulus) reinforcement conditions are randomly alternated. This design allows for visual inspection to detect not just the absolute reinforcement effects of preferred stimuli, but the relative reinforcement effect of each stimulus when multiple stimuli are included. For example, Carr et al. (2000) used a multielement design to evaluate the predictive validity of a brief MSWO assessment for three students with ASD. They measured the number of correct responses on individualized curricular targets in baseline (no stimulus contingent on correct responses) and then in three different reinforcement conditions each with a different stimulus from the preference assessment: the top-ranked stimulus (first), a moderately ranked stimulus (fourth or fifth), and the bottom-ranked (eighth) stimulus. The absolute reinforcer effect was shown for each stimulus by comparing the number of correct responses in each reinforcement condition to the baseline. Contingent delivery of the top-ranked stimulus functioned as a reinforcer for all participants with accuracy levels above baseline. Contingent delivery of the moderately ranked stimulus functioned as a reinforcer for two of three participants, and contingent delivery of the bottom-ranked stimulus had only a modest reinforcement effect for one participant with no reinforcer effect for the other two participants. Relative reinforcer effect was also shown for each contingent stimulus by comparing the number of correct responses in each reinforcement condition to each other. For each of the three participants, the effect of each of the contingent stimuli was orderly without any overlapping data points and in line with the hierarchy indicated by the preference assessment: highest levels of accuracy were shown with the top-ranked stimuli, middle levels of accuracy with the moderately ranked stimuli, and lowest levels of accuracy with the bottom-ranked stimuli.

More recently, behavior analysts have used progressive ratio (PR) assessments to evaluate reinforcer potency (e.g., Roane et al., 2001). A PR assessment is a type of single-operant assessment, but the response requirement to access reinforcement systematically increases within a session. For example, a participant may need to emit two responses to obtain the reinforcer initially, then four responses, then six responses, etc. The session ends when responding stops, and the last reinforcer schedule achieved, called the breakpoint, determines the reinforcer value. If Stimulus A has a breakpoint of 20, and Stimulus B has a breakpoint of 10, Stimulus A is considered the more potent reinforcer. Morris and Vollmer (2020) used PR assessments to evaluate the predictive validity of the rank ordering of stimuli generated by SPAs (i.e., SPA hierarchy, not just HP or LP). PR assessments were conducted with each stimulus in the SPA and were used to assign ranks to all stimuli (stimulus with the highest average break point was assigned Rank 1, stimulus with the next highest break point was assigned Rank 2, etc.). They then calculated rank-order correlation coefficients of SPA and PR assessments. They found that SPAs yielded valid hierarchies (an average rank-order coefficient of 0.7 or greater) for approximately half of the eight children with ASD who participated.

Relative Reinforcer Effect

Relative reinforcer effects, on the other hand, are shown when the effect of a contingent stimulus is shown *at the same time as* the effect of no contingent stimulus (or a different and presumably unpreferred or less preferred stimulus). Relative reinforcer effects are often used when a preference assessment identifies a hierarchy of preferences (e.g., PS or MSWO) and serves to provide predictive validity for that hierarchy (i.e., a preference hierarchy would be validated if the top-ranked stimulus in a preference assessment was shown to be more effective as a reinforcer than a mid- or bottom-ranked stimulus).

Relative reinforcer effects have been assessed with a variety of experimental arrangements, most notably concurrent-operants paradigms (e.g., Fisher et al., 1992; Roscoe et al., 1999) and concurrent-chain arrangements (e.g., Castelluccio & Johnson, 2019; Steinhilber & Johnson, 2007). Concurrent-operants arrangements measure free operant responding among two or more alternatives. For example, Fisher et al. (1992) used a concurrent-operants arrangement within a reversal design with two chairs (or squares) present and each chair (or square) had different stimuli available. Throughout each reinforcement session, participants could move from chair to chair and the dependent measure was the percentage of time spent in each chair (or in-square). A reinforcement effect was seen if time in chair (or square) increased when stimuli were available compared to when no stimuli were available. Relative reinforcer effect was measured by the amount of time a participant allocated to each of the chairs (or squares).

Concurrent-chain arrangements, on the other hand, measure restricted operant responding among two or more alternatives. In one example, Castelluccio and Johnson (2019) used a concurrent-chain arrangement with two to three cards depicting multitask sequences, each associated with a different break environment (or no break). Selecting a card with one of the task sequences (initial link) produced the materials to complete those tasks and completing the tasks in the specified order was reinforced with access to the associated break environment. Dependent measures included initial-link selections and task-sequence completions. A reinforcement effect was seen when there were more selections and completions of task sequences associated with a contingent break than with no break; relative reinforcement effects were shown as more selections and subsequent schedule completions were allocated to the initial link associated with the most highly preferred than with the least preferred break environment when they were both available.

Teaching Others to Conduct Stimulus Preference Assessments

Several methods for training inexperienced staff to conduct SPAs have been evaluated by researchers: behavioral skills training, pyramidal training, self-instruction packages, video modeling, and telehealth.

Behavioral Skills Training

Behavioral skills training (BST) has been shown to be an effective and efficient method to teach individuals how to accurate conduct SPAs. Typically, individuals are provided with training materials, and the trainers demonstrate how to implement the procedures. Trainees then conduct the procedures and are provided feedback on their performance. Lavie and Sturmey (2002) trained three teacher assistants, who had no previous experience identifying potential reinforcers, to conduct PS preference assessments. First, a task analysis of the target steps required to perform a preference assessment was created. Participants were given a checklist describing each target skill and a trainer verbally described each skill on the list. Participants then watched a videotaped model of the skills being performed. Next, participants conducted the assessment with clients, and the trainer observed and provided performance feedback. Training continued until participants conducted the SPA with 85% accuracy; all participants met mastery criteria following approximately 80 min of training. Other researchers have also found that trainees can master the skills required to implement SPAs in a relatively short period of time when using behavioral skills training (e.g., Roscoe et al., 2006; Roscoe & Fisher, 2008).

Pyramidal Training

In an attempt to improve the efficiency of SPA training procedures, Pence et al. (2012) used pyramidal training to train 27 teachers and clinicians to conduct PS, MSWO, and FO assessments. Three trainers were given copies of preference assessment protocols, data sheets, protocols for training the assessments, and instructions on how to provide feedback. Following training, the three teachers (Tier 1) trained a group of six teachers and clinicians (Tier 2) using the same training methods. Next, five Tier 2 individuals trained a group of 18 preschool teachers (Tier 3). Following training sessions, generalization sessions occurred in teachers' classrooms. Pyramidal training was effective to train three tiers of professionals to conduct all three assessments.

Self-Instruction

Researchers have also become interested in developing protocols that could be successfully implemented in the absence of an expert trainer. Graff and Karsten (2012a) evaluated the effectiveness of an antecedent-only self-instruction packet to train inexperienced staff to conduct and interpret the results of PS and MSWO preference assessments. A multiple-baseline across assessment types was used to evaluate the effectiveness of enhanced written instructions (EWIs). During baseline sessions, 11 teachers were given the methods section from the seminal journal article with a blank sheet of paper and instructed to conduct the assessment. Next, participants were given a self-instruction packet containing EWIs. The self-instruction packet provided instructions for completing each assessment without the use of technical jargon. The step-by-step instructions for conducting and scoring the assessments were supplemented with diagrams and pictures; no performance feedback was provided. Several target responses were assessed for each participant: stimulus presentation, positioning of stimuli, post-selection response, response blocking (if necessary), trial or session termination, data recording, data summary, and interpretation of preference assessment results. Accuracy for conducting both PS and MSWO assessments was low during baseline sessions. After being provided with the EWIs, all participants met the mastery criterion, suggesting that inexperienced staff can be trained without the use of expert-led training. In addition, participants successfully learned how to score the assessment and interpret the findings, in the absence of any performance feedback. Other researchers have also found the use of EWIs to be effective for training inexperienced individuals to conduct SPAs (e.g., Shapiro et al., 2016).

Video Modeling

The use of video modeling (without the addition of corrective feedback) to train inexperienced staff to conduct SPAs has been evaluated by several researchers. Weldy et al. (2014) trained nine inexperienced staff to implement a brief MSWO assessment and a brief FO assessment using video modeling. Participants viewed a PowerPoint presentation that demonstrated how to conduct both preference assessments. The researchers found that all participants accurately implemented both assessments after 60–90 min training with video models. Similarly, Rosales et al. (2015) evaluated the effects of video modeling plus embedded instructions to train three inexperienced staff to implement PS, MSWO, and FO assessments. Videos showed correct implementation of the target skills for each assessment with embedded written instructions, which provided explicit information for completing each target skill. Participants could watch and rewind the videos for an unlimited amount of time before conducting the assessment. The results showed that video modeling was effective in training staff to implement preference assessments. Other research has demonstrated the effectiveness of video modeling with voiceover instructions to teach inexperienced individuals to accurately implement SPAs (e.g., Bovi et al., 2017; Lipschultz et al. 2015). Some researchers have combined multiple strategies to teach inexperienced individuals how to conduct SPAs. For example, Hansard and Kazemi (2018) developed a video self-instruction package that used written instructions combined with voice-over instructions and video modeling of each step in the procedure. They found that participants were able to accurately implement the assessment, score, and interpret the results.

Telehealth

Recently, researchers have found that preference assessment procedures could be trained via telehealth. Higgins et al. (2017) implemented a training package via telehealth that was comprised of a self-paced multimedia presentation (that combined written material plus video models) plus video feedback and role-plays with immediate feedback. All participants implemented the procedures with high accuracy, demonstrating that BST could be delivered via telehealth. Inexperienced individuals have also learned how to conduct brief MSWO assessments via telehealth with real-time feedback on their performance (Ausenhus & Higgins, 2019).

Summary and Recommendations

When implementing behavior analytic programs to decrease problem behavior and to increase adaptive skills, it is critical that effective reinforcers are used. Over the past 40 years, behavior analysts have developed a variety of methods to identify potential reinforcers, and the development of procedures to effectively and efficiently identify preferences has accelerated in the past 20 years. In this chapter, we have reviewed much of this research and its implications.

The experimental literature on SPAs demonstrates that many different types of stimuli can be evaluated by measuring either approach responses or duration of engagement. SPAs have been used successfully in many different settings, including preschools (e.g., Hanley et al., 2007), inpatient units (e.g., DeLeon et al., 2001), residential schools (e.g., Cohen-Almeida et al., 2000), group homes (e.g., Conyers et al., 2002), sheltered workshops (e.g., Worsdell et al., 2002), early intervention day programs (e.g., Carr et al., 2000), and public schools (e.g., Mueller et al., 2001). Additionally, SPAs have been used to identify reinforcers for individuals with varying diagnoses such as intellectual disabilities (e.g., Pace et al., 1985), developmental disabilities (e.g., DeLeon & Iwata, 1996), visual impairments (Paclawskyj & Vollmer, 1995), schizophrenia (e.g., Wilder et al., 2003), emotional/behavior disorders (e.g., Paramore & Higbee, 2005), attention deficit hyperactivity disorder (e.g., Northup et al., 1996), and adults with dementia (Lucock et al., 2020). Thus, the extant literature on SPAs confirms that the procedures are applicable to a wide range of settings and participants.

Recommendations

In conclusion, based on the research literature just reviewed, we make six recommendations regarding SPAs.

Recommendation 1

SPAs should be conducted when developing or revising reinforcement-based programming. There are several situations when it may be especially important for clinicians to conduct SPAs. For example, when one begins working with a client, conducting SPAs to identify potential reinforcers may be an important first step in the development of effective behavioral programming. With established clients, there may be times when progress has slowed or stopped. When this occurs, conducting reinforcer assessments with previously identified preferred stimuli and SPAs with new stimuli to identify additional potential reinforcers is warranted. In addition, clients who are receiving intensive behavioral programming (e.g., individuals in residential placements who may be receiving behavioral programming during all waking hours) may satiate if the same stimuli are used as reinforcers across the day. Conducting SPAs to increase the pool of potentially reinforcing stimuli for different categories of stimuli (edibles, leisure items and activities, and social stimuli) would be beneficial to clients in such situations. Finally, for clients who receive behavioral programming for prolonged periods of time, it may be important to conduct SPAs occasionally to determine proactively (i.e., before deleterious changes in problem or adaptive behavior) if the preference for items has changed.

Recommendation 2

SPAs should be conducted or supervised by individuals knowledgeable on the extant preference assessment technology. To increase confidence that preference assessments provide clinicians and practitioners with valid and functional outcomes, several factors should be considered. It seems obvious that individuals attempting to conduct SPAs should have adequate knowledge of the procedures. Yet, in one recent survey of over 400 educators and clinicians who conducted preference assessments, 50% of respondents reported a lack of knowledge of preference assessment procedures. Twenty-eight percent of individuals with a degree in behavior analysis reported that the topic of SPAs was not covered in their college coursework, and 19% of Board Certified Behavior Analysts® reported a lack of knowledge of SPA procedures (Graff & Karsten, 2012b). Several studies have demonstrated that when individuals have not been trained on conducting SPAs, they do not implement procedures accurately (e.g., Graff & Karsten, 2012a; Lavie & Sturmey, 2002; Roscoe & Fisher, 2008).

Recommendation 3

Use SPA methods that best match the client's skills and reinforcer needs. Individual participant variables must be considered when conducting which SPA to conduct. Several recommendations have been made to aid clinicians in obtaining valid preference hierarchies (DeLeon et al., 2014). Most SPAs require that an individual have intact motor skills in order to make a selection response. If the individual has severe physical disabilities and cannot physically approach stimuli, clinicians should consider using microswitch technology to identify preferred stimuli (e.g., Wacker et al., 1985). In addition, clinicians might consider identifying behaviors that may be correlated with "happiness," and then expose the individual to a series of stimuli, to determine if any function as reinforcers (Green & Reid, 1996). All SPAs in which more than one stimulus is presented on a trial require that the participant be able to scan a visual array and make a selection response. If scanning is not in an individual's repertoire, clinicians should consider conducting SS assessments (Pace et al., 1985); reinforcers that are identified could then be used to teach scanning skills. If the individual can make valid choices when two items, but not more, are presented on a trial, a PS assessment (Fisher et al., 1992) should be conducted, as long as the individual does not display position biases. If position biases are noted when conducting a PS assessment, clinicians could attempt to change the positions of the items in the array (e.g., from side-by-side to top-to-bottom). This may or may not be successful, as some participants may continue to select items solely based on their position in the stimulus array. Some clinicians have overcome position biases by developing an immediate history with arrays that include non-preferred or less-magnitude items in the preferred position (e.g., Bourret et al., 2012). If the individual can accurately scan larger stimulus arrays and not attempt to select items that remain on the tabletop between trials, clinicians should consider conducting MSWO assessments (DeLeon & Iwata, 1996), as MSWO assessments may be faster to complete than PS assessments. Both PS and MSWO assessments require the participants to return a selected item after it is consumed, but for some individuals, terminating reinforcement may be associated with an increased probability of problem behavior. For these clients, a FO assessment (Roane et al., 1998) could be used, as the FO has been shown to be associated with less problem behavior when assessing preferences for tangible items than PS or MSWO assessments (e.g., Kang et al., 2011).

If practitioners are attempting to identify preferences for complex stimuli, stimuli that cannot be placed on the tabletop, or social stimuli, they should consider using verbal, pictorial, or video-based preference assessments. Before using these assessments, however, it is important to determine if the individual possesses the presumed prerequisite skills. This task could be done by conducting specific discrimination tests with the stimuli to be assessed (e.g., Clevenger & Graff, 2005), or by using a general discrimination skills assessment such as the Assessment of Basic Learning Abilities (ABLA; Kerr et al., 1977) or the New England Center for Children- Core Skills Assessment (Dickson et al., 2014).

Finally, the duration of access in the SPA should match the duration of access in the natural environment. Steinhilber and Johnson (2007) found differential preference hierarchies depending on the duration of access. If the stimulus will be used contingently on correct responses in discrete trial instructional settings, potential reinforcers should be evaluated in the context of a SPA with brief access such as 10–15 s; on the other hand, if the stimulus will be used contingently on more effortful responses such as those shown with greater PR break points, one should consider evaluating potential reinforcers in the context of a SPA with more extended access that matches what the reinforcement interval will be in the natural environment.

Recommendation 4

SPAs across different categories of stimuli should be conducted that incorporate caregiver-nominated items and are ecologically valid. Before conducting SPAs, clinicians must decide which stimuli to include. If a clinician is working with a new client and has limited information about the individual's reinforcement history, a starting point is to conduct the RAISD (Fisher et al., 1996) or another structured caregiver survey. Before conducting preference assessments, clinicians must be sure that their clients have previously interacted with items to be assessed. If unsure, clinicians should expose the client to the items before starting the assessment. For individuals who have previously participated in SPAs, clinicians should consider adding novel stimuli into the stimulus pool. In general, clinicians should conduct separate SPAs for each category of stimuli (e.g., edibles, activities, and social).

Clinicians conducting SPAs should consider the "ecological fit" of stimuli when deciding which items to include in a SPA (DeLeon et al., 2014). For example, if reinforcers are to be presented frequently, relatively inexpensive items may be the most practical. In the Graff and Karsten (2012b) survey of SPA practices, 38% of respondents reported that a barrier to conducting SPAs was the amount of money available to purchase reinforcers. Similarly, clinicians should also consider what the duration of reinforcer access will be. For example, different stimuli should be assessed if potential reinforcers will be delivered on a rich schedule, such as during discrete trial instruction, than if potential reinforcers will be delivered after more prolonged and effortful behavior such as a multi-task hygiene routine. In the first example, reinforcers should be those that are easily dispensed and consumed quickly so as not to disrupt the instructional session (e.g., brief social attention, an edible). In the latter example, there may be more latitude in how easily the reinforcer can be delivered, particularly if tokens are used and the token exchange can occur when the reinforcer is available, and the reinforcer access time may be more prolonged (e.g., video game, time on iPad®). DeLeon et al. (2013) suggested that clinicians conduct a sequence of preference and reinforcer assessments to address the issue of ecological fit. First, the authors suggest that preference and reinforcer assessment be conducted for social stimuli. If social stimuli function as reinforcers, they should be used, as they are quick and easy to deliver. If social stimuli do not function as reinforcers, leisure items and other non-edible tangible stimuli should be assessed. DeLeon et al. suggest that edible items be the last category of stimuli that should be assessed. Oftentimes, edible stimuli are most preferred by clients (e.g., Fahmie et al., 2015), but edible items may be difficult to deliver in certain situations (e.g., delivering candy to a child as a reinforcer for brushing their teeth), and the repeated delivery of food over long periods of time may impact on a client's health.

Recommendation 5

To the extent possible, minimize motivating operations that may affect SPA outcomes. Previous research has demonstrated that motivating operations can influence preference assessment outcomes (e.g., Gottschalk et al., 2000; Hanley et al., 2006; McAdam et al., 2005). Thus, clinicians should monitor or control the amount of presession access individuals have to the items being assessed. Although some studies have regulated the amount of presession access to items by providing pre-measured portions of all items, an easier method to control presession access may be to simply refrain from delivering any of the assessed items for a period of time just prior to conducting the assessment. Chappell et al. (2009) found that for two of three individuals with ASD, abolishing effects of presession access to edible items abated after 20 min. This finding should be considered tentative as it has not been replicated by other researchers or across other stimulus categories. Until additional research is conducted to better determine the necessary length of the presession deprivation period, restricting access to items for 1 hr prior to an assessment seems a reasonable guideline. In addition to controlling access to the specific items being assessed, it may be helpful to control for the delivery of items that are similar to those being assessed. For example, if gummy bears are to be included in an edible preference assessment, gummy bears and other gummy items (e.g., gummy worms) should be restricted, as these items could be considered substitutable.

Recommendation 6

When possible, provide access to selected items immediately and when this is not possible, consider pre-assessment reinforcement schedule thinning or the use of arbitrary reinforcers during the SPA. In general, following selection responses with the delivery of the corresponding item increases the probability of generating a valid preference hierarchy. This may not be possible when assessing preferences for some complex stimuli using verbal, pictorial, or video-based assessments. When it is not possible to deliver an item immediately following a selection response, it is suggested that schedule thinning be used to potentially increase the accuracy of preference assessment results (Heinicke et al., 2016). Although not extensively evaluated, it is possible that providing periodic access to arbitrary reinforcers between trials may reduce the possibility that participants may stop responding because approach responses are not reinforced.

Summary

In summary, identifying preferred stimuli is a critical function of behavior analysts working with individuals with IDD. In this chapter, we have reviewed the research on different SPA methods and outcomes and hopefully provided the information necessary for others to select the optimal assessment procedure to identify effective reinforcers to be incorporated into clinical practice.

Establishing Performance Criteria for Skill Mastery

22

Sarah M. Richling, Daniel M. Fienup, and Kristina Wong

What Are Performance Criteria?

Applied behavior analysis (ABA), as a field, focuses on addressing socially significant behaviors through the implementation of effective behavior analytic interventions (Baer et al., 1987). The functional extension of effectiveness of treatment procedures within the therapeutic context to the natural environment is a central goal of ABA (Stokes & Baer, 1977). Within skill acquisition programming, the basic structure of instruction includes clear antecedents, opportunities for the learner to respond, and feedback on responses (Skinner, 1968). This may involve a child with autism responding to repeated opportunities to tact colors, college students responding to quizzes, or youth learning accurate sports behaviors. In each case, the respective instructor continues with teaching until the learner's behavior meets a predetermined criterion used to evaluate sufficient skill proficiency, often labeled a *mastery criterion* or *performance criterion.* This is systematically done such that behavior continues to occur, or maintains, in the presence of naturally occurring antecedents and consequences, outside of contrived analogue teaching conditions. This process has often been labeled as *programming for maintenance,* or more accurately, *response maintenance* (as discussed in the section "Terminology Considerations").

The use of instructor-determined performance criteria that serve as discriminative stimuli for terminating a teaching phase is a widely adopted practice and has a long history in the field of behavior analysis. In fact, the first article printed in the *Journal of Applied Behavior Analysis* includes a reference to the discontinuation of programmed treatment once a satisfactory rate of behavior was achieved (Hall et al., 1968, pp. 2–3). In 1997, Sayrs and Ghezzi noted the rapid growth in the reporting of mastery criteria in the *Journal of Applied Behavior Analysis* between 1968 and 1995. Around this same time in 1996, 53% of articles in the *Journal of the Experimental Analysis of Behavior* included a report on mastery criteria (Rehfeldt & Ghezzi, 1996). Early treatment manuals (e.g., Lovaas, 1981) also included recommendations for adopting performance criteria such as 9 out of 10 consecutive trials correct as indication to move onto the next step of training. More recently, clinical survey data (Love et al., 2009; Richling et al., 2019) suggest the wide adoption of evaluative performance criteria. These studies report that all survey respondents indicated utilizing criteria of various types, such as those based on a percentage of trials correct or a consecutive number of trials

correct. As such, it is apparent that the use of performance criteria has a long-standing history and has become ubiquitous within the field of ABA.

Contemporary Use of Performance Criteria

Recently, researchers and clinicians have referred to predetermined performance goals as *mastery criteria.* Many performance criteria rules appear to come from clinical manuals or supervisors and seem to be accepted as universal rules (e.g., 80% correct responding or above for three consecutive sessions); however, these rules have little scientific support. The selection of performance criteria is undoubtedly nuanced and should be tailored to each unique behavioral target and each unique client. That is, the selected goal should be directly tied to how exactly this particular behavior is expected to occur, by this particular individual, in a particular natural context(s), at a particular time(s), in a particular way. For example, it may be the learner is expected to pass a written exam with a grade of B or better, requiring 80% accurate response on test items within a certain period of time. As such, the acceptable level of responding would need to be 80% accuracy or higher and occur at a certain rate of responding, to account for the timed test conditions. Performance on both of these features (i.e., accuracy and speed) of the response would need to be measured and observed in order to determine whether an intervention has been effective. In another case, it may be that an individual on a behavior analyst's caseload is being taught to cross the road safely. In this case, it would be important for the behavior analyst to require 100% accuracy with respect to safe behaviors while also ensuring programming is conducted such that behavior is likely to maintain 100% accuracy for a long duration of time post-training. There is less clinical need to require such stringent criteria for other topographies of behavior such as tacting animals, for example.

It is important we also recognize that for the above examples, it is possible a higher level of performance criteria must be established during teaching sessions in order to achieve desired levels of behavior which are expected to occur at a later time, accounting for behavioral deterioration over time. That is, there may be decreases in the accuracy and/or speed after a certain period has elapsed since the previous teaching session. Thus, the behavior analyst must also determine and assess what constitutes an effective teaching criterion that can reliably produce the desired response maintenance performance expectations at a later time during which the behavior actually needs to occur. In other words, we need to determine functional relations between performance criteria during teaching—when we reinforce correct responses and provide assistance as needed—and the resulting performances after teaching are done and the learner is expected to perform under more naturalistic conditions and rates of reinforcement. In behavior analysis, this initial teaching criterion has typically been referred to as the mastery criterion, or the criterion at which the learner must perform under teaching conditions before progressing to maintenance probe conditions. While these initial goals are important to indicate movement to the next phase of treatment, it is important to highlight here that the overall goal of demonstrating effectiveness does not end at the point of achieving a mastery criterion. Effectiveness is only demonstrated when the behavior occurs in the desired context following the termination of treatment. Only then might we consider the skill mastered. We discuss this and related issues with terminology in the following section.

Terminology Considerations

First, as pointed out by Cooper et al. (2007, p. 616) there is a need to distinguish between the terms *maintenance* and *response maintenance.* Response maintenance has been defined as *the degree to which* a behavior persists over time when all or part of the intervention variables responsible for training the behavior are no longer present (Freeland & Noell, 2002; Stokes & Baer, 1977). As such, it refers to a measurement of the occurrence of behavior and has also been referred to as behavioral persistence or durability. Maintenance, however, does not refer to the behavior, but to the environmental stimulus conditions. Maintenance is utilized to describe a condition in which all or part of the treatment has been removed, albeit often with the intent of observing a potential degree of response maintenance. As such, response maintenance is best conceptualized as a dependent variable and maintenance as an independent variable. Thus, a primary goal of ABA interventions is the demonstration of a predetermined acceptable level of response maintenance, not merely the implementation of maintenance procedures.

Second, the term *mastery criterion* also warrants further discussion. As it stands, a mastery criterion has been loosely defined as "a specific guideline for performing a skill such that if the guideline is met, the skill is likely to be mastered" (Martin & Pear, 2007, p. 223) or as "performance requirements for practicing a skill such that if the criteria are met, the behavior has been learned" (Martin & Pear, 2007, p. 343). Fuller and Fienup (2018) highlight circumstances under which this term is used to describe performance criteria that do not meet this definition. For example, the authors state that once responding meets a predetermined level of accuracy, an instructor may move to a less restrictive prompt level, which does not suggest mastery, but rather behavior meeting an acceptable criterion given the current context. This highlights one of several problems with the current use of the term mastery criterion, namely the inclusion of the term *mastery*, itself.

Colloquially, mastery typically refers to the possession or demonstration of an exceptional skill or technique and one who can perform at this level may be referred to as a master of that skill or subject matter. Keeping this definition in mind, it is odd to refer to the minimally acceptable levels of performance as *mastery*. This is particularly curious when we consider this in some contextual scenarios. Oftentimes, a mastery criterion might be set at 80% correct (McDougale et al., 2019). If one were to go to work wearing 80% of their clothing, do we consider them a master dresser? Or if someone stops at 80% of stop signs while driving, would we label them a masterful driver? However, within behavior analysis, mastery typically refers to a level of performance indicating a behavior has been sufficiently learned. This gives rise to another question, what do we mean by "learned" (as well as "sufficient"). As behavior analysts, we may use the term *learned* to indicate observation of the behavior being evoked at acceptable levels in the presence of given contextual discriminative stimuli. However, *learned* does not necessarily mean the behavior has been acquired by the individual such that it will occur at the same levels ad infinitum.

To this point, as suggested by Fuller and Fienup (2018), there is a problematic underlying assumption inherent in mastery criteria. That is because behavior meeting this criterion functions as a discriminative stimulus for the teacher to engage in another behavior (e.g., decrease prompt level or introduce new targets), there is an implied expectation that behavior will maintain once the current instructional behaviors are terminated. The problem here, however, lies in the lack of literature supporting this assumption of maintenance following achieving specific performance criterion levels (Fuller & Fienup, 2018; Richling et al., 2019).

Now, let us look at the point during the training context at which the term mastery is typically utilized (i.e., after behavior is observed to occur at initial performance criteria levels under teaching conditions) and why this is problematic. Consider the possible response deterioration that is likely to occur following the removal of teaching procedures as described earlier. If deterioration in responding occurs, we may not label this mastery; it is just the first step in a series of teaching milestones toward a terminal goal. If the term mastery is used at this point in teaching, it may indicate to the therapist that their job is done, when that is far from the case.

Within precision teaching literature, specific attention is paid to performance standards and empirically associated learning outcomes (Kubina & Starlin, 2003). Fluency aims are conceptually similar to mastery criteria. Within this area of research, the assumption is that performance occurring within a certain frequency range will be associated with retention and other extended learning outcomes (Kubina & Starlin, 2003). These learning outcomes include other behavioral measures such as retention across time, endurance of performance for a duration of time, performance in the presence of distractions, and application of a previously learned component in the context of learning a new composite skill (REAPS) (Binder, 1996; Haughton, 1984). These terms refer to various dimensions of performance (beyond a percentage of correct responses) that are expected to be observed before a skill is considered sufficiently learned. The importance placed on these other demonstrations of performance within the precision teaching literature highlights the need for adopting and clearly outlining the various dimensions of performance and milestones required for truly demonstrating mastery.

Mastery Redefined as a Collective of Multiple Performance Criteria

For the reasons outlined in the previous section, we have adopted the term *performance criteria* as an umbrella term encompassing individual criteria applied at separate learning goals. The term *mastery criterion* is reserved for describing the final milestone of having achieved all individual performance expectations. These individual performance criteria may include the initial acquisition criterion (e.g., 100% correct responding across three consecutive sessions), a fluency or rate criterion (e.g., 100% correct responding at a rate of 20 responses per minute), a response maintenance criterion (e.g., retained performance at 90% correct responding after a period of one month), and a generalization criterion (e.g., 90% correct performance in the natural environment, two additional novel settings, without the presence of the instructor, and in the presence of two novel individuals). If necessary, supplemental performance criteria may be adopted for the particular skills and expectations in the natural environment. For example, one may also require performance in the presence of distraction or for a duration of time without a decrease in rate. These features of performance might be expected, for example, for professional athletes or individuals taking long standardized tests. Throughout the remainder of this chapter, we will utilize the terms as described in this section. In the next section, we will address each of the abovementioned performance criteria in more detail.

Dimensions of Performance Across Which Criteria Can Be Applied

As suggested at the beginning of this chapter, conventional wisdom assumes a simple approach to the application of mastery criteria. The majority of practitioners and researchers within the field of ABA rely on percentages of correct responses as the standard for determining the mastery of any given skill (Richling et al., 2019). It is worth noting most of this work involves young children with developmental delays who are learning basic academic and social responses. Once an individual performs a task with 90–100% accuracy, it is typical to label the task as "mastered." What we will soon find, however, is that the application of mastery criteria is much more nuanced and complex.

Mastery encompasses several individual components for which a criterion should be uniquely established. As described in the previous section, we conceptualize mastery as a set of performances, comprised of acquisition, fluency, maintenance, and generalization (Fig. 22.1).

The initial stage of teaching requires the implementation of strategies to produce a response that was not previously in a learner's repertoire, also known as the acquisition stage. When a target behavior is in the acquisition stage, that is, the skill has yet to be performed successfully, acquisition criteria should be applied to determine when the intervention should be faded or terminated. The most commonly used dimension of acquisition criteria within ABA instruction is the level of accuracy during a session. Instructors administer a block, or set number, of teaching trials. Typically, practitioners and researchers report a percentage of correct responses across all trials within the session.

Fig. 22.1 The four pillars of mastery including acquisition, fluency, maintenance, and generalization for which instructors should establish a unique criterion for each

Higher percentages tend to lead to more durable responses as more time passes (Richling et al., 2019).

Another dimension of acquisition criteria identifies the frequency of observations at which the level of accuracy occurs. Practitioners and researchers typically establish a range of one to three consecutive sessions in which a predetermined accuracy level must be observed before they signal the termination of an intervention (Richling et al., 2019). To date, there have been no published studies systematically comparing the effectiveness of different frequencies of observation for producing subsequent response maintenance.

Selecting the right criterion for acquisition is nuanced. Many different variables should be considered during this process. Such variables include the type of novel skill that is targeted, the intervention procedure being used, and the skills the individual who is undergoing instruction possesses. For example, a 90% acquisition criterion may be adequate for an individual who is learning how to spell but certainly not adequate for an individual who is learning to stop at a stop light. An acquisition criterion of five consecutively correct responses to emit letter sounds may be appropriate for a student who demonstrates bidirectional naming (Miguel, 2016) but not for a student who does not demonstrate the ability to learn language incidentally. Bearing in mind all the nuances of skill acquisition, criterion selection needs to be a carefully thought out process.

The parameters of acquisition, which include the level of performance and frequency of observations should also be applied to the assessment of maintenance and generalization across settings and multiple instructors. For example, an instructor may establish a level-based criterion across two or more instructors to assess for the generalization across instructors. An instructor may also establish a level-based criterion across two or more settings to assess for the generalization across settings.

Performance criterion may be applied to a whole session/set of operants or to individual operants. Thus, identifying the unit of analysis when determining performance criteria is important (Wong, Bajwa et al., 2022). Level of accuracy may be conceptualized as a session-based unit of analysis. That is, the emphasis is on the overall accuracy within a session, and the criterion is applied to a set of operants rather than a single operant. This particular method of analyzing performance raises some important issues. ABA instruction within educational settings typically uses discrete trial instruction (DTI) that relies on teaching multiple operants or skills (a set of operants or skills) within one session. If a session contains 20 trials, there are usually four or five operants included in a teaching set. When performance criteria are applied to the session as a whole and the established criterion is less than 100% accuracy, errors centered on certain operants may be overlooked. For example, during tact instruction for four novel stimuli in a 20-trial session, a 90% correct criterion allows a student to respond incorrectly one or two times. Sometimes those two incorrect responses may fall on only one operant. Thus, the student responded correctly only three out of five times (60% accuracy) to one operant. The 90% correct criterion across one session hides this fact and assumes the student has acquired the entire set.

Another major issue with this method of analysis is that it affects the efficiency of instruction. Oftentimes, the raw data of skill acquisition programs show that students acquire a few operants in a set quickly, while needing additional sessions to acquire the remaining operants. Because the acquisition criterion is not met due to the pattern of errors for the remaining operants, the instructor delivers unnecessary instruction for the same set of operants until the set-based criterion is achieved. Thus, Wong, Bajwa et al (2022) proposed a unit of mastery analysis that is applied to individual operants rather than a set of operants. When the unit of analysis is at the individual operant level, the acquisition of discrete novel skills is not affected by other skills that are taught within the same set. Similarly, trial-based criteria that identify acquisition in terms of the number of correct *consecutive* responses can be used instead of set-based criteria. For example, an instructor may determine an adequate point to terminate a shoe-tying intervention when the child independently emits three consecutive correct shoe-tying responses. Approximately 28% of ABA practitioners and 18% of ABA researchers utilize trial-based criteria (McDougale et al., 2019; Richling et al., 2019).

The nuanced and diverse nature of selecting appropriate performance criteria is further complicated as we considered areas of practice outside of autism and developmental disabilities. The following section identifies the various areas in which performance criteria have historically been adopted. After reviewing this literature, we will return to a discussion of a standardized model for selecting performance criteria across a wide variety of practice areas.

Review of Literature Targeting Performance Criteria

Performance Criteria with Individuals with Autism Spectrum Disorder and Developmental Disabilities

ABA treatments are highly effective for teaching individuals with developmental disabilities, intellectual disabilities, and autism spectrum disorder (ASD) novel and socially significant skills. Individuals who receive ABA services are typically expected to achieve an established performance criterion for each skill they are taught. Love et al. (2009) surveyed 200 professional supervisors of Early Intensive Behavioral Intervention programs to identify different aspects of their teaching procedures. Over 60% of the respondents used a performance criterion that was either a certain percentage of accurate trials across multiple sessions or a certain percentage of trials across multiple therapists. Almost all the respondents (98%) included teaching procedures that promoted maintenance and generalization of the target skills.

Performance criteria are ubiquitous within ABA research. However, as ABA services have grown in scale, the standards to which skill is deemed learned or mastered varies across researchers and practitioners. Richling et al. (2019) conducted an online survey to gather information on common clinical practices as they relate to skill acquisition and mastery criteria. Approximately 200 BCBAs (Board Certified Behavior Analysts) and BCBA-Ds (Doctoral Level Board Certified Behavior Analysts) who serve individuals with ASD and intellectual disabilities responded. Similar to the results of Love et al. (2009), 68% of the clinicians used a session-based mastery criterion that was a certain percentage of accurate trials and 57% of those clinicians applied that mastery criterion across multiple sessions with additional variables. Only 35% of clinicians reported that they utilized a percentage of correct trials across multiple sessions. A small minority of clinicians (28%) used a certain number of consecutively correct responses to determine mastery and only 4% of clinicians used an established rate of correct responses per unit of time to determine mastery. There were also varied responses regarding the percentages used to determine mastery. Of the respondents who indicated that they applied a certain percentage of correct trials across multiple sessions, 52% of them used an 80% criterion. A smaller percentage of clinicians (28%) used a 90% criterion, and 7% of the clinicians used a 100% criterion. No clinicians applied a mastery criterion that was less than 80%. Richling et al. (2019) also sought to gain insight into the primary information source clinicians based on their mastery criterion. The primary source for the selection of mastery criteria for 44% of the respondents was a personal supervised experience. That is, many of the clinicians applied a particular mastery criterion because their supervisor directed them to do so. The second highest percentage of respondents (20%) reported that employer policies and requirements dictated their selection of mastery criterion. Sixteen percent of the respondents reported that graduate school training determined the established mastery criterion. A smaller percentage of respondents (10% and less) referenced continuing education programs, regulatory requirements, and funding sources as the primary information source for the mastery criterion.

To extend upon the responses that were submitted by the BCBAs and BCBA-Ds, Richling et al. (2019) conducted two additional experiments to systematically evaluate the most commonly reported mastery criterion level (80% across three consecutive sessions) with a 60% mastery criterion across three consecutive sessions and a 100% mastery criterion across three sessions on response maintenance. Four children with developmental disabilities were taught receptive identification skills and expressive identification skills (tacting). The results of Experiments 2 and 3 demonstrated that the only mastery criterion that produced reliably durable maintenance results (>70% accuracy) was the 100% mastery criterion across three sessions. A fourth experiment included a 90% criterion across three consecutive sessions in the comparison with an 80% and 100% criterion across three consecutive sessions. The results showed that even a 90% mastery criterion failed to produce durable maintenance responses. The 100% mastery criterion was the only criterion that predicted maintenance responses at or above 70% accuracy during 1-week follow-up sessions.

A similar study conducted by Fuller and Fienup (2018) demonstrated slightly different results. The authors investigated the effects of three skill acquisition mastery criteria (50% accuracy across one session, 80% accuracy across one session, and 90% accuracy across one session) on response maintenance and skill acquisition rate for students learning vocal and written spelling responses. The authors found differentiated maintenance responses across all three acquisition criteria and 90% accuracy across one session reliably predicted higher accuracy in responses 3–4 weeks following the completion of the acquisition phase. The highest acquisition criterion produced the most durable maintenance responses similar to the results demonstrated by Richling et al. (2019). However, in contrast to the findings of Richling et al. (2019), Fuller and Fienup (2019) found that a 90% performance criterion across one session was stringent enough to predict durable maintenance responses. One exclamation for the durable maintenance responses produced by the 90% criterion in Fuller and Fienup (2018) is that more instructional trials were used during the acquisition phase (20 trials) compared to 10 trials in Richling et al. (2019). Another reason for the discrepancy may be due to another instructional design component in which additional targets were taught after the initial acquisition of a set in Richling et al. (2019). Further, it is possible that the specific prompting procedure used in combination with particular mastery criteria may produce varying results. Longino et al. (2022) demonstrated that a 90% across three sessions criterion may be sufficient when employed in combination with a most-to-least prompting hierarchy rather than the least-to-most procedure adopted by Richling et al. (2019). Unlike Richling et al. (2019), Fuller & Fienup (2018), and Longino et al. (2022), Pitts and Hoerger (2021) reported that only small decreases in maintenance we observed following the employment of an 80% or above for three sessions criterion. However, these authors opted to provide reinforcement for correct responses during maintenance probes, which was not consistent with the aforementioned studies and may have resulted in the contrasting results. These various aspects of instructional design certainly warrant further research. New single-subject research in this area has been emerging to accomplish this goal over time. To help bridge the gap, Wong, Fienup et al. (2022) conducted a systematic analysis of the use of various forms of performance criteria on maintenance and found that even as specific procedural details varied, greater maintenance was observed with higher levels of a performance criterion.

McDougale et al. (2019) conducted a descriptive analysis to compare the performance criteria utilized by practitioners (Richling et al., 2019) with the performance criteria reported in articles published by behavior analyst researchers in three major journals between 2015 and 2017. Overall, the results showed many commonalities among the type of performance criteria utilized during skill acquisition interventions across both clinicians and researchers. The results show that the most utilized type of performance criterion was the session-based percentage of correct responses. There were differences in the level of accuracy. Among researchers, a 90% accuracy criterion was more widely used, and among clinicians, an 80% accuracy criterion was most widely used. With regard to the frequency of sessions observed at the established performance criterion, researchers favored a fewer number of consecutive sessions at 90% accuracy. As mentioned above, clinicians widely adopted an 80% accuracy across three consecutive sessions as mastery. The differences in performance criteria used between researchers and clinicians may be a result of different terminal goals of the researchers and the clinicians. Clinicians may operate within the constraints of the educational goals outlined in a learner's Individualized Education Plan and may have time limits to achieve the goals. In contrast, researchers may aim to achieve a greater difference in behavior change from baseline, and thus apply a higher, more stringent criterion for skill acquisition. Researchers may also have more flexibility and fewer time constraints compared to clinicians. An alarming finding from McDougale et al. (2019) is that greater than 50% of the research articles analyzed failed to include follow-up probe sessions to assess for maintenance of the skill.

Performance Criteria with School-Aged Children

In regular education settings, one common performance criterion is the use of fluency-based measures of performance. While many of the performance criteria discussed thus far relate to accuracy, fluency adds a time component. For example, one might define math fluency in terms of the number of math problems solved correctly within a minute or reading fluency as the number of words read accurately per minute. Indeed, whole systems of allocating educational services have been built on the notion of academic fluency benchmarks serving as indicators of (1) which children would benefit from universal educational services (tier 1), (2) which children require more intensive, small group instruction (tier 2), and (3) which children require highly individualized and possibly one-on-one instruction (tier 3). Called multi-tiered systems of support (MTSS; Jimerson et al., 2016), educators use student performance data—primarily measures of fluency—to make decisions about the appropriate educational support—whether the current instruction is effective or whether teaching tactics need to change.

MTSS begins with universal academic assessments of academic fluency, or curriculum-based measurement (CBM; Jimerson et al., 2016; Cummings & Petscher, 2016). The assessments include having children read, complete math problems, and write using materials from the school district's curriculum. Educators time the assessments and then calculate fluency. For example, a teacher or school psychologist may provide first graders with grade-level appropriate reading passages and ask the child to read the text aloud. The educator times the reading and marks which words were read incorrectly and then calculate words read correctly per minute (WRCPM) based on either the first minute of reading or based on reading the whole passage. The educator can then compare one child's reading fluency to peers and district norms to decide who should continue receiving current instruction (which should be empirically supported), who needs additional help, and who needs individualized services.

In one study, Ivarie (1986) utilized fluency-based measures to teach fourth-grade students concepts of Arabic and Roman numerals. The researchers manipulated the required fluency—either 70 correct responses per minute or 35 correct responses per minute—and observed that fourth graders who were taught to a higher fluency criterion maintained the skill longer and at a higher level than those whose criterion was set lower. These outcomes suggest faster fluency is associated with better educational outcomes. Additionally, they suggest that applying a more stringent teaching criterion produces better outcomes, which is similar to those effects found with a percentage correct criterion (Fuller & Fienup, 2018; Richling et al., 2019).

Another common performance measure in regular education settings is academic achievement—or scores on standardized assessments (Jimerson et al., 2016). Academic achievement tests (e.g., Woodcock-Johnson Tests of Achievement) involve an educator or school psychologist following a manual that includes academic antecedents related to reading, writing, and math to students, measuring responses to those antecedents, and providing no performance feedback. A test involves subtests which evaluate different aspects of an academic content area. For example, reading achievement often includes tests of letter identification, letter sounds, reading fluency, and reading comprehension. Achievement tests result in standard scores based on the child's grade and age. Standard scores are set such that the 50th percentile is a score of 100. The testing developer administers the test to many thousands of students at different educational levels and across different racial and economic groups to produce norms. Then, the educator can use software to evaluate how an individual student's academic achievement compares to other children in the same grade to make decisions about the type of instruction one requires to continue making academic gains.

While academic achievement tests are commonly used in practice for diagnosing learning disabilities, the use of academic achievement assessments for ongoing performance evaluation is limited (Jimerson et al., 2016). First, the tests are not designed to be administered frequently. Second, achievement tests are a general assessment across a number of academic areas that may not map onto specific educational goals that teachers are targeting. Thus, achievement assessments are only loosely related to performance on specific academic skills and the instruction going on in one's school. For these reasons, we suggest using CBM fluency measures and district norms to assess student performance on an ongoing basis in regular education settings. For more information on academic skills, refer to Chap. 55.

Performance Criteria with College Students

A number of studies have examined how altering performance criteria with college students affects student learning, generalization, and response maintenance. One of the first studies was conducted by Johnston and O'Neill (1973). The experiment was conducted within the context of Keller's Personalized System of Instruction (PSI; Keller, 1968), which includes weekly units composed of learning materials (e.g., readings) and terminal quizzes. In his original conception, Keller (1968) required 100% accuracy on a terminal quiz in order to move from one unit to the next. Thus, PSI is "mastery" based and progression through a PSI course requires meeting criteria during a particular unit. Johnston and O'Neill (1973) examined the effects of different performance criteria assigned to the unit quizzes. Students experienced different criterion levels (low, medium, and high, defined specifically as a rate of correct responding on unit quizzes, with a minimum rate of correct and a maximum rate of incorrect). The researcher found, not surprisingly, that student performance changed as a function of the minimum criterion. That is, when the criterion was high, students performed better than when the criterion was low, revealing a positive linear relationship between criterion and performance.

After the publication of Johnston and O'Neill's (1973), two additional studies examined criterion effects, also within a PSI context. Semb (1974) extended this area of research by examining low and high criteria for short and long assignments. In Semb's study, participants completed four units, all with quizzes, and a cumulative "review" exam that covered content across the four units. There were three experimental conditions: 100% criterion applied to each unit quiz (short assignment, high criterion), 60% criterion applied to each unit quiz (short assignment, low criterion), and 100% criterion only applied to the cumulative exam (long assignment, high criterion). Semb found that students in the short assignment, high criterion condition performed at a much higher level than peers in other conditions, suggesting the strength of breaking learning into small chunks and requiring 100% performance criteria to move from one unit to the next. This four-unit structure extended across the semester, repeating itself a few times. In this study, short assignments were individual units and mastery of each unit was required to move on to the next. There were two variations of short assignments, one which required 100% performance on each unit quiz and the review exam in order to progress through the course, and another which required 60% performance on each unit quiz and the review exam to progress. Semb also reported on response generalization and maintenance as some questions from the unit quizzes were replicated on the cumulative exams or modified. Again, participants in the short assignment, high criterion condition fared the best on generalization and maintenance questions.

Carlson and Minke (1975) further extended this area by examining different criterion levels, specifically 80% and 90% criterion levels. The authors observed that students repeatedly re-took unit quizzes following failure and this sometimes led to withdrawal from courses. Carlson and Minke compared 80% and 90% criterion levels to an ascending criterion that began with a low criterion (60%) and the criterion *ascended* every few units until the criterion was 90% near the end of the semester. Overall, the researchers found that students in the 80% criterion condition scored the highest grades in the class and passed a higher number of quizzes. Students in the 90% criterion condition did well, but less well than students in the 80% and ascending criterion conditions in terms of how many units the students completed. This study questioned the specific criterion requirements for college students completing PSI, but nonetheless demonstrated the need for relatively high-performance criteria.

More recently, this phenomenon was examined with a new type of performance: derived relations. Derived relations (see Sidman, 1994; Rehfeldt, 2011; Brodsky & Fienup, 2018), or inference making, begins with teaching overlapping conditional relations that result in multiple types of inferences, such as bi-directional relations (symmetry, if A goes with B, then B goes with A) and novel associations (equivalence, if A goes with B and A goes with C, then B and C go together). Fienup and Brodsky (2017) conducted an evaluation of this paradigm and studied how performance criteria during training affected the emergence of symmetry and equivalence relations. College students learned neuroanatomy classes that included the names of brain structures (A stimuli, e.g., Amygdala), a picture of the structure (B stimuli), a statement about the function of that structure (C stimuli), and a statement about the result of damage to that structure (D stimuli). Teaching involved conditionally relating the A stimuli to the B, C, and D stimuli in consecutive phases. There were three performance criterion conditions. In the first condition, during each conditional relation, there were blocks of 12 trials and the criterion was 100% during a single block of trials. In the second condition, trials were repeatedly administered until a participant responded correctly to 12 consecutive trials. Both of these conditions constituted "stringent" criterion conditions. The third condition was the less stringent condition and required a participant to respond correctly to six consecutive trials. Fienup and Brodsky evaluated the performance criteria by examining tests of symmetry and equivalence and found that only stringent criteria reliably produced inferences, regardless of whether the criterion was evaluated in blocks or consecutive trials.

Collectively and across different measures, the research suggests that college students learn more and retain the information longer when high levels of performance criteria are applied to skill acquisition. This has been found across fluency (Johnston & O'Neill, 1973) and percentage correct (e.g., Semb, 1974) measures of performance. This includes a broad array of outcomes, such as initial performance (Johnston & O'Neill, 1973; Semb, 1974), generalization (Semb, 1974), response maintenance (Semb, 1974), and inferences (Fienup & Brodsky, 2017).

Performance Criteria in Sports

The evaluation of skill acquisition is fundamental in behavioral analytic research in sports performance (see Chap. 47). Evidence-based practices in behavioral sport psychology began in the late 1960s and early 1970s with the implementations of reinforcement contingencies (Rushall & Pettinger, 1969), self-monitoring tactics (Rushall & Siedentop, 1972), and behavioral assessments (McKenzie & Rushall, 1974) in sport settings. Since then, the body of research on behavioral interventions within the athletic industry remains relatively small. The results of the research that exist suggest that behavior analytic procedures are beneficial in improving performance in a variety of different sports such as football, gymnastics, tennis, figure skating, soccer, and golf (Barker et al., 2020).

The interventions used in sport-related performances rarely implement singular components. Instead, several strategies or components are typically combined into a treatment package. As the body of research continues to grow, it is important to evaluate each individual component, and the performance criterion is an important one. Martin and Thomson (2011) outline several stages of mastery based on the instructional hierarchy model within behavioral sport psychology. Under this model, an individual begins at the acquisition phase, in which the target skill is learned and performed in response to key discriminative stimuli. As soon as an individual acquires the target skill, the next stage of mastery is focused on fluency. Speed and accuracy are essential during this stage (Binder, 1996; Martin & Thomson, 2011). That is, the individual performs complex behavioral chains so accurately and fluently that an observer may characterize the performance as effortless and automatic. The acquisition and fluency of an acquired skill under practice conditions must extend to more naturalistic settings during the maintenance stage of sports mastery. Target behaviors are under different discriminative stimuli that resemble game-like conditions. This eventually extends to the generalization and adaptation of the skill, in which the individual performs the target behaviors under completely novel conditions and is capable of responding to complex and changing situations.

The complex nature of mastery in sports performance suggests the need for precise criteria to address acquisition, fluency, maintenance, and generalization. Behavioral researchers who implement interventions for enhancing sports performance typically apply performance criteria in three forms, percentage of accurate responses, number of accurate responses in succession, and rate of accurate responses. However, it is worth to note that reports of performance criteria are often missing from the published studies that were reviewed.

Level-based performance criteria combined with a particular frequency of observations component were applied and reported in a variety of different behavioral interventions including behavioral coaching packages, goal setting, oral feedback, and public posting (Brobst & Ward, 2002; Stokes et al., 2010; Tai & Miltenberger, 2017; Ward & Carnes, 2002). The instructors all established a percentage of 90% or 100% acquisition criteria. The rationale for the particular level of performance criteria that was established varied between studies. Some instructors justified their level of performance criteria to be adequate based on precedents set by existing literature on the same sport and on their personal expertise of the sport (Brobst & Ward, 2002), while other instructors allowed their participants to establish their own personal performance criteria (Ward & Carnes, 2002).

Another dimension of performance criteria utilized in behavioral sports research is the number of correct consecutive responses. An intervention package called teaching with acoustic guidance (TAGTeach) was implemented with an adult novice golfer who learned a series of target skill sets that comprise the full golf swing (Fogel et al., 2010). Each skill set consisted of small component skills. During the intervention, the introduction of each component skill was contingent on the participant's emission of six independently correct responses to the previous skill in the chain. Assessment of maintenance responding was conducted following the sixth session of the intervention. The researchers also assessed for the generalization of skills to a different golf club. Similarly, a chaining-mastery procedure was implemented with little league baseball players (Simek & O'Brien, 1988). Each task of the chain had a predetermined criterion of a number of consecutive correct responses or a certain number of correct responses out of the total number of opportunities given.

Fluency criteria have also been applied to interventions within behavioral sports research. Pocock et al. (2010) targeted two roller skating skills by implementing a precision teaching methodology (Lindsley, 1971). Because precision teaching emphasizes fluent behavior, the researchers applied a criterion that targeted the rate of responding. The criterion was established based on the behaviors of a model exemplar who was not included in the study.

A limitation of performance criteria in behavioral sports research is that some movements are fluid and require precise body movements and positioning (e.g., gymnastics). A standard criterion that is typically used in say, academics may not be as viable with sports because near flawless performance (90–100% accuracy) may be difficult to achieve for even the most elite athletes. Establishing a performance criterion of 90% or 100% accuracy may also be problematic because participants have reported feeling emotionally distressed when their performance criteria were not achieved (Brobst & Ward, 2002). It is important to consider alternative means of signaling the termination of intervention, including the establishment of more modest levels of performance criteria dependent on the participant's skill levels or criterion that is based on a percentage of improvement from previous performances.

Performance Criteria in Organizational Behavior Management (OBM)

Organizational behavior management (OBM) is an approach that applies behavioral principles to increase the effectiveness and efficiency of workers in organizational settings within a wide range of disciplines such as government, industry, business, and human service. There is an emphasis on the implementation of practical interventions to change behavior. Like treatments in ABA research, OBM interventions have predetermined performance criteria to signal the termination of an experimental condition. Some widely used strategies in the human service sector include checklists, providing feedback, trainings or workshops, applying self-monitoring techniques, goal setting, and rewards (VanStelle et al., 2012). These strategies have the aim of improving the accuracy of treatment implementation (procedural integrity) and staff performance.

Many OBM studies related to human service published between 2010 and 2016 in JABA and BAP utilize a percentage of correct responses to signal the termination of an intervention or treatment (Gravina et al., 2018). The following studies applied an 80%, 90%, or 100% accuracy criterion across single or multiple sessions.

Casey and McWilliam (2011) implemented a checklist-based training procedure to help teachers and staff decrease student transition times within a classroom setting. The training was stopped if the staff members performed at least 80% of the checklist task most of the time for three consecutive sessions. In this study, the experimenters also conducted maintenance probes following the end of the training. Ditzian et al. (2015) also applied an 80% accuracy criterion for their feedback-based intervention to improve proper door closing of therapy rooms. The experimenters determined that 80% accuracy across two consecutive sessions was appropriate to stop the intervention. Graff and Karsten (2012) implemented an instructional package that included enhanced written instructions and written instructions with data sheet to increase the accuracy implementation of stimulus preference assessments for simulated consumers. The performance criterion was 90% accuracy across two consecutive sessions. The experimenters also conducted generalization probes with real consumers. Lambert et al. (2013) trained staff at a community residential facility to conduct trial-based functional analyses. In order for the training to conclude, the staff members were required to implement all trial types with 100% accuracy. Nabeyama and Sturmey (2010) also applied a 100% correct response to all target actions during a behavioral skills training program for staff. Additionally, the experimenters established an additional criterion for intervention enhancement if the staff members that included increased opportunities for training and rehearsing. The instructor also included modeling correct responses. These extra components were implemented if the staff members performed less than six target components correctly within the first two sessions of the intervention.

For interventions that target treatment fidelity, the research in OBM shows that a criterion of 80% or more is necessary before the training should be concluded. However, it is important to evaluate which percentage level is appropriate for different types of target skills. For example, interventions that target client safety should have a performance criterion of no less than 100% accuracy because client well-being and safety are at stake. In addition to the utilization of a percentage of accuracy for performance criterion, the number of sessions where performance is observed at a certain level is another aspect of the criterion. Typically, the number of observations range from one session to three consecutive sessions with an accurate performance at a certain percentage. Studies in OBM research also assess for response maintenance or generalization of the target skill across settings or people (Casey & McWilliam, 2011; Graff & Karsten, 2012; Nabeyama & Sturmey, 2010; Nigro-Bruzzi & Sturmey, 2010; Parsons et al., 2012). Response maintenance and generalization are crucial in the discussion of mastery.

A Model for Establishing Performance Criteria

A model for selecting performance criteria requires nuance and consideration of the learning context, educational goals, and type of learner. In some cases, the literature supports a specific model and in other cases, additional research is needed before clear, research-based suggestions can be made. When working with school-aged children in regular education settings, performance can be assessed using frequent curriculum-based assessments of fluency (e.g., reading, math, writing). Comparing an individual child's fluency to district or national norms should indicate to the teacher the child's current proficiency given the instruction and instructional modifications can be made as necessary (Cummings & Petscher, 2016). With college students, there is compelling evidence that performance criteria drive performance and, thus, performance criteria should be set as high as experts believe is necessary. In any given college class, this could involve setting performance criteria at a value such as 80% accuracy or 100% accuracy and providing additional instruction until the performance criterion is met.

Skill Acquisition for Learners with Disabilities

Much of ABA is conducted with young children with disabilities who require intensive, deliberate, and individualized instruction. At this point, there is too little research to suggest specific performance criteria guidelines with the exception that acquisition criteria should be set high (e.g., a high level of accuracy). Beyond establishing high levels of performance, the specific component of performance criteria should be individualized, just as the specific learning objectives are individualized. Indeed, this same approach has been argued for selecting other instructional components such as prompts (Seaver & Bourret, 2014; Cengher et al., 2016; Cengher et al., 2018; Schnell et al., 2020) and error correction procedures (Carroll et al., 2018). The impetus for individualized assessments is the fact that when comparing different instructional components, it is often the case the effects are idiosyncratic: no specific component that works best for all learners, but often there are components that are reliably better for a single learner. While the performance criterion data published thus far show consistency in terms of the need for high acquisition criteria (e.g., Richling et al., 2019), the research has been conducted with a narrow range of children and response types (e.g., tacts and sight words). A deeper understanding of learner characteristics and response characteristics will undoubtedly bring nuance to our understanding of how to tailor performance criteria. While we await such data, a framework for assessing learner-specific criteria is useful.

Determining Goals of Instruction

Prior to directly comparing performance criteria, one should begin by asking questions to help guide their own analysis. The first question is, "What are the goals of teaching?" Answers range from generalized responses that are not affected by context, teacher, or specific stimuli to durable responses that maintain over time after instruction has ceased. Answering this question sets up one's dependent variables. For example, if one is interested in promoting durable responses that maintain for at least a month, the appropriate dependent variable—or performance outcome variable from an analysis—to study. If one is interested in both response maintenance and generalization, then one should measure both.

Level of Performance for Specific Behaviors

After determining the desired effect of one's teaching, one should ask "What are acceptable levels of behavior?" There is not necessarily an agreed upon standard for what is an acceptable level of behavior and consensus may vary as a function of the skill being taught. For example, when teaching a child to tact colors, 100% performance may not be necessary; however, if teaching a child to look both ways before crossing a street, any performance level below 100% may be wholly unacceptable due to dangerous outcomes. Another manner of developing appropriate performance criteria is through social validation (Van Houten, 1979). In this approach, intervention targets are developed based on normative sample data or by observing competent individuals. For example, if one is trying to teach toy play to infants at risk for delayed motor development, social validation may involve defining what constitutes toy play for an infant and collecting data on the duration of toy play with several typically developing infants to derive an intervention goal for the infant you are working with. Social validation focuses on appropriate levels of behavior, rather than trying to fit behavior on a scale of percentage correct out of 10 opportunities.

An Experimental Approach to Establishing Individualized Performance Criteria (Approach 1 of 2)

Once a clinician has determined the goal and acceptable performance, she has a refined dependent variable—or outcomes variable. This is now the benchmark by which to compare the effects of different performance criteria. All that is left to do are some minor experimental preparations followed by a comparison of teaching responses to predetermined performance criteria and examining which produces the intended outcomes. To experimentally establish performance criteria, one must teach independent, but equally different targets. Cariveau et al. (2020) provide guidance on this process, but the basics are controlling for effort and difficulty. For instance, if your client is learning sight words, one would select two sets of sight words that are from the same grade level and have the same number of syllables and letters. By equating targets, one is in a better position to attribute the effects of the performance criteria to the criteria you implemented, and not that the sets of stimuli are simply more or less difficult. In the same vein, one should teach using the same procedures (e.g., using or not using error correction, prompt fading, etc.), regardless of performance criterion. After one sets up two or more conditions that should produce the same learning, they can assign one performance criterion to one set of stimuli and one to another set of stimuli and begin teaching. After the client's behavior meets the acquisition performance criterion, the therapist now tests for other relevant performances, such as response generalization and response maintenance. Performance of the behavior under different conditions (generalization) and after teaching has been terminated (maintenance) now serves as the indicator of which acquisition performance criterion produces the intended effects. If one acquisition performance criterion produces the intended effects, but the other does not, then the answer of which is more appropriate is clear. In the case where both performance criteria produce the intended effect, then the therapist should look back at the acquisition data and if one condition produced the quicker acquisition, then that should be the performance criterion moving forward. If both performance criteria fail to produce the intended generalization and maintenance effects, then the therapist should look to strengthen the performance criteria (higher level of performance, higher frequency component, across more instructors) or examine whether there are more effective teaching tactics.

A Naturalistic Approach to Establishing Performance Criteria (Approach 2 of 2)

Some therapists may not have the resources to conduct individualized evaluations. In this case, a more naturalistic evaluation is appropriate, although this comes with less confidence in the outcomes. In this case, the therapist should establish an acquisition criterion that appears reasonable based on the goals of instruction (e.g., 90–100% accuracy across two consecutive observations). Next, the therapist should establish acceptable generalization and maintenance performance criteria. From this point, the therapist simply teaches new behavior as she normally does until the acquisition criterion is met and then tests to see if the generalization and maintenance criteria are also met. If the generalization and maintenance criteria are met, this provides preliminary evidence that the acquisition criterion is sufficient to produce all of the intended effects of instruction. If the criteria are not met; however, the therapist should change the acquisition criterion in specific ways to produce better outcomes. For example, if the maintenance criterion is not met, consider a higher level of performance for the acquisition criterion and consider applying the criterion across a greater number of sessions or across multiple days (e.g., first-session of the day). If the generalization criterion is not met, consider adding a component that the acquisition criterion must be met across two or more instructors or two or more sets of stimuli (see Chap. 15).

Future Directions and Concluding Remarks

This chapter outlined some of the historical and contemporary treatments of performance criteria, highlighted related terminological issues, outlined a variety of areas of research utilizing performance criteria, and provided a potential model for selecting performance criteria for individual clinical use. As mentioned in the introduction of this chapter, many of the recommendations made here are speculative and constitute best practices based on scientific deduction and clinical recommendations. However, there is a need for further research evaluating performance criteria as independent variables which function in coordination with other training procedures and may directly impact response maintenance and other learning outcomes. Without a solid evidence base from which we can derive distinct rules regarding which performance criteria to use universally, we must be mindful to not fall victim to engaging in clinical lore practices. Instead, we can mitigate some of this risk by intentionally engaging in critical consideration of performance criteria on a case-by-case basis. In addition, we can supplement our confidence by engaging in individual assessment of the impact of specific performance criteria and directly measure-related learning outcomes using rigorous single-case designs (see Chap. 20) rather than adopting train-and-hope strategies.

Evaluating Physical Activity Levels

23

Carole M. Van Camp, Casey Irwin Helvey, and Wendy Donlin Washington

Introduction

Physical activity (PA) includes "body movements produced by skeletal muscles that result in energy expenditure" and may include light, moderate, and vigorous intensities; exercise is PA that is designed specifically to enhance health and physical fitness (p. c-3, Physical Activity Guidelines Advisory Committee [PAGAC], 2018). Engaging in moderate-to-vigorous physical activity (MVPA) is associated with weight loss and reduced risk of obesity in all age groups, as well as decreased risk of dementia, cancers, heart disease, and diabetes in adults, and improved attention and academic performance in children. Research also shows improved sleep and mental well-being as immediate effects of PA in adults. In addition, decreases in sedentary behavior (i.e., waking behavior such as sitting and lying), even if just to engage in light activity, also reduce mortality, type 2 diabetes, and certain types of cancer (PAGAC, 2018). There have also been calls for physicians to prescribe exercise and physical activity as medical treatment to treat muscular pain, anxiety, stress, and cardiovascular, metabolic, pulmonary, and neurological diseases (Pedersen & Saltin, 2015). The World Health Organization (WHO, 2018) estimates that physical inactivity can account for up to 3% of national health care costs, with total indirect and direct costs exceeding INT$ 68 billion per year.

The PAGAC report summarizes research on the specific types of PA that produces physical and mental health benefits and provides PA recommendations echoed by the Centers for Disease Control (CDC, 2020b) and is consistent with those of the World Health Organization (WHO, 2020a). School-aged children should engage in 60 min. of MVPA per day, including vigorous activity and bone- and muscle-strengthening activities three times per week. Adults should engage in 150–300 min of MVPA per week, or 75–150 min of vigorous PA, including 2 days a week of muscle strengthening. Adults older than 64 years should additionally include activities to improve balance. These recommendations should also be followed by children and adults with disabilities to the extent that they are able. It should be noted that although the recommendations target MVPA specifically, any PA over sedentary behavior is beneficial, and bouts of MVPA of any length are beneficial (PAGAC, 2018).

Minimizing the duration of inactivity and sitting may even be as important as meeting PA minimum guidelines. Engaging in long durations of this sedentary behavior (e.g., sitting at a computer, watching television) may attenuate the benefits of PA. Pandey et al. (2016) performed a meta-analysis

examining the relationship between sedentary time and cardiovascular disease risk and mortality. The nine studies included 720,425 participants and revealed a sedentary "dose-effect" relationship to cardiovascular risks. Those who were sedentary for at least a threshold of 10 h per day had higher risks that were not completely mitigated by the duration of PA levels. In a separate meta-analysis including 1,005,791 individuals, Ekelund et al. (2016) found that television viewing durations interacted with PA levels for all-cause mortality. Watching television for more than 5 h a day increased the risk of all-cause mortality in the most active individuals by 16% and in the least active individuals by 100%.

Many individuals would benefit from physical activity interventions, whether due to sedentary behavior, pre-existing medical conditions, or a failure to engage in recommended levels of PA. The WHO (2018) estimates that 23% of adults and 81% of adolescents fail to meet their global recommendations for physical activity. The prevalence of inactivity varies by global region, with the lowest levels of sedentary behavior in Southeast Asia, and the highest levels in Europe, North America, South America, the Eastern Mediterranean, and the Western Pacific Regions. In 2018, 54% of US adults engaged in minimum aerobic activity guidelines, with an increase of 0.9% per year since 2008. Though the increasing trend is encouraging, a quarter of US adults (25.4%) live sedentary lives, and most individuals (72%) do not engage in recommended muscle-strengthening exercises (CDC, 2019b). The WHO has set a goal to reduce the prevalence of physical activity by at least 10% by 2025, and 15% by 2030. However, the global pandemic in 2020 has likely interrupted progress in addressing physical inactivity globally due to social restrictions.

Closely associated with levels of physical activity is obesity. Obesity is typically defined by body mass index (BMI) calculations, see Eq. (23.1) (CDC, 2020a).

$$\mathrm{MI} = \mathrm{Weight}(\mathrm{kg}) / \left[\mathrm{Height}(\mathrm{m})\right]^2 \quad (23.1)$$

This equation is used for both adults and children. For adults, obesity is indicated by a BMI of 30 or more, and the category of overweight includes BMI ≥25 and < 30. Adult athletes may have high BMIs that do not indicate obesity due to a higher proportion of muscle than non-athletes. For children aged 2–19, BMI levels categorized as obese are dependent on age and gender norms; having a BMI in the 95th percentile for age and gender group would indicate obesity (CDC, 2020a). Globally, it is estimated that 13% of adults are obese, and 39% are overweight (WHO, 2020b). Rates of childhood overweight and obesity are lower, but are still alarming, with 18% of children aged 5–19 considered overweight, and 6% (girls) to 8% (boys) aged considered obese (WHO, 2020b). The United States has even higher rates of obesity in adults (<42%) and children (<18%) according to the CDC (2020a). Individuals with disabilities are experiencing even higher rates of obesity: 22% of children between 2 and 17 years with a disability are obese (CDC, 2010); whereas 30% of children with autism spectrum disorder (ASD) specifically are obese, which can be attributed (at least partially) to significantly lower levels of engagement in PA by children with ASD (Srinivasan et al., 2014). In addition, 36% of adults with a disability are obese (CDC, 2010). Impaired motor skills may account for the low levels of PA that are often observed among this population. Social and behavioral challenges may also limit the types of activities that are available or preferred, and a lack of adequate recreational and/or familial resources to support sustained PA has been commonly cited (Bremer et al., 2016; Hallett, 2019; Sorensen & Zarrett, 2014; Srinivasan et al., 2014).

Research in applied behavior analysis has focused on aerobic PA, which targets cardiovascular fitness. This chapter will review the behavioral literature on the direct and indirect measures of PA, assessments to determine environmental events associated with increased PA in children, and interventions to increase PA in typically developing adults and children, as well as those with developmental and intellectual disabilities.

Defining and Measuring Physical Activity

The PAGAC 2018 guidelines highlight the importance of distinguishing between light, moderate, and vigorous PA (LPA, MPA, and VPA, respectively). Examples of activities representative of MPA and VPA are based on absolute intensity (which does not consider the individual's cardiorespiratory fitness), including brisk walking as moderate physical activities (MPA), and running and playing soccer as vigorous physical activities (VPA). The guidelines also describe a subjective scale, based on self-perceived heart rate (HR) and breathing difficulty, that may be used to evaluate the relative intensity of activities, which do take into account an individual's cardiorespiratory fitness when assessing effort. However, some activities listed as MPA based on absolute intensity may be considered VPA depending on the individual's fitness and level of effort. Given that even adults underestimate the effort necessary to engage in MVPA (Canning et al., 2014), more precise and objective measures of PA have been used in the literature.

Screening Measures

It is important to make sure that individuals are healthy enough to engage in PA when they join research or treatment interventions. Researchers can require medical clearance or use validated screening tools. For adults, one common screening measure for typical adult populations is the Physical Activity Readiness Questionnaire (PAR-Q; Hafen & Hoeger, 1994). This questionnaire asks for self-reporting of diagnosed heart trouble, feeling chest pains, fainting and dizziness, high blood pressure, joint problems, and age. There is also a question about "other" reasons they should not engage in PA. Reporting any conditions that indicate a higher risk for adverse outcomes requires that medical clearance be obtained to participate. For added safety, screening patients with the Health Status Questionnaire (HSQ; Radosevich et al., 1994) for cardiovascular risk may also be advisable. For older populations, or sustained high-intensity physical activity, the requirement of medical clearance minimizes risk. Such screening measures are less frequently used with children, although some studies have utilized a modified version of the PAR-Q (e.g., Van Camp et al., 2021)

Pedometers

Mechanical devices, such as pedometers, accelerometers, and heart rate monitors, have been utilized as indirect measures of physical activity (Van Camp & Hayes, 2012). Pedometers are typically worn at the waist to measure steps using a pendulum mechanism. Steps are important dependent variables because walking is the safest and most common form of exercise, available to most individuals without the need for specialized exercise equipment or settings (PAGAC, 2018). Behavior studies have targeted day-long steps (steps per day; e.g., Kuhl et al., 2015; Donlin Washington et al., 2014) or steps taken during individual assessment or intervention sessions (often reported as steps per minute [SPM] and sometimes referred to as cadence; e.g., Hayes & Van Camp, 2015; Miller et al., 2018; Tudor-Locke et al., 2011b). It is recommended that adults take at least 10,000 steps per day (Tudor-Locke et al., 2011b). To achieve the recommended time engaged in MPA or VPA specifically, adults may consider measuring SPM, with 100 SPM indicative of MPA and 130 SPM indicative of VPA (O'Brien et al., 2018). In elementary school-aged children, 60 minutes of MVPA is achieved with 13,000–15,000 and 11,000–12,000 steps per day in boys and girls, respectively (Tudor-Locke et al., 2011a). In adolescents, the threshold is 10,000–11,700 steps per day regardless of gender. Specifically, 60–99 SPM is indicative of slow or medium walking (LPA), 100–119 SPM is indicative of brisk walking (MPA), and over 120 SPM is indicative of fast walking (VPA; Barreira et al., 2012; Migueles et al., 2020). These SPM thresholds may be useful in determining whether interventions are increasing MPA or VPA specifically; however, most pedometers do not have a time-stamped memory feature and thus do not allow for a fine-grained analysis of min-by-min steps.

Accelerometers

A recent increase in readily available and low-cost accelerometers to measure PA, such as the

Fitbit, has led to more refined research (see Coughlin & Stewart, 2016 for a review). Several variations have been used in behavioral research, from the first clip-on versions (e.g., Van Camp & Hayes, 2017) to wrist-based devices (e.g., Evans et al., 2017). The most common dependent variable remains steps, although newer models worn at the wrist also measure HR. A benefit of Fitbit is the memory feature, and accompanying website, from which min-by-min step data may be extracted via API researcher access (https://dev.fitbit.com/). For devices that record steps in short intervals like this, it is possible to measure and target specific patterns of movement. Though total daily step counts are useful targets for behavior, there are many different patterns of walking that could lead to equivalent step counts. For example, one might walk 7000 steps in a day by having one long "bout" of running with sedentary behavior the rest of the day, or by having low-intensity levels of movement dispersed throughout the day. Employing measurement that more specifically characterizes patterns in movement can help with balancing the PA recommendations for MVPA and minimizing sedentary behavior. Donlin Washington and colleagues (2014) describe the use of a bout-analysis to characterize the rate of initiation, within-bout responding, and the duration of pauses between bouts of walking. For each minute of the day, they calculated average interresponse times for each step. Additionally, they examined how many minutes per day included steps, the average duration of temporally adjacent intervals that contained steps, and the duration of temporally adjacent intervals that contained no steps (pauses). With a slightly different approach, Tudor-Locke et al. (2011b) characterized cadence, or SPM, walked throughout the day for 3744 healthy adults. They found that on average, adults only spend about 7 min moving at a pace that would at least be considered moderate physical activity (100+ steps per minute). These two approaches can be used to target specific patterns of movement that could be tailored to individual treatment plans. Some individuals may need to increase minutes of MVPA, which would require engaging in more minutes per day with a cadence of at least 100 steps per minute. Other individuals may need to reduce the duration of sedentary behavior, so treatment could address reducing the number of consecutive minutes with no steps. These approaches could inform the gradual shaping of treatment goals by avoiding unattainable or aversive targets, minimizing treatment disengagement.

Heart Rate Monitors

Although activity intensity may be estimated via SPM, beneficial physiological change cannot be assessed directly via pedometers. Energy expenditure from PA may be estimated by measuring HR (Armstrong & Welsman, 2006), using chest-strap monitors that transmit HR data in beats per minute (BPM) to a watch, computer, or phone (e.g., Polar HR monitors). HR may be affected by transient factors (e.g. an individual's emotional state, state of hydration) and climatic conditions (e.g., temperature and humidity; Armstrong, 1998), as well as genetic factors, such as gender, sex, and race (Sarzynski et al., 2013); however, these influences on HR are of much lower magnitude compared to changes associated with PA (Epstein et al., 2001), and in particular they are less likely to affect HR at moderate or vigorous levels (Armstrong 1998). A benefit of HR is that it is sensitive, capable of identifying small changes in activity (Sirard & Pate, 2001), and can detect changes from sedentary to light PA (Van Camp et al., 2021).

HR may also be used to determine the percentage of a session or a day in which an individual's HR reaches MPA or VPA thresholds. The CDC (2020) suggests that the target HR indicative of MPA and VPA is 65% and 76% of maximum HR based on age-based formulas (e.g., Tanaka et al., 2001). However, studies comparing expected HR to actual HR during exercise tests have found significant discrepancies, especially in children (Nikolaidis, 2014). Behavioral assessments of HR while children are engaged in behaviors typically considered LPA, MPA, and VPA have also found significant individual differences in the HRs (Larson et al., 2011; Van

Camp & Berth, 2018; Van Camp et al., 2021, 2022). This variability may be due to individual fitness levels, which are known to affect HR (Piercy et al., 2018); as such, fixed HR thresholds intended to indicate MPA and VPA may not be appropriate for all individuals. Researchers have recommended that formulas be abandoned in favor of individualized evaluations of exercise effort (Arena et al., 2016).

To date, three behavioral studies have evaluated an individualized HR assessment (IHRA) to identify MPA and VPA HR zones in children (Eckard et al., 2019; Van Camp et al., 2021, 2022). The IHRA consisted of participants engaging in different behaviors representative of four levels of activity: being still (sedentary), walking slowly (light PA), walking briskly (MPA), and jogging (VPA; Van Camp et al., 2021, 2022). HR measures were recorded every second, and each activity continued for 2 min. HR typically stabilized within-session during the last 30 s, and average HRs were consistent across repeated sessions. HR levels were differentiated within participants across activities, with running producing the highest average HRs followed by walking briskly, walking slowly, and sitting. However, absolute HRs were variable across participants, and when compared to standardized criteria, not all activities generated HRs within expected ranges (Van Camp et al., 2021, 2022). These individual differences are consistent with research that measured HR while children engaged in specified activities (Eckard et al., 2019; Larson et al., 2011; Van Camp et al., 2018), and with the CDC guidelines that indicate relative and absolute intensity may differ, as only the former accounts for fitness level. Genetic factors (e.g., sex, race, and maturation) also may have contributed to the individual differences, providing justification for conducting IHRAs rather than using standard criteria. These results suggest that even when engaged in behaviorally similar activities there exist individual differences in the physiological effects of those activities (i.e., HR), which may be due to differential exertion levels and physical fitness. Thus, when using HR as a measure of MPA or VPA, it may be prudent to use individual HR assessments.

Direct Observation

Direct observations of PA can produce quantitative and qualitative data. Although some studies focus on large muscle movement (e.g., Fogel et al., 2010; Shayne et al., 2012), most use the Observational System for Recording Activity in Children Preschool (OSRAC-P, Brown et al., 2006), which is based on the Children's Activity Rating Scales (CARS; Puhl et al., 1990). The OSRAC is used to code the topography of PA, as well as detailed indoor and outdoor social and nonsocial contextual information; however, the activity levels are used most often. Both OSRAC and CARS utilize a five-level system to code the intensity of PA: level 1, stationary-no-movement (e.g., standing, sitting); level 2, stationary with limb or trunk movement (e.g., holding a moderately heavy object, hanging off of bars); level 3, slow-easy movement (e.g., slow and easy cycling, walking); level 4, moderate movement (e.g., walking uphill, climbing on monkey bars); and level 5, fast movements (e.g., running, translocation across monkey bars with hands while hanging). The original OSRAC studies utilized momentary time sampling for recording behaviors at each of the five levels, but recent research has codes every second from videotapes and has combined levels 4 and 5 as the primary measure of MVPA (e.g., Larson et al., 2013; Zerger et al., 2016).

Reliability and Validity

An important consideration with both observational and mechanical measures of PA is assessments of reliability and validity. Studies utilizing the OSRAC measured reliability by having two observers simultaneously but independently observe the same session, and comparing their data (e.g., Larson et al., 2013). Some report that reliability is better when data are collected only on the presence or absence of MPVA (levels 4 and 5 combined; Hustyi et al., 2011); however, this precludes one from evaluating changes from sedentary to LPA, and it does not allow one to separate MPA from VPA.

The validity of the OSRAC activity levels has been assessed by evaluating whether HR covaries with activities at each of the five levels. In one study, children walked on a treadmill at various speeds and inclines (Puhl et al., 1990), and in two others, children engaged in example activities listed on the OSRAC (Larson et al., 2011; Van Camp & Berth, 2018). In the original CARS study (Puhl et al., 1990), observation codes (levels 1 through 5) were calibrated by having 25 preschool children engage in activities (controlled walking indoors on a treadmill at various speeds and inclines) while HR was measured. On average, the children's HRs did reach the expected ranges for each of the five activity levels: level 1, below 100 BPM; level 2, 100–119 BPM; level 3, 120–139 BPM; level 4, 140–160 BPM; and level 5 > 160 BPM. However, treadmill activities were more structured than those typically evaluated by the OSRAC (e.g., playing outdoors). When assessed under naturalistic conditions (i.e., while children are playing outside on a playground), activities listed in the OSRAC may not result in expected HR ranges, and individual differences are common (Larson et al., 2011; Van Camp & Berth, 2018). Both studies instructed typically developing children to engage in activities across the five levels while measuring HR and steps. Larson et al. evaluated one bipedal activity per levels 2 through 5 (e.g., walking, jogging; 2011), and Van Camp and Berth (2018) included similar bipedal activities, plus additional activities (e.g., swinging on monkey bars, biking). HR systematically increased across each intensity; however, there were individual differences in HRs associated with each activity, and in some cases, the HRs measured did not match the expected HRs for those activities. For example, level 4 activities led to HRs within levels 3, 4, and 5 ranges across participants, suggesting that despite engaging in similar behaviors, HRs reflected light, moderate, and vigorous levels depending on the individual (Van Camp & Berth, 2018). Though certain behaviors may topographically meet the definition of MVPA, HRs may not meet MVPA levels unless sustained for 30 or 60 seconds. Studies evaluating HRs during activities such as walking briskly and jogging may not reach MVPA levels until 60 s (Eckard et al., 2019; Van Camp et al., 2021, 2022).

The reliability of PA measures recorded via pedometers and accelerometers has been assessed primarily by evaluating interobserver agreement on the number of steps displayed on the device (e.g., Nieto & Wiskow, 2020; Zerger et al., 2017). Devices may be selected based on validity assessments in previous research (e.g., pedometers used in Larson et al., 2011), or be verified by a step test, in which a researcher takes a certain number of steps to verify that the devices register the correct number of steps (e.g., a 50-step test in Kuhl et al., 2015). However, few studies do assess reliability during the course of the study (inter-device reliability). This may be assessed by having an individual wear two devices simultaneously while engaged in PA (e.g., Hayes & Van Camp, 2015; Van Camp & Berth, 2018; Van Camp & Hayes, 2017). Depending on the specific activity, pedometers and accelerometers are not reliable (Van Camp & Berth, 2018). Validity has also been assessed by comparing steps to HR (e.g., Larson et al., 2011; Van Camp & Berth, 2018). Although in general steps and HR covary, discrepancies exist when no steps occur. For example, when children play on monkey bars, HRs increase but neither pedometers nor accelerometers reliably register steps.

When individuals use fixed equipment or bikes (i.e., activities other than those involving walking, jogging, running, or jumping), it is important to determine whether the devices measure steps in the situations specific to that study, even if the devices have been shown reliable and valid in other research. In addition, new Fitbits worn at the wrist can detect HR; however, it is not clear if they are as reliable and valid as chest-based measures of HR. An assessment of inter-device reliability may not assure the validity of the devices, but it may at least identify instances when low reliability deems the devices invalid. Finally, few studies have utilized multiple measures of PA during interventions (for a notable exception, see Hustyi et al. (2011), who measured both SPM and observed OSRAC levels). Given the limitations of certain measures as noted above, future research is needed to verify if PA measured in assessments and interventions are similar regardless of the measure used.

Assessment of Physical Activity in Children

Behavioral assessment of PA is aimed at identifying variables in the environment that maintain PA at differential rates. The behavior-analytic literature appears to categorize the variables relevant to PA into two contexts—environmental and social. Environmental variables include stimuli that are part of the physical environment (e.g., Brown et al., 2009; Hustyi et al., 2012; Van Camp & Hayes, 2017), whereas social variables are those mediated by another person, such as peer or adult attention (e.g., Gonzales et al., 2020; Larson et al., 2013; Larson et al., 2014a, b; Zerger et al., 2016). Behavioral assessment is critical for developing effective behavioral interventions for increasing PA. Two commonly reported methods of PA assessment, descriptive assessment, and functional/reinforcer analysis have been evaluated with children.

Descriptive Assessments

Descriptive assessments are correlational in nature, yet they are the most commonly reported method of assessment for PA. Brown et al. (2009) developed the OSRAC-P for coding five levels of PA, ranging from sedentary to vigorous movements, in various indoor and outdoor contexts under natural conditions. In general, they identified outdoor toys and open spaces to be associated with higher levels of MVPA. Subsequent studies also identified outdoor physical contexts associated with increased levels of PA. For example, Hustyi et al. (2012) used the OSRAC for coding children's PA in three different outdoor contexts and a control condition. Specifically, they observed and recorded children's PA during 5 min sessions of outdoor play, fixed equipment, open space, and control. Fixed equipment was associated with the highest levels of MVPA (≈ 20% MVPA) compared to the other three conditions (e.g., ≈6% in open space). Becerra et al. (2020) used similar procedures to evaluate PA in three children with ASD, with the exception of an added condition to evaluate MVPA in an indoor context with toys. All children engaged in the highest levels of MVPA in the indoor toys context (≈ 70% as coded by OSRAC levels 4 and 5). The empty field condition was associated with the lowest levels of MVPA for two children (≈22.5%), whereas the outdoor toys condition was associated with the lowest levels of MVPA for the third child (42%). Van Camp and Hayes (2017) used Fitbits to evaluate children's PA during recess while engaging in one of three patterns including free play only, structured activity (soccer or tag) followed by free play, or free play followed by a structured activity. Each PA session started with 5 min of laps during which children could walk or jog around the playground. The initial period of laps was associated with the highest levels of MVPA (as measured by a 100 SPM criterion), and similarly, lower levels of MVPA were associated with structured and free-play activities; however, the structured soccer activity was most consistently correlated with more SPM than the other activities. Similarly, Eckard et al. (2019) found differences in HR across biking, exergame boxing, elliptical, and basketball activities.

Social contexts have also been identified as relevant to PA using descriptive assessments. For example, in a systematic replication of Hustyi et al. (2012), Larson et al. (2014a) also found that fixed equipment produced differentially high levels of MVPA (≈35%), particularly when one or more peers were present (≈40%). In a more recent study, Gonzales et al. (2020) evaluated peer presence as a contextual variable during functional analyses of MVPA in preschool children. The presence of peers and/or peer interaction was not contingent on engagement in MVPA; peers were free to engage with the children during any condition in which a peer was present. The results of this study generally indicated that having a peer present produced relatively higher levels of MVPA than in their absence, especially during the interactive play condition (≈54% with and 28% without peers, respectively). To note, however, lower levels of MVPA were observed during conditions in which no adult was present, even in the presence of peers. Thus, peer presence may not be sufficient alone for promoting higher levels of PA. Nonetheless, the research tends to suggest that social variables, such as peer presence, may improve PA under natural conditions. Taken together, these findings suggest that peer presence is an important variable, but that individual differences may be observed for the physical contexts that promote MVPA across children. Thus far, descriptive assessments have been conducted with young children in school or day-care settings; thus, additional research is needed to assess variables associated with PA in older children. Overall, descriptive assessments are useful for quickly developing hypotheses about environmental variables that can be arranged to promote PA; however, because they are purely correlational, the primary limitation of this method is the lack of experimental control over PA.

Functional/Reinforcer Assessments

Recent studies have evaluated methods to identify reinforcers for PA, utilizing functional analysis methods (e.g., Larson et al., 2013, 2014b; Zerger et al., 2016). For example, following a naturalistic (no reinforcement) baseline, Larson et al. (2013) exposed children to interactive play, attention, escape (academic demands), alone, and control conditions in a multielement design. In the test conditions, putative reinforcers were delivered contingent on initiation of MVPA, described to children as "running, skipping, and jumping," and continued so long as the children's engagement in MVPA was maintained (as coded by OSRAC levels 4 and 5); that is, if children engaged in at least 1 s of MVPA, researchers then delivered the putative reinforcer and continued to do so every 10 s as long as the child continued to engage in MVPA. In the control condition, children were prompted to sit with the researchers, noncontingent attention was delivered every 30 s, and no programmed consequences occurred for MVPA. In the alone condition, children were prompted to play as usual and no attention (contingent or noncontingent) was provided. All conditions were conducted in an outdoor context. Differentially high levels of MVPA were observed in the attention (≈31%) and interactive play conditions (≈36%) compared to the alone condition (≈5%). Larson et al. (2014b) replicated and extended this study and observed the highest rates of MVPA in the interactive play condition, with differentially elevated rates also observed in the attention condition for two children. Zerger et al. (2016) also found that attention and interactive play produced the highest rates of MVPA. Taken together, these studies suggest that PA can be increased with social positive reinforcement contingencies, particularly adult attention. However, these findings are based on short sessions (5 min) with preschool children, and it is unclear if the levels of MVPA observed were sufficient to produce health benefits.

Functional analyses yield empirical demonstrations of functional relations between context (i.e., environmental and social) and PA. The few studies conducting functional analyses of PA used the Iwata et al. (1994) arrangement, including test conditions (e.g., attention; see also Jessel, Chap. 26, in this book). However, in the case of PA, these procedures might be more aptly described as reinforcer assessments when there is no known history of social reinforcement (Lambert & Houchins-Juárez, 2020), which is likely to be the case for PA among sedentary individuals. Unlike with problem behavior, it is likely that some level of PA maintained by automatic reinforcement may occur (albeit at low levels in some individuals). Identifying other reinforcers that may increase PA beyond levels maintained by automatic reinforcement could prove beneficial. Broader reinforcer assessments may also introduce other antecedent and consequent arrangements, as well as focus on relevant baseline and control conditions. For example, no-reinforcement baselines should be similar to alone or no interaction conditions. Control conditions should provide noncontingent access to the putative reinforcers while not inadvertently suppressing PA by setting up sedentary activities not present in the test conditions.

Most PA research using either descriptive assessment or functional/reinforcer analysis tends to rely on the use of the OSRAC (a notable exception includes Van Camp & Hayes, 2017). Although primarily conducted with child populations, these methods show promise in informing interventions (e.g., Larson et al., 2014b). These methods may also be amenable to other dependent variables, such as HR or steps, and additional populations. For example, Peña (2018) conducted functional analyses with individuals diagnosed with autism spectrum disorder and found that MVPA varied within and across children, and across experimental conditions. In addition, Pincus et al. (2019) replicated the methods of Hustyi et al. (2012) with three adolescents with disabilities including conditions for gross motor toys, exergaming (fixed activity), open space, and control. They found that exergaming produced the highest levels of MVPA for all participants and was most preferred by two participants. Taken together, these findings suggest that different variables might be relevant for maintaining PA across different populations.

Interventions with Children

Children spend a large proportion of their day in school, making recess and physical education classes important opportunities to engage in PA. However, many children do not engage in sufficient MVPA during school-based physical education (PE) classes (Hollis et al., 2017), and although there has been a rise in interventions to increase MVPA during recess in the last decade (Parrish et al., 2020), many involve multiple components and infrequent evaluation of individual effects. Research conducted by behavior analysts has targeted general PA, as well as MVPA, during both individualized and group-based interventions, during PE, recess, afterschool programs, and day-long evaluations.

Exergaming

One area of research has evaluated the effects of exergaming, which uses video game technology that requires exercise-related movements, during school PE and recess (Fogel et al., 2010). Four 5th-grade children, who were considered inactive by the PE teacher, were exposed to two conditions. In the regular PE condition, the teacher led the class by providing instructions and opportunities for the children to perform a skill. In the exergaming condition, children alternated between 10 different games (such as Dance Dance Revolution). Physical activity, defined as moving large muscle groups, was higher during exergaming, and notably, exergaming provided much more opportunity to engage in PA as less time was spent on listening to instructions and waiting to take a turn. A similar evaluation was conducted with four 3rd-grade boys who were active and not overweight, and who had already been exposed to similar games (Shayne et al., 2012). Definitions of PA and the two conditions were the same, and the results were similar in that more opportunities to engage in PA, and more PA, were observed during exergaming. The assessment of PA also identified the types of exergames that engender the most PA. The extent to which the PA observed was light, moderate, or vigorous was not assessed in these two studies, however. Although not conducted during PE, one study has evaluated HR during exergaming (Eckard et al., 2019) in three children during an afterschool program. The children engaged in a boxing game that varied across two difficulty levels, while wearing a chest-based HR monitor. All demonstrated increases in HR compared to being still, and heart rates were consistently at or above their individualized moderate heart rate zones, averaging 135–155 BPM. As a whole, behavioral studies on exergaming have demonstrated an increase in PA compared to typical PE classes, and compared to sitting still, although it would be important to evaluate the effects of specific games. In addition, even higher levels of PA may be observed during exergaming if reinforcement for engaging in PA was available.

Self-Management and Contingent Rewards.

The effects of contingent rewards have been evaluated in studies focusing on self-management-based approaches to increasing PA. Hustyi and colleagues (2011) measured PA in two 4-year-old children whose weight classified them as obese. Observers coded activity levels using the OSRAC-preschool version, using momentary time sampling (5-second observation and 25-second recording) and all five activity levels. Data on steps were also collected via pedometers. Data were collected during 20 min unstructured outdoor recess sessions, which included access to outdoor playground equipment. The pedometers were masked, and no programmed consequences were delivered at baseline. During the intervention, the children were given a step goal and were prompted to check the pedometers halfway through and at the end of recess. If they made their goals, they earned a prize from a box, which included items identified by the teacher (such as stickers and buttons). Modest increases in steps and OSRAC-measured PA were observed for only one child. It was not clear if the children attended the pedometer, and given no preference assessment was conducted, it is possible the rewards were not reinforcing. A similar study evaluated self-management and reinforcement during school recess in a group of six 3rd-grade children (Hayes & Van Camp, 2015). Physical activity was measured by steps recorded on Fitbits, which were masked during baseline. During the intervention, the Fitbits were unmasked, daily step goals were given to everyone on a slip of paper, and they were given a tangible for meeting the goal immediately at the end of recess. Tangibles were selected based on multiple stimuli without replacement preference assessment and consisted of small toys valued at $3 or less. Overall, the children took 47% more steps during the intervention, including four who took over 100 SPM, indicative of engaging in MVPA. On average, the percentage of recess time engaged in MVPA was 4% and 13% in the baseline phases, and 25% during the intervention. In this study, the children were engaged in recess simultaneously, but consequences were delivered to individuals. The use of Fitbits allowed for easy data collection, making it possible to assess all 6 children at once; however, consequences were delivered only at the end of the 20 min session, and not for engaging in MVPA behavior at the moment.

One way to deliver tangible reinforcement contingent on real-time instances of MVPA is to provide tokens. The effects of token reinforcement were evaluated in one study, during which the PA of four preschool children was assessed via the OSRAC-preschool version using a 1-second partial interval recording (Zerger et al., 2017). OSRAC levels 4 and 5 were combined as a measure of MVPA, and 5 min sessions were conducted with individual children on the school playground, which contained fixed equipment, open areas, and outdoor toys. During baseline, the experimenter remained out of sight, and there were no programmed consequences for engaging in MVPA. In the contingent token phase, children were told if they engaged in MVPA (running, skipping, and jumping), they would receive a token. The experimenter placed a token for each instance of MVPA (and every 10 s if MVPA continued to occur in any given bout) on a token board in sight of the participant, so as to not disrupt ongoing PA. At the end of the session, the children exchanged their tokens for prizes, which increased in presumed value based on the number of tokens required. Prizes were selected by parents and children from a checklist of small tangibles. In the noncontingent token phase, tokens were delivered on a yoked schedule based on previous contingent token sessions such that they received the same number of tokens, and at the same time, in both conditions. The results showed systematic increases in MVPA for two of four children during the contingent token condition, compared to baseline and noncontingent token conditions. Bout durations, defined as consecutive 1-sec intervals with MVPA, were slightly longer in the contingent token condition, but only by one or two seconds. Although tangibles were selected with the children's input, no formal preference assessments were conducted, which may have contributed to the lack of effectiveness for half of the participants. As with the earlier reviewed studies, the interventions were implemented by researchers, not teachers. The use of direct observation may limit a teacher's ability to conduct such evaluations, as typically children would be engaged in PE or recess as a group; however, the use of pedometers or Fitbits may allow for more group-based evaluations that require little additional time to collect data.

Group Contingencies

The effects of group contingencies on PA during PE and recess include modified versions of the Good Behavior Game (Barrish et al., 1969; see also Joslyn, Chap. 47, in this book), which typically involves an interdependent group contingency wherein children are divided into two or more teams, the behavior expected and rewards to be earned are clearly explained, and either the winning team, or any team that meets the stated goal, earns the reward. Jung et al. (2005) evaluated a group contingency during PE, during which children on teams could earn and lose points contingent on correct and incorrect classroom behavior, such as being punctual and engaging in the activity as instructed (e.g., playing ball or engaging in the gymnastics lesson). Each team could earn the reward (computer access during lunch time) contingent on earning sufficient points. Although not directly the focus of the intervention, motor activity increased during the intervention.

More formal evaluations of group contingencies have focused on objective measures of PA during the "Step it UP" game (Galbraith & Normand, 2017; Nieto & Wiskow, 2020; Normand & Burji, 2020). In the first study, PA was defined as steps taken measured via pedometers for 20 students from a third-grade class during outdoor recess, at which time children had access to open spaces and fixed equipment for 12–15 min (Galbraith & Normand, 2017). During baseline, children wore the pedometers but there were no programmed consequences for PA. During the intervention (the Step it UP game), members of the winning team (the one that on average achieved the most steps) won a "step it up champ" badge exchangeable for a lottery ticket in a school-wide lottery (which provided access to small tangibles such as stickers and crayons). The rules of the game were explained prior to each intervention session, and again during reminders every 3 min, and group members were identified by wearing colored belts. On average, both teams took more steps during the game compared to baseline, although the increases were modest (78 steps/min in baseline compared to 89 steps/min during the game). Fourteen of 20 individual participants showed an increase in steps during the game, and the game was rated as acceptable and effective by the teachers. Normand and Burji (2020) replicated and extended this study by evaluating the "Step It UP" game during an unstructured PE class in a group of 18 third-graders. Again, steps were measured via pedometers which were unmasked throughout the study, and children were divided into two groups identified by colored belts (in this case, based on baseline step data to ensure an equal distribution of high and low step-takers). During the game, the winning team earned the "step it up" badge, which, in this case, was not exchangeable for lottery tickets or tangibles. Again, only a modest (10 steps/min) increase was observed during the game, with 14 of 18 participants taking more steps during the 30–40 min PE class. Teachers agreed the game was effective, feasible, and they were willing to implement the game themselves. In addition, the majority of the children voted to play the game when given the choice. Finally, one study compared the effects of the "Step It UP" game with and without contingent adult interaction on the PA (steps measured via masked pedometers) in a group of 23 third-grade students during recess (Nieto & Wiskow, 2020). During the no-game condition, children engaged in typical recess activities for approximately 17 min on a playground with fixed equipment without programmed consequences or interaction from the researchers. Children were then divided into two teams (based on baseline step counts). During the game-only condition, the team with the highest step count received a small tangible prize (which had been selected by the teacher) within 10 min of the end of recess.

During the game plus interaction condition, researchers interacted with the children contingent on MVPA (defined as running, jump roping, etc.), by providing praise and engaging in similar activities as the children. Because there were up to 23 children on the playground simultaneously, this was accomplished by the researcher scanning the playground on a fixed time 30 s schedule and joining in the same activity as at least one child who was engaged in MVPA. After several intervention sessions, the researchers noted that children often stood still while waiting for their turn during various games; thus, they added pre-session reminders that while waiting they could still engage in PA by doing jumping jacks, jogging in place, etc. On average, the game plus contingent attention condition (after reminders were added) resulted in the highest number of steps (90–92 steps/min) compared to the game alone (85 steps/min) and the no game condition (80–85 steps/min). On an individual basis, 19 children showed the highest number of steps in the game plus attention condition, although only 7 averaged the 100 steps or more per minute indicative of MVPA. Children reported preferring the game plus attention condition; however, steps were no higher than baseline in a follow-up game plus attention session. The addition of reminders suggests that it may be important to instruct children on how they can increase PA (see also Eckard et al., 2019). In these Step It UP studies, teacher-selected tangibles, tokens, or badges were used, which may not have served as reinforcers for all children. Given the inconsistent effects on individuals, more research may be needed to identify effective reinforcers. In addition, only modest increases in steps have been observed, suggesting additional research is needed to increase PA to meet the CDC guidelines. Finally, more research is needed to evaluate teacher-lead interventions during the school-based intervention, as researchers conducted these interventions.

One study evaluated an interdependent group contingency-based intervention as part of class-wide function-related intervention teams (CW-FIT), similar to the Good Behavior Game. Twenty-two 2nd-grade children participated, and the teacher led the intervention while researchers served as the observers (Hirsch et al., 2016). The dependent variable was small group engagement, which included appropriately engaging in sports activity and waiting appropriately. The teacher separated the children into four teams, and in the CW-FIT condition, they explained rules, scanned the room every 2 min and delivered specific praise and points contingent on appropriate behavior, and rewarded teams that meant point goal by providing nontangible rewards selected based on a student preference survey, such as dance parties and peer interactions. This condition was compared to standard PE, which did not include programmed praise or points. On average, higher appropriate engagement was observed during CW-FIT, and teachers reported being somewhat satisfied with the intervention, and children reported being very satisfied. This preliminary study did not include all components of standard CW-FIT, and did not target PA per-say (i.e., waiting appropriately was included in the measure of appropriate behavior); however, as a teacher-lead intervention, this approach shows promise, especially as a package intervention that addresses several other classroom needs. Healy et al. (2017) provide a step-by-step guide that details each component of CW-FIT, but additional evaluations and component analyses are needed to ascertain the potential for improving PA during the school day.

Another school-based group intervention includes public posting, in addition to self-monitoring. Zerger et al. (2017) evaluated a class-wide intervention with 16 children, aged 9–12 years, during unstructured recess on the school playground. Steps were measured via pedometers, which were masked during baseline. Children were separated into pairs, based on baseline steps. During the intervention, children were encouraged to look at their step counts and those of their teammates and self-recorded steps at the end of recess. The researchers then showed the entire class a bar graph of the top 3 teams. No tangible or activity rewards were provided, just the public review. On average, increases in steps were observed during the intervention phases (99 and 94 SPM), which were compared to the baseline (67 and 59 SPM) in a reversal design. Eight (of 16) individuals' data demonstrated a consistent effect of intervention, and 12 took a sufficient number of steps to meet MVPA criteria (100 SPM) during the intervention. A follow-up study conducted a component analysis of a similar intervention with a group of 17 children, aged 5–8 years, during unstructured school recess (Miller et al., 2018). Children were separated into pairs and wore masked pedometers in baseline. In the first experiment, three conditions were compared. In the public posting-only condition, feedback was provided as public posting of the highest scoring teams and pedometers remained masked. In the public posting plus self-monitoring condition, pedometers were unmasked, and children self-recorded their step counts. Although the step data were variable, on average more steps were taken during the public posting-only condition (74.6 SPM) compared to the baseline (72.6 SPM), and a modest increase was observed when self-monitoring was added (86.3 SPM). The increase in steps during the combined intervention was replicated in a reversal design; however, although most individuals showed an increase during the intervention with the combined intervention, only four met the MVPA 100 SPM threshold. Experiment two was a replication of experiment 1 with added reinforcement. One condition included feedback with self-monitoring and goal setting, and the other condition was the same plus a reward. Raffle tickets, exchangeable for leisure items from a prize box, were delivered to each individual student meeting their step goal. Results showed increases in SPM with the added reinforcer, and 11 participants met the 100 SPM MVPA threshold during the final intervention phase that included reinforcement. In this study, feedback (in the form of public posting) alone did not increase steps, slight increase with self-monitoring were observed, and the highest increase was observed when reinforcement was added.

Researchers have also evaluated day-long PA with interventions conducted in school. Kuhl et al. (2015) measured steps via pedometers in thirty 3rd-grade children from two classrooms. Two interdependent group contingencies were evaluated (based on both individual and cumulative class goals). Teachers selected and presented five activities as possible rewards, and extra recess time was selected by the majority of children. Because the dependent variable was the total number of steps taken in a day, data on steps were recorded each following morning at the start of school, 4 days a week. During baseline, the pedometers were masked, the researchers recorded the steps, and no self-monitoring occurred. In the classroom cumulative total condition, the pedometers were unmasked allowing for self-monitoring, the criteria for reinforcement were based on the cumulative steps taken by the entire class over 4 days, and feedback was provided to the group via public posting of the total step count for each day. In the individual goals condition, pedometers were unmasked, individuals received praise for meeting their step goal daily, and the class earned extra recess if 80% of the participants met their daily goal each of the 4 days. During the feedback schedule thinning, goals and feedback went from daily, to every 2 days, to every 4 days. Recess was earned every week in both conditions, and generally, boys took more steps in all conditions compared to girls. Although baseline data were variable for the majority of individuals, making clear intervention effects difficult to ascertain, both interventions increased steps, with the highest number of steps seen in the individual goal condition (an increase of 4800–5000 steps per day). The results of this study highlight the importance of individual feedback, which was not available during the less effective group feedback condition. In addition, some decrease in effectiveness was observed as feedback was faded.

Another study evaluated the effects of incentives (study money exchangeable for gift cards at the end of the study) on day-long steps, which were also administered at school (Evans et al., 2017). Forty-two 6th-grade children from three classrooms wore Fitbits (wrist-based models) all day, and steps were recorded by researchers. In this study, a group design was used, wherein each class was assigned to one of three conditions. In the Fitbit plus goal and incentive condition, students were taught to self-monitor their steps, and both individual rewards ($1 per day in study money) and group rewards (bouncy house party for the class) were available contingent on meeting step goals based on engaging in the 60 min of MVPA per day. In addition, students competed against the teacher, with the losing team having to engage in an activity challenge selected by the winner (10 pushups for example). In the Fitbit-only condition, students were taught to self-monitor, but no goals or incentives were provided. In the control condition, students did not wear Fitbits, but this condition was included as weight at the beginning and end of the study was a secondary dependent variable. The results showed no group differences (notably no increase) in MVPA or steps from baseline to follow-up in the two Fitbit conditions, nor was there an effect on weight. The authors concluded that although the participants wore the Fitbits the majority of the day (adherence was 73–80%), they may require specific instructions on how to increase PA (e.g., Eckard et al., 2019).

Summary

All of the studies evaluating behavioral interventions for PA in children have been conducted at school (either during recess, PE, or day-long but reviewed at school). The results have been mixed, with some evidence that exergaming, contingent tangibles, and public posting have been effective for some participants. However, often increases are modest and do not frequently contribute significantly to the goal of engaging in 60 min of MVPA per day (although that limitation may be related to relatively short sessions). A common limitation reported by authors is that teacher- or parent-selected reinforcers (including those available in a "prize box") may not be reinforcing to all individuals; thus, it is important to conduct preference assessments with individuals if possible. It is also important that even if interventions are based on group contingencies, the effects on individuals still can be evaluated. The use of mechanical devices such as pedometers and Fitbits may aid in providing individual data without requiring additional personnel to conduct observations in such group evaluations. We may not expect these interventions to be effective for all individuals but focusing on individual data may allow one to determine the necessary and sufficient components of interventions on an individual basis. Indeed, many interventions involve several components, yet few component analyses have been conducted. Another potential area of research is the effects of choice, although a preliminary study suggests the choice of physical activities does not increase MVPA (Boga & Normand, 2017).

Interventions with Adults

Interventions with adults are often very different from interventions used with children. For one, adults are not typically in environments where they are required to spend time engaging in PA. Though workplaces sometimes have gyms or wellness programs that encourage PA, they are not typically compulsory (with some exceptions, e.g., in the military, law enforcement, firefighters, and professional athletes). Self-selection for participating in a PA treatment study may lead to individuals who are actively interested in becoming more physically active. Alternatively, individuals may contact PA treatments because of a medical diagnosis (e.g., cardiovascular disease, diabetes). Adults often engage in different topographies of physical activity. However, like child interventions, increasing the duration and intensity of physical activity is often the goal of the intervention. Functional analyses and assessments utilizing direct observation are rarely conducted in behavioral studies of adult PA; however, several studies have evaluated individuals' preferences for types of PA via self-report.

Physical activity norms vary according to some demographic variables like age, gender, geographic location, and socioeconomic status (CDC, 2019a). For example, the WHO (2020c) notes that cultural practices and low-income levels may limit the accessibility of PA to women internationally. Physical activity levels tend to decline with age, but the degree of change interacts with other demographic variables as well. Preference for the type of AP often varies according to these demographic variables as well. Kurti et al. (2015) surveyed rural adults in Florida and found that age, race, education status, and gender all affected self-reported barriers to engaging in PA, preferences for types of PA, and preferences for types of interventions to increase PA. For example, both males and females were likely to endorse walking or biking, but women were more likely than men to prefer dancing or aerobic exercise, whereas men were more likely than women to identify running and basketball as preferred activities. Childcare and monetary factors were more important to younger individuals compared to older individuals. Cadmus-Bertram et al. (2019) surveyed women in Wisconsin and found that inactive women reported having less use of community locations for PA (e.g., walking trails, gyms, and parks). Most women preferred a group-based intervention for PA and preferred walking or yoga as an activity. Several studies indicate that men prefer competitive PA more than women (e.g., Molanorouzi et al., 2015; van Uffelen et al. 2017) It is advisable to consider recent local demographic and cultural norms in PA engagement on the CDC, WHO, or other health organization websites. The Neighborhood Physical Activity Questionnaire (NPAQ, Giles-Corti et al., 2006) and the Neighborhood Environment Walkability Scale (NEWS, Saelens & Sallis, 2002) can be used to characterize the accessibility of physical activity opportunities geographically as well.

General Strategies

Adult PA programs may utilize several behavioral strategies, including goal setting, self-monitoring, feedback, competition, social cooperation, and consequence-based incentives. Though MVPA can certainly be reached in adults through several types of activities, the majority of behavioral research in adults has focused on taking steps (walking or running). This focus is likely due to the ease of both engaging in the activity and obtaining objective measurements of activity engagement using accelerometers (e.g., Fitbit, Actigraph). It is likely that approaches outlined to increase steps could generalize to other types of PA.

Tudor-Locke (2002), in a report to the President's Council on Physical Fitness and Sports, endorsed the use of pedometry to combat overweight and obesity problems, citing that lack of PA was a major contributor to the newly emerging epidemic. This paper is also the origin of the ubiquitous walking goal of 10,000 steps per day for healthy adults, though also endorsed tailored goal-setting and behaviorally oriented interventions to address problems with motivation to become physically active, stating "It is foolish to surmise that if we distributed enough pedometers to each household in the nation our work as physical activity promoters would be done (p. 4)". With rises in both obesity and pedometer and accelerometer use over the coming years, it is apparent that she was correct. Pedometers and accelerometers are tools for addressing PA rather than technology to treat motivational problems. Simply counting steps is not enough for all participants to meet MVPA recommendations (e.g., Normand, 2008; Van Wormer, 2004). Effective PA interventions for adults tend to use several strategies to maximize efficacy, including self-monitoring (e.g., Donaldson & Normand, 2009; Normand, 2008; Van Wormer, 2004) goal-setting, feedback, and prompts (e.g., Andrade et al., 2014; Donaldson & Normand, 2009; Donlin Washington et al., 2014, 2016; Green et al., 2016; Irons et al., 2013; Kurti & Dallery, 2013; Normand, 2008; Stedman-Falls & Dallery, 2020; Van Wormer, 2004) and consequence-based incentives (e.g., Andrade et al., 2014; Irons et al., 2013; Donlin Washington et al., 2014, 2016; Kurti & Dallery, 2013; Stedman-Falls & Dallery, 2020).

The simplest intervention to increase PA would be to train individuals to set goals, monitor, and graph their own behavior. Van Wormer (2004) monitored walking via a pedometer in three overweight adults during a baseline period. During the monitoring phase, a goal was set to the average of baseline steps per day, and individuals recorded their step counts on an excel sheet daily. All participants increased step counts during this phase, with the two participants with the lowest baseline averages able to more than double their step counts. Subsequent addition of e-counseling with praise and weekly goal setting did not further improve step counts. All three participants failed to maintain PA improvements at a 6-month follow-up. Normand (2008) sought to expand on Van Wormer's finding by creating a package of goal setting, self-monitoring, and feedback for four non-obese adults using an ABAB reversal design. During baseline, individuals wore covered pedometers for 1 week, and the average of those days was set as a goal for subsequent conditions. During the package-intervention phase, participants reported daily steps via email. The researcher responded via email by providing praise or encouragement. During a weekly in-person meeting, graphs, verbal descriptions of progress, and praise or encouragement were provided. Three of the four participants increased PA by at least 2500 steps per day. Both interventions would be considered inexpensive, as they required only the purchase of pedometers and minimal researcher intervention.

With technological advances, behavioral research incorporated new tools to collect data beyond the capability of pedometers: Heart rate monitors and accelerometers. Donaldson and Normand (2008) used a Polar heart rate monitor with 12-day memory to calculate calorie expenditure in five obese or overweight adults. Using a 22-week multiple-baseline across-participants design, they evaluated a package intervention of goal-setting, self-monitoring, and feedback. During baseline, participants wore the Polar monitor, but the output was blocked from view. During the intervention, the polar monitor displayed caloric output. Goals were set to be 10% higher than the average daily caloric expenditure during baseline. Participants reported daily expenditures via email and received feedback based on performance. Additionally, weekly in-person meetings were held to obtain data from the monitor, provide feedback and alter goals for the upcoming week. Two participants requested modifications to the study designs. One subject requested omitting daily feedback because it was "discouraging" when goals were not met. Another participant requested an alteration of goals depending on the daily schedule and availability of time to work out. Additionally, two participants dropped out at the onset of the baseline reversal because the polar monitor output would not be visible. All participants showed an increase in caloric output ranging from 10% to 54% during the intervention phases. However, the dropouts and study accommodations emphasize the need for interventions to be flexible to accommodate individual preferences and abilities.

One way to address setting individualized goals is to use percentile schedules. Galbicka (1994) describes how to implement this operant shaping strategy. The approach emphasizes an incremental change in behavior that adjusts with the most recent output of behavior. First, behavior is measured over time. For example, daily step counts may be measured over a week. Those counts are then rank ordered. One of the previous step counts is then set as the upcoming goal. The difficulty of meeting the goal can be balanced with the likelihood that the participant will meet the goal. If the median step count is set as a goal, it should be easy to meet, as the participant has already exceeded that goal about half of the time over the previous week. With each successive day, the "window" of ranked previous step counts shifts by 1 day as well. This should gradually increase the goals for individuals, always requiring them to exceed the steps taken on about half of the days in the previous week. Targeting a higher-ranked step count may be harder to attain but would likely lead to quicker increases in daily step counts. Galbicka recommends targeting around the 70th percentile over short periods of time to optimize behavioral gains. This would require individuals to perform better than they did on 70% of the previous week's days.

Accelerometers have become the more-frequently utilized technology to capture PA in more recent studies. Valbuena et al. (2015) examined the effectiveness of accessing the Fitbit website to address PA in seven overweight adults. Individuals wore a Fitbit during all waking hours throughout the study. During a baseline, the Fitbit display was covered, and individuals did not have access to the website. In the next phase, individuals could log into the Fitbit website to view step counts, track calories, BMI, weight, set goals, earn badges, and post in forums. In a final condition, access to the website was paired with coaching; the individuals received 80th percentile goals set from the last 10 days, got tailored feedback, and social support via videoconferencing. By the end of the website phase, six of the seven participants increased PA (4.6–199%). With the addition of the coach, gains rose to 44–256%. Participants reported liking the program and finding it easy to use.

Green et al. (2016) specifically targeted the reduction of sedentary behavior in three office workers, using tactics prompts, feedback, and goal setting. During the study, participants wore an Actigraph accelerometer on their legs. During the intervention phase, a watch that could vibrate to deliver tactile prompts was also worn. Sedentary behavior was defined as having fewer than 100 movements per minute. Bouts of sitting were calculated by adding together the consecutive minutes of sedentary behavior. After a baseline phase, participants were given information about minimizing the length of sedentary behavior, which led to small and transient effects on sedentary behavior. During a subsequent phase that included a tactile prompt, feedback, and goal setting, there were reductions in the sedentary bouts that lasted longer than 30 min (ranging from 33% to 44% decrease). Additionally, the average length of the sedentary bouts decreased by 4–12 min. Batchelder and Donlin Washington (2021) conducted a similar study, in which 16 university faculty and staff received interventions using prompts, feedback, goal-setting, and financial incentives. Individuals were randomized to receive goals and prompts, goals and monetary consequences, or goals, prompts, and monetary consequences. Goals were set to walk at least 400 steps within each work hour, for at least 7 out of the 8 h of the workday. In conditions with a prompt, participants received a text message reminding them to walk at least 400 steps at the beginning of each hour. In conditions with monetary consequences, participants earned $0.25 per hour in which 400 steps were taken which could escalate by $0.10 per hour each consecutive day in which goals were met. If goals were not met on consecutive days, the value was reset to $0.25. The most effective condition was prompts-only, with two out of the three participants in that condition meeting goals on three consecutive days. Incentives did not improve outcomes, though the amount of the reinforcer was likely low for the population.

Kurti and Dallery (2013) conducted two studies to increase PA in older, sedentary adults. In both studies, adults ≥50 years old, who reported less than 3 days of PA per week and averaged ≤6000 steps per day were given initial goals equal to the baseline average plus 1000 steps per day. Participants in both studies logged onto the researcher website, MOtiv8, to report step totals, and fill out activity logs, earning $1 per activity log in baseline and $0.50 per log during the intervention. The website displayed graphs of step counts. Subsequent goals used an 80th percentile schedule, requiring participants to exceed the 2nd highest step count over the last 5 days, or an increase of 1000 steps over the previous block's goals, whichever was higher. In study 1, six participants could earn money for meeting goals. If goals were between 2000 and 2999 steps, they could earn $2 a day, and the value incremented by a dollar for every 1000-step increase in range. A $3 bonus was awarded for moving to the next higher block of goals. The intervention lasted for 2 months, or when an individual averaged 10,000 steps for at least two consecutive blocks of days. All six participants increased stepping, from 80% to 256% improvement. As a group, they met 91% of their goals and earned between $56 and $102.50. These gains in PA were clinically significant but came with a cost to researchers; the Fitbits used were more expensive than the pedometers in previous studies (at least $100 each), and participants were earning more than a dollar a day on average. In study 2, the methods were repeated except that no money could be earned for meeting goals, but they could earn $0.50 per day for filling out an activity log. Five of the six participants in this study improved between 8.7% and 186%. They met 63.6% of their goals. Without financial incentives, not as many participants improved, and those who improved had generally smaller gains in PA.

Donlin Washington et al. (2014) studied the effects of an intermittent “prize bowl” intervention on physical activity in 15 healthy adults using an ABA reversal design. Throughout the study, participants could earn prize draws out of a “fishbowl,” which had a 50% probability of earning a prize. During the initial weeklong baseline, participants earned one prize draw per day for wearing a Fitbit and text-messaging their step count at the end of the day. Prizes during this phase were valued up to $5. During a one-week intervention period, participants were texted goals set to ~71st percentile (3rd highest day of the last 7) for the previous week. Prize draws were earned for meeting goals and were valued from $5 to $120 (with the probability of winning inversely proportional to the value of the prize). There was an effect of the intervention, with four subjects showing improvements in step count greater than 4300 steps per day, and another four subjects improving by around 2800 steps per day. The intervention cost about $1.80 per day per person, which was not much financial savings over the Kurti and Dallery (2013) study.

Two more recent studies have sought to further decrease the cost of financial incentive-based interventions by using “deposit contracts” or “commitment contracts” (Donlin Washington et al., 2016; Stedman-Falls & Dallery, 2020). These contracts require that a participant contribute at least part of the money to be used for reinforcing goal attainment. In Donlin Washington et al., 19 underactive adults were randomized to either a deposit-contract condition, in which they deposited $25 with the researcher to be used toward subsequent incentives, or to a non-deposit-contract condition. All participants could earn $1.50 a day for meeting goals during the intervention, and a bonus of $2.65 for meeting 3 consecutive goals, for a total of $50 during the phase. Goals were set to the 70th percentile over a week-long period. Both groups showed equivalent increases in PA, with the deposit group increasing step counts by about 49% and the non-deposit group increasing by about 45%. Similarly, the percentage of goals met were not different (70.9% vs. 77.7%, for deposit and non-deposit), and neither were earnings ($34.56 vs. $40.25 for deposit and non-deposit groups). Requiring participants to deposit half of the money delivered for meeting goals reduced the research cost from $1.81 per day per participant in the non-deposit group to only $0.48 per day per participant when some of what they were earning back was from their own deposit.

Stedman-Falls and Dallery (2020) further streamlined these interventions by examining whether in-person or a mobile-based delivery of a deposit contract treatment was equally effective with a within-subject reversal design. Twelve underactive adults wore Fitbits and uploaded data through the Fitbit app. During baseline, no goals nor consequences were programmed. They were then randomized to start either an in-person or mobile-based deposit-contract intervention. For the in-person phase, individuals visited a lab and deposited $10 in person. For the mobile phase, deposits were made through PayPal. For both conditions, reminders and goals were sent via text or phone message, and goals were set to 2000 steps higher than the initial baseline average and did not change. At the end of intervention conditions, performance graphs and feedback were delivered either in-person or via mobile messaging. Money earned was delivered either in-person or via PayPal refunds. Nine participants completed both types of intervention. The modality (face-to-face or mobile) of the intervention did not obviously affect the gain in PA (83% of goals were met in at least one treatment condition for all subjects). Only two participants failed to meet treatment goals in any conditions. The authors report the net cost of the entire study was $27, greatly reducing the per-day cost for participants. Importantly, participants reported that the mobile treatments were more cost and time effective, and acceptable. They also reported that deposit contracts were effective in changing their behavior.

Another hurdle to the dissemination of behavioral interventions is the maintenance of behavior change. The length of intervention has varied across the studies reviewed. Andrade et al. (2014) examined whether a reinforcement-thinning schedule would lead to longer maintenance of PA gains in 77 adults. After a seven-day baseline period, participants could earn prize draws for meeting a standard goal of 10,000 steps per day. They visited the lab three times a week and could earn money prizes varying from $1 to $100 by drawing from a prize bowl with 50% of the tickets being winners. They could earn additional prize draws by having consecutive days of meeting goals. This phase cost researchers about $7.38 a day per person, quite expensive compared to previous studies. If they successfully met 10,000 step count goals on 14 of the last 21 days, by the end of the phase, they were randomized to either a Monitoring-only phase or a Monitoring with reinforcement thinning condition. The “thinning” of the schedule was met by randomly choosing days to have participants visit the lab for a prize draw, with the probability of a day being chosen reducing throughout the phase. They could earn draws based on the previous 4 days of walking. Therefore, there were fewer opportunities to earn prize draws. Individuals in the monitoring-only condition met about 26% of their walking goals over 3 weeks, whereas the reinforcement-thinning group met 61% of their goals over the same period. The cost of monitoring only averaged about $0.71 a day (earned for attending meetings rather than meeting goals), whereas the monitoring plus reinforcement phase cost about $1.63 a day per subject. Though this study showed that thinning out reinforcement was more effective than simply monitoring behavior, the cost of this intervention was high compared to that of the deposit contract studies.

Studies that refine the scalability and cost of behavioral interventions for PA are important to the dissemination of these effective interventions. Keeping pace with technological advances has allowed for easier delivery of interventions, with more acceptability by participants, and bigger gains in health behavior change. Behavioral interventions will be most effective when they incorporate individualized goal setting, prompting, feedback, and consequence-based incentives.

Interventions with Special Populations

As mentioned earlier in this chapter, children and adults are not engaging in sufficient levels of MVPA during the day at school or otherwise. Further still, individuals with ASD and other disabilities are engaging in even less PA than their typically developing peers (Srinivasan et al., 2014). Few studies outside of behavior analysis have evaluated interventions focused on improving PA or related health measures for individuals with ASDs and/or other disabilities; however, the majority of those that have tended to target cardiovascular and resistance activities, including jogging/running, horseback riding, martial arts, yoga and dance, and swimming, and most studies with children took place in school settings (for reviews, see Bremer et al., 2016; Hallett, 2019; Sorensen & Zarrett, 2014; Srinivasan et al., 2014). A similar dearth of research exists within the behavior-analytic literature as typically developing children and adults have been the focus of most PA interventions (see earlier sections of this chapter for reviews). However, in contrast to the non-behavioral studies, the majority of behavior-analytic studies have included adults with disabilities and have taken place at educational day programs or in residential facilities (a notable exception is Becerra et al., 2020). As well, these studies have targeted a variety of activities, including walking, jogging/running, hopping (and other child-typical activities), high-intensity interval training (HIIT), and resistance training.

Visual Schedules

One recent area of research involving children with ASD has evaluated the use of photographic activity schedules for increasing MVPA (Becerra et al., 2020). Participants included three 4-year-olds diagnosed with ASD. Researchers used most-to-least prompting to teach children nine steps for completing the photographic activity schedule, and they earned a flavored sports drink upon completion of the schedule. The photographic stimuli representing each activity were randomized between each session and included pictures of activities that were expected to be age-appropriate, such as running, hopping, and crawling. All children demonstrated improvements in the percentage of MVPA compared to baseline (over 50% as coded by OSRAC levels 4 and 5), and MVPA was maintained at consistently high levels during generalization and maintenance (albeit at slightly lower levels). Notably, MVPA increased in an environment without additional stimuli to help promote PA, such as toys, peers, or fixed equipment. Further, activity schedules may serve as a common stimulus to promote the generalization of MVPA to other environments with or without additional activity-promoting stimuli (Becerra et al., 2020); however, it may be important to evaluate the maintenance of PA when the presence of activity schedules are faded out, as schedules may not always be feasible or appropriate to use.

Researchers have also evaluated visual schedules as part of a multicomponent intervention package for increasing PA among individuals with ASD using technology. Bassette et al. (2018) evaluated a multicomponent treatment package that involved the use of a mobile fitness application, the Exercise Buddy, which included video models, visual schedules, and feedback. Four participants between the ages of 18 and 21 watched video models in the Exercise Buddy application of other individuals with ASD performing one of four exercises, including squats, hip extensions, dumbbell lateral raises, and dumbbell push-up rows. Following the video model, researchers instructed the young adults to begin exercising by providing the prompt "show me how you do [*n*] reps of [targeted exercise]". Access to preferred activities and/or monetary reinforcement was delivered contingent on completing a predetermined number of reps. The number of reps for each exercise was initially set at two and increased by another two reps upon mastery. Least-to-most prompting was used if the young adults did not independently complete a step of any given exercise. Following mastery in phase 1, the same procedures were used to teach the same exercises at a local YMCA in phase 2. In the final phase, each young adult selected their most preferred community setting (other than the YMCA) to complete the exercises. Phase 3 also consisted of teaching young adults to develop a visual schedule within the Exercise Buddy application in which targeted exercises were chained together. Auditory feedback was provided to the young adults while they were using the app, which consisted of brief statements of praise such as "keep it up." The young adults were able to choose the order of the workouts in the visual schedule and the same teaching procedures as in the first two phases were used. Improvements in the number of exercise steps completed independently were observed for all young adults and across all phases, and all indicated that they enjoyed using the app and were able to use it successfully. Although it is difficult to ascertain the effect of each behavioral component in the intervention, the results of this study indicate the utility of technology for teaching PA among individuals with ASD. Additionally, the amenability of the Exercise Buddy application to developing visual workout schedules was an effective means for producing longer bouts of PA, which are likely to have greater health benefits than single exercises. Additional evaluations with dependent measures directly related to PA are necessary, as well as component analyses to help determine the necessary and sufficient conditions for promoting PA among individuals with ASD.

Self-Monitoring and Contingent Rewards

Other multicomponent intervention packages have been evaluated using self-monitoring (Valbuena et al., 2019) and self-monitoring with goal setting (LaLonde et al., 2014). LaLonde et al. (2014) evaluated walking behavior among four adults with ASD using goal setting with self-monitoring and reinforcement. Daily steps were recorded during the adults' time at an educational day program that focused on vocational and independent living skills. Adults wore pedometers to track their daily steps and a new goal was set each day. Each adult's initial goal was determined by adding 10% to the average number of steps in the baseline. Goals then increased by 10% each time the previous goal was met for two consecutive days. Each morning, adults wrote their daily goals on a datasheet kept in the classroom. Thirty minutes prior to the time at which the classroom was released for the day, adults were prompted to check their pedometers to see if their goal had been met. If the adults met their goal, they wrote "yes" on their datasheet and were able to choose a prize from the prize box. If they did not meet their goal, they wrote "no" on their datasheet and were told they had the remaining 30 min of free time in class to do so, but they did not receive a prize. Although variable both within and across adults, walking behavior increased for all adults such that they were regularly meeting their daily goals and were walking more than 10,000 steps per day by the end of the intervention. In addition, all adults indicated that they liked wearing the device and teachers found the intervention highly acceptable. Thus, the goal-setting intervention was both effective and socially valid. It is possible that the activities included as part of the educational program helped facilitate such high levels of walking behavior and similar levels may not be observed in other settings, such as workplace environments for adults or in school settings for young children. However, including other incentives, such as monetary reinforcement, may be effective at promoting increased PA in adults with disabilities.

Valbuena et al. (2019) evaluated walking behavior among five adult men with intellectual disability (ID) using self-monitoring and monetary reinforcement. Adults attended an educational day program that focused on vocational and independent living skills, and the first hour of the day was spent outdoors during free time. Daily steps were recorded using pedometers that were worn on the hip and could be monitored by the adults during the intervention phase. At the end of each day, researchers recorded the total number of steps displayed on the pedometer and the adults were given $0.25 for every 1000 steps they had walked. The intervention was compared to the baseline, in which the adults could not see the steps displayed on the pedometer, in an ABAB reversal design. Average steps per min increased for all adults during intervention phases and were maintained during staff implementation. In addition, both adults and staff rated the intervention as effective and acceptable; however, lower ratings were observed when adults were asked the question "I will continue walking more if I do not receive money for it." This finding might suggest that monetary reinforcement was a critical component of the intervention, although further evaluations using monetary reinforcement without self-monitoring are warranted. Nonetheless, the authors concluded that the intervention was successful and suggested that monetary reinforcement might be beneficial for adults with disabilities because of its effectiveness as a generalized reinforcer. Further, money can be used to engage in important life skills while purchasing essential goods and services (Valbuena et al., 2019).

The above-described studies have focused on increasing walking behavior or resistance training. Although these studies have indicated improved outcomes, such low-intensity exercises may not produce beneficial increases in PA. Another study evaluated the effects of using a lottery reinforcement system to teach HIIT to three adults with developmental disabilities (DD; May & Treadwell, 2020). Specifically, this intervention targeted HR using a changing criterion design. These adults were residents in an independent supported-living facility that included a fitness center. Each adult's target HR was identified by calculating 75%–80% of HRMax. Prior to HIIT sessions, behavioral skills training (BST) was used to teach the adults how to raise their HR by running in intervals on a treadmill. Back-up reinforcers for the lottery were identified by a self-report preference assessment. During HIIT sessions, adults were on the treadmill for three 10 min blocks (i.e., 30 min), each divided into distinct intervals. Each 10 min block started with a 6 min self-paced interval followed by a 2 min (or less) warm-up interval, and a 2 min high-intensity interval began once the adult's target HR was met. Tokens were provided after each 10 min block if the adult maintained their target HR during the entire 2 min high-intensity interval. Each token could then be exchanged for a lottery slip at the end of the session to be entered into a drawing for each adult. Back-up reinforcers for the lottery drawing included edible items or one-on-one time with the researchers, except 50% of the drawings were labeled as "No Reward". Results indicated that all adults increased their HR to meet criterion changes more than 80% of the time and average HRs increased overall by 35–52%. These findings suggest that the lottery system was effective in increasing HR to beneficial levels, even when no reward was earned for half of the drawings. Tokens were used as conditioned reinforcers during the HIIT sessions and adults had a history of exposure to a token economy that was previously implemented to increase PA, though not high-intensity activity. It is therefore possible that token delivery during HIIT sessions influenced running behavior on the treadmill, which was delivered throughout each 30 min session contingent on real-time HR.

Providing tokens was discussed earlier in this chapter as one method to deliver tangible reinforcement contingent on real-time engagement in MVPA for typically developing children. The effects of token reinforcement have also been evaluated among adults with DD. Krentz et al. (2016) evaluated the effects of tokens on PA at a day training facility with five adult men with ID. Researchers delivered tokens contingent on each lap completed by the adults while walking during 1-h sessions. Tokens were exchanged for low- or high-preferred items that were identified based on a Multiple Stimulus Without Replacement preference assessment, and the exchange ratio was based on individual performance. An increase in laps was observed for all five adults during the intervention. Token economies have also been evaluated across extended observation periods. Nastasi et al. (2020) delivered tokens to four adults with DD contingent on walking behavior over a period of several days. Specifically, each adult had a daily goal for steps and a token was delivered contingent on meeting their goal from the previous day (as recorded by Fitbit devices worn on the wrist). Tokens were accumulated on a poster board and could be exchanged on Fridays for a prize (two tokens per prize). In addition, out of every 5 days during the token economy program, step goals were increased if the adults met their goal on at least 3 of the days. Three of the four adults demonstrated increases in steps relative to baseline, but only one adult increased their daily steps to meet the recommended 10,000 daily step goal. The authors concluded that token delivery across several days was effective at improving walking behavior among sedentary individuals with DD, though additional modifications may be necessary to increase walking to beneficial levels (Nastasi et al., 2020). Nonetheless, delivering tokens over an extended period during the intervention may be a more economic and feasible approach to improving PA.

Physical Activity as an Intervention

Finally, PA interventions have also been evaluated to reduce problem behaviors and/or improve skill acquisition among individuals with disabilities. In an early study evaluating the effects of PA on problem behaviors, Larson and Miltenberger (1992) found that neither leisure games nor structured walk-jog sessions reduced behavior to consistently low levels. Conversely, Neely et al. (2015) found increases in academic engagement and decreases in stereotypy when children with ASD were allowed to jump on a trampoline before instructional sessions. Notably, this intervention was most effective when children could jump until they showed indicators of satiation, suggesting that jumping on the trampoline may have been an abolishing operation for stereotypy. Other non-behavioral studies have found reductions in stereotypy, aggression, self-injury, and improvement in social and daily-living skills when using, for example, goal-setting, instructions, modeling, praise, rewards, and picture schedules (for reviews, see Bremer et al., 2016; Hallett, 2019; Sorensen & Zarrett, 2014; Srinivasan et al., 2014).

Conclusions and Future Directions

In the last two decades, research in applied behavior analysis has made great strides in identifying reliable, valid, and meaningful measures of PA, assessing antecedents and consequences associated with increasing PA in general, increasing MVPA, and decreasing sedentary behavior. Direct observations (e.g., using the complete OSRAC) provide important qualitative information about PA and the environment in which PA is most likely to occur, during time-limited sessions. In addition, sophisticated yet affordable devices allow for automatic data collection of steps or heart rate, which may be used to provide an estimate of PA. However, given emerging technology, studies should continue to assess the reliability and validity of the indirect and direct measures of PA, including comparative studies across a wider range of populations and activities.

Intervention studies have often focused on the delivery of positive reinforcers contingent on engaging in MVPA at the moment, meeting individual session goals, or day-long goals. Individual differences are common and not all individuals display increases in PA; however, the methods and procedures used in applied behavior analysis are well suited to discovering the constellation of antecedents and consequences best suited to increase PA in any given individual. Specifically, it is important to establish the level of PA during no-interaction baselines when individuals can freely engage in PA. Direct observation of PA should be systematic and include all levels of PA, as increases in light over sedentary is also beneficial. That said, specifically increasing the duration of time engaged in MVPA is also important. For day-long assessment of PA, the use of devices such as accelerometers and heart rate monitors with memory features may allow for bout analyses, such that the individual's specific pattern of PA can be understood and treated if necessary. In addition, more refined reinforcer assessments should be developed to inform interventions for both children and adults.

Behavioral research in PA has often been informed by the methods and procedures first utilized to address skill deficits, as well as decrease problematic behaviors, in special populations. Yet, the health consequences of engaging in low levels of PA are ubiquitous, calling for effective interventions for all individuals who are not already meeting PA guidelines. Several lines of research have already identified approaches that increase PA, although not necessarily yet to the levels recommended by the CDC. In addition, a particular challenge for behavioral research is to address individual differences we know may affect PA, while designing group- or community-based interventions to reach more people. Finally, to date relatively less behavioral research has been conducted on bone-strengthening, muscle-strengthening, and flexibility and balance-related exercise. Indeed, despite the advancements of behavioral research in the area of PA, there remains a great deal to learn for the ultimate benefit of the world's population.

24 Treatment Integrity

Candice L. Colón and Robert Wallander

The behavior analyst who develops a work ethic, inclusive of a desire for robust treatment integrity and validated training practices can provide an empowering and enriching experience for those they serve and supervise. Striving for accurate, consistent, and uniform treatment implementation allows a practitioner to lay the groundwork for continual support of client progress. Maintaining optimal treatment implementation requires clinical decision-making and translation into actionable steps via evidence-based supervision and training methods. Whether the treatment setting is a school, clinic, community, home-based or residential group home, upholding the integrity of applied behavior analytic practice is a necessary quality indicator and a required skill for practitioners who seek to join and/or lead a team of applied behavior analysis (ABA) professionals. Fortunately, research from the last 40+ years can assist with the preparation, monitoring, and maintenance of adequate treatment implementation. This chapter aims to provide an in-depth look at this research and provide actionable steps for practitioners. This chapter will first provide an overview of the treatment integrity literature and its relationship to client outcomes. A discussion regarding the clinical implications of the existing literature and it's relationship with strategies necessary to provide training and supervision then follows.

ABA research has a proven track record of investigating procedures that improve socially significant behavior. Once effective procedures have been identified, having awareness of the practical constraints associated with these procedures is necessary to determine the generality of their effects and parameters associated with maximal and minimal treatment effectiveness (Baer et al., 1968, 1987). An approach common in ABA for identifying these effects and parameters entails an investigation of treatment integrity. Treatment integrity has been defined as the extent to which an independent variable (IV) is implemented as intended (Gresham, 1989; Gresham et al., 1993). Practitioners often choose evidence-based procedures that were proven effective in controlled settings with near-perfect integrity; however, the generality of such treatment effects in the natural setting under conditions of less-than-optimal treatment integrity is of particular concern in the clinical setting. Those implementing ABA treatment often have multiple responsibilities (e.g., data collection, conducting lessons, and facilitating peer interactions) and competing contingencies (e.g., avoidance of target behavior or collateral behavior; Allen & Warzak, 2000; Miller et al., 2010; Sloman et al., 2005; Stocco &

Thompson, 2015) that may interfere or conflict with treatment implementation. Moreover, treatments requiring a high response effort such as multiple component treatments (Yeaton & Seachrest, 1981), treatments requiring material resources (Woodward, 1993), and treatments requiring a lot of time to implement (Noell & Gresham, 1993; Noell et al., 1997) may also put a treatment at risk for intervention integrity failures.

The investigation of treatment integrity includes the observation and measurement of the accuracy and/or consistency of implementation (Gresham et al., 2000; McIntyre et al., 2007; Peterson et al., 1982). Consistency refers to the extent to which the treatment is implemented according to a set schedule (Homer & Peterson, 1980; Peterson et al., 1982). Under these circumstances, failing to implement a treatment on a fixed ratio (FR) 1 schedule and instead providing it less frequently would be a consistency error of omission. On the other hand, providing the treatment on a denser schedule than prescribed or for a behavior that it is not prescribed would be a consistency error of commission. Accuracy refers to the extent to which the treatment's definition matches the implementation of the treatment in practice, inclusive of all components (Gresham et al., 2000; Peterson et al., 1982). Therefore, if a therapist adds a treatment component, it is considered an accuracy error of commission whereas failing to implement a treatment component is referred to as an accuracy error of omission. If a therapist adds a non-prescribed component, it is considered an error of commission, whereas failing to implement a treatment component is referred to as an accuracy error of omission. In addition, accuracy errors may occur in isolation (an error on one component) or in combination (more than one error at a time).

The above-mentioned considerations of consistency and accuracy focus on the performance of each individual person implementing a specific treatment. However, it is important to note that on a more global level there are also varying degrees of treatment implementation across people and/or settings. For example, if all staff members employed at a day program follow a plan with strong homogeneity but their performance differs greatly from staff members working in the client's residential setting this would be termed a lack of uniformity. In one setting, consistency and accuracy may be high, but divergence may occur in comparison to another setting. Similarly, in a single setting, multiple caregivers who carry out a treatment in a dissimilar manner create a lack of uniform treatment delivery. The term uniform is characterized as being the same as or consonant with another or others (Merriam-Webster, n.d.). This definition provides two equally important qualities for consideration in relation to treatment integrity: (1) calling attention to "sameness" or at least degrees of similarity, and (2) the word "consonant" as used here refers to an agreement with others, extending the notion of working in a manner that is mutually beneficial and cohesive. If treatment implementation is not uniform, a phenomenon known as behavioral contrast may arise. Behavioral contrast is described as a change in responding under one set of stimulus conditions as a result of a change in the reinforcement conditions associated with another set of stimulus conditions (Mazur, 2006; Reynolds, 1961). Therefore, this reinforcement change in one condition directly affects responding in other conditions due to more or less reinforcement being available (Hernstein, 1970). Along the same lines, researchers should examine the extent to which the implementation of the same treatment at varying levels (poor uniformity) may evoke challenging behavior that can be termed iatrogenic. In the fields of medicine and psychology, iatrogenic events are adverse conditions that are caused by any number of medical oversights or errors. A few examples of iatrogenic events include if a patient were to develop an infection because a medical professional did not wash his or her hands after touching a previous patient, a surgery in which the wrong kidney is removed, or the wrong hip is replaced or psychological therapy that results in a worsened mental health condition. Hospitals are particularly concerned with preventing iatrogenic events and therefore identify trends and areas to work on for system-wide improvement. ABA practitioners and their organizations should focus on treatment integrity in a similar manner and realize that iatrogenic effects may occur if careful measurement and subsequent performance diagnostics are not pursued to mitigate divergence between persons or settings to prevent unwelcome circumstances that are inadvertently caused by a lack of uniform treatment delivery.

In summary, treatment integrity can be analyzed across three broad areas of concern: (a) consistency encompasses whether the treatment was conducted when it is supposed to be conducted (regardless of accuracy); (b) when the treatment is implemented, accuracy refers to whether or not all treatment components were implemented as trained, and lastly; (c) uniformity describes the cohesive implementation across people and settings (see Table 24.1 for an overview of the three types of errors). Therefore, a procedure may be implemented by an individual in a consistent but inaccurate manner and vice versa. Likewise, an intervention may be uniform across persons and/or settings, but may be low in accuracy and/or consistency across those individuals or it may in fact be uniformly high in consistency and/or accuracy, the latter of which is the ultimate goal for treatment implementation.

Lapses in treatment integrity may have desirable or undesirable effects on treatment outcomes (Gresham et al., 2000) and may lead to the addition of procedures that are not intended to be used. For example, if the therapist engages in an error of commission such as adding a reprimand following a challenging behavior during differential reinforcement of alternative behavior (DRA) plus extinction (EXT) procedure, then the original treatment may be altered if the reprimand functions as a punisher and strengthens the intervention, albeit in a manner that was not prescribed. Another less desirable outcome can occur if the addition of the reprimand functioned as a reinforcer and the challenging behavior increased as a result of this lapse in treatment integrity. Treatment components may also be omitted from a treatment plan. Errors of omission may also affect the outcome of treatment if an essential treatment component is not implemented or the treatment is not implemented at all. Even when inaccurate treatment implementation is acknowledged and beneficial effects of treatment are demonstrated, it may be unclear what the outcome would have been if the designed treatment procedure had been followed. Ultimately, without knowledge of the specific variables affecting IV parameters, no definitive conclusion regarding the functional relation between the intended IV and the dependent variable (DV) can be drawn (Alkhateeb, 1988; Gresham et al., 1993). Therefore, when faced with a treatment that is not producing optimal results, investigating treatment integrity (along

Table 24.1 Overview of treatment integrity errors

Type	Consistency		Accuracy		Uniformity	
Description	A treatment is implemented per the schedule prescribed		All components of a treatment are implemented as prescribed and no additional/unprescribed components are included		A treatment is delivered consistently and accurately across settings and people	
Error types	Commission	Omission	Commission	Omission	Across settings	Across people
Error examples	Delivering treatment on an FR1 schedule when a plan calls for an FR5 schedule	Delivering treatment on an FR5 schedule when a plan calls for an FR1 schedule	Providing an edible and a token for correct responses when a plan indicates that only a token should be provided	Delivering a pretzel contingent on manding for one but not providing verbal praise although the plan indicates both should be provided	All staff members at a day program follow a plan as trained, but caregivers in the residential setting do not	In a school setting, 3 of the 5 teachers in a classroom are implementing a plan with accuracy and consistency

with interobserver agreement) should be the first step in clinical decision-making prior to considering treatment modifications (see Fig. 24.1). Having reliable and objective information about why an intervention may be ineffective and how to address it with a targeted and informed solution can be the difference between obtaining socially significant changes or producing ineffective client progress and staff member dissatisfaction.

Fryling et al. (2012) completed a brief review that focused on treatment integrity and intervention effectiveness. That review led the authors to conclude further empirical evaluation could benefit from including descriptive research depicting treatment integrity in natural settings. In that review, they found it uncommon for descriptive assessments to highlight the occurrence of treatment integrity errors in both the home and classroom setting (Arkoosh et al., 2007; Northup et al., 1994; Taylor & Miller, 1997; Wood et al., 2007). For instance, following a yearlong descriptive study, Arkoosh et al. found that a parent-delivered treatment for the reduction of challenging behavior was delivered inconsistently (range, 0–75%). Likewise, Northup et al. (1994) found that treatment consistency was highly variable when delivered in the classroom setting (range, 0–100%). Moreover, their direct observations indicated that procedures for appropriate responses (DRA) were implemented more frequently (*M* = 76–80%) than procedures implemented contingent on self-injurious behaviors (physical guidance, response blocking; *M* = 27–72%). Likewise, with regard to the accuracy, several descriptive studies have shown low levels of integrity (DiGennaro et al., 2013; Gross et al., 2014). This is concerning given that levels of accuracy may not only influence the treatment effects related to the target behavior but may also have collateral effects on other behavior. For instance, a study conducted by Dib and Sturmey (2007), demonstrated that improvements in accuracy during discrete-trial teaching led to a collateral decrease in stereotypy for three children diagnosed with autism spectrum disorder (ASD).

A few other descriptive studies have also drawn correlational comparisons between treatment integrity and treatment outcome (Carr et al., 1996; Gerhardt et al., 2003; Northup et al., 1994; Wood et al., 2007) For instance, Wood et al. examined interval by interval treatment integrity data in the classroom setting to determine whether poor treatment implementation of a DRA with EXT procedure was correlated with a difference in intervention results. When the classroom teacher implemented the intervention with integrity, the participant was on task 91% of the time in comparison to 9% of the time when the treatment was implemented with poor integrity. In addition, the participants' on-task behavior decreased to pre-treatment levels when treatment

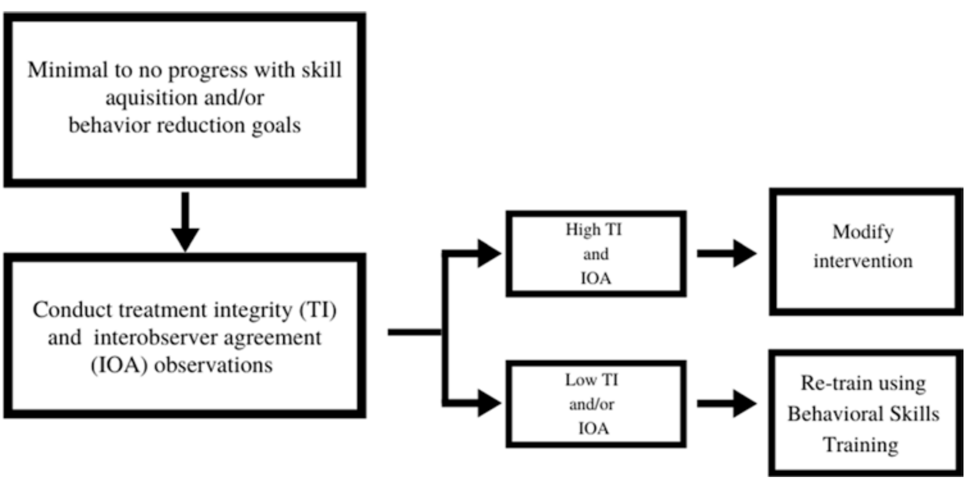

Fig. 24.1 Treatment integrity clinical decision-making model

consistency fell below 80%. Due to the prevalence of such treatment integrity errors, analyses in a controlled setting have been conducted to analyze the impact on treatment outcomes.

Although the behavior analytic literature has used experimental methods to investigate the relationship between treatment integrity and treatment outcome, very few studies have been conducted for this exact purpose. Reviews conducted by Fiske (2008), Fryling et al. (2012), McIntyre et al. (2007), and Progar et al. (2001) touched upon the emerging literature, briefly discussed studies that analyzed treatment integrity effects on treatment outcome, and found that treatment outcomes were sometimes successful under degraded levels of treatment integrity (e.g., Northup et al., 1994; Vollmer et al., 1999). In the present chapter, additional considerations including the conditions under which treatment integrity affects treatment outcomes for different types of behavioral interventions will be reviewed and the clinical recommendations based on these findings will be shared.

Consistency

The strength of treatment must be considered when interpreting how treatment consistency affects treatment outcomes. Related to this is *contingency* strength, or the varying probabilities of responses and consequences in the context of environmental events (Vollmer et al., 2001) can be conceptualized along a continuum from very strong (FR1) to neutral and negative contingencies (Hammond, 1980). While similar, overall *treatment* strength requires knowledge of the probability that the responses are being reliably followed by programmed consequences outlined in a treatment procedure. Many practical questions regarding treatment effects following exposure to degraded levels of integrity can be answered by manipulating the schedule of treatment implementation (McIntyre et al., 2007; Peterson et al., 1982). For instance, intermittent schedules reflect a pattern that can be representative of naturally occurring lapses in treatment integrity. Empirical questions regarding treatment outcomes under degraded levels of integrity can be answered by manipulating the consistency of treatment implementation (McIntyre et al., 2007; Peterson et al., 1982). Parametric analyses have been used to investigate such phenomenon. Parametric analyses manipulate a specific range of values of an independent variable for the purpose of establishing the extent to which each value influences responding (Ahrens et al., 2011; Kliebert et al., 2011; Lerman & Iwata, 1996; Smith et al., 1999; St. Peter Pipkin et al., 2010; Vollmer et al., 1999). As a result, parametric analyses are useful to derive treatment outcome effects produced across a range of treatment integrity values.

Interventions for Challenging Behavior

Differential Reinforcement Procedures Several studies have investigated treatment consistency in relation to differential reinforcement procedures with and without EXT. For instance, Vollmer et al. (1999) exposed three participants to several levels of combined commission (providing a reinforcer for challenging behavior) and omission (failure to provide a reinforcer following the alternative behavior) consistency errors during a DRA with EXT procedure. Specifically, Vollmer et al. tested various schedules of reinforcement in differing orders, across a continuum from baseline (0% reinforcement for appropriate behavior and 100% reinforcement of inappropriate behavior) to a continuous DRA with EXT procedure (100% reinforcement of appropriate behavior plus 0% reinforcement inappropriate behavior). Baseline followed by the continuous implementation of DRA with EXT (100%) were always the first two conditions of participant exposure. When the schedule of reinforcement was equal (50% reinforcement for inappropriate behavior and 50% reinforcement for appropriate behavior) the participant's responding was allocated to appropriate behavior, indicating that recent history with 100% implementation may minimize the effects of treatment integrity failures.

In a subsequent study, St. Peter Pipkin et al. (2010) asserted that sequence effects may have played a role in the Vollmer et al. findings. Thus, St. Peter Pipkin and colleagues conducted a translational study consisting of a series of DRA with EXT experiments to test this hypothesis. Among these experiments were a parametric analysis (80%, 60%, 40%, and 20%) conducted with one participant and an analysis of sequence effects comparing exposure to baseline versus 100% treatment implementation directly before treatment integrity failure conditions with another participant. The parametric analysis results indicated that unfavorable treatment outcomes were obtained when levels of consistency were 40% or lower. In addition, when 50% integrity was evaluated during the sequence effect analysis a favorable treatment outcome was obtained only when the 100% condition directly preceded it. Leon et al. (2014) investigated the consistency of a DRA without EXT procedure following no treatment (baseline) versus full treatment implementation (100%) and similar to St. Peter Pipkin et al. (2010), Leon et al. also found that a slightly more favorable outcome was obtained when the 100% condition directly preceded a 60% consistency condition rather than the baseline condition.

Prompting Procedures Wilder et al. (2006) evaluated the effect of three levels of accuracy (20%, 50%, and 0%) of a three-step prompting procedure via a multielement design with a baseline phase non-compliance with two typically developing preschool children. The dependent measure was compliance to an initial directive to complete known motor tasks (e.g., “Give me X” and “Put X away”). The prompting procedure steps were as follows: (1) call the child’s name, (2) model the correct response, and (3) physically guide the child through the correct response. Correct responses after the second or third prompt were not scored as compliance. Each demand was associated with a different level of treatment integrity for each participant and varied across participants. Response effort was kept equal across demands by keeping the distance a participant had to travel (to comply with the directive) the same for all demands. For both participants, during 50% consistency, compliance was above baseline levels but well below the 100% condition. In a related study, Stephenson and Hanley (2010) also manipulated the integrity of a non-compliance intervention with two typically developing preschoolers. They found that a similar prompting procedure was effective at increasing compliance for two participants when implemented at degraded levels of integrity. However, it is important to note the procedural variations between the studies. Their intervention consisted of a three-part antecedent procedure (the teacher crouched within 0.3 m of the child, touched the child’s shoulder, and delivered 5 s of vocal attention before delivering the directive) and a three-step prompting procedure (initial directive, model, and physical guidance). Compliance was also measured as engagement in motor responses; however, each response was not associated with a different treatment condition as they were in the Wilder et al. study. Instead, all participants were first exposed to 100% treatment consistency followed by the procedure being systematically degraded based on a set criterion. Under these conditions, the procedure was effective when delivered as little as 20% of the time. Therefore, recent reinforcement history may have again been a determining factor in the stability of treatment outcome. It is also possible that gradually degrading treatment consistency may have contributed to the success of treatment at lower levels of integrity.

Punishment Procedures Few studies have directly assessed the effects of degraded levels of treatment integrity on punishment-based procedures. Nonetheless, a study conducted by Clark et al. (1973) first found that an FR1 schedule of time out (TO) was effective in treating several challenging behaviors for one participant with special needs. They then tested the following variable ratio (VR) schedules: 33% (VR3), 25% (VR4), and 12% (VR8) and found that low rates of challenging behavior were maintained under VR3 and VR4 schedules. Furthermore, Northrup et al. (1997) investigated the consistency of a

DRA plus EXT procedure paired with TO. During the intervention, the schedule of DRA plus EXT and TO was systematically manipulated from 100% (FR1), to 50% (VR2) to 25% (VR4). Therefore, all participants in this study had a recent history with 100% integrity levels prior to exposure to degraded treatment integrity levels. For two participants, treatment strength for both DRA and TO was simultaneously manipulated in this manner. For both participants, the DRA plus TO procedure was effectively implemented at 50% consistency. In a more recent study, St. Peter et al. (2016) investigated the effects of both omission and commission consistency errors and found that 50% also produced adequate treatment effects for a DRA with response cost procedure in the context of a translational human operant arrangement.

A few studies have evaluated the extent to which treatment integrity impacts the treatment outcome of response interruption and redirection (RIRD). For example, Ahrens et al. (2011) implemented a parametric analysis using the values 50%, 25%, and 10%. Their results indicated that RIRD was effective during the 50% condition but treatment effects were not maintained at the lower values of implementation. In a more recent study, Colón and Ahearn (2019) also investigated RIRD treatment integrity via a descriptive assessment followed by parametric analysis of RIRD consistency for the treatment of the automatically maintained vocal stereotypy of three participants in a classroom setting of a private school. The types of treatment integrity errors that occur in the natural setting were determined via descriptive assessment. The results of the descriptive assessment indicated that consistency of implementation was the most common error. However, when the procedure was implemented, it was implemented with a high degree of accuracy. Therefore, a parametric analysis was conducted in a controlled setting to determine the impact of consistency errors on RIRD treatment outcomes. Following an ABAB (baseline, 100%; baseline, 100%) treatment analysis, a withdrawal design was used to analyze 75%, 50%, and 25% consistency in alternation with baseline during the parametric analysis. In addition, 25% consistency interspersed with booster sessions at 100% were also evaluated. The results indicated that RIRD was generally effective at 50% consistency or higher. In addition, treatment effects similar to those observed in the 50% condition were also obtained when 25% consistency was interspersed with 100% booster sessions. In a follow-up study, Gauthier et al. (2020) compared the treatment effects of RIRD at two levels of integrity (100% and 33%). In this study, however, degraded treatment integrity conditions were not preceded by exposure to full integrity. Four children diagnosed with an autism spectrum disorder between the ages of 8 and 16 participated. The effects of treatment integrity on vocal stereotypy were assessed using an ABAB-variant design in which B consisted of an alternating treatments comparison of different levels of integrity. Results varied across participants, and although both conditions decreased stereotypy, 100% integrity produced lower levels of stereotypy quicker than 33%. For two participants, following a second exposure to both 33% and 100% in an alternating fashion, suppression of vocal stereotypy was maintained during the 33% condition in the absence of the 100% condition. However, given minimal differentiation between the 33% and 100% alternating conditions for these two participants, it is possible that a lack of discrimination may have produced cumulative exposure to a mean schedule of 66% consistency. This phenomenon may be more closely examined in future studies by associating each condition with salient putative discriminative stimuli. For instance, each condition could be implemented by different experimenters to simulate how caregivers may implement the procedure at different integrity levels in the natural environment.

Moreover, RIRD is an excellent example of an intervention that has been proven to be an effective treatment (for automatically maintained behavior) but can potentially prove to be time-consuming; particularly if participants engage in high levels of the target behavior (Colón & Ahearn, 2019; Duffy-Cassella et al., 2011; Love et al., 2012). However, based on these results, it may be possible to implement RIRD less often while still producing significant treatment effects. In addition, even though the implementation of RIRD with full treatment integrity (100%) resulted in a faster and greater reduction of vocal stereotypy, more time was spent implementing RIRD during this condition, leading to longer session durations. This increase may potentially lead to treatment integrity errors in the natural environment. Environmental constraints such as a classroom setup, as well as teacher-to-client ratios, may prevent the implementation of RIRD following all instances of the target behavior. Future research should determine if treatments that are more time-consuming result in more integrity errors. If two procedures are equally effective, it could be useful to assess which one is the less resource-intensive treatment option. Given that Colón and Ahearn (2019) found that RIRD was effective when implemented with at least 50% consistency following recent exposure to 100%, if the current procedure was in fact functioning at 66% consistency (average between 100% and 33% condition), this would have provided the participants with recent exposure to RIRD above 50% consistency prior to experiencing the 33% alone. Therefore, future studies could examine treatment consistency below 50% from the outset of treatment (following baseline) via a reversal design, to determine if treatment effects are adequate under such conditions.

In addition, the RIRD procedure was ineffective during the 33% condition for one participant. Moreover, for one participant, when 100% consistency was interspersed with diminished consistency, over time both conditions suppressed stereotypy. However, when conducted alone, the 33% condition did not effectively suppress stereotypy. This finding also extended those of Colón and Ahearn (2019), by demonstrating that, interspersing 100% integrity booster sessions can increase the efficacy of the procedure under impaired integrity conditions. Therefore, booster sessions may be beneficial in sustaining treatment effects in the clinical setting. Additional research in this area is necessary to gather more information on the maintenance of treatment effects over time. Nonetheless, these results generally replicated previous research, showing that lower levels of integrity can be effective in suppressing stereotypy.

Summary

The existing literature pertaining to consistency has yet to establish a clear difference between omission errors or a combination of omission and commission errors as it relates to their impact on the level of consistency necessary to produce a beneficial treatment outcome. Instead, the existing literature indicates that if treatment failure follows exposure to full treatment implementation the impact on treatment outcome may be less substantial. Further research is required to determine whether treatment effects would be stronger if treatment failure conditions are directly preceded by 100% integrity conditions rather than BL conditions (St. Peter Pipkin et al., 2010; Vollmer et al., 1999). It also remains unknown how recent or how long the exposure to 100% treatment integrity must be to afford a successful treatment outcome during treatment integrity failures. Another relevant question for future research is whether or not a longer history of reinforcement for one behavior over another affects response allocation in the face of less-than-optimal treatment integrity (Vollmer et al., 1999).

Accuracy

Analyzing the accuracy of a procedure and its effects on treatment outcomes can be investigated via comparative analyses and component analyses. Comparative analyses are used to determine the impact of inaccuracies on previously validated procedures via evaluations of programmed accuracy errors versus conditions of 100% accuracy. Whereas, component analyses can systematically determine the necessity and/or relative impact of treatment steps (Carroll et al., 2013; Cook et al., 2015; Ward-Horner & Sturmey, 2010).

Interventions for Challenging Behavior

Differential Reinforcement Procedures A few treatment integrity studies have explicitly investigated accuracy as it pertains to interventions for challenging behavior. Of these studies, the vast majority examined differential reinforcement procedures paired with other procedures. For example, several studies have investigated FCT procedures and found that EXT was a necessary component to achieve significant treatment effects (e.g., Shirley et al., 1997; Volkert et al., 2009; Worsdell et al., 2000). For instance, Worsdell et al. investigated the effects of the inconsistent application of EXT during the acquisition of functional communication training (FCT). Without any previous exposure to EXT for the challenging behavior, EXT was manipulated by thinning the schedule of reinforcement for the challenging behavior while reinforcement for the functional communication response was delivered on a continuous schedule. When the schedules of reinforcement were equal for both the challenging behavior and the alternative behavior, the procedure was ineffective for four out of five participants. For the participant who acquired the alternative response during continuous reinforcement for both responses, the authors indicated that it was possible that the participant's challenging behavior (SIB) may have also produced aversive consequences (e.g., pain) influencing response allocation towards the alternative behavior. For all other participants, the procedure was not effective until at least half of the target responses were followed by EXT (i.e., FR2, FR10, and FR20). Furthermore, for the two participants for which the treatment was not effective until the FR20 schedule was implemented, it was rare that they engaged in 20 responses per session, therefore these sessions may have functioned as 100% EXT conditions. In addition, the authors did not provide exposure to EXT in order to minimize recent history effects; therefore, it is unclear whether these results would have been different following recent exposure to EXT at 100% treatment integrity. Furthermore, Pritchard et al. (2014) conducted a review of behavioral momentum theory (BMT) including how the theory relates to recent history and treatment integrity. BMT research has shown that behavior is more persistent when faced with disruptors (e.g., EXT) in contexts associated with higher rates or density of reinforcement (e.g., Grimes & Shull, 2001; MacDonald et al., 2013; Nevin et al., 1990). Moreover, in line with this theory, basic and translational research has shown that recent exposure to alternative reinforcement may actually increase resistance to EXT (Ahearn et al., 2003; Mace et al., 2010; Nevin et al., 1990). This is problematically paired with the reality that a caregiver may occasionally fail to provide reinforcement for functional communication responses causing the challenging behavior to reemerge (Durand & Carr, 1991). This phenomenon has been referred to as a resurgence. A study conducted by Volkert et al. highlighted the occurrence of EXT-induced resurgence following a successful implementation of an FCT + EXT procedure. In this study, a resurgence occurred with four out of five participants when reinforcement was either provided on a thin schedule (FR12) or no longer provided at all for the functional communication response.

Punishment Procedures Northrup et al. (1997) investigated the accuracy of DRA plus EXT paired with TO with two participants. Both participants had a recent history with 100% integrity levels prior to exposure to degraded levels. DRA was held constant at 100%, and TO was effectively reduced to 50% (VR2) for one participant and 25% (VR4) for the other participant. For this participant, 25% TO was also effective in the absence of DRA (EXT for appropriate behavior). Although the results for the third participant may be idiosyncratic, it is also possible that the use of a VR schedule may have contributed to a lack of discrimination between conditions, leading to similar results across the 50% and 25% conditions. Saini et al. (2015) also found that a low level of accuracy produced significant treatment effects when they reduced the response requirement component of the RIRD procedure from three demands (100%) to one demand (33%) without diminishing treatment effects on stereotypic behavior for the four children diagnosed with ASD who participated in their study. Following baseline, Saini et al. introduced a multielement design inclusive of baseline alternating with 100% and 33% accuracy conditions, followed by the reintroduction of baseline and finally 33% alone. The 33% condition which consisted of one demand instead of three demands produced similar results to that of the 100% condition and was maintained over time when the 33% condition was implemented alone.

Given the few existing analyses of treatment accuracy targeting the treatment of challenging behavior, future research inclusive of descriptive studies and experimental studies is encouraged to determine the relative impact and parameters of treatment steps/components.

Academic Skill Acquisition Procedures

In recent years, there is emerging research regarding treatment integrity effects on academic teaching procedures. In specific, multiple studies have explored the impact of one or more components of academic skill acquisition procedures. For example, Carroll et al. (2013) conducted a descriptive assessment to determine relevant treatment integrity errors that occur during discrete-trial (DT) instruction in the classroom setting. They then manipulated the treatment integrity of the three most commonly observed errors (failure to deliver a tangible following correct responses, failure to deliver a controlling prompt, and failure to present the correct instruction once) combined and in isolation. Future research should investigate the other components of DT instruction that were also observed to be low in the classroom setting (e.g., establishing attending behavior prior to each trial). When combined errors were tested in comparison to 100% accuracy they found that 100% accuracy led to a greater likelihood of acquisition. Only one of the six participants acquired the skill under low accuracy conditions, the rest of the participants required exposure to 100% accuracy to acquire the skill. Furthermore, the targets exposed to the three combined errors 67% of the time (33% accuracy) required more instruction sessions than those targets taught using all components. When the three errors were tested in isolation with three participants from the previous study, two of the three participants acquired the skills under all conditions. However, one participant required exposure to 100% accuracy for the targets previously presented with 33% accuracy to acquire all target skills. Moreover, two participants who did not acquire the target stimuli when the errors were combined in the previous study did acquire the skills when the errors were tested in isolation. This finding indicates that combined errors may have a greater impact on skill acquisition than singular errors. Furthermore, correct responding was lowest when the controlling prompt was omitted or a different instruction was given for two participants. For the other participant, the lowest levels of correct responding occurred when a tangible was not provided contingent on correct responding. Although this study presents an elegant evaluation of treatment integrity errors encountered during DT teaching, it requires replication and further extension. Moreover, the authors point out that conducting a within-subject replication with additional target sets may be beneficial as it is possible that assigning different stimuli to different test conditions affected the outcome.

Pence and St. Peter (2015) conducted two experiments that tested the accuracy of consequences for correct responding during a mand training procedure. In experiment 1, they evaluated the effects of delivering an incorrect item across three participants, and in experiment 2, they evaluated the delivery of an item independent of a mand response across three participants. Four levels of accuracy (0%, 40%, 70%, and 100%) were tested in each study. Overall, the results indicated that mands were acquired when accuracy was high (70% and 100%), and the acquisition was less efficient during the 70% condition. However, the manner in which preferred stimuli were assigned to each treatment integrity condition presents a potential confound. For example, the highest preference item was assigned to the lowest integrity condition and the lowest preferred item was assigned to the high integrity condition. Consequently, one participant acquired a mand under conditions of 0% accuracy (when an incorrect item was delivered) presumably due to the potency of the reinforcer which was in sight during all sessions. The extent to which the assignment of preferred items to each condition and possible fluctuations in preference may have affected the results as a whole is uncertain and requires further investigation.

Holcombe et al. (1994) investigated the impact of accuracy as it relates to constant time delay prompt delivery. Via a comparative analysis, efficiency and effectiveness were measured with six preschool children with developmental disabilities during a DT procedure. Specifically, they used an adapted alternating treatments design to apply two different treatment accuracy conditions to independent sets of target stimuli. They compared 100% accuracy with low accuracy prompt delivery. During the low accuracy condition, the controlling prompt was not delivered during an average of 44% (range, 35–52%) of opportunities across all participants (66% accuracy). One participant did not acquire the target skills under either condition. Of the remaining five participants, all five acquired the skill with 100% accuracy. During the low accuracy condition, four of the remaining five acquired the skill. However, following exposure to 100% accuracy, this participant demonstrated mastery of the stimuli previously associated with low accuracy. In addition, when the 100% accuracy condition was in effect, four of the five participants required less time to acquire the skill relative to lower accuracy conditions.

Grow et al. (2009) also found that altering the accuracy of a prompting procedure produced less efficient learning in comparison to the recommended and validated prompting strategy when teaching a five-step response chain (pattern design) was conducted with four children diagnosed with ASD. Specifically, they compared the use of a least to most prompt hierarchy, verbal, model, and physical with a 5 s delay, (100% prompting accuracy) to a condition that entailed repeating the verbal prompt three times, not providing the opportunity to respond after the model prompt and omitting the physical prompt (0% prompting accuracy). In the 100% condition, if the participant completed a step following a model prompt, they received praise only. Under both conditions, if the participant completed the entire response chain without experimenter prompts, they received access to a toy for 30 s. Although all participants acquired the skill, three of the four participants required additional trials to acquire the skill, resulting in approximately 3–9 min of additional teaching time. Although this is not a considerable amount of time in isolation, the possible cumulative effects overtime and across several skill domains are unknown. It is important to note that this study altered all elements of their prompting procedure, therefore further research may be necessary to determine whether one or more modifications to the prompting are responsible for these findings. Although this study was framed in reference to treatment integrity, given that the study compared 0% accuracy with 100% accuracy this study may instead be considered a general test of the efficacy of this procedure's utility, rather than a treatment integrity analysis of prompting accuracy. Therefore, the merit in this study as it relates to treatment accuracy relates to the possible impact on the efficiency of a procedure when the prompting procedure is not run accurately but consequence procedures remain intact.

In a similar study, Groskreutz et al. (2011) examined three levels of accuracy (100%, 50%, and 10%) of physical prompting for a three-step appropriate play sequence with two participants. Three toys were selected for each participant dependent on high levels of inappropriate toy play and low levels of appropriate toy play. As with previous studies, each toy was assigned to a specific accuracy level. For one participant, appropriate toy manipulation increased under both 50% and 100% accuracy. However, for the other participant, toy manipulation was only acquired during the 100% accuracy condition. Furthermore, this participant did not acquire the other target skills even after 100% was introduced following failures in the 50% and 10% conditions. Therefore, these findings may be due to recent history effects comparable to past treatment integrity consistency studies (Ahrens et al., 2011; Lerman & Iwata, 1996; Northrup et al., 1997; St. Peter Pipkin et al., 2010; Stephenson & Hanley, 2010; Vollmer et al., 1999). Therefore, due to a lack of exposure to 100% accuracy prior to degraded levels of treatment integrity, treatment effects were not salvageable. Nevertheless, due to the fact that toys were selected based upon levels of engagement in inappropriate play rather than a lack of engagement it is possible that a concurrent operant arrangement was also a factor.

The error correction component of DT instruction was evaluated by Worsdell et al. (2005). They found that more sight words were acquired with 100% accuracy versus 33% accuracy; however, both levels of accuracy were adequate for all six of their participants to acquire more sight words than previously demonstrated during baseline. Further analysis of the error correction procedure to test other values would be beneficial to determine if a certain level of accuracy (above 33%) produces a similar rate of acquisition to 100% accuracy. Furthermore, during this study, all other components were held constant, including positive reinforcement for correct responses. Therefore, it is unclear how such inaccuracies of consequences for incorrect responding would impact acquisition if inaccuracies of the consequences for correct responding occurred simultaneously. Future studies could determine the parameters of inaccuracies for both consequence components similar to the combined investigation carried out by Carroll et al. (2013) but perhaps with titration of each schedule via a parametric analysis.

The majority of skill acquisition studies have investigated treatment integrity errors of omission. Conversely, DiGennaro Reed et al. (2011b) investigated errors of commission during a receptive identification program for nonsense shapes taught via discrete-trial instruction to three participants. Following the baseline condition in which no programmed consequences were delivered contingent on performance, three different integrity levels were tested (0%, 50%, and 100%). Each level was associated with a different nonsense shape. Commission errors entailed providing tokens and social praise following an incorrect response and before implementing the error correction procedure. Their findings demonstrated that acquisition only occurred in the absence of commission errors (100% integrity) for all participants. In an extension of this study, Jenkins et al. (2015) tested commission errors in the same manner as the previous study however they did not implement the error correction procedure following reinforcement. They also added putative discriminative stimuli by printing the match-to-sample stimuli (modified Japanese alphabet characters) on different colored paper associated with each treatment integrity level (0%, 50%, and 100%). Furthermore, they introduced 100% treatment integrity following exposure to degraded integrity with three of the four participants. The results for these three participants replicated the findings of the DiGennaro Reed, Reed, Baez, and Maguire study. The other participant did not meet the mastery criterion in any condition indicating that the proposed discriminative stimuli may not have assisted with discrimination between conditions for this participant. When 100% integrity was introduced, two of the three participants showed a delay in acquisition, but the adverse effects of degraded treatment integrity were reversible for all three participants. It is important to note that the ecological validity of these two studies is uncertain given that such errors do not seem likely to occur at such high rates in the natural setting. Descriptive assessments may be beneficial in identifying whether this type of error is common and indicate components to analyze in future studies.

Summary

In summary, accuracy studies that solely entailed commission errors (DiGennaro Reed et al., 2011b; Jenkins et al., 2015; Pence & St. Peter, 2015) all required a fairly high level of accuracy to be effective (70–100%). These three studies also all manipulated consequence errors; therefore, it is difficult to determine whether errors of commission, consequence errors, or a combination of commission consequence errors may be responsible for this outcome. Therefore, further research should be conducted to determine the conditions presumably warranting this high level of accuracy. In contrast, the studies that solely investigated omission errors included four studies that manipulated antecedent errors (Groskreutz et al., 2011; Grow et al., 2009; Holcombe et al., 1994; Saini et al., 2015) and three studies that manipulated consequence manipulations (Northup et al., 1997; Worsdell et al., 2000, 2005). In comparison to the commission studies, these studies generally required a lower level of accuracy (33–66%), indicating that perhaps errors of omission are less detrimental than errors of commission. Yet, as previously mentioned additional studies would be necessary regarding errors of commission to further support this conclusion.

When studying accuracy specific to discriminative stimuli presentation, Carroll et al. (2013) found inaccuracies to lead to lower rates of correct responses but did not prevent the eventual acquisition of the target skill. Of the three studies that investigated the impact of prompting procedure inaccuracies, the majority of the participants acquired target skills under conditions with as low as 50% accuracy. However, two of these studies also found that inaccurate prompting compromised the efficiency of the teaching procedure (Grow et al., 2009; Holcombe et al., 1994). Efficiency may also be affected when the consequence delivered for a correct responding is inaccurate (Pence & St. Peter, 2015). Given that few studies have investigated the accuracy of antecedent implementation, further research is warranted. As for, the accuracy of consequences delivered for incorrect responses (error correction) the existing literature indicates that although acquisition may occur following inaccurate error correction procedures, more skills may be acquired when accuracy remains intact (Worsdell et al., 2005). The existing literature also demonstrates that providing reinforcement for incorrect responses is detrimental to skill acquisition (DiGennaro et al., 2011a; Jenkins et al., 2015). However, Jenkins et al. (2015) demonstrated that skill acquisition is eventually possible following exposure to inaccuracies related to the consequence delivered for incorrect responding when 100% accuracy is subsequently implemented. Similar results were found regarding combined inaccuracies in the Carroll et al. (2013) study. Unfortunately, Groskreutz et al. (2011) found that one participant who failed to acquire skills at 50% and 10% prompting accuracy also did not meet the mastery criterion when 100% accuracy was ultimately implemented.

Discussion

Contemporary treatment integrity research (1973–2019) consists of only 20 experimental analyses that examined treatment integrity with enough rigor to determine an impact on treatment outcome. To provide insight into the available evidence on intervention integrity for adoption into practice or for informing future research, there are twice as many studies regarding treatment accuracy than those concerned with treatment consistency. Echoing the findings of Fryling et al. (2012), there remains a void in the reinforcement-based literature with respect to non-contingent reinforcement and differential reinforcement of other behavior, therefore, future research should investigate treatment integrity as it relates to both of these procedures.

With respect to punishment-based procedures, there is a considerable gap in the literature. It is important that we make every effort to study the parameters of any and all procedures we may use in clinical practice. Thus, further knowledge regarding punishment parameters (i.e., intermittent punishment without extinction, availability of alternative reinforcement, magnitude of relevant stimuli, and recent history) is imperative to ensure that practitioners are fully equipped with the technology to provide behavioral treatment in an effective and efficient manner. In like fashion, many of the consistency studies focused on variations of DRA procedures (with and without extinction or time out) with minimal examination of other procedures. For instance, one study investigated timeout alone, one investigated response cost, one investigated RIRD and two manipulated prompting procedures. Likewise, the accuracy literature lacked variety as well with the majority of accuracy studies investigating skill acquisition procedures rather than treatments for challenging behavior. More specifically, these studies predominantly investigated DT instruction components with little or no emphasis on various other skill acquisition procedures (e.g., task analyses, natural environment teaching, and video modeling) indicating an area for future research. Given the lack of repeated studies across various treatment procedures represented in the literature, further analyses are necessary to determine if there is a certain level of accuracy and/or consistency necessary to produce beneficial treatment outcomes for specific types of treatments.

However, when comparing antecedent versus consequence procedures the literature does appear to indicate a likely difference between the levels of integrity that are effective. With regard to consistency studies, in the studies that investigated antecedent manipulations (Stephenson & Hanley, 2010; Wilder et al., 2006) the integrity level under which they were effective was 20–50%, whereas the studies that examined consequence manipulations (Leon et al., 2014; Northup et al., 1997; St. Peter Pipkin et al., 2010; Vollmer et al., 1999; St. Peter et al., 2016; Colón & Ahearn, 2019) were generally effective for most participants within a slightly higher range of 50–100% with the exception of the Clark et al. (1973) study which reported treatment effects with consistency as low as 25% consistency. With regard to accuracy, a similar pattern was evident. Studies that investigated antecedent manipulations (Groskreutz et al., 2011; Grow et al., 2009; Holcombe et al., 1994; Saini et al., 2015) were effective under relatively low levels of accuracy 0–66%, in comparison to the studies that examined consequence manipulations (DiGennaro Reed et al., 2011b; Holcombe et al., 1994; Jenkins et al., 2015; Pence & St. Peter, 2015; Worsdell et al., 2000, 2005) which were generally effective for most participants at a slightly higher range of 50–100%, with the exception of the Northup et al. (1997) study which reported treatment effects with consistency as low as 25% accuracy. Notably, this study was also the only accuracy study in which the participants were first exposed to a recent history of 100% accuracy which poses the question of whether or not this was the determining factor for the low level of accuracy necessary to obtain a favorable treatment outcome. The lack of studies examining the accuracy and recent history indicates a need for further investigation in this area. Ward-Horner and Sturmey (2010) described two types of component analyses. The add-in method involves systematically introducing components (e.g., Hanley et al., 2000) while the dropout method entails the systematic removal of components (e.g., Cooper et al., 1995). Future research could use dropout analyses to establish clear findings regarding the accuracy parameters of specific treatments. Once this literature base has been established, a comparison to add-in analyses could assist in determining the impact of recent history and sequence effects. Common multi-step treatments should be investigated in this manner to determine the weight of each component or step. This also assists with paring down treatments for the sake of efficiency as well as determining the parameters of certain treatment components for treatment success.

Several parametric analyses of treatment consistency have simulated systematic schedule thinning by implementing variations of treatment integrity on a continuum (Northup et al., 1997; Stephenson & Hanley, 2010; Vollmer et al., 1999) and obtaining behavioral stability before titrating up or down the schedule. Schedule thinning requires a systematic approach to gradually decreasing the amount of time or number of instances that an individual has access to a consequence until a desired schedule is reached. Although these data are useful in providing an overall scope of the necessary level of treatment integrity, it is unlikely that treatment implementation in the natural environment occurs with such a systematic pattern of delivery. A range of environmental factors (e.g., other children to attend to, time constraints, and avoidance of collateral behavior) may produce variability in treatment delivery. Therefore, future research investigating a random schedule of treatment consistency may be more relevant to testing the effects of naturally occurring treatment implementation on treatment outcomes.

It is also important to note that considerations related to treatment outcomes not only include the consistency and accuracy of implementation but also the immediacy and magnitude. Substantial research has yet to be conducted to determine how immediacy and magnitude are associated with treatment integrity and how they may interact with consistency and accuracy errors. One study that investigated immediacy as it relates to treatment integrity was conducted by Kliebert et al. (2011). Via a parametric analysis, the authors manipulated delays (3 s, 15 s, and 30 s) to implementation of a response interruption procedure with two participants who engaged in automatically maintained skin picking and hair twirling. They found that delayed response interruption was effective for one of the two participants. The participant with whom delayed response interruption was effective was first exposed to immediate response interruption. In contrast, the second participant (for whom delayed response interruption was ineffective) was first exposed to all three delay conditions prior to the immediate response interruption condition. Other studies have found that delays as little as 3 s can generally weaken treatment strength and in turn can decrease treatment impact (Leon et al., 2016), particularly if the delay is unsignaled and not introduced via systematic fading (Fisher et al., 2000; Hanley et al., 2001; Kelley et al., 2011; Lattal, 1984). Due to these mixed results and a lack of replication for each experimental sequence further investigation is warranted. Similar to the lack of applied studies that specifically analyze treatment integrity parameters of delayed implementation, current studies have not analyzed magnitude parameters from a treatment integrity perspective. However, past research concerning reinforcer magnitude indicates that differences in magnitude effect response rate. For instance, during time-based reinforcement a larger reinforcer magnitude results in a lower response rate (Carr et al., 1998; Roscoe et al., 2003) whereas a larger magnitude when faced with delays to reinforcement may produce a higher likelihood of acquisition (Doughty et al., 2012). Given the various changes that different magnitudes can produce, future research should manipulate the magnitude of consequence stimuli to determine whether magnitude can make a treatment more or less susceptible to undesirable treatment outcomes during lapses in treatment consistency across different types of procedures (Leon et al., 2014).

In 2012, Fryling et al. asserted that it is possible that treatment integrity failures are less detrimental if preceded by a history of high integrity. Despite significant gaps in the treatment integrity literature, the current review indicates that across procedures, recent history appears to be a pivotal factor affecting treatment outcomes following exposure to treatment consistency errors (e.g., Clark et al., 1973; Stephenson & Hanley, 2010; St. Peter Pipkin et al., 2010; Vollmer et al., 1999). Therefore, this finding reiterates and extends the literature base supporting the role of recent history and its impact on treatment consistency. Furthermore, consistency and accuracy delivered at 50% or higher were reliably effective across several studies (e.g., Leon et al., 2014; St. Peter Pipkin et al., 2010; Vollmer et al., 1999; Wilder et al., 2006). In other studies, a successful treatment outcome was possible when consistency and accuracy were delivered even less than 50% of the time (e.g., Carroll et al., 2013; Clark et al., 1973; Stephenson & Hanley, 2010). In terms of efficiency, Pence and St. Peter (2015) indicated that learning may take longer following accuracy errors. However, the existing studies did not investigate the efficiency of a procedure following consistency errors. Moreover, amongst the variety of unresolved questions, it is unclear how a combination of consistency and accuracy errors may affect treatment outcomes. To resolve such questions, a connection between treatment integrity and empirically supported behavioral principles and parameters (e.g., immediacy, magnitude, schedule, concurrent operant) must be made to provide a scope for future research and subsequent improvements in clinical practice. In an effort to make such information more consumable and easier to locate, as a field, we can make an effort to reliably include treatment integrity considerations in the discussion section of any research article that covers content relevant to the above-mentioned questions, even if it is not the primary purpose of the research.

Clinical Implications and Recommendations

Based on existing literature some general clinical considerations can be gleaned. For instance, the parametric analysis research indicates that one of the most critical times to ensure exposure to 100% treatment integrity is when the treatment is first introduced. This finding highlights the necessity of evidence-based training practices and increased clinical oversight at the outset of a new intervention. Behavioral skills training (BST) is an evidence-based methodology that comprises an explicitly stated order of steps that, when followed in its entirety, fosters a high degree of competence. BST can (a) *teach new* skills or (b) *improve skills* already in a person's repertoire. When staff members are trained using this model and provided with appropriate and ongoing feedback, treatment integrity can be expected to increase. Even experienced staff members can benefit from client-specific training and supervision to refine their skills. Parsons et al. (2012) emphasized this distinction by stating: "Though knowledge enhancement is clearly an important function of certain training endeavors, the goal of this protocol is improved performance. The distinction between training performance versus verbal skills is important because of the different outcomes expected..." (p. 2). When working to eliminate treatment integrity barriers, employing BST can have far-reaching benefits, therefore BST is highlighted in this chapter to show how it is suitable to address practical treatment integrity issues. For a thorough description of BST's essential components, please refer to Parsons et al. (2012). A summary of the standard steps encompassed in the BST model and their relationship to treatment integrity is presented in Table 24.2 and outlined in the following section.

The Relationship Between Treatment Integrity and BST A chief goal of training is to assure staff members and/or caregivers that the proposed intervention will improve the client's quality of life. Without an adequate reference tool, the implementation may suffer from mistakes related

Table 24.2 Behavioral skills training (BST) steps and their relation to treatment integrity

BST Step	Description	Relation to treatment integrity
1	*Communicate a description of the* intervention steps and *provide a rationale*	Provides a question and answer forum and strives for buy-in from trainees
2	Provide a *written summary* of the intervention	Provides a clear, concise, and objective reference tool that promotes consistency, accuracy, and uniformity
3	*Model performance* of the intervention	Provides the instructor the show the trainee the skills and offers the opportunity to emphasize all subtleties that are difficult to communicate in written form alone
4	rainees *practice* implementing the intervention (in vivo or via role-playing)	Provides objective confirmation that trainees deliver an intervention consistently, accurately (and uniformly acorss trainees).
5	*Observe trainee performance* and *provide affirmative and supportive feedback*	Provides instructor opportunities to shape accuracy and demonstrate how ongoing observations and feedback will be delivered
6	*Repeat steps 4 and 5* until the trainee demonstrates mastery of implementation	Provides necessary opportunities to improve performance and increase the likelihood of 100% treatment integrity at the outset of treatment
M	*Post-training* treatment integrity observations inclusive of data collection with BST components embedded as needed	Provides opportunities to promote optimal treatment integrity, boost degraded integrity, and maintain desired treatment outcomes

to poor recall or unclear expectations which in turn may also encourage improvisation in the form of further errors of omission and/or commission.

For that reason, the first step in BST includes communicating a description of and rationale for the intervention. By starting out with a description and rationale, the behavior analyst can gauge audience reaction, answer questions, recognize treatment aspects that may require modification, and create a firm foundation to deliver written instructions and subsequent training steps. This step allows the behavior analyst the opportunity to describe *why* the course of action has been chosen and what impact it is expected to have for the client. After delivering a description and rationale for the intervention procedures, BST directs a practitioner to provide written instructions outlining what trainee behaviors comprise the intervention you are training (e.g., break the intervention down into easy-to-follow steps similar to a task analysis) and how to implement the intervention across relevant scenarios. A written version offers a standard reference tool for use by multiple staff members and/or caregivers, which is consistent with the technological dimension of ABA (Baer et al., 1968). To accomplish uniformity across staff members and caregivers it is recommended that the intervention be operationally defined in a clear, concise, and objective manner (Gresham et al., 1993).

The next three BST components (modeling, practice, feedback delivery) have been linked to the most significant improvements in staff performance (e.g., Gardner, 1972; Hogan et al., 2015). Modeling via role-playing, video model, or in vivo provides the instructor the opportunity to show the treatment in action and emphasize any subtleties that may be difficult to communicate in written form alone. Building knowledge about particular skills is valuable as an initial means of learning; however, it is ineffective for the continued maintenance of client-specific treatment implementation (Parsons et al., 2012). Thus, the next BST step advances the process into the observable and requires that trainees practice the target skill in its entirety. To complete this key step, trainers typically create role-play scenarios that replicate circumstances in which the intervention is to be employed. It is important to model various situations that may occur when working with a client (e.g., "This is what you do if... But if this happens, do this..." "In this setting you may need to do this..."). For instance, when training a skill acquisition program, the role play should include the practice of both the error correction procedure and the reinforcement procedure. Failure to include multiple practice opportunities is likely to degrade treatment integrity being that an explanation alone may not adequately illustrate motor movements, pauses, and non-vocal expressions (i.e., demeanor and body language). Therefore, trainees are asked to practice the skill and receive feedback. Carrying out modeling and practice with feedback furnishes the practitioner with the opportunity to share how post-training treatment integrity observations will occur. By using this model, a practitioner is able to share performance evaluation criteria via verbal and written instruction modeling and practice with feedback so that trainees are then familiar with the post-training feedback style and the breadth of expectations.

The last formal step of conventional BST involves trainees continuing to practice all necessary skills until competency is demonstrated (ideally more than once). Although conducting initial training to competency is valuable it is likely ineffective for the continued maintenance of client-specific treatment implementation. Thus, this final step in the BST model has been termed the "last formal step" because in actuality the periodic replication of the BST model should become a part of one's ongoing clinical practice. This maintenance phase is integral to foster ongoing accuracy, consistency, and uniformity; therefore, practitioners should set aside ample time to conduct regular treatment integrity observations for each individual staff member or caregiver as part of a supportive client supervision structure. Moreover, as errors are observed, retraining per the BST model should be employed. As previously mentioned, the use of the BST model during treatment integrity observations is beneficial as it offers a framework that staff members and/or caregivers are familiar with given their previous experience during initial training. Moreover, treatment integrity observations should entail data collection based on the written steps of the procedure. This practice is in line with the Behavior Analyst Certification Board® (BACB®) Ethics Code for Behavior Analysts (2020). Specifically, code 3.11 Documenting Professional Activity states that "Throughout the service relationship, behavior analysts create and maintain detailed and high-quality documentation of their professional activities to facilitate provision of services by them or by other professionals, to ensure accountability, and to meet applicable requirements (e.g., laws, regulations, funder and organization policies). Documentation must be created and maintained in a manner that allows for timely communication and transition of services, should the need arise." *In addition,* Therefore, initial training, treatment integrity monitoring, and retraining should all be documented by a practitioner. Figure 24.2 offers an example of recommended treatment integrity documentation components. These components can be used to create a data sheet that coincides with a behavior intervention plan or a skill acquisition program. Figure 24.2 utilizes the procedural steps of a hypothetical program to illustrate the following components of a treatment integrity data collection form: (1) a section to tally all observed opportunities to implement the treatment, (2) a section to tally observed implementation of the treatment per the schedule trained (consistency), (3) a section to tally the number of opportunities to implement each component of the treatment, (4) a section to check off each step of the intervention that was observed to be completed as trained (accuracy), (5) sections to note errors of commission (This section is important as a reminder to that practitioner do not overlook such errors and are helpful to reference in terms of interference with clinical outcomes.), (6) a section to calculate the percentage of consistency and percentage of accuracy, and (7) a section to document all support provided during and after each observation inclusive of training details, affirmative feedback (e.g., "That was such a great way to set-up a teaching opportunity. It really captured your cleints interest") and supportive feedback (e.g., "Dont' forget to have preferred items readily available so that you can provide the reinforcer as immediately as possible. Do you need any help with ideas for arranging your set-up before running the next program?").

The frequency and duration of treatment integrity observations will depend on the level of support required to oversee a particular case. Nevertheless, a practitioner should set a minimum expectation regarding the regularity (e.g., at least monthly) of treatment integrity observations and increase support as needed based on data gathered via progress monitoring and treatment integrity observations. In addition, having objective and clear data collection allows a practitioner to provide impartial feedback to foster a supportive training process.

During initial training, practitioners should be transparent by sharing how training practices will be ongoing and outline how treatment integrity observations will be included in these practices while being sure to highlight the benefits for staff professional development, generalization of client skills with caregivers, and overall client progress alike. Treatment integrity monitoring assists with the challenge of providing feedback by structuring performance expectations and thereby offering objectivity to the feedback provided. A practitioner should provide affirmative feedback often so that supportive feedback does not stand out as the only feedback given. Formal treatment integrity allows for a structured account for affirmative feedback opportunities, but feedback should also be provided outside of these observations. Also, the BACB® Ethics code for behavior analysts *4.08 Performance Monitoring and Feedback states that "Behavior analysts engage in and document ongoing, evidence-based data collection and performance monitoring (e.g., observations, structured evaluations) of supervisees or trainees. They provide timely informal and formal praise and feedback designed to improve performance and document formal feedback delivered."* (Behavior Analyst Certification Board, 2020). When feedback is provided done

Treatment Implementation (Consistency)

Staff member or Caregiver action	Number of opportunities to implement	Number of times implemented
Procedure is implemented when it is prescribed to be conducted (whether or not all components are included or implemented correctly)		
TOTALS		
Errors of commission (e.g., was the procedure implemented when it was *not* prescribed to be conducted?)		

Treatment Components (Accuracy)

Staff member or Caregiver action	Number of opportunities to implement	Number of times implemented
1. Set up activity and omit one item necessary to complete the activity.		
2. Provide instruction to engage in the activity.		
3. If child does not request missing item within 2 seconds provide the next prompt in least to most prompt hierarchy.		
4. If child accurately requests the missing item (with *or* without prompting), immediately (within 2 seconds) provide the missing item.		
5. If child accurately requests the missing item (with *or* without prompting), immediately (within 2 seconds) deliver praise (e.g. "Nice job asking for that!").		
6. If child accurately and independently requests the missing item (*without* prompting), immediately provide the missing item (within 2 seconds) AND a small preferred edible.		
7. If child engages in an incorrect response, error correction is conducted.		
TOTALS		
Errors of Commission Were any additional components added to the procedure that are not prescribed?		

Data Collection Summary

Fig. 24.2 Example of treatment integrity data collection components

per current clinical and ethical standards, it fosters an environment of support, education, respect, and compassion. In turn, staff members and caregivers are more likely to welcome the treatment integrity observation process as a means to sharpen their skill set and readily accept suggestions for continuous improvement. Practitioners should strive to promote an environment that emphasizes supportive feedback as a learning opportunity and not a punitive event. An enriching relationship is best established when a practitioner is transparent about training and treatment integrity practices and lets the staff member or caregiver know when treatment integrity observations will take place, what they will entail and the purpose of such practices prior to their first observation, ideally at the outset of the professional relationship. There should be complete transparency regarding the process as well as the outcome. In fact, as part of the feedback process staff members and caregivers should be provided with both a discussion of feedback as well as written feedback on their performance via the BST training model and a copy of their treatment integrity documentation (e.g., completed treatment integrity data collection form and/or graphs of their performance). In addition, open lines of communication between a practitioner and those implementing treatment are crucial to client success. All staff members and caregivers should be encouraged to ask for clarification or feedback. For instance, they should be encouraged to ask questions if a program or plan is difficult to run or hard to understand. This type of ongoing communication will allow optimal responsiveness on the part of the clinician to achieve client progress and foster staff member and caregiver confidence and proficiency.

Several studies have referred to the abovementioned maintenance phase as BST booster training inclusive of role-play has proven effective in re-establishing high treatment integrity across various settings (e.g., Miller et al., 2014). In addition, Hogan et al. (2015) extended this research by forgoing role-play and instead conducting in vivo BST booster training with actual clients in a classroom setting to improve staff member implementation of a behavioral intervention plan. Because treatment integrity research has shown that interspersing booster sessions (consisting of 100% treatment integrity) with a client offers a promising method to salvage previous treatment effects (e.g., Colón & Ahearn, 2019; Gauthier et al., 2020), if the opportunity to ensure initially high integrity has been missed, or treatment integrity erodes over time the in vivo use of the BST model will create an instance of client exposure to 100% integrity while also bolstering staff and caregiver performance. Thus, the dual benefits of BST integrated into treatment integrity observations is seemingly the best course of action to maintain high levels of treatment integrity and improve client outcomes. However, if ample practice opportunities are not available during in vivo training, the addition of separate training sessions inclusive of role-playing can also be used in combination with in vivo BST booster sessions. Nonetheless, given that a lack of training and supervision can contribute to a considerable percentage of staff resignations (Kazemi et al., 2015), the use of BST and treatment integrity observations alongside frequent progress monitoring should be part of a practitioner's comprehensive plan to support clients, caregivers and staff members, regardless of the combination of application.

Treatment Integrity Monitoring From treatment selection to ongoing treatment monitoring and modification, gaining further knowledge of various procedures may allow practitioners to engage in more efficient and effective practices. For instance, aside from procedures that require 100% treatment integrity due to safety concerns, practitioners often choose an arbitrary retraining criterion such as 80% consistency and accuracy. However, the type of procedure, component, or error may determine the level of integrity necessary to produce significant treatment effects. Treatment integrity research offers a means to determine what level of integrity is necessary for optimal treatment effects and may assist in determining a more precise criterion for retraining based on the treatment or error being observed.

This information allows practitioners to allocate their time and resources accordingly. Specifically, treatment integrity analyses may identify the level of risk associated with specific treatment integrity failures, the boundaries of a procedure for clinical application and the ideal context to conduct a particular treatment (i.e., Vollmer et al., 1999). It is beneficial to know which treatment procedures can be used intermittently versus those that require closer monitoring, again allowing practitioners to determine the time and resources necessary to implement and monitor a given treatment procedure. In the medical field, doctors, nurses, and therapists focus on precautions to avoid medical errors, which would be considered an iatrogenic event. These mistakes are never intended, of course, but they are no less harmful to the patient. At the same time, some recommended treatments are known to produce potentially adverse effects, and therefore the healthcare team would weigh the pros and cons of these treatments and be aware of the risks. Our practice is no different and should be executed in a similar manner, therefore once a procedure or a component of a procedure is determined to be at high risk for treatment integrity failures or susceptible to poor treatment outcomes at certain levels of treatment integrity, strategies can be developed for practitioners to most efficiently avoid the detrimental effects of such treatment integrity failures. Overall, further analyses are necessary to solidify the level of accuracy and consistency necessary to produce beneficial treatment outcomes across various types of treatments (e.g., punishment procedures). However, the existing literature indicates that consequence errors should be of particular interest for practitioners to monitor as higher levels of accuracy and consistency were necessary to obtain a favorable treatment outcome for consequence manipulations in comparison to antecedent manipulations. Nonetheless, while the treatment integrity literature is developed further, it is integral for practitioners to monitor treatment integrity and treatment effects simultaneously to ensure that the level of ongoing treatment integrity is producing significant change and determine whether treatment modifications are necessary (De Fazio et al., 2011).

Conclusion

Because the practice of ABA is so closely tied to a foundation of supporting research, studies that result in predictable outcomes are easily translated into best practice standards (Ayllon & Michael, 1959). However, practitioners must be aware that in comparison to a research context, control over many programmed and/or extraneous variables cannot be equally replicated when addressing socially valid problems in the natural setting (Peterson et al., 1982). Therefore, it is key for a practitioner to adopt the perspective that their work will encounter obstacles and that they can draw upon well-researched and validated strategies to continuously improve consistency, accuracy, and uniformity. The present chapter illustrated one such empirically-validated strategy in the form of BST. While BST can be highly effective in shoring up problems with treatment integrity, it is strongly recommended that research using BST to combat low treatment integrity continue to be refined and shared.

Many are attracted to research and practice from a behavior analytic perspective due to its emphasis on parsimony, both in philosophy, explanation, and individualized treatment design. However, efforts to create a well-designed intervention in a community-based or school setting may reveal inevitable treatment integrity challenges. Overcoming barriers and proceeding to limit the unwelcome influence on treatment variables personifies a practitioner's commitment to an important recommendation made by B.F. Skinner (1972), "A failure is not always a mistake, it may simply be the best one can do under the circumstances. The real mistake is to stop trying."

Social Validation

25

John J. Wheeler and Stacy L. Carter

Historical Development of Social Validation

Origins of Social Validation

Social validation (Kazdin, 1977; Wolf, 1978) emerged in the field of applied behavior analysis out of concern for determining whether behavioral treatments were of social relevance (Houten, 1979). Van Houten noted that there were two methods of social validation that emerged, that is, in the mid-1970s that were used in the selection of target behaviors and to determine whether a treatment was successful. These two methods were social comparison and subjective evaluation. Social comparison is a method that uses exemplars such as non-disabled, same-aged peers to establish a "behavioral norm" used for comparison when designing treatment programs and in evaluating the performance of students or consumers on their acquisition and performance of these target behaviors. With subjective evaluation, individuals such as teachers and clinicians provide feedback on the appropriateness of target behaviors selected for treatment and in turn evaluate and rate the behavior of the student or consumer before and after the treatment to provide a measure of feedback on their performance of the behavior. It could be interpreted by some that in the early formation years of social validation, the process was driven more by the viewpoints and direction of the interventionists and or researchers than from the perspective of the consumers for whom the treatments were intended.

It was during this time that Wolf's (1978) three-component definition of social validity emerged and made an impact on how treatment and research were viewed. Wolf believed that behavior analysts should ask consumers about their level of satisfaction with their treatment and the services they received which was a departure from previous practices. Wolf's definition of social validity included the following components (a) the social significance of the goals of treatment, (b) the social appropriateness of treatment procedures, and (c) the social importance of the effects of treatment. The inclusion of all three components was termed total construct social validity and stressed by Wolf that anything less than these components would be termed partial construct.

Kazdin (1980) was a proponent of this viewpoint and asserted that it was important to determine whether treatments were socially

acceptable. Kazdin also believed that a treatment should be acceptable to the individual receiving it and that treatments should not infringe upon the rights of the persons receiving the treatment, and finally it was important in determining key variables associated with treatment acceptability. Evaluating treatment acceptability as advocated by Kazdin (1980) would not only assist in refining the design and delivery of treatments but also in promoting treatment compliance on the part of the recipient. A person is more apt to engage and adhere to a treatment that they find acceptable. Adherence to treatment on the part of the stakeholder is critical to the success of any treatment program be it in the domains of education, behavior, or health care.

Schwartz and Baer (1991) further advanced this thinking and noted that the purpose of social validity assessment was to garner information that would contribute to the survival of a treatment program. They stressed that for a treatment to survive it must of course be effective and must address behaviors that are important to the consumer, that is, the individual receiving the treatment. The value to the consumer must take priority in the planning, delivery, and evaluation of a treatment program. Feedback from the consumer is vital to the success of any treatment program as it can assist us in identifying aspects of a treatment that are liked or disliked by consumers that could lead to increased engagement on the part of the consumer to fully participate and adhere to the treatment. Given the benefit of consumer feedback to the treatment process, it points to the value of total construct in the assessment of social validity. Finney (1991) reinforced this view and believed that it should be reflected in an ongoing interaction between researcher and consumer and that both grow in their understanding and refinement of the treatment resulting from this exchange. Unfortunately following the early establishment of social validity and its importance to the design, delivery, and evaluation of treatments there has been a decreasing trend over time in the development and reporting of social validity measures in the literature (Carter & Wheeler, 2019b).

Social Validity and Positive Behavior Interventions and Supports (PBIS)

With the advent of the PBIS movement, the field witnessed a deepening commitment to person-centered planning in the design, implementation, and evaluation of interventions and supports for persons with disabilities. PBIS placed great emphasis on the development of programs that were committed to the quality of life of the consumer such as expanded access to the community and opportunities for peer interactions (Dunlap & Fox, 1996). The PBIS model in many ways extended the values of the normalization principle in that it placed emphasis on the dignity and worth of the individual as its focus and the building of individualized supports through person-centered planning to foster success in daily life and environments of the individual. Basically, PBIS has been summarized as (a) a person-centered approach that is directed toward the needs and preferences of the consumer; (b) PBIS recognizes the individuality of the consumer in the delivery of support; and (c) PBIS seeks to produce meaningful outcomes that enhance the quality of life of consumers (Anderson & Freeman, 2000). These values were reflected in the original criteria that Horner and colleagues (1990) who proposed that behavioral treatments must address three criteria that included (a) the intrusiveness of treatment upon the individual targeted for treatment, (b) the social acceptability of the treatment, and (c) the degree to which a competent professional supervises and monitors the treatment. Later Carr et al. (2002) expanded on these foundations and identified nine critical features of PBIS which included (a) a focus on lifestyle change and quality of life, (b) an emphasis on lifespan supports, (c) ecological validity, (d) stakeholder participation, (d) social validity, (e) systems change and multicomponent intervention, (f) an emphasis on prevention, (g) flexibility with respect to scientific practices, and (h) multiple theoretical perspectives.

Clearly, PBIS places an emphasis on the individual and the importance of person-centered supports with social validity being one of the anchors in the development and evaluation of these individualized supports. Despite these values, the question that bears asking is how is social validity reflected in the empirical literature and to what extent has it been applied as Wolf (1978) intended, from a total construct approach.

Reviews and Empirical Findings

There have been several recent reviews of social validity in the literature ranging across the years 2010–2019 that have examined social validity within single-case studies across persons with disabilities. Unfortunately, the trend observed from all of these reviews has been a scarcity of reporting of social validity measures in general, and even more infrequent has been the use of total construct social validity in experimental studies.

Brosnan and Healy (2011) conducted a review of $n = 18$ studies in the area of developmental disabilities and only one study reported on the use of an informal measure of treatment satisfaction whereas none of the studies reviewed used any formal measures of social validity. In a subsequent review, Spear et al. (2013) reviewed single-case studies conducted with students deemed at-risk for emotional and behavioral disorders (E/BD) and though social validity was mentioned in studies, the use and reporting of social validity measures were low.

Ledford et al. (2016) reviewed single-case studies with young children with autism from 1993–2013 and reported only 44% of the studies reviewed actually included the measurement of social validity. This trend of reviews reporting low percentages of social validity continued. Callahan et al. (2017) conducted an extensive review of $n = 828$ articles of which only 26.7% or $n = 221$ studies reported on measures of social validity. In another study, Snodgrass et al. (2018) conducted a systematic and in-depth review of single-case studies across six journals dating from 2005–2016. In total, they reviewed $n = 429$ studies from the years 2005–2016 and only 27% of studies reported social validity of which only 7% of the studies reviewed utilized total construct social validity as defined by Wolf's (1978) three-part definition. Carter and Wheeler (2019b) conducted a comprehensive review similar to that of Snodgrass et al. (2018) but targeted their review to single-case design studies from one journal, *Education and Training in Autism and Developmental Disabilities* (*ETADD*) spanning from 1997–2018. They conducted an initial electronic and hand search that revealed a total of $n = 858$ articles of which 85% of the articles or $n = 298$ were single-case design studies. Carter and Wheeler (2019b) had three objectives for their review, the first being to identify the percentage of studies that utilized total construct social validity, second, to determine how total construct was measured in terms of instrumentation and finally to present a reliable instrument for measuring the types of social validity in the literature.

The results from the Carter and Wheeler (2019b) review indicated that of the 298 single-case design studies reviewed, $n = 138$ or 46% of the studies reported social validity. Of this number, $n = 128$ or 93% of studies used partial construct social validity and $n = 10$ or 7% of the studies used total construct. The review also determined that single-case designs in the journal *ETADD* reported social validity more frequently, that is, 46%, and also total construct social validity was reported more frequently, that is, 7% greater than other journals as referenced from previous reviews.

When one considers the data from these reviews it is apparent that there is a need for the increased reporting of social validity within single-case research studies and also a need to examine journal review practices relative to social validity as a fundamental component in single-case studies. Studies submitted for review should not be judged solely based on the efficacy of their data related to behavior change with no consideration given to inputs or feedback from the consumers with regard to their acceptability and satisfaction with such treatments. Carter and Wheeler (2019b) stressed the importance of total construct social validity as defined by Wolf (1978) as the "gold standard" of practice when designing, implementing, and evaluating interventions. This practice reinforces the person-centered philosophy advocated within the PBIS model and reinforces the points made earlier by Wolf (1978) and others. Finally, Carter and Wheeler (2019b) posed the question if the absence of social validity data was a function of editing practices across various journals with respect to page limits of manuscripts and whether or not social validity should be an element within a single-case research study that is required for publication? Is the absence of these data a matter of having not collected them or a failure to report them? The inclusion of a standard requiring that social validity is reported within a study prior to a review would reinforce this evidence-based practice within the literature and subsequently enhance our understanding of the acceptability of specific treatments from the perspective of consumers that could potentially better inform research and practice.

Methods of Evaluating Social Validity

There are several methods for measuring social validity, which could broadly be categorized as informal and formal methods (Carter & Wheeler, 2019a). Informal methods include such options as researcher-developed scales, interviews, open-ended questions, and personal narratives. Formal methods include questionnaires and rating scales that have undergone some level of validation in terms of their reliability and validity. It is recommended that both informal and formalized measures are necessary to present an accurate depiction of the social validity of interventions to control for researchers who could possibly develop a bias and use only those methods that provide favorable social validity ratings. It is frequently the case that informal methods are most often used in the development of treatment goals, treatment acceptability, and treatment satisfaction. The benefits associated with informal methods of evaluation are that they are specific to the individual consumer, the setting, and the situation. Given this, they are the most useful in terms of the development of a treatment program for an individual and in determining the level of satisfaction on the part of the consumer with the treatment and the treatment outcomes for the individual and their quality of life.

Informal Measures

Though the informal method of social validity has a great deal of functional utility when in applied contexts, on an individual level there are challenges when assessing social validity. Snodgrass et al. (2018) highlighted the challenges of evaluating social validity in applied settings given the vast variety of factors that must be considered. One of these challenges is that informal measures lack validity and reliability. Another obvious challenge is the variability found among consumers with disabilities including presenting characteristics, individual strengths, and support needs especially among persons with severe disabilities. The use of formal measures seems more applicable when working with groups of stakeholders as in the case of school districts that are looking at implementing interventions or policies that will affect a greater number of stakeholders such as teachers, students, and families.

One area of formal measurement within social validity is treatment acceptability (Kazdin, 1980) which is defined as the subjective judgment of persons concerning the acceptability of treatments. These individuals can be consumers, family members, and/or nonprofessionals. The importance of treatment acceptability reinforces the views of Wolf (1978) who spoke of the social importance of treatment in terms of the social significance of treatment for the individual, the social acceptability of the treatment in the view of society, and finally that the treatment should have clinical significance (Carter & Wheeler, 2019a, b). The research on treatment acceptability is a new area of study within the fields of education and psychology and even less in the area of health sciences, but certainly an area worth further investigation in the future. Unfortunately, the trend within social validity research, in general, is that it is typically not the topic of interest, but rather a secondary topic within treatment studies aimed at behavior change (Kennedy, 2002).

There are several methods for evaluating social validity under the categories of informal and formal measures. Informal measures are most popular and are developed for a specific treatment and as stated do not include any formal validation of the instrument. Formal instrumentation however is used within some research studies. Both methods pose challenges in terms of monitoring the frequency and efficacy of their use within the research given they are a methodological component of a study and are secondary to the major focus of the study. Table 25.1 provides some examples of methods used to assess social validity.

With respect to the use of interviews in assessing social validity as Carter and Wheeler (2019a, b) have indicated this method allows for the gathering of a great deal of information in a brief amount of time, though as the authors warn it can result in information that is not necessarily related to the evaluation of a treatment. There have been references made in the literature as to the use of interview formats such as the semi-structured interview, a method that utilizes a question and answer format pertaining to specific areas of social validity. One early illustration of this method was a study conducted by Gresham and Lopez (1996) that consisted of 21-initial questions with the addition of follow-up questions. These questions reflected the three areas of social validity, the first set of questions 1–9, were directed toward the significance of treatment goals, the second set of questions 10–15 assessed treatment acceptability, and the remaining set of questions, items 16–21 addressed the social importance of effects. The format created by Gresham and Lopez (1996) provides a very systematic and cohesive structure for the semi-structured interview when assessing social validity.

Table 25.1 Examples of methods used to assess social validity

Formal instruments
Social comparison using performance criteria, for example, normative such as peers
Behavioral observation

Behavioral observation is a useful method for determining the social validity of treatment including peer comparison and acceptability (Carter & Wheeler, 2019a, b; Schwartz & Baer, 1991). Though peer comparison has not been cited as frequently in the literature in recent years a study conducted by Ennis et al. (2013) offered suggestions to researchers when using peer comparison for evaluating social validity within the context of learners with challenging behaviors. They provided examples of using multiple baseline and withdrawal designs to monitor challenging behaviors and also the behaviors of comparison peers on the same graph to allow for peer comparison. Ennis et al. (2013) emphasized that peer comparison is the most objective form of social validity and these recommendations for data collection allow for ease in both data collection and allowing for peer comparison.

Formal Measures

There are a variety of formal measures designed to measure social validity, of which we will identify and discuss a representative sample. For a more exhaustive analysis of formal measures, the reader is encouraged to consult Carter and Wheeler (2019a).

Of the emerging number of formal measures aimed at assessing treatment acceptability the *Treatment Evaluation Inventory* (TEI) developed by Kazdin (1980) along with the *Intervention Rating Profile* (IRP) designed by Witt and Elliot (1985) are the most widely used. Kazdin (1980) developed the TEI to assess treatment acceptability for treatments developed for children with behavior disorders. The intent of the TEI was to evaluate treatment acceptability independent of the effectiveness of the treatment. The TEI consists of a 15-item in the form of questions using a seven-point Likert scale regarding specific treatment procedures. Scores are tallied and totaled by summing the responses from all the items with the higher summed total scores indicating greater levels of treatment acceptability. A principal component analysis of the TEI resulted in item loadings from 0.61 to 0.95 on a unitary factor accounting for 51.4% of the variance (Carter & Wheeler, 2019a, b).

The *Intervention Rating Profile* (IRP) (Witt & Elliott, 1985) was created in an effort to increase treatment acceptability research in educational treatments and to increase awareness among practitioners of treatments deemed acceptable by teachers. The IRP consists of 20 items that are rated on a six-point Likert scale. Scores are summed and totaled with higher scores indicating greater levels of acceptability. The internal consistency of this instrument was reported to be 0.89 (Carter & Wheeler, 2019a, b). The IRP was modified in an effort to shorten the instrument and improve internal consistency and became known as the *IRP-15* (Martens, Witt, Elliot, & Darveaux, 1985). The IRP-15 includes a 15-item, six-point Likert scale with higher summed scores indicating greater levels of acceptability (Carter & Wheeler, 2019a, b).

The *Treatment Acceptability Rating Form* (TARF; Reimers & Wacker, 1988) is a measure designed to assess treatment acceptability as perceived by parents within a clinical setting. The TARF consists of 15 items and utilizes a seven-point Likert scale with the internal consistency of this instrument ranging from 0.80 to 0.91. The *Treatment Acceptability Rating Form-Revised* (TARF-R; Reimers et al., 1991) is an expanded version of the TARF designed to measure the acceptability of treatments within clinical settings. The internal consistency of this instrument was reported as 0.92. The TARF-R consists of 20 items of which 17 items address treatment acceptability, two questions are dedicated to addressing problem severity and one question addresses understanding the intervention. The scoring involves arriving at total scores by summing all items with higher summed scores indicating greater levels of acceptability (Carter & Wheeler, 2019a, b).

In spite of the increased number of formal instruments available to assess treatment acceptability there does not appear to be an increasing trend in the use of these tools by researchers. One possible reason for their lack of use is their inability to detect small changes in behavior (Elliot et al., 1993; Carter & Wheeler, 2019a, b). Carter and Wheeler (2019a, b) provided some potential strategies for increasing the usage of acceptability measures that included making these instruments more readily available to researchers and clinicians as often the instrument is only referenced in an article but obtaining the actual instrument can sometimes prove quite difficult. Increasing a fluent knowledge and understanding of these instruments within graduate training programs will assist in improving their use and understanding among researchers and practitioners and hopefully result in their visibility within programs serving persons with disabilities. Finally, there needs to be a resurgence in both personnel preparation programs within colleges and universities and also within program delivery as to the importance of social validity and the value of these data in serving consumers.

A Summary of Research on Social Validity

The research that has been conducted on social validity has focused on three areas, namely (a) treatment acceptability or social appropriateness of treatment, (b) significance of treatment goals, and (c) the effects of treatment. Of these three dimensions, the area of treatment acceptability has been the most widely researched (Carter & Wheeler, 2019a, b).

Treatment Acceptability

The area of treatment acceptability was initiated by Kazdin (1980) who in the formative stages of developing the Treatment Evaluation Inventory (TEI) evaluated the acceptability of four treatments for deviant child behavior described to 88 undergraduate college student raters. The four treatments ranged from least-intrusive-to-most intrusive and consisted of (a) reinforcement of incompatible behavior, (b) time-out, (c) drug therapy, and (d) electric shock. The procedures involved the presentation of one of two different case descriptions, that is, details on the behavioral challenges, the person seeking treatment, characteristics and diagnostic label, the setting, and four differential treatments for a child with significant behavioral challenges. After listening to these cases, the participants completed the TEI and selected items from the Semantic Differential (Osgood et al., 1957). This process was repeated until all cases were completed. Statistically significant differences were found across all treatments with the order of acceptability as rated by participants as reinforcement of incompatible behavior, time-out, drug therapy, and electric shock.

Kazdin (1980) completed a subsequent replication study aimed at studying the potential impact of the severity of the presenting problems contained in the case study descriptions. The second study differed in terms of the specifics of the case studies as one child was reported to have moderate behavioral challenges and the other one severe behavioral challenges such as self-injury, property damage and severe disruptive behaviors associated with intellectual disabilities and based within an institutional setting. The procedure was the same as the first study. Each of the $n = 94$ participants was presented with one of the four case descriptions. The findings from this study indicated that reinforcement was rated significantly more acceptable than the other treatments and notably electric shock was rated significantly less acceptable than the other treatments. No differences were noted between the remaining two treatment options, that is, time-out and drug therapy. The studies conducted by Kazdin (1980) serve as a template for studying treatment acceptability and as a model for research investigations in this area.

Treatment acceptability has been widely reviewed in the literature on a variety of topics. These reviews have resulted in information designed to guide practice in the area of treatment acceptable. One such review by Reimers et al. (1987) resulted in the identification of five factors believed to influence treatment acceptability that included (a) severity, (b) treatment approach, (c) time required to implement a treatment, (d) the side effects associated with a treatment, and (e) the cost of a treatment. Several additional reviews on treatment acceptability have been conducted and have included reviews on the acceptability of behavioral interventions and support for school-aged children (Elliott, 1988); early childhood education (Miltenberger, 1990); measurement trends in social validity (Kennedy, 1992); schoolwide positive behavior supports (Rasnake, 1993); school-wide delivery services (Eckert & Hintze, 2000) among others.

Significance of Treatment Goals

Though most of the research on social validity has centered on treatment acceptability and the social significance of treatment effects, it is most important to consider the development of treatment goals as a major component of the three-component process that qualifies as total construct social validity (Wolf, 1978). When selecting socially significant treatment goals several considerations must be taken into account.

Critical to this period of consideration in the development of treatment goals is what Carter and Wheeler (2019a, b) have referred to as pre-treatment assessment. This phase of the process allows for careful consideration of the variables that must be considered in the formation of socially significant goals. Important in this individualized process are the inputs from the consumer, their family, any data pertinent to the discussion, and the resources in terms of support that are available for the individual. Most development of treatment goals relies on informal interviews, but Carter and Wheeler (2019a, b) devised a list of the questions to be considered in the development of socially significant treatment goals from an extensive review of the literature on the development of treatment goals. From this review, a number of specific questions were developed to aid in the process and in the enhancement of the social significance of treatment goals. These questions were arranged into five categories (1) preferences and values of the consumer; (2) normalization; (3) choice; (4) habilitative potential; and (5) awareness of coercion.

Preferences and Values of the Consumer

The personal preferences/values of the consumer must be a primary consideration. Goals are individualized based on the input received from the consumer and their family in many cases. It is important to determine the values of the consumer and family as a foundation for goal development (Carr, 1996). In previous years, many persons with disabilities were denied these inputs, and personal choice was not something readily available to them as individuals and is something of the utmost importance especially as it pertains to behavior change. This is often a challenge as many professionals see their role as of greater importance and their input as more valued when in reality it must be a partnership between professionals/consumers and family members when applicable. This is perhaps, even more, a concern when professionals are working with individuals from diverse cultures where the cultural norms and values may be something unknown to the professional. During this pre-assessment phase, it is important that professionals utilize both formal and informal means to gather the relevant information needed to consider the personal preferences and values of the consumer.

One example of this from the field of special education is the use of the McGill Action Planning System (MAPS) (Forest & Lusthaus, 1989; Vandercook et al., 1989). It represents a team-based approach with the student, their family including siblings and grandparents, members of their educational team including teachers, instructional assistants and therapists, and significant others including same-aged peers and is a process by which goals and supports are identified through a series of questions led by a facilitator. The group is asked about (a) the student's history, (b) the student's dreams and goals and that of their family, (c) the concerns the student or parents have, (d) the individual student's gifts and strengths, and (e) the individual student's needs? After gathering this information, these inputs are discussed and then prioritized with the team forming a plan of action to aid in providing a student-centered plan with the support needed for the student to realize their goals.

Some examples of relevant questions to ask when developing goals are, do the goals align with the personal preferences and values of the consumer? Is the consumer comfortable with the goals and potential outcomes associated with the goals? Do the treatment goals involve other individuals valued by the consumer? (Carter & Wheeler, 2019a, b).

Normalization

Another important aspect of developing socially significant goals is to distinguish to what degree the proposed goals promote increased opportunities for normalization for the consumer. Questions to consider in his area are the treatment goals focused on age-appropriate activities and behaviors. Do the treatment goals reflect activities engaged in by typical same-aged peers and do treatment goals provide support for existing skills needed for normalization (Carter & Wheeler, 2019a, b).

Choice

The opportunities for personal choice in life are important to everyone and one consideration when developing socially significant goals is to consider whether are there opportunities for choice as a component of the goals. Freedom of choice is an essential component to one's quality of life and treatment goals should reflect that. Carter and Wheeler (2019a, b) state that the choice of treatment goals may be a factor in influencing the significance of the treatment goal. Directly related to this are the questions of will the treatment goals generate high-quality reinforcement and do the treatment goals allow for immediate reinforcement. So as the choice is an essential component to the development of treatment goals, access to reinforcement associated with the goal should be considered also.

Habilitative Potential

“Habilitative potential” is a term that Hawkins (1991) operationalized behaviors that maximize increased opportunities for reinforcement and minimize opportunities for punishment. Carter and Wheeler (2019a, b) summarized this area with the following relevant questions to be considered. Are treatment goals aimed at the development of new and emerging skills such as social skills, leisure skills, and educational skills? Do treatment goals increase access to new environments? Are treatment goals focused on acquisition and fluency or more long-term gains such as maintenance and generalization?

Awareness of Coercion

Coercion should never be a part of any form of treatment, but obviously, it is likely to be something that still occurs too often. For consumers who do not have the requisite self-determination skills and for those who are limited in terms of their abilities to communicate, self-advocate, and who are passive, they may experience a greater likelihood of coercion pertaining to treatment goals than others.

In summary, some strategies for increasing the social significance of treatment goals are to consider conducting semi-structured interviews with the consumer and their family gathering their input on their specific goals, their values, and the things that they enjoy. Next, seek information from multiple sources to provide clarity in the development and selection of treatment goals. Take into account all relevant aspects of the individual’s life in terms of what it generally consists of, the people who comprise it, the environments that surround it, and also the opportunities and areas where support is needed. Once goals are established, then rank-order them in order of importance and develop desired outcomes associated with them.

Treatment Effects

The social significance of treatment effects is the final criterion identified by Wolf (1978). Treatment effects are an area that behavioral research has typically addressed within research studies. Treatment effects are consistent with outcomes and those effects or outcomes realized speak to the merits of a treatment. An important aspect of treatment effects that often is overlooked is the benefits of a treatment to the consumer. Simply put, the impact that the treatment has on the life of the individual for whom it is intended. Carter and Wheeler (2019a, b) point out that treatments may produce significant clinical benefits and demonstrate a functional relationship between an intervention and the dependent measure, but if the treatment fails to have valuable consequences (benefits) for the consumer it fails to address the most important consideration.

If a treatment program is aimed at changing behavior and the outcome of the treatment produces no measurable impact on the individual’s quality of life can it be judged effective? Kazdin (1994) identified three types of data collection that are essential for evaluating social validity in terms of treatment effects and these are (a) peer comparison data, (b) subject evaluation data, and (c) social impact measure data. Peer comparison data involves data from typical same-aged peers who are the normative group that serve as the comparison group thus providing a model of desired behavior.

Subject evaluation consists of having the consumer collect data with support if needed on how important some of their individual behaviors are to them and then using this information to develop treatment goals. After a treatment has been implemented, these same behaviors can be re-evaluated by the consumer to determine if the same behaviors are still considered a high priority or if they are considered less detrimental to the consumer because of the treatment (Carter & Wheeler, 2019a, b). Social impact data are those data contained in formal reports such as school office referrals and or informal reports such as teacher, or parent narratives. Each of these sources of data can be used to enhance the development of treatment goals by providing a written record of occurrences of certain events.

Future Research Considerations

Though research in the area of social validity has progressed over time since its inception there are areas where future research could expand the field's understanding of the application of this important construct. These areas will be briefly discussed with recommendations provided for future consideration.

Research on Social Validity and Ethics

When one considers the importance of ethics within a profession and the code of ethical practices that guide professionals in the delivery of services the relationship between these values and the use of social validity in the delivery of these practices to individuals would appear to be very strong. Hayes and Tarbox (2007) defined ethical conduct in behavior analysis as (a) comparing and contrasting the options that are available and (b) after considering these options, then making a decision as to the course of action to take to address the situation. In the future, it would benefit the field to further explore this relationship between social validity and ethical practices, especially in areas such as treatment acceptability. The value of the individual, a respect for their rights and freedoms, and a responsibility to uphold these in the design, delivery, and evaluation of treatment are embedded within the ethics and values that serve to govern practice and also as the foundation for social validity. Professional organizations have ethical standards that govern professional conduct in the areas of PBIS and ABA.

Wheeler and Richey (2019) summarized the ethical practices across professional bodies including the National Education Association (NEA), the Council for Exceptional Children (CEC), the standards of practice for the Association for Positive Behavior Support (APBS), and the Behavior Analysis Certification Board that resulted in nine organizing themes. In summary these organizing themes derived from the code of ethics from each of these organizations affirmed (1) the worth and dignity of the individual; (2) the behavior of children and youth serves a function or a need for the individual; (3) systematic and thoughtful management of learning environments will serve to help in preventing and mitigating challenging behavior; (4) families, children and youth should be central to all aspects of PBIS including active participation in the planning, implementation an evaluation of interventions; (5) the uniqueness of children and youth as reflected by their family's diversity (race, culture, ethnicity, and religious practices) should be taken into consideration when addressing their behavior support needs; (6) natural environments and inclusive settings are desirable for children and youth with challenging behavior, but school personnel must do so in a responsible manner by providing supports to all involved including the student(s) and teachers and a continuum of placement alternatives should also be available when needed; (7) naturally and logically occurring consequences are preferable to contrived consequences for promoting self-discipline independence and self-determination; (8) behavior supports should be positive and should not include punitive practices; and (9) actions on the part of professionals aimed at addressing challenging behaviors should be aimed at the development of meaningful replacement behaviors that are positively related to the quality of life for the individual.

Schalock and Luckasson (2005) synthesized the ethical principles governing many professional organizations into five principles that included (1) competence, (2) professional and scientific responsibility, (3) respect for people's rights and dignity, (4) concern for the welfare of others, and (5) contributions to society.

Carter and Wheeler (2019a, b) took these same five points as described by Schalock and Luckasson (2005) and proposed a framework for conducting research in the area of social validity along these same principles. More specifically Carter and Wheeler (2019a, b) proposed that in the area of competence professionals should become fluent in their understanding and application of the conceptualizations and methods used in the area of social validity. Within the principle of professional and scientific responsibility, they recommended that professionals be directly focused on improving and promoting the methods used in the evaluation of social validity. In the area of respect for the dignity and rights of the individual, it was recommended that research be conducted on the input of consumers on the development of goals, procedures, and the effects of treatment. The need for research on standardizing a process for conducting social validity assessments was recommended as a method for reflecting the welfare of others through new research in this area. Finally, concerning the last principle of contribution to society and others, Carter and Wheeler (2019a, b) note that research on social validity assessment and its relationship to ethical conduct be a topic at the forefront of future research on contributing to the betterment of society and others in the area of ethics.

Research on Social Validity and Cultural Diversity

The role of social validity when working with persons from diverse cultures is an area in need of further research to better inform our practices. This is an area that has long been overlooked. Unfortunately, professionals with limited knowledge and background respective to persons from diverse cultures have had their professional efficacy diminished because of a lack of cultural competence. The term cultural competence defined by Rew et al. (2003) included four components. These included (1) cultural awareness, (2) cultural sensitivity, (3) cultural knowledge, and (4) cultural skills. Basically, cultural competency includes one's ability to meaningfully interact with persons from diverse cultures in a manner that invokes one's awareness of the culture, sensitivity, respect for the culture, and a working knowledge of the culture to allow for a working relationship. More research is needed on the applications of social validity within educational, community, and healthcare programs serving persons from diverse cultures. Some research on embedding culturally sensitive and responsive practices in the delivery of healthcare has emerged that has included the field of nursing (Campinha-Bacote, 2002; Shen, 2015).

Some specific areas to examine would be the development of social validity measures sensitive to the cultural norms of persons from diverse cultures. Also critical to this is the assessment of cultural preferences and norms. One example from the healthcare literature was a review of culturally competent healthcare practices conducted by Anderson et al. (2003). They referenced a framework that could be used to evaluate the effectiveness of programs designed to enhance the cultural competence of healthcare providers. This framework utilized the following interventions with a focus on developing cultural competence among the staff. These included (a) programs aimed at the recruitment and retention of staff members who reflected the cultural diversity of the community, (b) the use of interpreters and bilingual staff to accommodate the communication needs of the patients, (c) cultural competency training and professional development for staff, and (d) the use of linguistically diverse and culturally specific health education materials for patients. So, more research is needed to improve our delivery practices to persons from culturally diverse populations and social validity assessment can be a tool to assist in these efforts.

Fong et al. (2016) provided practical considerations for behavior analysts working with persons from diverse cultures. These recommendations though targeted for behavior analysts do have broader applicability to professionals from other disciplines including education and allied health. Minimizing the technical language within the discipline could serve to confuse consumers. Unfortunately, the cultural context of the consumers including that of family members, is sensitive to the native language of the consumer and their family, and utilizing available resources to better inform one's cultural competence can help maximize person-centered service delivery (Fong et al., 2016). These recommendations serve as general guidelines for enhancing the delivery of services and support to consumers from diverse cultural backgrounds. The need for targeted research on enhancing these relationships and the development of culturally sensitive social validity measures is warranted.

Research on Social Validity and Healthcare

Finally, healthcare represents an area where social validity is most needed to improve the accessibility of healthcare interventions (WHO, 2016). This has become more evident given the Covid-19 pandemic and its global impact that reinforced the need for efficient and patient-centered healthcare delivery systems. Social validity measures in the area of treatment acceptability could enhance healthcare delivery in areas such as patient compliance and adherence to treatment. There is a need for research on this as examples are minimal in the literature. However, the field of nursing has to some degree addressed the topic. These have included studies on treatment acceptability and patient preferences (Sidani et al., 2009) treatment acceptability in the geriatric patient population (Fox et al., 2018).

More research is needed on the acceptability of healthcare interventions and social validity is recommended as a means by which to increase our understanding of the acceptability of specific interventions from the perspectives of patients and to increase the probability of their use (WHO, 2016). Such treatment acceptability data could enhance the efficacy of patient care practices and in turn could lead to more optimal patient outcomes as a result of improved treatment adherence.

Summary and Conclusions

In summary, this chapter has attempted to provide a brief over on the construct of social validity (Kazdin, 1977; & Wolf, 1978). We have discussed the value of social validation as an efficacious method for ensuring that behavioral treatments, goals, methods, and outcomes reflect the values and goals of the individual and are satisfactory to the individuals served and their families. This chapter examined the historical development of social validity, the application, and implementation of these methods across behaviors and populations, the need for reporting social validity in empirical studies, and the need for expanded research on social validity with regard to professional ethics and practices, the need for culturally sensitive social validity measures and finally the applications of social validity in healthcare and the acceptability of treatments.

Functional Assessment

26 Experimental Functional Analysis

Joshua Jessel and Rachel Metras

The experimental functional analysis (EFA) technology maintains a strict adherence to establishing a believable demonstration of the influence of environmental events over problem behavior. The EFA distinguishes itself from other functional assessment methods (i.e., indirect assessments, descriptive assessments) in that its core procedures involve the direct observation of measurable, operant behavior and systematic manipulation of environmental events in a single-subject experimental design (Hanley et al., 2003). When the EFA methodology is stripped of any defining features of specific formats, the requirements are simplified to a test–control comparison of contingent putative reinforcement presented in the test condition and noncontingent delivery of those same reinforcers in the control condition. In other words, the most conservative demonstration of functional control over problem behavior involves a simple change in the contingency while maintaining all other constants across the test and control conditions.

It is important to point out that EFA is not simply an empirical demonstration of control over problem behavior. Considering that the target behavior will always be one of social importance, the purpose of conducting an EFA is to inform effective, function-based treatment. Therefore, an EFA always incorporates a level of clinical and experimental relevance, with an underlying focus on clinical implications. That is, an EFA is only as good as the treatment it informs. This connection between EFA and treatment is defined as treatment utility.

Treatment utility broadly refers to the importance of a set of procedures for improving the socially relevant outcomes of a client. When applied to the EFA, it means that clinicians should select the method that best informs the design of the most effective and acceptable set of treatment procedures (Hayes et al., 1987; Slaton et al., 2017). In that regard, an EFA can only be validated as having utility by evaluating the subsequent treatment it has informed. Therefore, an EFA is more than just an analytic tool for identifying relations between environmental events and problem behavior. There are a seemingly infinite number of contingencies that can be evaluated if applied researchers were so inclined to identify and catalog them. The usefulness of an EFA is determined by its ability to (a) identify the ecologically relevant contingency in a reasonable amount of time and (b) influence the clinician's decision-making process when developing a subsequent treatment package (Kratochwill & Shapiro, 2000).

Researchers and clinicians both share the need to understand why behavior is occurring; however, clinicians are bound by a level of restraint to understand only to the point that is useful in helping the clients they serve. The concept of treatment utility seems to be at direct odds with the views shared by many staunch basic scientists who wish to understand behavioral mechanisms down to the intricate details. Applied behavior analysts may, therefore, find themselves caught in a balancing act of scientific inquiry and practical demonstrations of functional control. However, that which separates those who are applied behavior analysts and those who are basic behavior analysts are dimensions of societal relevance (Baer et al., 1968). Therefore, applied researchers need to keep in mind that what clinicians define as effective is dependent on the clinical goals they are looking to achieve. In other words, clinicians use the EFA to determine the best care that can be provided to a patient. Understanding clinical utility will help applied researchers determine the socially relevant boundaries of the EFA and how to establish a level of control that sufficiently contributes to meaningful change in problem behavior.

The purpose of conducting an EFA is, and always has been, to develop effective behavioral interventions for problem behavior based on an operant understanding of environmental variables that are believed to be contributing to problem behavior. Although this purpose has remained immutable over the years, EFA technology has changed considerably since its early founding in behavior analysis.

Historical Influence

Behavior is a direct product of environmental variables, and these environmental variables substantially impact the occurrence of problem behavior. Early behavior analytic researchers were tasked with first demonstrating that problem behavior as obscure as self-injurious behavior (SIB) could be influenced by the same operant principles as lever-pressing or key-pecking in a laboratory. That is, early accounts of problem behavior were often mentalistic or appealed to genetic contributors because operant causes were conceptually difficult to consider without empirical demonstrations. Furthermore, behavior modification approaches in some of the first applications of operant principles to socially relevant situations provided evidence that problem behavior could be reduced using powerful arbitrary punishers (Aexlrod & Apsche, 1983); however, these demonstrations did not implicate that environmental variables including reinforcement necessarily contributed to the original development of the problem behavior. In other words, it was well understood that problem behavior could be modified, mollified, or suppressed using behavioral interventions, but the origins of maintaining variables remained a mystery.

Schaefer (1970) provided one of the first demonstrations of problem behavior being shaped by reinforcement. Using two docile rhesus monkeys, Schaefer began providing various fruits contingent on raising a paw and subsequently reinforced closer approximations until the animals were making contact with their heads. In addition, the experimenter was able to gain discriminative control over head hitting using verbal cues, including statements of concern (e.g., “poor boy”). Schaefer even, possibly unintentionally, foreshadowed the evaluation of common contingencies to be evaluated in future applied work when describing the potential perception of the arrangement to others (p. 113): “To a naïve onlooker it might well have appeared that the experimenter showed extreme ‘compassion’ or ‘attention’ during the S^D periods, while he was ‘indifferent’ during the S^Δ period.” Schaefer may have been alluding to the fact that some caregiver actions that appease an individual’s problem behavior, although empathetic, can come to serve as reinforcers and thereby worsen the behavior, contraindicative to the caregiver’s well-meaning intent. Early basic studies such as Schaefer led to the conceptualization of problem behavior being sensitive to and influenced by an underlying history of reinforcement, a belief now regarded as a well-solidified assumption by current applied behavior analysts.

After discovering that problem behavior, although topographically distinct, could be influenced by environmental events, early applied researchers paved the way for determining exactly what contingencies existed in an individual's context that could possibly lead to such deleterious outcomes. It is one thing to show that problem behavior can act as an operant if you systematically arrange for arbitrary reinforcers to follow their occurrence. This evidence, in and of itself, is limited to informing the clinician that problem behavior is *susceptible* to reinforcement in the broad sense but not necessarily sensitive to naturally occurring contingencies. Teachers and caregivers are not openly attempting to reinforce problem behavior in the school or home environment. Therefore, the experimental question needs to be reverse-engineered to understand contingencies supporting problem behavior that already exists. It is one of our truths that we must accept as behavior analysts that if operant behavior is occurring, there must be a source of reinforcement. To be of more clinical value, applied researchers needed to create an EFA technology that could identify the reinforcement responsible for problem behavior in a socially relevant environment.

The logic of unmasking reinforcers in the natural environment contributing to problem behavior using experimental designs has been of interest as early as the 1960s. In one of the first published demonstrations, Lovaas (1965) was working with a young girl in a psychiatric ward who had been diagnosed with schizophrenia. The patient exhibited severe SIB and, based on his experience with her, Lovaas was well aware that various forms of social approval were the preferred consequence. Through multiple experiments, Lovaas systematically drew conclusions regarding the relation between social approval and SIB, beginning with displays of elevated levels when the positive attention was removed in the context of play (i.e., problem behavior was evoked during extinction) and ending with a demonstration of the contingent delivery of attention following SIB. This case proved to be an important step in the development of the EFA for two reasons. First, environmental events that contribute to problem behavior can include antecedent variables in addition to reinforcers. Lovaas established the value of attention by removing it from observations and saw a corresponding increase in SIB without the manipulation of consequences. Second, attention is a common event that occurs within a child's life and is likely to hold some value with many individuals. Many applied researchers were influenced by Lovaas to further develop standardized approaches to understanding the evocative effects of common antecedents and strengthening effects of select consequences beyond a demonstration with a single individual.

The validation of common environmental events contributing to problem behavior leads to applied researchers establishing categories of possible operant mechanisms that any individual could be experiencing. Carr (1977) put forth his own hypotheses for common variables, of which many are still identifiable to this day. Three categories included (a) positive reinforcement in the form of social consequences, (b) negative reinforcement often in the form of escape from academic demands, and (c) self-stimulation we would now consider automatic reinforcement. Carr repeatedly expressed that neither of these categories were necessarily all-encompassing in that attention was the only form of possible positive reinforcement and escape from academic work the only form of negative reinforcement; however, it put forth the assumption that these were common culprits. This was enough to establish two EFA models based on Carr's general categories of positive, negative, and automatic reinforcement.

The first EFA focused solely on the evocative effects of academic demands and has been termed an antecedent–behavior (AB) model because any consequences are not manipulated. In some early demonstrations, researchers would select easy and difficult academic tasks for the participant to complete and found that more problem behavior tended to occur in the condition with the difficult tasks (Carr & Durand, 1985). The AB model is somewhat incomplete in that it only empirically validates the influence of academic tasks as discriminative stimuli that evoke problem behavior, and the behavior analyst is left to infer the value of removing those tasks as negative reinforcers. This is juxtaposed with the second functional analysis model in which the antecedents and consequences are systematically presented and removed contingent on problem behavior, termed the antecedent–behavior–consequence (ABC) model. The ABC model thereby completes the contingency manipulating both the discriminative stimuli that evoke problem behavior and the reinforcers likely to maintain the problem behavior.

An early ABC model (Iwata et al., 1982/1994) used a similar condition evaluating the influence of academic tasks; however, escape is provided contingent on the occurrence of problem behavior. This escape condition is then alternated with two other test conditions and one omnibus control. The test condition evaluating positive reinforcement includes contingent reprimands following any instances of problem behavior, and the remaining test condition acts as a default to determine if the behavior will continue to occur in the absence of any socially mediated reinforcement (i.e., automatic). All of these conditions are compared to the control that includes a synthesis of establishing operations to reduce the occurrence of problem behavior, whether it is influenced by escape from tasks, access to attention, or self-stimulation. In other words, the participants were provided with continuous access to preferred toys, noncontingent attention, and no demands. Of course, this is not an ideal preparation to compare individual test conditions to a single omnibus control, but adherence to experimental precision gave way to practical considerations (it is more efficient to only include a single omnibus control instead of multiple control conditions per each test condition).

EFA Core Components

The ABC model designed by Iwata et al. (1982/1994) has come to be designated as the standard EFA and is comprised of five core procedural components. These five components are identifiable as being replicated in studies across decades of EFA research and are mutually exclusive in that an EFA model either has a core component of the standard or does not (Jessel et al., 2020a). Therefore, components juxtaposed with the standard EFA can be identified as countercomponents.

The first core component is the inclusion of multiple test conditions compared to a single, omnibus control condition. Behavior analysts may have multiple hypotheses for what could be contributing to problem behavior or may be interested in understanding the effects of different components of a reinforcement contingency. More commonly, multiple test conditions are used to separate general classes of reinforcement to create a broad but superficial interpretation of many different environmental events. A limitation of including multiple test conditions is the possibility of creating an overwhelming environment for the participant that extends exposure to a multitude of different conditions during an assessment period. That is, differences between conditions and the contingencies being evaluated can begin to be muddled, making discrimination difficult. Researchers have attempted to reduce this limitation by including salient discriminative stimuli (Conner et al., 2000) or arranging a specific order of implementation to capitalize on establishing operations (Hammond et al., 2013). A second limitation of using multiple test conditions is the potential confounded comparison of isolated reinforcement in each test condition to the synthesized reinforcement of the control condition. The EFA including multiple test conditions reduces the experimental rigor of the analysis procedures because more variables are being manipulated in the play control than compared to each individual test condition. The countercomponent eliminates these limitations by creating a single test–control comparison. The applied researcher could develop an EFA with a single test condition in one of two ways. First, multiple hypotheses could still be evaluated; however, they are conducted in separate analyses with their own control conditions. Second, hypothesized contingencies could be combined into a single test condition, creating an equal and opposite omnibus test compared to the omnibus control (Jessel et al., 2016).

The second core component of the standard EFA is the use of uniform test conditions across participants. The general contingencies evaluated with one participant are replicated and repeated with each individual during an EFA that uses uniform test conditions. From an economical perspective, using uniform conditions implies using the same set of materials across clients, potentially reducing cost. Furthermore, training staff members on how to conduct the EFA may become simplified because the procedures will hardly differ between clients and the same training can be used to conduct multiple assessments. That being said, any qualitative information specific to the history of reinforcement and experiences of each individual is lost. This is especially pertinent to individuals with problem behavior that is not sensitive to general classes of reinforcement (Schlichenmeyer et al., 2013). Therefore, the countercomponent is to create unique test conditions representing individualized contingencies designed from qualitative information obtained through open-ended interviews with caregivers and direct observations. EFAs with unique test conditions are tailor-made to understand specific contingencies affecting problem behavior, requiring each assessment to include distinctive procedures.

The third core component involves attempting to isolate the effects of positive and negative reinforcement on problem behavior. Doing so emulates the basic laboratory, decoupling events that naturally co-occur in an attempt to understand the main effects. Socially mediated reinforcers in the natural environment tend to co-mingle to establish complex contingent relations, and isolated reinforcement is rarely recognized for contributing to human communicative behavior (Skinner, 1957). Like the single atom in an object, what we see and interact with is the combination of molecules sorted and configured in a very specific manner. The behavior analyst conducting the EFA can use isolated test conditions to quash empirical curiosities of the individual properties of reinforcement or include the countercomponent of synthesized contingencies aimed to represent the daily experiences that contribute to the problem behavior in the client's natural environment. Thus, the level of synthesis in a test condition is more of a continuum in that a behavior analyst can combine every potential reinforcer or attempt to reduce the contingency to its basic elements. From a practical standpoint, the contingency should be synthesized to the point that best informs effective therapeutic strategies (Slaton & Hanley, 2018).

The fourth core component of the standard EFA is the inclusion of a play control condition whereby the clients are provided with additional tangible items unrelated to the test conditions and presented with qualitatively different attention in the form of natural interactions in the context of engagement with the preferred items or general praise. The play control creates an enriched environment that suppresses problem behavior with a collection of potential reinforcers and preferred items. The countercomponent matches reinforcement in the control to that of the test condition to reduce exposure to multiple confounds. For example, if problem behavior is assumed to be sensitive to attention, much like the test condition, the control should incorporate only attention to reduce the influence of other potential contingencies. The matched control ensures that the elimination of the contingency is the only difference between the two conditions (Thompson & Iwata, 2005). Rather than suppressing problem behavior using an enriched environment, the matched control eliminates problem behavior using the same reinforcement identified in the test condition that maintains it.

The standard EFA may have created a commitment to using a set of specific core components; however, variations in EFA formats exist and have been developed for expressed practical purposes (Iwata & Dozier, 2008; Metras & Jessel, 2021). The historical influence of the standard EFA should not be overlooked for its impact on the movement in applied behavior analysis toward relying on experimental demonstrations of control over problem behavior. In addition, it is safe to say that many, if not all, EFA formats developed in the past three decades have some ancestral connection to the standard model, be it sharing some of the core components or being influenced by the original ingenuity. That being said, the EFA technology continues to evolve as the research shifts in the direction of evaluating socially relevant procedures for improved adoption of the EFA among clinicians and acceptability among constituents.

Variations in EFA Formats

The standardization of EFA laboratory procedures allowed researchers to clearly communicate their findings with one another, and the amount of research published on functional analyses of problem behaviors rapidly grew (Beavers et al., 2013; Hanley et al., 2003). As the efficacy of this standard EFA format increased, so too did the demand for function-based treatments of problem behaviors. As an assessment model, the standard EFA developed by Iwata et al. (1982/1994) was sufficiently general to be used across a variety of behavior topographies. The inclusion of categories of reinforcement commonly reported to maintain problem behavior (e.g., access to attention or tangibles, escape from instructions) ensured that the widest variety of clients possible would have had an opportunity for their behavior to come under the control of these contingencies. Testing for a behavior's broad sensitivity to each purported general consequence for problem behavior attempted to ensure that no possible reinforcement effect was left untested.

Although successful in the experimental settings, the procedural generality did not necessarily translate to differentiated analyses or effective treatment outcomes outside of the laboratory (e.g., Hagopian et al., 2013). The procedures that had become reliable during experiments did not capture the range of unique stimulus arrangements naturally present in the contingencies reinforcing problem behavior. These individual differences were unintentionally expunged from experiments and were instead replaced by a set of average experiences that were common to all participants but specific to none. In addition, the precise and standardized procedures that had been such a boon to scientists identifying functional relations were often cumbersome and impractical to clinicians working in home, clinic, and school settings (Hanley, 2012; Oliver et al., 2015; Roscoe et al., 2015). Researchers then began modifying the core components of the standard EFA to better address the concerns of clinicians and aid in the transition of an experimental technology to more practical applications in ecologically relevant settings.

Initial modifications to the standard EFA were designed to increase the specificity and relevance of the analysis. They included adding additional uniform conditions apart from attention and escape conditions, such as a tangible condition (e.g., Day et al., 1988), incorporating idiosyncratic or preferred reinforcers into test conditions (e.g., Carr et al., 1997; Mueller et al., 2005; Schlichenmeyer et al., 2013), and opening the contingency class to include less-dangerous precursor behavior (Borrero & Borrero, 2008; Smith & Churchill, 2002). Later modifications of the standard EFA changed core components of the analysis to address specific clinical concerns (e.g., efficiency, ecological relevance, safety), some of which resulted in the development of novel EFA formats (Fig. 26.1). The key characteristics of these novel EFA formats are briefly described below.

Latency-Based EFA

One broad concern with EFA methodology is that the rate-based measures common to experimental analyses preclude some socially significant responses from these assessments. Responses may be excluded from an EFA because the topography is too dangerous to be allowed to occur (e.g., eye-gouging) or because assessing the topography with a rate measure adds confounds to the experiment (e.g., elopement). Thomason-Sassi et al. (2011) circumvented these problems by making one change to the standard EFA methodology while maintaining all of the core components. This change resulted in what is now known as the latency-based EFA. The latency-based EFA relies on the same multi-element condition presentation characteristic of standard EFAs but uses latency-to-the-first-response in place of rate

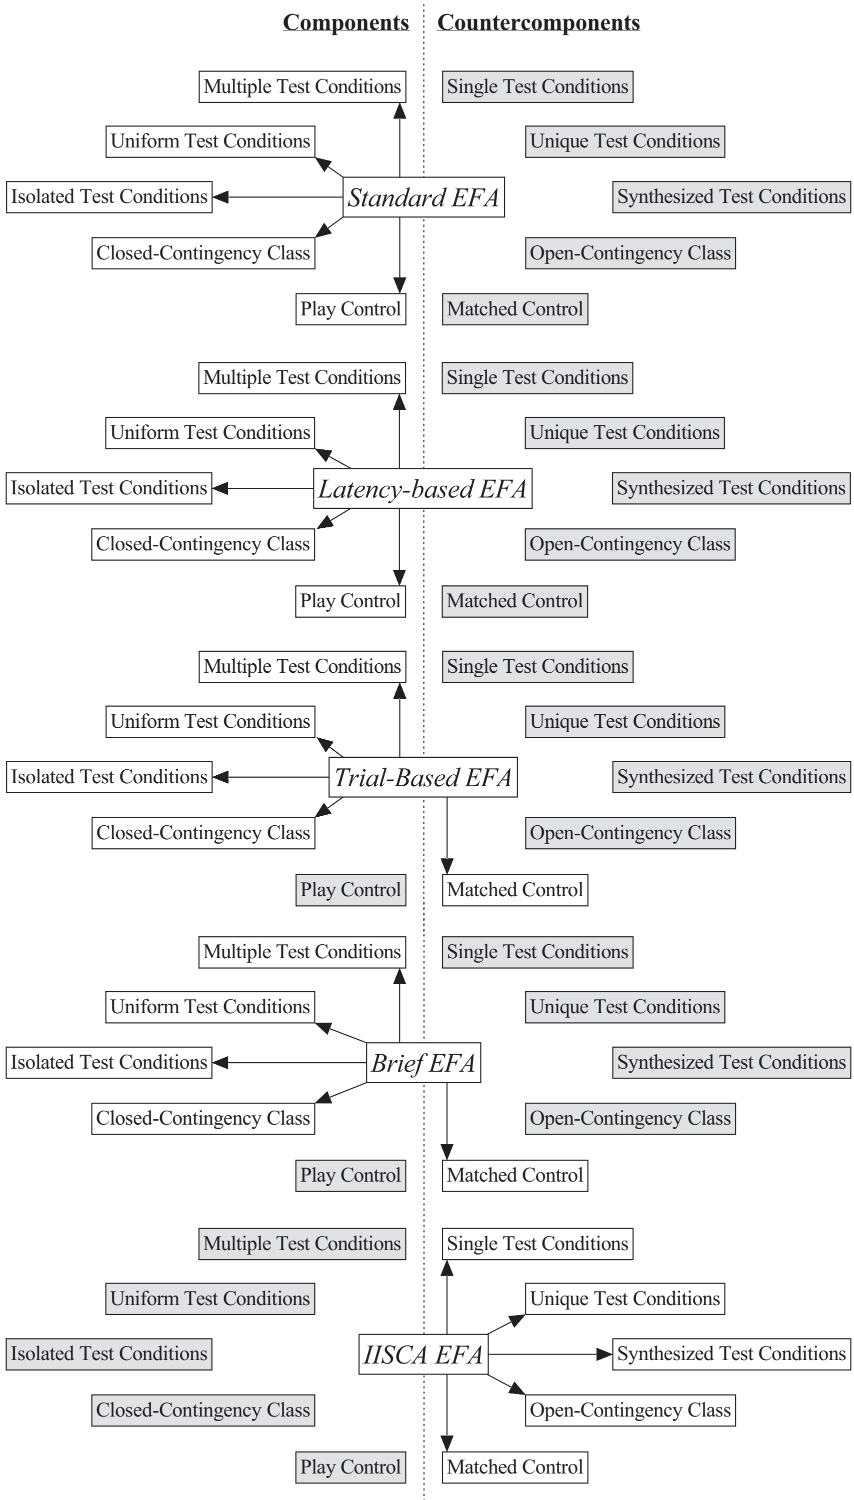

Fig. 26.1 EFA components and countercomponents

measures. During test conditions, an experimenter presents an EO that remains in place until an instance of target behavior occurs. Condition-specific reinforcement is then delivered contingent on this response. Following the conclusion of the reinforcement interval or the session's time limit, the next session is initiated.

By measuring response latency, Thomason-Sassi et al. (2011) achieved differentiated analyses for their participants in analogue settings in less time than the standard EFA and with fewer instances of problem behavior observed before achieving differentiation. These results have since been replicated in residential facilities, hospitals, and schools across various topographies of SIB, aggression, noncompliance, and elopement (e.g., Hansen et al., 2019; Lambert et al., 2017; Neidert et al., 2013; Perrin et al., 2018). Treatments for problem behavior informed by latency-based FAs have also been successful in replacing problem behavior with skills (e.g., Caruthers et al., 2015; Falcomata et al., 2016; Lambert et al., 2017).

Trial-Based EFA

Because the EFA is an analogue of conditions found outside of the laboratory, there is a significant risk that any effects observed within the experimental setting will not generalize to the target treatment context (Mace, 1994). The use of general categories of reinforcement in place of individual, context-specific stimuli may also preclude desired treatment effects in the natural environment (Carr, 1994; Horner, 1994). Sigafoos and Saggers (1995) developed the trial-based EFA format to address this concern in the classroom setting, where problem behavior could be assessed under ecologically relevant conditions. The researchers managed to maintain most of the core components of the standard EFA while replacing only the play control condition with a matched control. The trial-based format was conducted by embedding trials of three uniform test conditions (i.e., attention, escape, tangible) into two students' daily routines. Trials consisted of two 1-min segments, with the first segment serving as the test and the second serving as the control. During the first segment, a putative establishing operation was in place, and the first instance of problem behavior resulted in the presentation of the second segment, noncontingent access to the reinforcement matched to the establishing operation. Because the assessment was conducted under the same conditions where treatment would eventually occur, the trial-based format increased the confidence that any effects observed during the analysis would also transfer to the treatment context.

These procedures have since been replicated: across public school, head start, and special education settings; with children with and without intellectual and developmental disabilities; when implemented by parents, graduate students, teachers, and paraprofessionals; and across severe and emerging problem behavior topographies (Fahmie et al., 2020; Gerow et al., 2019; Rispoli et al., 2014; Ruiz & Kubina, 2017). More recently, trial-based EFAs have also been used to inform treatments for elopement and vocal scripting (Lambert et al., 2017; Rispoli et al., 2018). Although trial-based EFAs have been used across a variety of settings, the components of each are relatively static. All trial-based EFAs included the characteristic set of trials split into test and control segments, as well as standard EFA conditions that were adapted to participants' individual preferences. Experimenters generally conducted between 10 and 20 trials during each trial-based EFA, and trial segments usually lasted between 30 s and 1 min. The brevity of this analysis offers an improvement over the extended time taken to conduct a standard EFA. A recent study by Dowdy et al. (2021) comparing interrater reliability of the trial-based FA found that a panel of experts could reliably identify problem behavior function for three participants after 10, 15, and 20 trials of the trial-based FA had been completed, suggesting that total assessment time need not take more than 10 min of a participant or implementer's time.

Brief EFA

Even though the standard EFA provided empirical evidence of a behavior's sensitivity to consequences, this procedure was not widely adopted into clinical practice. Achieving a differentiated analysis with a standard EFA initially required behavior analysts to conduct equal amounts of 15-min sessions for any conditions included in the analysis. These sessions were not usually completed in one sitting, often resulting in hours of functional assessment time spread across weeks or months. Clinicians reported that these procedures were too time- and resource-intensive to be incorporated into regular work schedules, and as a result, they primarily relied on descriptive assessments and structured interviews to identify purported reinforcers for problem behaviors (Axelrod, 1987; Doss & Reichle, 1989). To demonstrate that the EFA could be modified to meet the challenges of providing assessment services in an outpatient clinic, Northup et al. (1991) modified the EFA to develop what would eventually be known as the brief EFA format.

Northup et al. (1991) made four changes to the standard EFA, including one main modification to a core component to develop the brief format. First, the researchers reduced the duration of all sessions from 15 min to a range of 5–10 min. Second, rates of a predetermined replacement behavior were measured during sessions in addition to problem behavior. Third, participants were exposed to only one to two sessions of each condition during the assessment. The final modification was the substitution of the play control condition with a matched control whereby the implicated contingency was reversed to support the replacement behavior. Otherwise, all components of the standard EFA remained the same. Participants were exposed to social negative, social positive, and alone conditions, and brief access to the purported reinforcer in each condition was contingent on one topography of severe problem behavior (aggression). These modifications allowed Northup et al. to complete an EFA with three individuals with intellectual or developmental disabilities within one 90-min outpatient visit. At the end of the outpatient visit, the experimenters also demonstrated that each participant's replacement behavior was sensitive to the same consequence(s) as their aggression, providing some direction for later treatment efforts.

Northup et al. (1991) demonstrated that EFAs could be made more practical for clinicians by greatly reducing the time needed to conduct an analysis and identifying one replacement behavior for future function-based treatments. Initial replications of these procedures showed some generality with respect to analysis outcomes (e.g., Derby et al., 1992), but the failure of later researchers to consistently achieve correspondence between brief and standard EFA outcomes raised questions about the level of experimental control demonstrated by the brief FA (Kahng & Iwata, 1999).

Interview-Informed Synthesized Contingency Analysis (IISCA)

Concerns about the standard EFA have occasioned a variety of different FA formats. These formats were created by changing only one component of the standard EFA, making each format well suited to accomplish a goal of analytic efficiency, safety, or utility while leaving all other components of the EFA intact. Preserving most elements of the standard EFA while changing one or two component parts enables experimenters to carefully evaluate the effect of their change on the outcomes of the analysis. However, this may also limit what the analysis itself can achieve. Optimizing any one particular component of an EFA based on the standard format will greatly increase the effectiveness of that component, but those outcomes are unlikely to carry over to the other components of the analysis. For example, designing an incredibly efficient EFA does not guarantee that participants are safer within that analysis. Likewise, optimizing an EFA for experimental precision does not guarantee clinical utility. It follows, then, that individual components of the analysis can be greatly improved in isolation, but comprehensive improvements in analytic safety, utility, and efficiency can only be achieved through all-encompassing changes to the standard EFA format.

Hanley et al. (2014) introduced an EFA format called the interview-informed synthesized contingency analysis, or IISCA, which combined multiple modifications to the individual components from the EFA formats described above to create one comprehensive EFA aimed at increasing safety and efficiency. The combination of these components resulted in a format that shares minimal procedural similarities with the standard EFA apart from the systematic manipulation of establishing operations and contingent delivery of reinforcement following behavior (i.e., ABC model). Thus, the IISCA represented a complete departure from the core components, now relying on the full set of five countercomponents. Whereas the standard EFA alternates between a play control condition and multiple uniform test conditions, each designed to assess the effect of one set of antecedents and consequences on one response topography, the IISCA alternates between brief (3–5 min) matched test and control sessions. These conditions assess the sensitivity of multiple forms of problem behavior to one unique reinforcement contingency composed of synthesized establishing operations and reinforcers reported to co-occur in the natural environment by caregivers. Incorporating the unique establishing operations and consequences caregivers report to co-occur with problem behavior (i.e., unique test conditions) ensures that the analysis conditions are more similar to the conditions that maintain problem behavior under ecologically relevant settings.

In one sense, using synthesized contingencies increases the clinician's confidence that a functional relation has been established because the synthesized contingency accounts for all other plausible alternatives of behavior change. In another sense, this modification may lack the precision some researchers are interested in achieving because the isolated effects of each establishing operation and purported reinforcer on behavior are unclear (Fisher et al., 2016). The question then becomes, *what level of specificity regarding reinforcement is necessary*?, with applied researchers and clinicians likely leaning to answer that question, *the level in which informs the most effective treatment while maintaining elements of pragmatism and practicality.* Thus, the likely outcome is not so easily parsed between a dichotomy of synthesized or isolated conditions but a continuum of synthesis that is suitable for the individual and informed by caregiver reports of the problematic context as a whole.

The procedures and outcomes of Hanley et al. (2014) have since been replicated across settings, cultures, problem behavior topographies, and participant characteristics (Coffey et al., 2020). Researchers have also continued to further modify the IISCA to better suit the needs of particular individuals or settings. These additional modifications have in turn created novel IISCA formats modeled after the EFA formats described above. A shorter version of the IISCA, the single-session IISCA, was developed to further reduce the time clients spend in assessment (Jessel et al., 2019), and trial- and latency-based IISCAs were developed to better capture ecologically relevant contingencies and assess elopement, respectively (Curtis et al., 2020; Jessel et al., 2018b). Combining pre-existing EFA formats exemplifies the flexibility of the EFA technology and may further enhance the clinical utility of EFA procedures that were once almost entirely an experimental model.

Evaluating Control During EFA

Evaluating the outcomes after conducting an EFA has engendered its own avenue of research because the standard EFA model required advanced training to visually analyze. The overlap between multiple test conditions rapidly alternating with a single control made it difficult for behavior analysts to interpret potential functional relations. In order to identify a functional relation, behavior analysts would need to compare changes in level, trend, and variability in one test condition in comparison to the control while ignoring all data from the other test conditions. This process would need to be repeated for each test condition to create independent interpretations of the influence of each isolated contingency over problem behavior. In addition, visual analysis has often been traditionally preserved as more of an art that will appropriately develop with enough practice and feedback from expert mentors. To that end, researchers began developing structured criteria to serve as aids to the more subjective process.

The original structured criteria used to supplement visual analysis of EFA results (Hagopian et al., 1997) created quantified ranges of mean rates that would be indicative of differentiated outcomes for each EFA conducted. Standard deviations were calculated based on the rate of responding in the control condition, and the structured criteria used a binary system to identify if there was or was not a functional relation based on the number of data that appeared above that standard deviation. The structured criteria were later modified (Roane et al., 2013) to improve sensitivity to EFA of varying lengths and included additional criteria related to other aspects of visual analysis such as trends. However, the interpretations remained limited to a binary outcome. Therefore, behavior analysts using the structured criteria could only establish an answer of whether or not the problem behavior is likely to be sensitive to the environmental variables but not the degree to which those variables influenced problem behavior.

The structured criteria were later adapted to create categories of differentiated levels of outcomes (Jessel et al., 2020b, c). That is, the interpretation of the results of an EFA was no longer the overly simplified "yes" or "no" answer. The structured criteria now allowed for more refined interpretations of levels of potential control. For the EFAs with interpretable control, the behavior analyst used the multilevel structured criteria to further establish if the control was strong, moderate, or weak.

The determination of level of control is dependent on two criteria: overlap between conditions and observing problem behavior during the control. The EFA has strong control if there is no overlap between the test and control conditions and no problem behavior is observed during the control condition. This relation identifies a properly motivating context in the test condition if rates of problem behavior remain elevated and stable when the putative reinforcer is contingently provided. In addition, the lack of problem behavior in the control condition provides confidence that the influence of extraneous variables has been sufficiently eliminated. A behavior analyst who has identified a strong level of control during an EFA can go on to develop an effective function-based treatment. A step lower would be an EFA with moderate control whereby there may be some overlap between test and control conditions or problem behavior during the control condition. The moderate relation indicates that there is some sort of extraneous influence, but putative reinforcers are still the central contributors to problem behavior, and the behavior analyst should still be confident that they can develop an effective treatment. Once an EFA is identified as having weak control—both overlap between conditions and problem behavior during the control—the behavior analyst must now question if they have sufficiently identified the contingency as a whole that influences problem behavior. Weak control is indicative of a need to modify the EFA or the necessary concession that any function-based treatment based on an EFA with weak control will likely be only mildly effective without supplemental procedures (e.g., arbitrary reinforcers or punishment) and may not produce meaningful change.

Being able to evaluate control during an EFA is central to a behavior analyst's training because those interpretations will have direct implications for the selection of function-based treatment procedures. For example, the process of extinction requires the general knowledge that the contingent relation between reinforcement and problem behavior should be broken; however, the procedures for implementing extinction will differ depending on which functional reinforcer is identified (Iwata et al., 1994). Furthermore, problem behavior that is sensitive to multiple reinforcers requires a far more complex understanding of extinction (Jessel et al., 2018a). That is to say, interpretations of control during an EFA are important because they will impact treatment efficacy.

Other Considerations of EFA

Multiple issues could arise when conducting an EFA such as undifferentiated outcomes or identification of sensitivity to automatic reinforcement. An undifferentiated outcome could infer multiple potential interpretations depending on the patterns of problem behavior observed. First, EFAs that include multiple test conditions could result in poor discrimination with the rapid alternation of those conditions in a multielement design. Therefore, the saliency of the experienced contingency could be improved by including arbitrary and distinctive discriminative stimuli, or the design could be modified to a reversal or pairwise comparison (Hagopian et al., 2013).

Second, the results of the EFA may not clearly rule out automatic reinforcement, and to appropriately treat, the behavior analyst will need to parse out that which is sensitive to socially mediated and automatic reinforcement. Querim et al. (2013) suggested conducting pre-analysis screening of automatic reinforcement with the conduction of multiple extended alone sessions. If problem behavior eliminates during these extended alone sessions, the behavior analyst is encouraged to search for more potential means of modifying the EFA to improve the chances of identifying socially mediated reinforcement. If problem behavior continues to occur, the behavior analyst must continue with other means for targeting this problem behavior that is sensitive to automatic reinforcement. The open-ended interview that informs the IISCA also includes questions for caregivers screening potential automatic reinforcement to address these behaviors before spending the time and resources to conduct an EFA.

Third, the EFA could also result in undifferentiated outcomes without problem behavior occurring. With the assumption being that the patients are referred for services because some level of problem behavior exists, this suggests a potential false-negative outcome, implying that there is a history of reinforcement and the EFA failed to appropriately identify this history. This is potentially the worst possible outcome because it means the behavior analyst must either (a) send the patient home without treatment, (b) continue conducting assessment and delay implementation of function-based treatment, or (c) implement treatment with powerful arbitrary reinforcers and punishers. To put this into perspective, mammograms are x-ray screenings of a woman's breast that are conducted to detect tumors that could lead to breast cancer. The physician is unable to provide appropriate treatment if the mammogram incorrectly concludes that no cancerous tumors exist (i.e., false negative). Therefore, in this case, the mistake is potentially fatal. For the most part, problem behavior will not be severe enough to reach such extreme cases as the example of breast cancer, but the implications regarding false-negative outcomes remain a cautionary analogy.

Reducing False-Negative Outcomes

Individualizing procedures incorporating contingencies informed by caregiver reports and descriptive observations have often been found to reduce the potential false-negative outcome (e.g., Bowman et al., 1997; Hagopian et al., 2007; Hausman et al., 2009). For example, Bowman et al. conducted a standard EFA for the problem behavior of two individuals admitted to an inpatient hospital. Problem behavior for both participants was infrequently observed during the standard EFA, and the behavior analysts were unable to successfully identify isolated functions of the problem behavior. Bowman et al. returned to the caregivers for idiosyncratic information regarding the context in which problem behavior occurred in the natural environment and began collecting descriptive data during observations. Informed by the parental reports and observations, the behavior analysts concluded that problem behavior was likely evoked by denials and was sensitive to honored requests as reinforcement. The subsequent individualized EFA was designed using that information and validated these conclusions with positive or negative reinforcers provided upon request for a period of time only following instances of problem behavior in the test condition. Encounters of this kind implicating the necessity of modifying standardized procedures may be more common than not.

Hagopian et al. (2013) reviewed 176 standard EFAs conducted with patients admitted to an inpatient hospital to categorize common modifications that were necessary following the common occurrence of false-negative outcomes when using standard EFA procedures. The authors found that 53% of initial EFAs were unable to identify a function for problem behavior, and the behavior analysts often employed changes to the experimental design, antecedents, consequences, or, quite commonly, a combination of procedure changes. It wasn't until tertiary EFAs were conducted did the behavior analysts reach differentiated outcomes above 85% in the 176 applications. Therefore, considering these modifications from the start could improve the efficiency of the assessment and treatment process and reduce overly extended analysis periods (Jessel et al., 2016).

Automatic Reinforcement

The EFA is strategic for determining the influence of socially mediated environmental events on problem behavior, but complications arise when the reinforcement comes directly from the behavior of the individual. Behavior analysts often provide the default category of automatic reinforcement when the results of an EFA are undifferentiated with elevated levels of problem behavior across conditions or when elevated rates are observed in an alone/ignore condition. Current EFA methodology cannot necessarily pinpoint the source of automatic reinforcement without extensive analysis. For example, after conducting a standard EFA and determining that the problem behavior of two individuals diagnosed with intellectual and developmental disabilities was sensitive to automatic reinforcement, Patel et al. (2000) extended EFA conditions to include different sensory stimuli (auditory and different tactile stimulations). Although the researchers were only able to rule out some potential stimulation, a treatment of differential reinforcement of other behavior (DRO) using preferred items that produced the hypothesized stimulation was effective in reducing problem behavior. Others have similarly designed a preference assessment to be conducted following the EFA to identify matched and un-matched stimuli that appear to produce the same or similar automatic reinforcement (e.g., Piazza et al., 2000; Rapp, 2007). However, the precision of these multiple assessments in identifying specific sources of automatic reinforcement remains in question, and the conclusions drawn from an EFA are far more likely to support the general assumption regarding the continued observation of problem behavior when socially mediated reinforcers are not forthcoming.

Finding the source of automatic reinforcement may yield an opportunity to implement function-based sensory extinction (Iwata et al., 1994), but the reliance on secondary and tertiary modified procedures calls into question the practicality of an EFA process that can produce a potentially effective intervention. The over-analytic assumption that fuels multiple and complex EFAs is that a precise identification of isolated, or pure, reinforcement contingencies may inform the best treatment; however, a more parsimonious solution is to delineate patterns of automatic reinforcement and identify treatment strategies that are likely to correspond with those patterns (Hagopian et al., 2015, 2016). This treatment utility approach allows the behavior analyst the ability to make confident EFA-informed decisions when designing a treatment following the results of only a single analysis.

Hagopian et al. (2015) delineated between three subtypes of SIB dependent on the patterns observed during standard EFA. Figure 26.2 depicts these patterns using hypothetical data in an EFA stripped to the core essentials for identifying the three subtypes. That is, the EFA needs a control condition of enriched reinforcement, a test condition without social reinforcement (alone or ignore), and a measure of self-restraint. The top panel of Fig. 26.2 identifies automatic reinforcement (Subtype 1) in which the control condition effectively suppresses SIB and, without this alternative form of stimulation, elevated rates are observed in the alone condition. This is

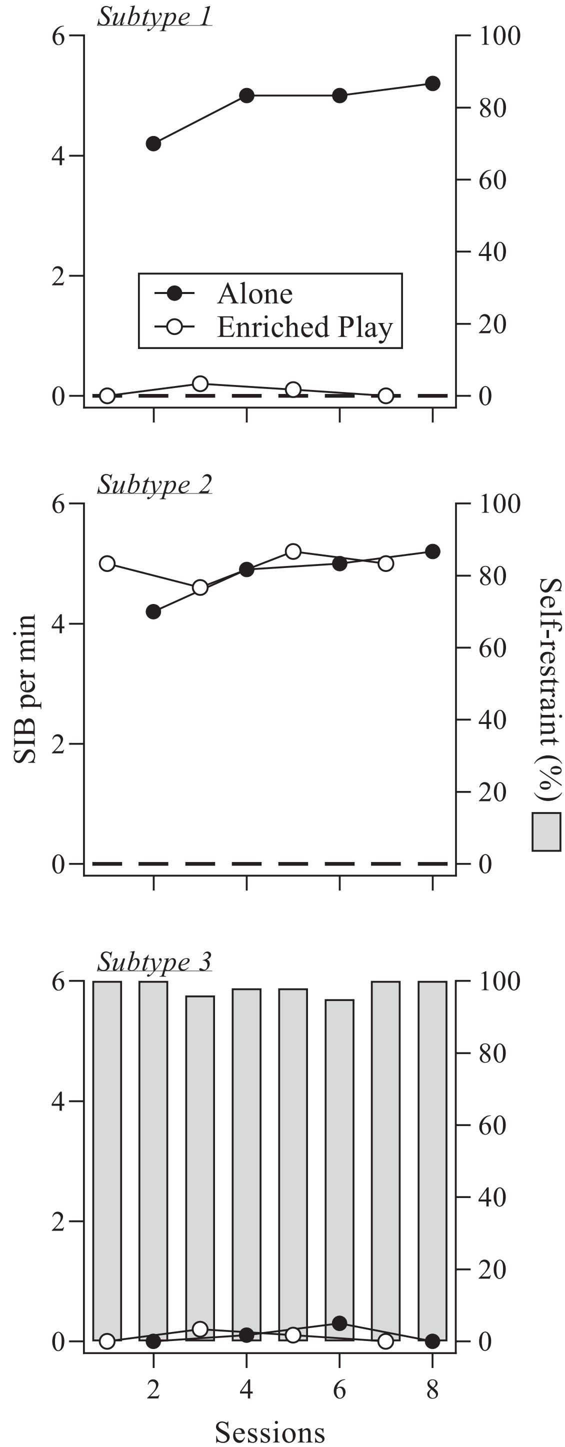

Fig. 26.2 Hypothetical data representing the three subtypes of automatic reinforcement

a highly differentiated outcome supportive of the subsequent effectiveness of reinforcement-based strategies considering that the noncontingent delivery of rich reinforcement in the control condition could compete with the automatic reinforcement obtained from the SIB. Automatic reinforcement (Subtype 2) is far more pervasive across conditions (middle panel) and, unfortunately, is predictive of a resistance to treatment and the necessity of treatment packages with multiple, more intrusive, treatment components such as response blocking, punishment, or restraint. The bottom panel provides the hypothetical pattern observed during automatic reinforcement (Subtype 3). When the patient is provided access to self-restraint, SIB tends to be low across conditions with high levels of engagement in self-restraint. Much like Subtype 2, there is little differentiation across conditions, but treatments including restraint or protective equipment are likely to be effective. Therefore, each delineated subtype of automatic reinforcement informed the selection of different treatment procedures.

Social Acceptability of Procedures

In clinical practice, EFAs are conducted to increase the likelihood of a successful intervention outcome. When clinicians identify the contingencies that evoke problem behavior, they are better equipped to begin building skills under relevant conditions than they would have been had no EFA been conducted at all. Although the ultimate purpose of the EFA is to identify a context that can be used to teach ecologically relevant skills, it is important that the quality of the analysis not be overlooked to fast-track a treatment program. An EFA's procedures should be designed with the same care and consideration for client well-being as any of the intervention procedures that it will later inform. As with any skill acquisition program, an EFA that prioritizes client well-being includes procedures that ensure client assent, happiness, safety, and dignity throughout the entire assessment process. Some strategies clinicians can use to create more considerate EFAs are briefly discussed below.

Behavior analysts are required to obtain written consent from clients prior to beginning any behavioral assessment (Behavior Analyst Certification Board, 2014). In many situations, caregivers or legal guardians will provide written consent on behalf of the service recipient because their age or disability status may legally prevent them from doing so themselves. Even if the client is not the person signing the consent forms for the EFA, their preferences and comfortability during the assessment process should still be taken into account. Behavior analysts can accomplish this by asking clients for their assent to participate in an EFA. Like informed consent, assent to participate in an EFA can be given, discussed, or revoked at any time during the assessment process. If the client and the clinician can communicate easily with one another, this assent may be written, spoken, or signed. However, nonverbal behavior might also be used as an index of client assent if clients are given a choice to participate in the assessment or to leave and participate in other activities. If different contingencies are arranged in a concurrent operant or concurrent chains procedure, a client remaining in the session space or continuing to engage with their preferred items and activities during an EFA might be interpreted as assenting to the current environmental conditions arranged by the clinician. If that same client makes any attempt to leave the session space or seems continuously discontented by the clinician's actions, these responses might be interpreted as a withdrawal of assent (see Hanley, 2010, for further discussion on objective measures of preference).

One recent example of this interpretation of client assent can be found in Rajaraman et al.'s (2022) enhanced choice model procedures. Participants in this study experienced a concurrent operant treatment model following the completion of an IISCA, where they could select to terminate services for that day, participate in the treatment process (i.e., differential reinforcement of skills and extinction of problem behavior), or take a break from the treatment procedures and "hangout" with their caregivers and preferred activities (i.e., noncontingent reinforcement). All participants selected to hangout and take a break from function-based treatment at least once during the study, but chose to spend most of their time in the treatment context. By the end of the experiment, all participants had learned communication skills, followed instructions provided by the experimenter, and emitted reduced rates of problem behavior relative to baseline. In this instance, providing participants with a clear response to make when withdrawing their assent to participate in treatment did not prevent the experimenters from teaching functional replacement skills. Programming a similar concurrent operant arrangement during an EFA may provide clinicians with an objective means to evaluate their client's assent to participate in the EFA. In the event of client nonparticipation, a concurrent chains arrangement also provides data about the conditions under which their clients withdraw consent to participate in EFAs, teaching clinicians about which procedures to avoid arranging during their analyses.

In addition to measuring client assent through concurrent operant or concurrent chains procedures, clinicians might also consider directly measuring indices of happiness, such as smiling, laughing, or emitting social bids during the EFA. Although happiness measures cannot be conflated with client assent or preference for a particular set of EFA procedures, they do provide clinicians with some objective evidence of a client's experience during an analysis. Baseline measures of happiness or engagement along with traditional problem behavior measures could also be used to inform intervention procedures by providing clinicians information on which conditions are the most likely to produce simultaneous increases in client happiness and decreases in problem behavior.

A recent study by Thomas et al. (2021), for example, found that interventions based on the function of happiness responses instead of the function of problem behavior may still result in problem behavior reduction. After conducting trial-based functional analyses for the problem behavior of four children with autism, the authors found that happiness responses were most likely to occur during the control segment of the attention condition and that problem behavior was most likely to occur during the tangible test condition. Interventions conducted based on the function of happiness (attention) produced greater increases in happiness responses and similar decreases in problem behavior relative to interventions based on the function of problem behavior (tangible). Though these data are preliminary, Thomas et al.'s study provides some evidence to suggest that including measures of happiness during an EFA may yield additional benefits to clients during later function-based treatments.
