Self-Management Self-management strategies have been used to teach children with autism to engage in independent play in the absence of a treatment provider. Self-management may rely on self-monitoring, self-evaluation of play performance, and self-reinforcement (Stahmer & Schreibman, 1992). In a study conducted by Newman et al. (2000), two, six-year-old children and one preschool child with a diagnosis of autism were taught to engage in varied play responses with preferred toys. Children were instructed to take a token contingent upon the display of a variation in play behavior. All three children were successfully able to use the self-management system and showed an increase in variability in responding.

In 1992, Stahmer and Schreibman targeted appropriate toy-play in three children with autism using a self-management training package. During training, the experimenter modeled both appropriate and inappropriate toy-play behavior and asked the question, "Is this right?" Following this training, the participants were taught to self-manage their own behavior and to mark a check in a box if they engaged in appropriate play behavior during a specified interval. Access to a reinforcer was provided contingent upon appropriate self-monitoring a toy-play behavior. Over time, the experimenter systematically faded his or her presence from the child. The results showed a functional relationship between the self-management system and an increase in appropriate play in unsupervised settings, along with a reduction in self-stimulatory behavior.

In Vivo Modeling and Play Scripts Researchers have found that children with autism can increase play skills via observation of predictable and repeated sequences. Jahr et al. (2000) compared two in vivo modeling procedures to teach children with autism to engage in play. One procedure provided opportunity for the child to observe two models engage in a scripted cooperative play episode. Following the episode, the child took the place of one of the models and the play episode was repeated. The second procedure was the same as the previously described procedure with one exception. The child participant was taught to verbally describe the modeled play episode prior to taking the place of one of the models. The authors found that modeling, in conjunction with training with verbal description, was effective in evoking play behavior across settings, time, and play partners.

Video Modeling Similar to in vivo modeling, video modeling allows a child with autism to observe repeated and predictable play episodes presented in a video format. In 2002, Schwandt, Pieropan, Glesne, Lundahl, Foley, and Larsson (as cited in Stahmer et al., 2003) used video modeling to teach three- and four-year-old children to engage in play for extended periods of time, to increase variation in play responses, and to emit play-related verbal statements. Each child was provided three repeated opportunities to observe play with target toys. Following the third video presentation, the child was presented with the same toys depicted in the video. Variation in toy play responses and engagement in play were differentially reinforced throughout the play activity. Over time, the videos were removed. The authors found that the children engaged in toy play responses in novel settings with novel toys. Some of the participants emitted verbal toy-related responses similar to those on the video.

Charlop-Christy et al. (2000) conducted a study designed to compare in vivo modeling with video modeling with five children with autism. After viewing the video model twice, the child was provided the instruction, "Let's do the same, just like on TV." After viewing the in vivo model twice, the child was provided the instruction, "Let's do the same, just like they did." The authors found that video modeling was effective in teaching different behavior, including independent and cooperative and social play. Although both in vivo and video modeling were effective in increasing play, video modeling led to faster acquisition and was more time effective than in vivo modeling.

Overall, the importance of play has been well established. The sampling of research reviewed suggests that there are a variety of behavioral approaches used to increase play behavior. Whether one uses discrete-trial teaching, video-modeling with play scripts, or self-management techniques, a systematic approach to the application of the teaching procedure should result in an increase in the desired play behavior.

Conclusion

Social skills are essential in creating relationships with others. Clear verbal expression of one's self, attention to the verbal behavior of others, and cooperation and interest in games and stories with peers are just some of the necessary components of a positive relationship. Over the years, behavioral research has continued to analyze the effectiveness of strategies that teach social skills to those who display deficits. The research reviewed in this chapter demonstrates the operant nature of various components of social skills behavior. Through techniques including differential reinforcement, modeling, incidental teaching, discrete-trial teaching, script fading, and self-management, behavior analysts have been able to teach social skills responses such as eye contact, prosody, gestures, affect, language and interactions, joint attention, and play behavior. As applied behavior analysts continue to examine these functional relations, the lives of many can continue to improve and develop successfully.

52 Applied Behavior Analysis to Teach Academic Skills

Janet L. Applin

> Behavioral principles offer a wealth of effective and empirically validated practices to offer public education. The research is here. The desire is here.
> Fielding et al. (2013)

The gold standard characteristics or defining principles of Applied Behavior Analysis (ABA) are those provided by Baer et al. (1968, 1987): applied, behavioral, analytic, technological, conceptual, effective, and capable of generalized outcomes. While one typically thinks of ABA in relation to affecting and eliciting desirable behaviors and/or decreasing undesirable behaviors, the principles have also been applied to the teaching of academic skills.

Combining Baer et al. (1968, 1987) ABA principles with teacher behaviors and strategies aligned with ABA principles are at the heart of teaching methods and curriculums utilizing ABA. These teaching methods utilizing ABA are applied, behavioral, analytic, technological, conceptual, effective, capable of generalized outcomes, and may include teachers' use of modeling, prompting and fading, providing frequent active response opportunities, giving performance feedback, using reinforcement contingencies, providing systematic review, and programming for generalization (Joseph et al., 2015).

This chapter will examine evidence-based strategies which make use of ABA principles to improve academic achievement and learning. First, this chapter provides a historical overview of the use of ABA to teach academic skills. Second, this chapter presents selected ABA principles and strategies as part of an instructional system and critical learning skills. Third, a review of commonly used ABA methods used to teach critical learning skills is presented.

Historical Use of ABA in Teaching Academics

B.F. Skinner

B.F. Skinner, often called the "father of operant conditioning," and credited with introducing the term "reinforcement" into the field, also was creator and patent holder on a "teaching-machine," which used operant conditioning principles to teach academic skills. Skinner (1960) believed if our, then current, knowledge of verbal behavior acquisition and maintenance was to be applied to education, that a teaching machine was needed. Skinner was testing his machine in the late 1950s and was granted a patent in 1961. The ABA principles incorporated into Skinner's teaching machine included frequent feedback, positive reinforcement for correct responses, self-paced practice, and prompting and fading (Skinner,

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_52

1960). One of Skinner's teaching machines is housed at the Smithsonian's National Museum of American History (Smithsonian, NMAH, 2020).

Direct Instruction

Another, now historical but still in wide use, of ABA principles to teach academics was created by Engelmann and Becker (1968) in the late 1960s when they developed comprehensive reading and math programs for young children in historically disadvantaged public-school districts. It was first used with preschoolers in the mid-1960s and showed great success at that time. Engelmann and Becker developed what are now known as Direct Instruction (DI) programs which use explicit teaching methods with tutorials, discussion, recitation, observation, and active learning. DI is known for its scripted curriculum delivered by teachers who have had training delivering the instruction with fidelity. The original goals were to accelerate the progress of students who were disadvantaged and at risk for falling behind their peers in reading and mathematics. After DI's programs were piloted and found to be effective at increasing student learning outcomes, Engelmann and colleagues went further with the development of a formal language, reading, and mathematics program named DISTAR, for Direct Instruction System for Teaching Arithmetic and Reading. DI has been studied extensively and compared to other interventions and, in one large government funded study, was shown to be the only intervention that significantly improved learning. It has been embraced by teachers of children with special needs, those at-risk for learning difficulties, and those without disabilities (Engelmann, 1968; Hattie, 2009; Stockard et al., 2018). One should not confuse Direct Instruction with direct instruction. Programs using the capitalization of DI are referring to specific commercially available Direct Instruction programs such as DISTAR. The strategy of direct instruction (with lower case d and i) incorporates many of the same principles for teaching in an explicit manner yet does not refer to a specific curriculum. While there is criticism of Direct Instruction and direct instruction, notably from Jonathan Kozol (2005) who, in his book *The Shame of the Nation*, believed DI was "excessively dogmatic, utilitarian, and authoritarian," there is no denying the effectiveness of these methods with a multitude of populations and they continue to be effective, updated, and in use today. DISTAR and related products remain commercially available and in wide use today and are offered by McGraw Hill under the names DISTAR Arithmetic I and II (Engelmann & Carnine, 1975), Corrective Mathematics (Engelmann & Carnine, 1982), Connecting Math Concepts (Engelmann et al., 1996), DISTAR Reading, Reading Mastery for grade levels PreK-5 (2008), and Corrective Reading for struggling older students (2008). Critics aside, practitioners have had success with Direct Instruction curriculums to serve and teach many thousands of children over the years and their systematic strategies use many principles of applied behavior analysis such as providing prompts, requiring responses, providing consequences, and monitoring progress systematically.

Precision Teaching

Precision Teaching is another method which incorporates principles of applied behavior analysis and has its roots in free-operant conditioning. In the 1960s Ogden Lindsley shifted his focus from a laboratory at Harvard to special education teacher training. His goal was to introduce free-operant technology into public school classrooms as he theorized that free-operant conditioning could be a powerful enhancement to learning and that frequency recording was superior to the standard recording of percentage correct (Lindsley, 1990). He was correct and documented great success. He developed a standard chart, or celeration chart, for teacher and student recording that, "bases educational decisions on changes in continuous self-monitored performance frequencies displaced on standard celebration charts." These charts may be easily found by googling "precision teaching," and/or "celeration chart." The key to Precision Teaching is not that it tells us "what" to teach or "how" to teach it, but it is a method of evaluating our strategies and curricula to determine effectiveness. The guiding principles of Precision Teaching are to: (a) focus on directly observable behavior; (b) frequency as a measure of performance; (c) the standard celeration chart, and; (d) the learner knows best. Teachers utilizing the method of Precision Teaching must find ways to frame learning objectives into concrete, directly observable behaviors that can be counted and recorded. Next, the frequency of said behaviors is recorded as the average number of responses during each minute of the assessment time on the celeration chart. Last, one determines, from the visual data on the celeration chart, whether or not a student is progressing according to plan. If so, the instructional programming being used may be deemed appropriate for this student. If not, the instructional programming, intervention, curricula, etc. need to be examined and changed because it is not working for said student. Note that all of the Precision Teaching steps are indicative of common applied behavior analysis techniques and principals: applied, behavioral, analytic, technological, conceptual, effective, and capable of generalized outcomes. McGreevy (1983) views Precision Teaching as a five-step process: (1) Select a Task; (2) Set an aim; (3) Count and teach; (4) Develop a learning picture; and (5) Decide what to do. While very effective, it is rare to see twenty-first-century teachers utilizing Precision Teaching and Lindsley's celeration chart; however, they do use many of the same principles that guide Precision Teaching when utilizing various progress monitoring methods such as Curriculum-Based Measurement, Curriculum-Based Assessment (Fuchs & Fuchs, 2004; Hosp & Hosp, 2003) and commercially available progress monitoring tools such as AIMS Web (2020), and University of Oregon's DIBELS, or Dynamic Indicators of basic Early Literacy Skills (2020). There was a journal, *Journal of Precision Teaching*, in active publication from 1980 through 2010 but it was discontinued at that time as the editors "began to shift our focus to more dynamic forms of communication…" (Standard Celeration Society, 2021).

ABA Principles as Part of an Instructional System

Many instructional systems utilize ABA principles as part of the system. In 1962, Robert Glaser described an instructional system as one having five components: Instructional goals (system objectives); entering behavior (system input); instructional procedures (system operator); performance assessments (output monitor); and research and development logistics (analysis and evaluation) (Glaser, 1962). When coupled with the concepts of ABA, instructional systems are similar in that they require goals, specific targets (entering behavior), systematic procedures (instructional procedures), are analytic (performance assessments), and must be effective (research and development analysis).

Applied behavior analysis as an instructional system has been extensively researched in the peer-reviewed literature, not only to modify social behaviors but in teaching academic skills. ABA is often seen as a strategy (or instructional system) for individuals on the Autism Spectrum. However, these same teaching strategies are effective when teaching individuals with other disabilities as well as those with no disabilities.

Given the alarming statistics of proficiency in basic reading, writing, and mathematics performance of children in today's public schools, the focus on best practices of teachers incorporating ABA, and using ABA principles to teach proficiency in language arts (reading and writing), and mathematics has never been more urgent. There is a proliferation of data showing that a large percentage of students tested are not proficient in basic reading and math skills. Data from the 2019 National Assessment of Educational Progress or NAEP show that 40% of students tested performed below NAEP basic which denotes partial mastery of prerequisite knowledge and skills that are fundamental for performance at the NAEP-proficient level (NCES, 2020). It has long been considered urgent to close this achievement gap between marginalized and minority populations of students and their majority peers.

Using ABA principles as part of an instructional system is not only urgent and best practice but is also required by federal legislation governing public education in the United States. The Individuals with Disabilities Education Act (IDEA) (2004), Section 1414 (d)(1)(A)(I)(IV), requires that Individual Education Programs include, "a statement of the special education and related services and supplementary aids and services, *based on peer-reviewed research* to the extent practicable to be provided to the child" [italics added] (IDEA, 2004). In addition, the Elementary and Secondary Education Act, ESEA (United States, 1965) which was reauthorized as the No Child Left Behind, NCLB (United States, 2001) and again as Every Child Succeeds Act, ESSA (2015) has the goal of improving educational equity for students from low-income families by providing federal funds to school districts serving these families such as Title I schools. The ESSA (2015) calls on districts and schools to use evidence-based interventions to ensure that interventions being implemented have proven to be effective in leading to improved student achievement.

Given that both federal laws call for the use of evidence-based interventions in teaching, it follows that ABA strategies and curricula claiming to be evidence-based or based on principles of ABA have seen an increase in use across student populations and levels. A word of caution here: because a commercially available curricular product or new teaching strategy claims to be "research-based" or "evidence-based" or based on ABA principles does not necessarily equal quality or student academic gains. Practitioners should carefully examine products and strategies and search out peer-reviewed research on the product or strategy as a consumer of these products or strategies. In addition, even those products or strategies deemed to have sufficient and robust research supporting their use are not effective if not used with fidelity by the practitioner utilizing the product or strategy to teach critical learning skills and academic content.

Critical Learning Skills

What are critical learning skills? There has been some consensus among educators that have narrowed down the answer to what is known as "the four C's" or critical thinking, creative thinking, communicating, and collaborating. It is believed that the four C's are essential skills that help students learn and experience success in and out of school. The Partnership for twenty-first Century Skills first identified the 4 C's (Plucker et al., 2016). Others might say that you cannot teach the four C's until basic academics such as reading, writing, and arithmetic are mastered. Still others might say that the 4 C's should be taught in concert with the three r's. For the purposes of this chapter, critical learning skills will refer to those skills that are traditionally thought of as basic academic skills, the three r's if you will: reading, writing, and arithmetic. So, how do we make use of applied behavior analysis to teach these critical learning skills? To answer that question, we will examine basic teaching strategies which incorporate principles and methods from applied behavior analysis. It must be noted that many social and behavioral skills are needed to engage in academic instruction, and it is difficult to separate the two. One must be able to attend to a prompt to learn how to read sight words, for example. If one uses an ABA approach to teach the skill of attending to a prompt so that reading may be taught, does that mean that ABA is being used to teach the skill of reading or is it just being used to modify behavior? ABA strategies that have been shown to be effective at modifying academic skills and/or behaviors must be implemented with fidelity to replicate positive outcomes and increased academic achievement.

Explicit Teaching

Explicit teaching has been around for decades and the practice entails having a clear academic focus, or objective of what is to be taught; setting realistic and ambitious goals; progress monitoring of student achievement; and delivering lessons at a brisk pace (Rosenshine, 1986). Similar to procedures associated with Direct Instruction programs and the principles of ABA applied to the strategy of explicit teaching, one can see that the gold standard ABA components of being applied (practitioners apply the strategy in real world classrooms), behavioral (practitioners have clear objectives and academic focus—in other words, what are the students expected to do?), analytic (goal setting and progress monitoring), technological (use of graphic visuals to depict progress), conceptual (adhering to the philosophies of applied behavior analysis), effective (as shown through progress monitoring), and capable of generalized outcomes (providing students with practices in different situations) are in play in Explicit Teaching models. Explicit teaching is also conceptualized as a set of steps in an instructional sequence. At its most basic are five phases: (1) Direct explanation; (2) Demonstration and modeling; (3) Guided practice; (4) Corrective feedback/verification; and (5) Independent practice. Others frame the basic five steps with different verbiage, but basically the same steps. Hudson et al. (2006) offer the following steps: (1) Providing an advanced organizer; (2) Modeling instruction; (3) Providing guided practice; (4) Providing independent practice; and (5) Providing a post-organizer. Regardless of how one labels the steps, explicit teaching always involves clear goals, clear explanations and demonstrations or modeling instruction, guided practice with feedback, independent practice with feedback, and finally providing a summary of what was to be learned.

Explicit teaching practices are included in Hattie's (2009) high-impact teaching practices. Hattie (2009) synthesized over 500,000 studies related to student achievement and concluded that some teaching practices have far more impact than others. Hattie (2009) concluded that student achievement is higher when teachers focus on and are responsive to student learning; are clear about what they want their student to learn and select appropriate curricula and strategies; explicitly explain what students should learn and demonstrate what they need to be able to do; get students to mentally engage with the materials; and give meaningful feedback to their students. Hattie (2009) is adamant that teacher clarity is paramount to improved achievement. Teachers must provide students with clear and explicit goals and objectives of what they are to learn. These explicit teaching practices or strategies clearly encompass applied behavior analysis principles of teachers' use of modeling, prompting and fading, providing frequent active response opportunities, giving performance feedback, using reinforcement contingencies, providing systematic review, and programming for generalization (Joseph et al., 2015).

It is a myth that ABA and its component use for academic instruction is only for those with disabilities such as those on the Autism spectrum. Although ABA procedures to intervene on behavior and their use for academic instruction have frequently been studied for those with autism spectrum disorders (ASD) and individuals with low incidence disabilities which impact educational achievement, the same strategies are effective for many children with high incidence disabilities as well as those children without disabilities. However, according to Dunlap et al. (2001), ABA is especially relevant in special education because of the emphasis on individualization, empiricism, replicable instructional practices, function over form, and the fact that it is a dynamic discipline. Specific strategies discussed here that are clearly ABA procedures used in academic instruction include discrete trial training, differential reinforcement, pivotal response training, antecedent-based interventions, and task analysis (Fielding, et al., 2013). Following is an overview of each of the above ABA techniques and how they have been shown to be effective in teaching academic skills. Table 52.1 provides selected references that demonstrate the efficacy of each of the ABA techniques discussed here: Discrete Trial Training; Differential Reinforcement; Pivotal Response Training; Antecedent Based Interventions; and Task Analysis Interventions.

Evidenced-Based ABA Techniques Utilized to Teach Academics

Discrete Trial Training

Discrete Trial Training or DTT has been in use and studied for over 40 years and has been found to be

effective for remediating academic skills as well as other functional skills, particularly with young children (Lerman et al., 2016). The seminal work of Lovaas (1981, 1987) is the framework for most modern uses of DTT. In DTT, skills are broken down into smaller subskills and are taught using repeated practice. Each small unit of instruction is referred to as a trial. Tarbox and Najdowski (2008) describe DTT as, "instructional units composed of an antecedent, a response, and a consequence." They note that there are five parts to a discrete trial including the antecedent stimulus, a prompt, a response, a consequence, and an intertrial interval. DTT has been shown to be effective at teaching language arts skills (Kitchen & Kraus, 2018) and arithmetic skills (DiGenarro Reed et al., 2011), and is commonly used with individuals on the Autism Spectrum (Leaf et al., 2016).

Differential Reinforcement

Differential reinforcement, also known as Differential Reinforcement of Other Behaviors (DRO), Differential Reinforcement of Alternative Behaviors (DRA), Differential Reinforcement of Incompatible Behavior (DRI), and Differential Reinforcement of Low Rates (DRL), involves reinforcing one behavior while withholding reinforcement for other behaviors. DR is an operant procedure that is typically used to increase the occurrence of desired behaviors and decrease undesirable behaviors (Vladescu & Kodak, 2010). Educators may use DR to shape responses and to reduce dependency on prompts (Fiske, et al. 2014). Reviews of the literature have investigated the impact of differential reinforcement on skill acquisition to determine the most efficient arrangements (Vladescu & Kodak, 2010; Efaw, 2021). These reviews support the use of differential reinforcement for skill acquisition for students with disabilities.

So how can DR be used to teach academic skills? Just as with social behavior, DR is used to reinforce the academic behavior desired and withhold reinforcement for undesired academic behavior. In its simplest form, Differential Reinforcement is particularly useful when teaching fluency and automaticity in sight words or math facts such as basic multiplication facts. Baseline data would be collected on the target skill, reinforcers chosen through knowledge of the student or a preference assessment, and a plan made to determine how the prompts would be provided and faded. Students would be reinforced for correct responses and no reinforcement would be provided for incorrect responses. It might look something like the following scenario:

> Mr. Garcia is working with Tony, a third grader, to build fluency and automaticity on basic multiplication facts. Mr. Garcia has conducted a preference assessment and found that a high preference reinforcement for Tony is to earn tokens that may be traded/cashed-in for prizes at the end of each week. Mr. Garcia uses a software program which flashes multiplication facts on a computer monitor with a touch screen, Tony touches the correct answer from a choice of three, and the next problem flashes on the screen. Once the predetermined number of prompts are completed, Mr. Garcia is provided a report of the number or percent correct and the amount of time it took to complete the predetermined number of problems so that a rate of correct responses may be calculated for progress monitoring. Tony then receives one token for every predetermined number of answers he chose correctly.

The predetermined number would be based on the baseline data and predictions of rate of improvement and is increased as progress is made. So, it is prompt, correct response, consequence. There are no consequences for incorrect responses, only for correct responses. As Tony progresses to meet predetermined goals, the reinforcement will be faded out and the natural reinforcement of mastering the multiplication facts and verbal praise would replace the tokens.

Pivotal Response Training

Pivotal Response Training (PRT) is also known as pivotal response teaching, pivotal response treatment, pivotal response therapy, and pivotal response intervention (Bozkus-Genc & Yucesoy-Ozkn, 2021). PRT applies principles of ABA to teach learners through building on their initiative and interests. PRT integrates principles of child development with those of ABA and considers the learner's developmental levels and progression and cycles through the three-part sequence so common to ABA strategies: antecedent, response/behavior, and consequence (Suhrheinrich et al., 2018). It was developed to enhance pivotal learning variables such as motivation, responding to cues, self-management, and self-initiations. It is thought that these skills are "pivotal" because they are skills that may be used to acquire many other skills. Basic steps of teaching motivation through PRT would include establishing learner attention, using shared control, using learner choice, varying tasks, interspersing acquisition tasks and maintenance tasks, reinforcing response attempts, and using natural and direct reinforcers (Vismara & Bogin, 2009). As noted previously, strategies such as PRT may be used to address behaviors that are pre-requisite academic behaviors such as pointing, staying on task, and responding to prompts. Although widely studied in increasing or improving the "pivotal" behaviors mentioned, PRT has also shown success in academic skills (Koegel et al., 2010). Koegel et al. (2010) conducted a meta-analysis on 34 research studies from 12 different journals and concluded that PRT is effective in teaching a variety of behaviors to children with Autism. The scenario below provides an example of PRT in use based on Suhrheinrich et al.'s (2018) step-by-step guide to PRT.

Ms. Jones is working with Shauna, a 2nd grader who is on the Autism Spectrum, to learn to recognize and read new sight words. Ms. Jones has decided to use Pivotal Response Training or PRT, to increase Shauna's response rate to being prompted with a list of sight words one at a time. Ms. Jones has prepared and planned by identifying the words to be used based on Shauna's developmental level and selected words that can be incorporated into a sight word game. She has chosen preferred games and reinforcers through preference assessments prior to instruction. Ms. Jones knows, for PRT to be successful, Shauna must be motivated to perform the activity (in this case, reading the sight words) and is using materials Shauna prefers, offering choices, and providing reinforcement during the intervention. Ms. Jones has arranged the environment, determined the prompts, and has received training to use PRT. She creates an opportunity for Shauna to respond through first gaining Shauna's attention and providing the first prompt (a sight word). Ms. Jones then pauses and allows Shauna time to process the prompt. If Shauna responds within a predetermined time (5 to 10 seconds, for example), she is rewarded for correct responses through reinforcement. Ms. Jones continues with this process through the predetermined set of sight words, collects data on Shauna's performance, and plans to conduct generalization probes as correct responses increase. Ms. Jones analyzes data collected and makes data-based decisions on whether her chosen intervention is effective or needs to be adjusted.

Antecedent-Based Interventions

Antecedent-based interventions (ABI) are an ABA strategy that modifies an environment to decrease interfering behaviors and can allow the student to attend to academic tasks (Carter, 2001; Rispoli et al., 2011). Examples of interfering behaviors might be repetitive or disruptive and often prevent a child from attending to academic instruction and tasks. The goals of ABI are to modify the antecedent thought to control the interfering behavior so the child may increase their on-task behaviors (Sam & AFIRM Team, 2016). When implementing ABI, teachers should plan through conducting a functional behavior analysis to determine what antecedents are controlling the behaviors that may be interfering with a student's attention to the academic task. An ABI strategy should be chosen that addresses the function of the interfering behavior and then monitor and determine next steps. When interfering behaviors are under control of the reinforcer, students may focus on acquiring academic skills. ABI strategies may include using learner preferences, changing schedules or routines, implementing pre-activity interventions as needed, using choice-making, altering how instruction is delivered, or enriching the environment with sensory stimuli (Sam & AFIRM Team, 2016). The scenario below provides an example of how one teacher might use ABI to address behaviors that are interfering with a child's on-task academic time.

Mr. Kaufmann is teaching a grade 6 social studies unit that most of the students are engaged in and excited about the projects and activities. One student, Kyle, has been disruptive throughout the unit by making unkind, sarcastic remarks about the activities, the teacher, and other students in the classroom. He has been asked to leave the class several times in the past two weeks due to his disruptive behavior and refusal to work on assigned tasks with his group. Mr. Kaufmann has decided to use ABI strategies, in which he has been trained, to address Kyle's behavior and increase his time on task. First, Mr. Kaufmann conducts a Functional Behavior Assessment to determine the function of Kyle's off task behavior. He collects data on the interfering behavior using A-B-C charts to help identify what is happening directly before the target behavior is occurring (antecedent), to describe the behavior in operational terms (behavior), and to determine what happens directly after the behavior occurs (consequence). Once data are collected Mr. Kaufmann analyzes the data to try and understand why Kyle might be engaging in the disruptive behavior which is causing him to lose instructional and academic time. Based on this information and data collected, Mr. Kaufmann makes a hypothesis that the function of Kyle's behavior is to escape the group work which requires him to read materials that may be written at Kyle's frustration level meaning he has difficulty reading and comprehending the material. Mr. Kaufmann decides to alter how the assignment instructions are given to Kyle so that Kyle will not have to read the instructions that are written at his frustration level. Mr. Kaufmann assigns a student teacher to discretely work with Kyle's group and read the instructions with them each day and make sure that the instructions are understood by all. In future lesson planning, Mr. Kaufmann will include pre-activity interventions for Kyle so he will not reach his frustration level and be able to participate. No reinforcement will be provided for the interfering disruptive behavior if it does occur and positive reinforcement in the form of verbal praise will be provided to reinforce desired work behaviors such as engagement and on-task and task completion. Reinforcement will be provided each time Kyle completes an assignment while not engaging in the interfering disruptive behavior. Progress will be monitored, and reinforcement schedules faded as interfering behavior decreases.

Task Analytic Instruction

Task Analytic Instruction, as defined by Spooner et al. (2011), is the "step-by-step" teaching for a chain of responses to complete an activity (e.g., to solve an algebraic equation or make a purchase). Spooner et al. (2011) found that prompting procedures used with task analysis were always combined with methods for reinforcement, usually praise. Spooner et al.'s (2011) examination of 18 studies supports treatment packages that target a chain or discrete responses, use prompting and fading, and provide feedback and correction. Three strategies used with task analysis are forward chaining, backward chaining, and total task presentation. The National Professional Development Center on ASD (2015) provides step-by-step instructions for implementing a task analysis: Plan, Implement, and using task analysis. When planning, one must identify the components of the target skill or behavior and determine methods for teaching using task analysis. When using forward chaining, an adult begins by teaching the steps of the task analysis in order and when each step is mastered, the next step in the chain is introduced. In backward chaining, the steps are taught in reverse order beginning with the final step in the chain. As always, data should be collected on the target behaviors and next steps must be determined based on learner progress (National Professional Development Center on ASD, 2015). Task Analytic Instruction is especially useful for teaching arithmetic that requires multiple steps for solving. The steps of solving the math problem can be task analyzed using forward chaining and students reinforced for each step mastered.

Fidelity of Treatment and Commercially Available ABA Curricula

Note that in each scenario provided throughout this chapter, each fictional teacher had been trained in the ABA strategy they were utilizing to improve academic achievement. Fidelity of treatment refers to ABA strategies being applied exactly as intended or the positive results likely will not be produced. Many teachers have criticized ABA methods over the years thinking that "they do not work." Perhaps it is because they didn't apply the treatments with fidelity, and they didn't have the proper training to use the chosen strategy. Practitioners should have had supervised practice and training before they attempt these evidence-based methods on children, particularly those who may be vulnerable due to their disabilities. All ABA treatments must be used with integrity, fidelity, ethically, and with the well-being of children in mind always.

There are many commercially available curricula incorporating ABA methods and shown to be evidenced-based and effective. There are also many which are not effective and make many claims to be research-based or scientifically based. It is a buyer beware industry and consumers of these products must know what they are looking for and must implement those quality designed products with fidelity. There are many advertisements, websites, and organizations which claim to offer evidence-based materials for academic instruction. Two places to begin a search for reputable, evidence-based, and vetted curricula are the Institute of Education Science, What Works Clearinghouse (n.d.), and IRIS Center Modules (n.d.).

Summary

In education, we like to say what is old is new again. By this we mean that we often take concepts and methods that are effective and update them with new names and phrases but keeping their original intent and implementation. This is also true with using applied behavior analysis in teaching academic skills. We are still using the same basic principles that Skinner used over 50 years ago in his teaching machines: frequent feedback, positive reinforcement for correct responses, self-paced practice, and prompting and fading (Skinner, 1958). We put it in a new package, update the look, update the marketing, if you will, to appeal to a new generation of educators. However, what worked then, still works now. It's what one teacher colleague framed as, "good teaching is good teaching – no matter to whom or by whom – the best practices still work just as they did long ago." The great thing is that we know even more about what works now than we did back when Skinner was pioneering the field of ABA and instruction. As Fielding et al. (2013) said, "The research is here. The desire is here."

This chapter examined evidence-based strategies which utilize the principles of applied behavior analysis to improve academic achievement and learning. Through a historical review, examining ABA principles as part of instructional systems, and reviewing prominent methods used to teach critical learning skills, the basic principles of ABA have been shown to be effective teaching strategies and have been incorporated into many commercially available curriculums and used in many classrooms to manage behavior as well as teach academic skills.

53 Technology to Increase Vocalizations and Speech

James W. Moore and Alexandra G. Brunner

Approximately 8–9% of young children have difficulty producing vocal speech with roughly 5% experiencing significant trouble with speech (National Institute on Deafness and Other Communication Disorders, 2016). Although many different conditions may cause delays or lack of vocal speech, the cause of most of these problems is unknown (Abadi et al., 2016). Some of these include apraxia, developmental disabilities, brain injury, and intellectual disabilities (Johns Hopkins All Children's Hospital, 2021). Autism spectrum disorder (ASD) is one of the most common developmental disabilities and is highlighted by deficits in language and communication (Center for Disease Control and Prevention, 2020). Many individuals with ASD are slow to develop or fail to develop spoken language skills (Sigafoos, 2005). In a 20-year review of the literature, McNaughton and Light (2015) found that 20% of the interventions involved non-vocal clients with cerebral palsy, 20% with developmental disabilities, 17% acquired disabilities, such as traumatic brain injury, 9% had autism, 7% demonstrated intellectual disability, and 25% showed more than one disability.

Effective communication represents a critical and essential life skill. In the absence of vocal speech, children often develop alternative forms of communication, especially related to obtaining wants and needs. Grunting, eye gazing, reaching, or manipulating the hands or body of another may serve as alternative forms of communication, but can be difficult for others to interpret. Failure to emit even a limited vocal repertoire presents serious challenges and barriers to the development of vocal verbal behavior later in life (Whitehurst et al., 1991). For example, some individuals may develop significant problem behaviors. Problem behaviors such as self-injury, tantrums, and/or aggression become functionally equivalent to the more acceptable ways to communicate their wants and needs (Carr & Durand, 1985; Sigafoos, 2005). Imagine an active child who has not consumed liquids for several hours. A child without impairments in communication and vocal speech may approach their caregiver and say, "may I have some juice?" If a child with limited skills in this area encounters the same situation, they may learn over time that other behaviors, such as those listed above, serve the same function as saying, "may I have some juice?"

Children of typical development often demonstrate a wide variety of vocal responses without the need for explicit teaching or planned intervention. Some have argued that this language acquisition occurs mainly through a combination

of automatic reinforcement that may not be sufficient to support varied and frequent vocal output in children with ASD (Carbone, 2016) or derived relational responding that is often impaired for those with limited vocal repertoires (Murphy & Barnes-Holmes, 2017). Therefore, the performance of such vocal responses in children with ASD may require the use of contrived and direct contingencies of reinforcement intended to increase the probability of vocal sound production (Tincani et al., 2006).

Applied Behavior Analysis

In contrast to other approaches, behavior analysts view communication as verbal behavior. In the landmark book *Verbal Behavior*, Skinner (1957) posited that language is a learned behavior under the same types of control as non-verbal behavior. Variables such as reinforcement, extinction, and motivating operations shape the way we communicate. Skinner also shifted the focus away from the formal properties of language, such as parts of speech, phonetics, and other topographical views of language, to the functional properties of language. In other words, the sources of reinforcement influence the use of various types of language. Skinner proposed that several verbal operants, as well as different types of speaker and listener behavior, make up an individual's verbal repertoire. Although the unique names Skinner (1957) provided for the verbal operants may seem confusing at first, establishing a child's mand, tact, intraverbal, or echoic repertoire can provide valuable information on how that child communicates and where they might have a deficit (Sundberg, 2007).

Basic Verbal Operants Verbal operants are basic units of language as described by Skinner (1957) and are classified by the antecedents and consequences that control them. The mand is the first type of verbal operant acquired by children and it is essentially a request (Sundberg, 2007). In technical terms, a mand is a verbal operant under the direct control of motivating operations (MO) and specific reinforcement. Deprivation, satiation, and aversive stimulation are MOs directly tied to the evoking of a mand. For example, a child who has not eaten in several hours may put forth more effort to say "eat" when temporarily deprived of food. In such an arrangement, the MO alters the *value* of reinforcement. In this example, the MO is unconditioned (UMO) in that no learning is required to produce an effect. Conditioned motivating operations (CMOs), on the other hand, acquire this value-altering influence through a specific learning history (Cooper et al., 2019). The three kinds of CMOs are surrogate (CMO-S), reflexive (CMO-R), and transitive (CMO-T). CMO-S, through many pairings of neutral stimuli with unconditioned stimuli, creates a surrogacy in which the neutral stimuli now have the same effects as the UMO. The effects of CMO-Ss are debatable (Cooper et al., 2019); however, CMO-Rs have been shown to greatly affect our everyday interactions. The CMO-R is defined as any stimulus that precedes an aversive situation and achieves avoidance of that situation, including how individuals react to mands from others. Cooper et al. (2019) give the example of a stranger asking for directions. By responding to the stranger's request, the individual responding avoids the social awkwardness that would result from a non-response. Similarly, CMO-Ts also affect our everyday interactions. A variable function as a CMO-T when it is related to the presence of another variable and some form of improvement. UMOs also function as CMO-Ts for conditioned stimuli that are paired with unconditioned stimuli. CMO-Ts are important for mand training; an individual wants something, mands for it, and is reinforced by delivery of the item or activity. Unconditioned reinforcers can be used to teach mands, but CMO-Ts allow for unlimited ways to achieve the items. If socks and shoes are required to go outside, the individual would need to mand for "shoes" and "socks" to reap the larger reward of playing outside. The interruption of reinforcement often associated with a CMO-T offers not only an effective instructional tool in basic mand acquisition but also the development of more elaborate and sophisticated mands (Carbone et al., 2010).

Skinner (1957) chose the word mand as a condensed form of words like "command" and "demand." A child's mand repertoire may include words ("cookie, please") or non-verbal communication such as pointing to the item, crying, or hitting as long as a clear relationship exists between the source of reinforcement (e.g., cookies), the behavior (e.g., saying "cookie" or hitting) and the antecedent condition influencing the contingency (e.g., 5 hours of food deprivation, an establishing operation). Many therapists first focus on mand training because problem behaviors can be reduced or eliminated when one is taught other ways to communicate their needs. Additionally, the child reaps the rewards of using the new skill when the item requested is delivered and gains autonomy as the delivery of reinforcement comes under the control of their manding (Sundberg, 2007). The mand is the only verbal operant that directly benefits the speaker.

The tact (Skinner's variation on "contact") shows how a child interacts with their surroundings. Tacting consists of naming things from the environment. Specifically, the presence of a nonverbal stimulus (like a flower) controls the verbal response ("flower!") through a consistent history of generalized conditioned reinforcement, such as praise for tacting (Sundberg, 2007).

When a prior verbal stimulus controls a verbal response that bears formal similarity and point-to-point correspondence (as in repeating the word your communication partner just said), the response is called an echoic. A strong echoic repertoire facilitates mand and tact training. For example, when providing mand training, it would be advantageous for the client to be able to repeat the therapist's verbal prompts in order to gain immediate access to a preferred item for correct responding.

Another type of verbal operant is an intraverbal in which a speaker differentially responds to the verbal behavior of others. Like the echoic, it is evoked by prior verbal stimuli and followed by generalized conditioned reinforcement but lacks point-to-point correspondence. Intraverbals can include answering questions and social responding. These skills may not develop even when mand, tact, and echoic skills are robust. Children with ASD who experience language delays often have weak or non-existent intraverbal skills, perhaps because intraverbals are often not directly assessed and taught the way the other verbal operants are (Sundberg, 2007).

Transcription, also called taking dictation, is another verbal operant even though the verbal behavior is not audible. Transcription consists of writing and spelling words that are spoken by a communication partner. It is a response to a verbal stimulus with point-to-point correspondence but without formal similarity. Similar to the transcription operant, textual operants have point-to-point correspondence with the stimulus and response and no formal similarity. Textual behavior includes the ability to identify a word, but not necessarily comprehend the reading (Sundberg, 2007). For example, a child may be able to read a passage with acceptable fluency (textual behavior) but be unable to answer questions about the passage (intraverbal behavior).

Augmentative Alternative Communication

Although vocal responses remain the goal of intervention, the more immediate need of non-vocal children may include the development of non-vocal forms of communication. In the absence of vocal speech, these children may not have alternative responses sufficient to evoke the behavior of listeners in order to access reinforcement, potentially supporting the acquisition of problem behaviors as a means to gain access. As such, methods have emerged to study the effects of teaching alternative methods of communication on the development of vocalizations in children with autism (Schlosser & Wendt, 2008; Tincani, 2004; Tincani et al., 2006). In order to help individuals with limited vocal speech acquire functional communication skills like the ones discussed above, therapists may employ alternative and augmentative communication (AAC) modalities to progress beyond prelinguistic strategies (Mirenda, 2003). The initial goal of AAC utilization involves mand training.

As previously stated, when an individual is able to ask for what they want, he or she may develop increased independence while decreasing the need for problem behavior.

AACs are divided into two categories: unaided and aided. Unaided AACs do not require technology apart from the human body, exemplified by sign language. Aided AACs require additional technology (Mirenda, 2003). Examples of aided technology include picture exchange communication systems (PECS) and speech-generating devices (SGD), also known as vocal output communication aides (VOCA). Technology is ever-changing. It is imperative for behavior analysts to remain updated on current AAC technologies (Lund et al., 2017).

The use of sign language as a functional communication aide has shown mixed results (Mirenda, 2003). Its primary benefit boasts technology that is free and accessible wherever the user's body goes. However, many drawbacks prevent this AAC from being utilized as often as its aided counterparts. Sign language requires a great deal of training and has produced unsatisfactory results for spontaneous use and generalization (Bondy & Frost, 1994; Mirenda, 2003). Additionally, sign language requires fine motor skills and pre-requisites from the user, such as eye contact and imitation (Sigafoos et al., 2004). However, arguably the biggest drawback of this form of alternative communication could be that it requires any potential communication partner to also know sign language (Bondy & Frost, 1994; Mirenda, 2003).

Bock et al. (2005) compared PECS to SGD to determine which of the two communication strategies produced repetition skills at an accelerated rate and if the skills generalized to a classroom setting. Students moved through PECS phases more quickly and completed more phases than SGD. Three of the four participants showed a preference for PECS and one showed no preference at all. Students using SGD needed more hand-to-hand guidance than when using PECS.

Tincani (2004) compared sign language to picture exchange for mand training using the presentation of preferred items with prompting and prompt fading procedures with two elementary school students with ASD and severely limited functional speech. Using an alternating treatments design, both students received sign language and PECS training counterbalanced across days, times, instructor, and order to reduce confounding variables. The final phase for each student was a best-treatment phase, utilizing which ever method worked best for that student. Tincani found that sign language produced greater independent mands for one of the two students participating in the study (from 2.1% in baseline to 34.1% during training). The other student lacked hand-motor imitation skills and favored PECS. However, most interestingly, the sign language training produced more vocal output compared to baseline for both students (46.3% compared to 22.3% for PECS for student one and 93.4% compared to 77.9% for PECS).

PECS was first developed by Bondy and Frost (2002) in response to the drawbacks of sign language. This system initially involves exchanging a picture representation for a preferred item. The user performs a basic request and receives a positive consequence, increasing the frequency of its use. More complex responding happens in phases where the user is required to discriminate between pictures, travel to the PECS book and communication partner, and eventually make complex sentences. PECS does not require any pre-requisites for use and can be immediately utilized to request preferred items and activities. Most conversation partners would be able to identify the meaning of the card. However, the picture exchange system is bulky, containing either a gigantic PECS book or numerous cards which would have to be transported wherever the user wishes to communicate. Responses would be limited to the pictures available.

Tincani and Devis (2011) conducted a quantitative synthesis and component analysis of PECS in single-participant studies. They confirmed that data supports PECS as an effective intervention for mand training for individuals with autism as well as other disabilities. However, the 16 studies included in their meta-analysis failed to demonstrate more advanced communication, such as tacts or intraverbals. Most participants from these studies met criterion for Phases I-III, whereas the more advanced communication training is exclusive to Phases IV and V. This analysis demonstrates a great variability among how successfully and readily participants employ picture exchange; for example, one participant mastered all six phases in a total of 246 trials (Charlop-Christy et al., 2002), while another participant met criterion for the first two phases with 358 trials (Tincani et al., 2006). Despite this variability, typical for studies conducted using children with ASD, Tincani and Devis (2011) found that 10 out of the 16 participants in the analysis increased vocal output with a range from mild to substantial, supporting findings by Schlosser and Wendt (2008).

Speech-Generating Devices

While all AACs are used for functional communication training, research supports the hypothesis that AACs may have the potential to increase vocal speech (e.g., Schlosser & Wendt, 2008; Tincani, 2004; Tincani & Devis, 2011; Tincani et al., 2006). AACs have shown vast improvements in children with a developmental disability diagnosis and their peers (Biggs & Snodgrass, 2020; Thiemann-Bourque et al., 2016; Thiemann-Bourque et al., 2019; Alzrayer & Banda, 2017; King et al., 2014; Lorah, 2016a, b; Lorah et al., 2013, 2018; van der Meer et al., 2011; Waddington, 2018; Xin & Leonard, 2015). This is in direct contradiction to fears cited by clinicians and parents that a child may become dependent on an alternative modality to communicate, inhibiting the acquisition of verbal speech (Schlosser & Wendt, 2008). The promising data using AAC to increase vocal output leads to new paths for research: Which modality most successfully generates vocal speech? Why do some individuals increase vocal output when trained in AAC and others do not? Can the likelihood of generating speech be increased when training clients with AAC?

Speech-generating devices (SGD), also known as voice output communication aides (VOCA), are electronic devices that convert non-vocal communication behavior (pressing a button) into synthesized verbal messages. The voice output can be understood by a wide range of communication partners, including strangers. Large and heavy stand-alone systems made original SGDs difficult to generalize to different locations; however, applications for tablets and smartphones transform widely used technology into SGD that can hold unlimited amounts of words in a light weight, easily portable device. Applications within SGDs can be instantly customized to include novel responses and pictures and the number of icons (stimuli) seen on the screen. According to Common Sense Media and Rideout (2013), 75% of families in 2013 had access to the internet in their home with 10% of children owning their own tablet. In 2013, there were over 265 SGD apps available in the Apple Store. Tablets and smartphones are highly desired items that may lessen the stigma of carrying and using an SGD. Gevarter et al. (2013) suggest that VOCA (and other aided AAC) produces quicker acquisitions perhaps because of the addition of the graphic symbol which may act as a prompt and that its user needs only learn one response class (pointing to a picture) for a variety of requests. Many SGD formats include a grid format where the learner scrolls through several icons in order to select the appropriate communication target.

There are various types of SGDs from which to choose. Over the years, advances in technology have widened the available options. For example, alphabet-driven devices involve the client using an on-screen alphabet or text system that the client uses to create words, sentences, and other forms of communication. Visual scene displays uses imagery, often personal photographs in order to capture language within the various social contexts in which clients often experience, which is claimed to support generalization and ongoing visual contextual support, though no research currently exists to validate this assertion. Picture tablets involve an application or program downloaded on a device, such as a tablet or smartphone in which pictures are organized in a grid display of individual pictures that correlate to specific items, emotions, contexts, and other communication targets.

More recently, advances in SGDs have made possible the inclusion of photographic visual scene displays (VSD) that synthesize objects, familiar people, community helpers, and common actions, to name a few, into an integrated image of these things (see Beukelman & Mirenda, 2013, for more information). Some have suggested that SGDs, particularly those that incorporate VSD, may have benefits for young learners who may benefit from visual support. To date, little research has emerged on prerequisite skills necessary to successfully use any type of SGD, with some studies finding mixed results with typically developing learners across traditional SGD formats and VSD. Robillard and colleagues found that certain cognitive factors, such as sustained attention, categorization, and fluid reasoning, were necessary prerequisite skills in order to benefit from the use of SGD. Hand-eye coordination, fine motor coordination, prior history with technology, overall cognitive deficits, and severity of disability may also predict the success of SGD for certain learners. Unfortunately, little research has been conducted in training individuals to use this type of technology. For example, Gevarter and Horan (2019) found that the traditional grid display served as a distraction to some learners using SGD. A large body of the training literature on correct SGD use has focused on a discrete-trial teaching (DTT) format (e.g., Lorah et al., 2015), with more recent research focusing on naturalistic teaching strategies in which the SGD is embedded into naturally occurring contexts with the learning receiving prompting, error correction, and reinforcement to support skill acquisition.

Although studies have demonstrated that all three major forms of AAC (manual signs, picture exchange, and SGDs) may be used to train individuals with autism and developmental delays to communicate a functional request, the question emerges of which form is superior. The results of the Achamadi study highlighted advantages of determining AAC preference. Several studies have found that mand acquisition in children with ASD was roughly equal, though the children showed a preference for PECS (Bock et al., 2005; Son et al., 2006). However, these studies compared PECS to the cumbersome stand-alone speech-generating devices (SGD). With the popularity and availability of smartphones and tablets that can be easily converted to an SGD (through the purchase of an AAC application directly from the smart device, the differential response effort may have tipped in favor of SGD.

Lorah et al. (2013) compared picture exchange (PE) and the iPad as an SGD (or VOCA) in mand training for children with ASD. Data were collected from five boys diagnosed with autism, aged between 3 and 5. All participants scored limited or absent for manding and echoic skills on the *VB-MAPP Barriers Assessment* (Sundberg, 2007). It was reported that the boys had no history with PE or SGD. The study employed an alternating treatment design in which the dependent measure was observed. The dependent variable included independent and prompted mands. For the PE, this would involve placing a picture representation into the hand of the therapist. For SGD, the icon representing the item must be pressed with enough force to elicit vocal output. The application Proloquo2Go was utilized to transform the iPad into an SGD. Pictures taken from Proloquo2Go (*see* Fig. 53.1) were then used to create the pictures for PE. Following baseline, the two training conditions were presented in random order with an equal number of trials each. During training, a preferred item was placed in view but just out of reach with the appropriate AAC arranged directly in front of the participant. A 5-second time delay followed by a physical prompt ensured skill acquisition. Upon criterion of both modalities, the therapist conducted a preference assessment.

The results of the study show SGD produced an 85% overall higher rate of prompted or unprompted manding during training and maintenance, compared to a rate of 64% produced using PE. Additionally, four out of five of the participants showed a preference for the iPad as an SGD. While one could surmise that the ease and customizability make the iPad (or other smart device) the obvious choice for an SGD, this study does have limitations that should be further

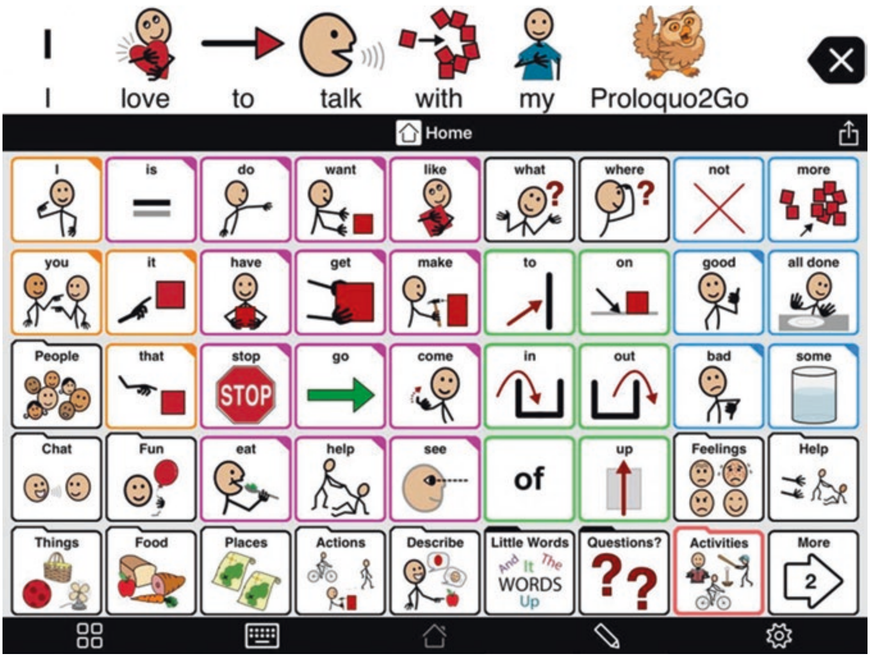

Fig. 53.1 Proloque2go sample screen

explored. First, no discrimination training was conducted for either AAC, an important factor in communicating functionally. Second, the absence of data for generalization across trainers or environments limits any conclusions drawn from the study. Finally, future research should investigate the effects of using AAC for mand training on increasing vocal speech.

A study by Tincani et al. (2006) explored the effects of PECS on manding and speech development for non-vocal children with autism. Tincani et al. (2006) particularly wondered about the effects on manding in older children using PECS and wanted to confirm reports of spontaneous speech development during Phase IV of PECS. Speech development would be a highly desirable outcome of functional communication interventions.

Tincani et al. (2006) broke the study down into two smaller studies. Participants in the first study comprised two boys with autism, ages 10 and 12, neither of whom used speech to communicate nor had prior training with AAC. The dependent variables included independent and prompted manding (either physical or gestural) and speech (words or approximations). Baseline data confirmed that neither participant used PECS to request a preferred item nor manded vocally. During PECS training within a delayed multiple baseline design, the therapists followed the protocol established by Bondy and Frost (2002). The participants moved from one level to the next after mastering 80% criterion during at least one session of that phase (see introduction for further explanation of PECS phases). Speech was neither reinforced nor prompted for the first three phases. However, in Phase IV, participants were trained to create sentences using the PECS cards. Additionally, a 3- to 5-second delay for the delivery of the reinforcer was employed for word vocalization or approximates. When the participant would successfully place the sentence in the hand of his communication partner, the partner would delay the delivery of the reinforcer. If the participant vocalized during the delay, reinforcement was immediately delivered. If not, the reinforcer would be delivered at the conclusion of the delay. A generalization condition included the child's teacher as therapist. During Study 1, both participants increased manding significantly compared to baseline. One participant progressed through Phase IV and produced vocal output. Because of the presence of vocal output during the addition of the prompt delay procedure, a second study was conducted to explore the relationship between the additional procedure and speech development.

A 9-year-old boy with autism participated in Study 2. He had a history with PECS but did not use it functionally. The therapists retrained him in Phases I–III, using identical procedures to Study 1, until he met criterion for each. Study 2 began at Phase IV using an ABAB design. The "A" condition included Phase IV training with no prompt delay, while the "B" condition included training plus prompt delay. Although the number of independent mands was not affected by the condition changes, the participant's approximations increased greatly from A to B. The first change increased from 3% to 83% and the second change saw increases from 2% to 80%. No full words were observed during Study 2.

Tincani et al. (2006) expanded the literature on AAC in a very important way. It affirms that AAC can effectively be used to teach functional communication (like manding) to non-vocal children with ASD. However, it also confirms the possibility of speech generation in some previously non-vocal children with ASD using AAC techniques. Further, it introduces the prompt delay as a possible means of increasing speech production and imitative skills when used in conjunction with AAC training.

Carbone et al. (2010) performed a study to evaluate the effectiveness of the addition of prompt delay and vocal prompting to manual sign mand training when used to increase vocalizations in children with autism and developmental delays. Previous research had suggested that sign language may increase vocal responding in children with strong imitative repertoires. Carbone and colleagues hypothesized that the addition of prompt delays and vocal prompting may increase vocal responding in children with poor imitative skills, based on previous research by Tincani et al. (2006) that combined a prompt delay procedure with PECS as the alternative communication system. Two boys with autism (ages 4 and 6) and one boy with Down syndrome (age 4) participated in the study. All three had no functional verbal speech, though two used signs to request between 10 and 15 strongly preferred items.

Carbone et al. (2010) used a multiple baseline design across participants to measure the occurrence of unprompted and prompted vocal responses including sounds, approximations of words, or full words. Unprompted vocal responses were counted if they occurred while signing, after a non-vocal prompt to sign, or with 5 seconds of the manual sign. Prompted responses were counted if they occurred after a vocal prompt. Sessions were conducted twice a day for 50 trials. Six items selected from a preference assessment conducted prior to intervention were presented one at a time to the participant at eye level. If the participant did not look at or reach for the item, the next item was presented. If the participate did indicate interest but did not mand for the item within 5 seconds, the therapist would begin a prompt sequence until the participant successfully requested the item. The therapist first gestured, then provided a physical prompt if 2 seconds passed without response. The participant was then provided 30 seconds of access to the item. During the prompt delay and vocal prompt condition, the therapist performed a 5-second prompt delay of the reinforcer when the participant correctly signed for the item. If the child produced vocal output without the sign, the therapist used the prompt sequence and then performed the 5-second delay. During the delay in either scenario, if the child produced a vocal response, the reinforcer was delivered immediately. If the child failed to produce vocal output, the instructor provided vocal modeling of the item's name. If vocal output was then produced within 2 seconds, the item was delivered. If not, the therapist repeated the sequence two more times.

All participants in Carbone et al.'s study showed increases in unprompted vocal responding during intervention as compared to baseline (as much as three times the amount). The study supports other findings that AAC may not hinder vocal output, but facilitate it. After increasing vocal output, the participant could access a form of communication that brought immediate results from his communication partner while strengthening the more desired skill. Increased vocal output in previously non-vocal participants also provides the therapist with a foundation in which to shape sound into speech. While Carbone and colleagues acknowledge that similar results may be produced without the addition of alternative communication, the use of sign language allowed for immediate reinforcement for the participant while the new skill was being mastered.

A study by Gevarter et al. (2016) examined the use of an SGD to increase independent target vocalizations for children with ASD who exhibit very limited vocal output. Gevarter and colleagues proposed to determine whether a combination of differential reinforcement and delayed reinforcement (a 5-second delay before reinforcement to provide opportunities for the preferred response and therefore access to the highly preferred item) while using an SGD could increase vocalizations, and if not, could vocalizations be increased through the addition of echoic prompts and prompt delays. This study also aimed to produce independent vocalizations that would remain even upon the removal of the device.

Gevarter et al. (2016) collected data on four boys, aged 4–7 years, diagnosed with ASD. Requirements for participants included limited vocalizations (assessed by the Vineland Adaptive Behavior Scale), limited echoic skills (assessed using the VB-MAPP), and experience using an SGD for manding. Sessions were conducted in-home using an iPad as an SGD with the AAC application GoTalkNow. Multiple stimulus without replacement (MSWO) preference assessments conducted prior to intervention determined items used as reinforcement and did not include any items with a request history. Items were labeled in the AAC application with efforts to include sounds reported emitted by the individual (e.g., “Sun,” instead of “Capri Sun” for the participant with an “S” sound in their vocalization history).

Gevarter and colleagues used a multiple baseline across participants design to evaluate their interventions. Although the number of baseline sessions was determined randomly, Greenberg et al. (2014) set the precedent for allowing up to 15 intervention sessions for everyone to reach criterion for the dependent variable, independent vocalizations (full words or approximations). During baseline, the SGD was placed within reach of the child and in view of a highly preferred item. A correct response occurring within 5 seconds, one that produced speech output on the SGD for that item, allowed access to 20 seconds of reinforcement. Vocal responses, incorrect responses, or no response was followed by physically prompting the correct response on the SGD and then providing access to the preferred item. After baseline, the intervention unfolded into three phases: Phase I, Reinforcer delay and differential reinforcement; Phase II, Addition of echoic prompt after delay; and Phase III, generalization probes.

Phase I continued the protocol of the baseline condition; however, full vocal responses for the preferred item received immediate reinforcement whether utilization of the SGD occurred or not. Responses using only the SGD were not immediately reinforced, but instead initiated a 5-second delay. If during that delay a vocal mand was performed, reinforcement would follow immediately. If no vocalization occurred, a simple request (like “clap your hands”) was given followed by access to a less preferred item. Following vocal word approximations, the SGD response would be physically prompted and then reinforcement would be delivered. So, only full vocal responses or approximations in conjunction with an SDG response provided access to the highly preferred item. Children who did not meet criterion during this phase moved on to Phase II.

Phase II procedures continued to follow the protocol for Phase I but added a vocal echoic prompt if vocalization did not occur in tandem with the SGD response. Vocal responses yielded access to the highly preferred item, but failure to respond initiated the “distractor trial” (“clap your hands”) followed by access to the less preferred item. Once the child demonstrated mastery of this phase, Phase I would be repeated. Generalization probes occurred throughout the conditions and provided opportunities to request for items vocally without the presence of the SGD.

Two of three participants reached criterion at Phase I, one required the supplemental procedures in Phase II to then reach criterion for Phase I, and the other participant never met criterion despite mastering the Phase II skills. During intervention, only one participant emitted target vocalizations (approximates) during the generalization probe. However, three participants showed an increase in post-intervention probes (all approximations). Additionally, initiations were observed in three out of the four participants on extinction. However, only one child ever emitted full words during any of the phases.

Gevarter et al. (2016) provided a valuable extension to previous research on SGDs and PECS. All participants successfully emitted target vocalizations, and, of particular interest, two of the participants did not require vocal modeling from the therapist to be successful. This could arguable be a great advantage over using the PECS system in interventions. Gevarter and colleagues also solidified the research suggesting that children with ASD will employ an alternative form of manding when their initial form is ignored; more specifically, vocal speech (a higher effort mand) increases when possibility of the SGD response (a lower effort mand) is placed on extinction. Results of this study also indicate that vocalizations may increase for children with ASD when adding a vocal instruction component (with reinforcement) to the SGD training, consistent with previous research. This could be an effective procedure for children who display poor imitation skills initially. Implications for this study include reducing fear that assisted communication procedures hinder talking, giving the child an immediate outlet to communicate while developing further skills. Further, vocal output can be maintained and improved upon even while fading the use of the device.

This study made great strides in expanding the literature; however, it was not without limitations. First, the study did not account for SGD proficiency in language acquisition. This study also failed to provide a comparison for language acquisition with only vocal instruction. Gevarter et al. (2016) suggest that further research addresses these issues while also exploring how targeting novel sounds might affect the procedures and how well the skill acquisition might generalize to requesting for other items. Finally, the variance in the study's data proved to be a limitation in that stable responding was not achieved. One explanation could be that the study utilized ineffective motivating operations in the form of weak potential reinforcers. While Gevarter et al. (2016) performed an initial MSWO to identify preferred items, research suggests that daily preference assessments produce more effective stimuli (Call et al., 2012; Deleon et al., 2001).

Bishop et al. (2019) replicated and extended the findings of Gevarter et al. (2016), showing that the Carbone prompt-delay method, demonstrated as effective with sign language, can also be implemented easily with a SGD. One major extension of the Bishop et al. study was the implementation of session-by-session preference assessments. Like Gevarter et al. (2016), Bishop and colleagues found that the inclusion of the prompt delay method with an SGD increased the vocal speech of three individuals with autism. The addition of the more frequent preference assessment also led to more novel vocalizations and less variance than seen in previous studies. This line of research clearly establishes mand training as an appropriate target for use with SGDs. More research is still needed on other verbal behavior targets, such as echoics, tacts, and intraverbals.

In summary, given the similarities in the efficacy of various forms of AAC, the ease, portability, likelihood of caregiver and educator buy-in, forms of SGDs on tablets and/or smartphones offer the most convenient and effective approach to providing avenues for AAC for children with deficits in vocal speech. As with all ABA interventions, however, practitioners should conduct careful and thorough assessments in the feasibility of any type of AAC that may be considered with a particular client. Though the field of speech and hearing sciences have developed a handful of standardized assessment for AAC, such as the Checklist of Communication Competencies (Bloomberg et al., 2009), the Functional Communication Profile (Kleiman, 2003), and the Test of Aided-Communication Symbol Performance (Bruno, 2010), none of these published assessments consider the verbal behavior perspective used in ABA to conceptualize spoken human language. In terms of ABA assessments, the field currently has a crisis of limited research on most of the assessment methods employed related to language and learning (Ackley et al., 2019). This is especially true for assessments that determine the appropriateness of an AAC for a particular client. For example, *Essentials for Living* contains a *Methods of Alternative Speaking* assessment that attempts to match client strengths with the benefits of various AAC methodologies. Unfortunately, no research to-date has evaluated the efficacy of such assessment or provided the type of psychometric data typically seen with published assessment tools.

Implications for Practice

The literature indicates that sign language, PECS, and SGD function effectively as functional communication aides. As demonstrated by Gevarter et al. (2013) and Bishop et al. (2019), effective methodologies employed in other approaches, such as sign language, can be effectively employed on SGDs. Research also suggests that SGDs produce increased verbal output for some previously non-vocal children with ASD, particularly when used with a prompt delay. Modalities selected by the clinician for AAC training may reflect the preference or ability of the client; for example, a child with limited imitative skills may not respond well to sign language and a child with poor fine motor skills may be unable to manipulate a Velcro board of picture exchange cards. SGD, in its most modern form as a smartphone app, most appropriately addresses the variability in skill sets among children with vocal speech difficulties, including the added benefit of instant customization through the device camera function; ability to store endless graphics and words while remaining lightweight and portable; and providing a means to communicate functionally without the stigma of other modalities. Additionally, caregivers may be more likely to embrace and use SGDs given the technology and ease of use over more labor-intensive approaches, such as having to learning sign language or keeping up with a PECS book.

The first decision a practitioner must make prior to designing intervention using an SGD, they should assess for needed prerequisite skills. As noted previously, there are no currently published assessment methods for AAC in general with empirical support. A task analysis of SGD use should uncover the skills clients need to effectively use SGDs. First, the practitioner should determine if the client has sufficient attending skill to the device screen. As screen arrays increase, the client will need precise fine motor skills, specifically refined proximal pointing. The client must have sufficient access skills, which may involve both gross and fine motor skills, such as obtaining the device, accessing it, swiping, pointing, and other skills. Additionally, the client must have the ability to make simple visual discriminations. Finally, due to the voice output delays indigenous to many of the SGDs, the client must tolerate delayed access to reinforcement.

If an ABA practitioner works with a client who uses an SGD, what types of language targets and other programs can incorporate the technology to support client progress? In keeping with assertions made by Skinner (1957) and the subsequent literature that has emerged with verbal behavior and the use of AAC, mand training seems like an obvious first step. Skinner believed that mands are the first topography of verbal behavior to emerge in humans, likely because the source of reinforcement for mands is directly related to an MO that is currently active in the learner's environment. As demonstrated by both Gevarter et al. (2016) and Bishop et al. (2019), the prompt-delay method demonstrated with sign-language by Carbone et al. (2010) shows great promise, not only in providing a source of functional communication for learners who do not currently possess vocal speech, but also led to the emergence of vocal mands. Mands likely represent the most appropriate and effective initial target of SGD intervention due to the relationship between an active MO with the source of reinforcement for manding directly related to the MO. For example, if the individual has not consumed liquid for several hours, they would likely demonstrate greater motivation to mand for a drink than to simply label a drink to receive some other generalized reinforcement, such as with tact targets.

The approach employed by Gevarter et al. (2016) and Bishop et al. (2019) involve methods that most practicing behavior analysts could easily integrate into ongoing treatment plans. Although the setting of training could occur in a more structured discreet-trial training (DTT) format, a more naturalistic approach where the therapist follows the client's motivation may prove more effective. Future research should compare training formats related to mand training with SGD. To begin mand training with technology, first the client must be taught to use the device to access specific reinforcement. Initially, place the device in close proximity to the client with sources of MO-related specific reinforcement visible but not necessarily available without communication. If the client correctly uses the device to request a specific reinforcer, that stimulus is immediately delivered for at least 20 seconds. If the client does not engage in a correct SGD demand, the therapist should physically guide the client to the correct SGD response. At first, physically guided responses should still produce the reinforcer, but over time, reinforcement should be only delivered for correct independent SGD mands. Given the findings of past research, intervention should involve a prompt-delay and an echoic prompt.

In this methodology, correct independent SGD responses produce a 5-second delay. During that delay, vocalizations immediately produce access to the reinforcer. The practitioner should decide on a client-by-client basis if full or partial vocalizations will access reinforcement. If a correct vocalization does not occur within the delay, the therapist then provides a full echoic model of the vocalization. For example, if the client used the SGD to mand for bubbles, the therapist would model "bubbles" following the 5-second delay. If the client still does not engage in vocal mands, the therapist would then provide a distractor trial, such as "touch your nose" and then provide contingent reinforcement with a lesser preferred stimulus. In other words, once manding is captured within the SGD response, extinction is implemented with SGD in the hopes of producing variability leading to vocal mands. The echoic prompt has shown in multiple studies to provide adequate support to the client in emitting vocal mands (Carbone et al., 2010; Gevarter et al., 2016; Bishop et al., 2019). Bishop et al. varied from Gevarter et al. in one key aspect. Bishop et al. conducted one-trial MSWO preference assessments prior to each session, whereas preference assessments used by Gevarter et al. were more temporally distant from the actual training trials. Although the more frequent assessment of stimulus preference led to less variability seen in previous research, data reported by Bishop et al. were still highly variable for some participants. Practitioners and researchers may wish to evaluate a more client-directed approach, such as seen in naturalistic environmental training, in which the environment is baited with multiple potential mand targets. The client then can shift mand targets from trial-to-trial. This approach may not only reduce response variability but may also led to faster acquisition of novel vocalizations.

In addition to manding, a tacting repertoire can be built in the absence of vocal speech with the aid of a SGD. Lorah and Parnell (2017) described an effective and efficient approach to teaching tacts with a SGD. This approach also employs delays to responding in hopes of evoking the target response, though no data to date have been reported that shows the emergence of vocal speech following tact training with a SGD. Lorah and Parnell targeted tacts during "circle time" within a classroom. The teacher would read a pop-up book with various animal tact targets. Upon reaching the target animal for a student, the teacher would pause for 5 seconds. If the student independently selected the SGD icon that corresponded to the target stimulus, the teacher would provide verbal praise. If the child failed to provide the correct SGD response, the teacher would deliver a full physical prompt to evoke the tact of the animal.

Future Directions

Technology has shown great promise in the development of communication, vocalizations, and speech for many individuals with speech difficulties. Despite emerging literature showing the efficacy of SGDs in speech and language treatment, more research is needed, not only comparing SGDs with other forms of AAC but also comparisons of various SGD formats. Research should not only include single subject design but randomized clinical trials as well to establish the legitimacy of the verbal behavior approach with technology beyond the field of ABA. Two major practice implications that require much more research involve training individuals to use SGDs as well as effective assessment methods in the appropriate use of AAC and SGD. More efficiency data is also needed for interventions beyond mand training, such as intraverbal training, matching-to-sample, receptive labeling, and discrimination training, to name a few. Although promising, the rise of technology remains relatively young and still requires empirical evaluation to not only further demonstrate the efficacy of SGDs but also refine and improve methodologies to produce better client outcomes over time.

54 Remembering and Cognition

Rebecca J. Sargisson

Who Can Benefit from Remembering Interventions?

I am sure we have all wished, at some time in our lives, that we were better at remembering. We have all had the experience of entering a room and forgetting why we walked in there. We go to the supermarket and return without the item we needed. We lose our keys. We panic that we have missed an appointment. We forget where we parked the car. For some members of our world, however, remembering is particularly difficult.

Older persons often report problems with remembering (Verhaeghen et al., 2000), and, indeed, there is robust evidence that memory performance deteriorates with age (Verhaeghen, 2012). Older persons are also more likely to experience memory difficulties due to dementia and Alzheimer's disease (Arvanitakis et al., 2019). With virtually every country in the world facing an aging population, memory-related issues among older persons are likely to become an important focus for psychologists (Caprani et al., 2006).

Many other individuals have problems with remembering, making memory a very relevant issue for psychological practice. There is evidence to suggest that memory problems are experienced by persons with autism spectrum disorder (ASD) (Kercood et al., 2014), Down syndrome (Doerr et al., 2019), and attention deficit/hyperactivity disorder (ADHD) (Ramos et al., 2020), among others. The ability to report past events is important for the development and maintenance of relationships with others and for health and well-being (Shillingsburg et al., 2017).

When we think about remembering, we tend to think of recalling stimuli and events that occurred in the past—known as *retrospective remembering*. However, another form of remembering—*prospective remembering*—refers to remembering to perform certain behavior in the future (Peisley et al., 2020). Prospective remembering can be time-based or event-based. We are engaging in time-based prospective remembering when we remember to go to the dentist next Wednesday, for example. It is time-based because we need to remember to complete the action at a certain time. Remembering to take our antibiotic tablet when we eat dinner is event-based prospective remembering because an event serves as the cue to complete the behavior. Prospective remembering contains elements of retrospective remembering, in that the person must remember what it is that they need to do. The additional requirement is remembering to perform the behavior at the right time, or in response to the right cue.

Many groups of people have impairments in prospective remembering, including older persons (Henry et al., 2004), people with

schizophrenia (Wang et al., 2018), multiple sclerosis (Rouleau et al., 2018), dyslexia (Smith-Spark, 2018), traumatic brain injury (McCauley et al., 2009), and children with ASD (Sheppard et al., 2018) and ADHD (Talbot et al., 2018). Such impairments have implications for people's day-to-day lives. My 90-year-old grandmother needs to remember to take her medication at certain times. If she takes it at the wrong time, it could seriously affect her health. Children need to remember to do their homework and to deliver notes from their teacher to their parents.

Aside from the day-to-day issues that arise for people who have memory problems, such as remembering to perform actions in the future, and being able to connect with family and friends by talking about shared historical events, there is evidence that memory ability is important for the performance of other behaviors. For example, people with ASD who score poorly on tests of working memory also score lower on tests of mathematical ability (Kercood et al., 2014) and other cognitive tasks (Kenworthy et al., 2008). Therefore, interventions to improve remembering may also lead to improvement on other tasks.

How Do We Remember?

One puzzle for early philosophers was how humans could seemingly resurrect stimuli and events from their past. If an object is no longer here, how is it that we can respond as if it were?

The Cognitive View

Cognitive views of short-term memory evolved from early philosophical theories that when people encounter stimuli or experience events, copies of these stimuli and events are "stored" or "stamped" in our brains (Delaney & Austin, 1998; Palmer, 1991). They reasoned that as we cannot store the original stimulus or event, we must store a copy. If we rehearse the copy (or trace) of the stimulus, we can hold it in short-term memory, and if the trace is associated with other stored stimuli, it may be transferred to long-term memory. It is these stored copies of past stimuli and events, retrieved from our memory stores that are assumed to affect our current behavior (Fryling & Hayes, 2010). It is assumed that our short-term memory store has a finite capacity and cognitive psychologists have placed some focus on measuring the limits of this store. As Delaney and Austin (1998) point out, if remembering involves the storage of copies or traces, then counting the number of such traces that can be stored is a logical step. Most people have heard of the cited "fact" that humans can generally hold seven items, or chunked pieces of information, in their short-term memory store (Miller, 1956).

Over time, the nature and number of memory stores described by cognitive psychologists have changed. Since Atkinson and Shiffrin's (1968) three-stage model consisting of the sensory register, working memory, and long-term memory, other cognitive models involving memory stores have been proposed. Some models suggest that different types of information are stored in different places (e.g., the working model of memory; Baddeley & Hitch, 1974) and others that traces are generated in short- and long-term memory stores simultaneously (the Feature Model; Nairn, 1990). These cognitive models all have in common the notion that information is received in some sort of (hypothetical) memory store and must be rehearsed or in some way processed (e.g., by association with other information; Woodward et al., 1973) to be retained. When asked to remember, a person must search the long-term store for the relevant information and then recall it. The problem of remembering then becomes one of retrieval of information from the long-term store.

The Behavioral View

Behaviorists argue that viewing remembering from the perspective of memory stores and traces is unhelpful. Firstly, behaviorists insist on studying behavior, not hypothetical structures such as memory stores or copies. Hypothetical memory stores engender all the usual behavioral objections to mentalisms; scientific enquiry is directed to explaining how the memory stores work, which is not necessary to the study of the behavior of remembering, and distracts researchers from explaining the behavior itself (Baum, 1994). Secondly, even if copies of stimuli and events are stored in our brains, the cognitive perspective does not shed any light on how we search through the stores to retrieve the copies (Palmer, 1991).

White and McKenzie (1982) describe remembering as "discriminative behavior under the delayed control of prior stimuli differing in degree of discriminability" (p. 311). The delay between the stimulus presentation and the opportunity to respond (or "remember") makes the discrimination more difficult than discriminations made in the presence of the stimuli, but there is no requirement to hypothesize internal memory stores to explain the behavior. The time that has passed between the presentation of a stimulus or event and the opportunity to remember it is a dimension of the discrimination, just as the color, size, and distance of such stimuli are. In the same way that we may have difficulty identifying an object that is far away from us in space, we might have difficulty describing a stimulus that is further away in time (in the past). When we remember, just as when we see, we "do" something, and although no one else can easily observe the "doing," it does not mean that it is somehow different to overt behaviors. Behaviorists argue that public and private behaviors differ only in the number of people who can observe or report on them (Baum, 1994)—they otherwise have the same properties and are subject to the same contingencies, shaped and maintained by the same processes (Baltruschat et al., 2011a).

According to the behavioral view, we learn to perform remembering behaviors in the same way as we learn to perform other behaviors (Palmer, 1991). Adults shape the remembering behavior of children, just as they shape other behaviors (Palmer, 1991). For example, a parent may say to a child, "Tell Grandma what did you did today." The adults present will reinforce the child's response with attention, approval, interest, and so on. If the child is unable to answer, the parent might provide prompts to facilitate the response, for example, "Remember? We went to the park. What did you play on there?" Adults can provide more and more explicit prompts until the child responds, and prompts can be faded as remembering behavior emerges. Adults will also shape "correct" remembering behavior, to the extent that they are aware of the accuracy of the description of the past events. They might correct the child's remembering behavior, for example, by saying "No, you didn't play on the swings today, but you did play in the sandbox."

Natural consequences also shape and maintain remembering behavior. Forgetting a person's name will lead to embarrassment. Remembering to bring your lunchbox to school will prevent hunger, and so on.

Why Does the Perspective on Memory Matter?

In practical terms, does it really matter whether we take a cognitive or a behavioral approach to remembering? Behaviorists would argue that it does. If remembering behavior is explained using storage models, failure to remember is attributed to failure of the hypothetical structure (Chiesa, 1994). As Chiesa (1994) points out, in applied settings, how can a psychologist intervene to enhance a hypothetical structure? In other words, understanding and explaining the storage model do not help us in our efforts to improve remembering behavior.

There are other implications of the storage model. If our short-term memory capacity is limited, as assumed by the cognitive perspective, then it is presumably not possible to improve our memory beyond its limits. With a limited physical capacity for storing and retrieving information, we can presumably only improve to some maximum and further efforts to improve will be unsuccessful. Also, if items and events are stored temporarily as fading traces, remembering accuracy will necessarily decline over time since the presentation of the information to-be-remembered. The strength of the trace should be strongest at a zero delay. When introduced to a new person, for example, the likelihood that I will remember that person's name should diminish as time passes due to the fading of the trace of the name, unless I rehearse the name to hold it in my short-term memory. With the view that remembering involves fading traces, there is an assumed inevitability that our ability to recall a stimulus will decrease over time.

Some behavioral researchers have attempted to demonstrate that it is possible to train an animal to remember better after longer delays than after shorter delays after the presentation of a stimulus. Such a finding would throw doubt on the idea that remembering involves copies of stimuli that fade over time. In an attempt to dispute trace-decay theories of remembering, Sargisson and White (2001) trained pigeons in a delayed-matching-to-sample task to perform a remembering behavior after a certain delay. We reinforced the pecking of a key (the comparison stimulus) when the key color matched a sample key color presented earlier. Each group of pigeons experienced a different, single delay between the presentation of the sample and the comparison keys during training; either 0, 2, 4, or 6s. In a probe test using delays of 0, 2, 4, 6, 8, and 10s, the pigeons performed more accurately at their training delay, even when it was longer than other delays (Fig. 54.1). Remembering performance also generalized to proximal delays—pigeons were better at remembering after delays close to their training delay than they were after delays that were more different. These results aligned with findings of researchers measuring purely visual behavior—or "seeing" (Blough, 1972), and provided evidence that "remembering" is similar to other, immediate behaviors. Increasing the delay between the presentation of a stimulus and the opportunity to recall it increases the difficulty of the remembering task (seen in the lower discriminability scores for longer delays in Fig. 54.1) in the same way that increasing the physical distance between an observer and an object makes it more difficult to see the object. Neither situation requires reference to hypothetical "copies" stored in the brain.

White and Brown (2011) found further evidence that remembering can be more accurate after longer delays than after shorter delays. In a

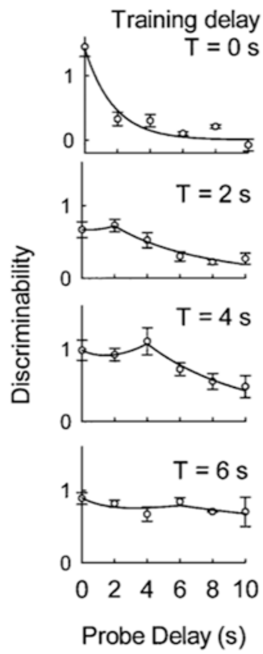

Fig. 54.1 Mean discriminability (remembering accuracy) at different delays by pigeons trained with a single delay of 0, 2, 4, or 6s. (Reproduced with permission by Wiley from Sargisson and White (2001))

delayed-matching-to-sample task, they presented a signal during the delay interval to indicate whether the reinforcer on the current trial would be small or large. Pigeons performed the remembering task more accurately when large reinforcers were signaled, but, importantly, when the cue was changed partway through the delay interval, accuracy increased after longer delays when the cue changed from a small to a large reinforcer. White and Brown's result is important because rehearsal of the correct stimulus during the delay could not explain the enhanced performance at longer delays. These results and others (Sargisson & White, 2007; White & Sargisson, 2011) demonstrate that it is possible to train animals to "do" better remembering after longer delays than after shorter delays—a finding incompatible with trace theories of remembering.

Unlike the approaches of cognitive psychology, where memory is viewed as a limited resource in which copies of information are stored, a behavioral approach to remembering assumes that remembering, as a behavior like any other, is subject to modification through its contingencies. That is, just as we can improve a person's reading or writing, we can improve their remembering, for example, by changing the contexts in which the remembering occurs, or by manipulating the consequences of remembering behavior. The behavioral approach suggests that applied behavior analysts can use any of the behavior modification tools in their repertoire to enhance remembering behavior. In fact, there may be no need for interventions tailored specifically to problems of remembering.

Behavioral Assessment

The first step a behavior therapist takes when working with a client is to understand and measure the behavior of interest. Establishing a baseline of current behavior will help a therapist to demonstrate that a particular intervention has resulted in improvement of that behavior. In terms of remembering behavior, one common way of assessing current memory ability is to use *indirect assessment* methods, such as questionnaires like the Instrumental Activities of Daily Living: Compensation Scale (IADL-C) (Schmitter-Edgecombe et al., 2014) and the Multifactorial Memory Questionnaire (Troyer & Rich, 2002). Such instruments measure what an individual perceives their remembering ability to be, their satisfaction with their memory, and which memorial strategies they use. The problem with indirect methods—especially in the self-report format—is that they do not occur at the time that the target behavior is performed, but rely on the individual's recollection of their own behavior (Miltenberger, 2016), an obvious drawback for people who have problems with remembering. In fact, Troyer and Rich (2002) found no significant correlations between self-reported memory ability and performance on objective tests of remembering with a sample of older persons *without* memory difficulties.

Another way to assess remembering ability is through *direct assessment* methods—observing and recording remembering behavior as it occurs. To assess remembering ability, for example, an observer could ask a person about events that occurred in their personal histories, or ask them to recall items from a list presented earlier (Richardson-Klavehn & Bjork, 1988). A behavior analyst could also devise a more unobtrusive recording method to measure remembering behavior, for example, by observing the person interacting with friends and family, or after being asked to perform a task by a third person. Behavior analysts generally prefer direct assessment methods (Miltenberger, 2016). However, although direct, and to some extent indirect, assessment methods will provide a baseline of a person's remembering ability, only the verbal responses of the individual are overtly visible, and as such, they may not reveal which strategies the person is using to remember, and which interventions might be especially effective to improve remembering outcomes.

Talking Aloud

One challenge, then, when seeking to intervene to improve the remembering performance of our clients is that some parts of the remembering behavior are performed covertly, making it difficult to ascertain the nature of the remembering problem, or to identify strategies that might be efficacious in improving the client's remembering behavior. One way to overcome the challenge is to make the covert overt. Delaney and Austin (1998) recommend "talking aloud" to determine the specific challenges a person is experiencing with their memory. Talking aloud involves verbalizing the thinking process, without reflection or interpretation, as a person engages in remembering behavior. By verbalizing the thought process, covert behavior becomes overt behavior giving a practitioner some insight into the strategies that a person is already using, and which interventions might be most helpful.

Using the talking-aloud approach, Williams and Hollan (1981) investigated the process taken by individuals as they attempted to recall first and last names of students in their year group at high school. Multiple sessions over many hours produced an impressive number of names recalled by their subjects—up to 214 for one subject. The verbalizations of the subjects revealed a process whereby participants sought discriminative stimuli that would lead to the recall of the names, for example, by recalling specific classrooms, events, and friends who might be linked to peers. The participants sometimes tested each letter of the alphabet for names that they recognized.

The talking-aloud approach, then, might be a useful tool as part of an assessment of a person's remembering behavior. It may highlight strategies that the person is already using, and suggest other strategies that could be taught to improve the person's remembering performance.

Cognitive Approaches to Improving Remembering

Many cognitive strategies for improving short-term memory ability stress the importance of practice. Unless we rehearse information, or transfer it to a long-term memory store, it is assumed that information will be forgotten, either because information held in short-term stores fades, or because we lack the mental resources to hold the information and perform other mental processes simultaneously, or because it will be overwritten by new incoming information (Oberauer et al., 2016).

Cognitive techniques to increase memory capacity have centered on rehearsal and practice (Bahar-Fuchs et al., 2013)—with the idea that repeatedly using our memory will strengthen our ability to remember, much like exercise improves muscle tone (Melby-Lervåg & Hulme, 2013). *Articulatory rehearsal*, the type of rehearsal that people most commonly use (Oberauer, 2019), describes the simple repetition of stimuli (usually by silent verbalization) until the information is needed. An example is repeating a phone number to yourself until you can enter it or otherwise record it. From a behavior analytic perspective, each verbalization of the stimuli serves as the discriminative stimulus for the next verbalization and the behavior of rehearsal is reinforced by successful completion of the task requiring the stimuli (correctly dialing the phone number, for example) (Delaney & Austin, 1998). Such behavior closely resembles behavior *chaining*, where each behavior in a sequence acts as the discriminative stimulus for the next behavior (Miltenberger, 2016).

Based on the assumption that practice will improve ability, computer programs have been designed specifically to improve short-term remembering ability. These programs include memory exercises to "challenge" working memory. Such programs are typically referred to as *working memory training* or *cognitive training*. The programs guide users through memory tasks of increasing difficulty in different domains (Bahar-Fuchs et al., 2013) to "strengthen" and increase brain activity. Improvements gained in one type of task are expected to generalize to other types of tasks (Melby-Lervåg & Hulme, 2013). In terms of generalization, a distinction is made between near-transfer and far-transfer. Near-transfer is the generalization of a skill or ability to tasks similar to, or in the same domain as, the training task. For example, a cognitive training program in verbal memory might improve remembering skills not only for the specific verbal memory task presented in training, but in other, similar, verbal memory tasks. Far-transfer is achieved when improvement in the verbal memory task leads to improvements not only in verbal memory, but other kinds of memory, or even in more general domains, such as reading or writing (Sala et al., 2019b).

One such cognitive training program, Cogmed (https://www.cogmed.com/), claims that, because their visuospatial and verbal memory training strengthens neural networks—in a different way to behavioral strategies—the process of network strengthening will enhance performance in non-trained tasks. They state that their tasks "challenge the working memory capacity" at its limits. The website for another memory-training program, Jungle Memory (https://www.junglememory.com/), again refers to their program as a way to "strengthen" memory, and claims that by training children to "use" their working memory, improvements can also be seen in reading and writing skills.

Despite the claims, however, such memory training programs have shown rather unconvincing outcomes. Several meta-analyses, presenting the combined effect of many individual studies, have been published. Melby-Lervåg and Hulme's (2013) meta-analysis of 23 studies of memory training programs reported immediate benefits in visuospatial and verbal memory, but the improvement was only maintained long-term for verbal tasks. There was no evidence that improvements in one domain generalized to other domains. A meta-analysis of 11 randomized-control trials where cognitive training was used in an attempt to improve the remembering ability of persons with dementia showed no improvements relative to control groups (Bahar-Fuchs et al., 2013). A review of 10 studies investigating cognitive training (most delivered using a computer program) with persons with mild cognitive impairment found mixed results (Gates et al., 2011). Although a few studies in Gates et al.'s (2011) analysis reported improvement in memory performance after cognitive training, some reported negative effects, whereby controls performed better than those in the treatment group, and there was little evidence of generalization to other domains.

For children with ASD, there is also little evidence to support the use of working memory training. De Vries et al. (2015) concluded, after a large, randomized control trial, that there were only marginal effects on working memory and that computerized memory training, of the type used in their study, is not a feasible treatment for children with ASD.

A second-order meta-analysis (a meta-analysis of meta-analyses) showed that cognitive training generalized successfully to near-transfer tasks (that is, memory training improved performance on other memory tasks), with the improvement being greater for children than for adults (Sala et al., 2019b). However, far-transfer (improvement in other tasks, such as language tasks) did not occur for any population, a finding also reported in other meta-analyses (e.g., for Cogmed specifically, Aksayli et al., 2019; for older adults, Sala et al., 2019a; for typically developing children, Sala & Gobet, 2020). Some scholars have cautioned psychologists to take care when recommending computerized cognitive training programs, given the lack of evidence to support claims that they result in real-world improvements (Hague et al., 2019).

Interventions Classified by the Three-Term Contingency

Many factors affect our ability to remember, and in the language of behaviorism, I will categorize them according to Skinner's three-term contingency into antecedent, behavior, and consequence factors. From a behavioral perspective, these factors are all located in the environment, and are therefore available for manipulation to improve remembering performance. However, Baltruschat et al. (2012) note that there has been little published research on working memory from behavior analysts. They state that research on memory from a behavior analytic perspective is important because, firstly, behavior analysis needs to demonstrate that it can address the full scope of psychological phenomena, and secondly, remembering behaviors are legitimate and interesting behaviors that are critical to the successful performance of many other behaviors.

The two main approaches to assisting people with memory problems are either *restorative* or *compensatory* (Wade & Troy, 2001). A restorative approach seeks to improve innate remembering ability, while a compensatory approach seeks to teach a person strategies to cope with their remembering difficulties, without assuming that memory ability itself can be improved. In behavioral terms, there is no real difference between these strategies—both involve teaching techniques to enable the person to perform memory-related tasks. If a therapist teaches a client how to create mnemonic devices to help them remember the names of people they meet, and the person is later able to successfully remember the names of a person they meet, is this strategy restorative or compensatory? How would an observer know? Thus, I will make no distinction between the two types of approaches.

Antecedent Factors

All currently occurring events and stimuli are things that we will potentially want to remember in the future. Sometimes we know at the time events occur that we will need to remember them later. For example, when we park our car at the airport, we know that we will need to remember where it is when we return from our trip. How can we manipulate the antecedent conditions to optimize later remembering behavior?

Behavioral antecedents are the stimuli or events that are present prior to an operant response (Miltenberger, 2016). Antecedent stimuli gain control over behavior when behavior is reinforced in the presence of those stimuli. Stimuli thus become discriminative, and certain behavior is more likely to occur in the presence of such discriminative stimuli. Such behavior is said, then, to be under stimulus control by a discriminative stimulus. Most behavior under stimulus control is performed in the presence of the discriminative stimulus, and not in its absence. We are more likely to drive through a green traffic light than a red one—the light is present at the time we drive through the intersection. When we remember, however, we are performing behavior in relation to a discriminative stimulus that may no longer be present. It is easier to describe your mother's face (here, your mother's face is a discriminative stimulus, and your description of it is behavior under stimulus control) when she is present than when she is absent. When she is absent, and your behavior is therefore under delayed stimulus control, if you are unable to recall your mother's face immediately, you may need to recall other discriminative stimuli related to your mother to assist your remembering behavior. For example, you may recall her in locations, and performing tasks, that are particularly associated with her.

If the behavior to be performed in the future (remembering) is associated strongly with the stimulus to be recalled, or is associated with other stimuli that can serve as discriminative stimuli at the time remembering is required, then we will be more likely to produce accurate remembering. Conversely, forgetting is a failure of stimulus control—there are insufficient stimuli available, or the association with the stimuli is too weak, to cue accurate remembering.

Many studies have demonstrated that the strength of the initial discriminative stimulus is important to remembering. In animal memory research, for example, presenting the sample stimulus for a longer period, or requiring the animal to respond to it a greater number of times, improves the animal's remembering accuracy of that stimulus across various delays (White, 1985). With humans, we might think of stimulus strength as a problem of attention. If we were not paying attention at the time that the stimulus or event occurred, it is unlikely we will be able to recall that stimulus after a delay. Cognitive psychologists might argue that increasing the strength of the initial stimulus serves to increase the strength of the trace, and a stronger trace will be available longer than a weaker trace. Behaviorists, however, would argue that stimulus strength is about providing opportunities for the current stimulus to be associated with other stimuli that, when they appear in the environment later, can serve as discriminative stimuli to evoke remembering behavior (Fryling & Hayes, 2010).

Researchers have reported that people do not always notice, or attend to, unexpected or surprising stimuli in their environment (Simons, 2000)—a phenomenon referred to as *attentional blindness*. A well-known experiment, for example, demonstrated that when people were asked to count the number of passes made during a short segment of a basketball game, most failed to notice, and were unable to recall, a person walk across the court wearing a gorilla suit (Simons & Chabris, 1999). There is some evidence that using mindfulness techniques can reduce attentional blindness (Schofield et al., 2015). Schofield et al. (2015) reported that participants in a brief mindfulness condition detected distractor stimuli at a significantly higher rate than participants in the control conditions. Lueke and Lueke (2019), who found that participants in a brief mindfulness condition performed better on tasks requiring them to remember lists of words than did controls, propose that the improvement in remembering ability is due to "encoding" of the stimuli; in other words, something the participant is doing prior to the opportunity to recall the words. Being mindful when parking your car at the airport, for example, would imply that you pay particular attention to the car's surroundings, noticing landmarks that might be useful for remembering at a later time where the car is parked. These promising recent findings suggest that a client engaging in mindfulness therapies might also experience improvements in their memory.

If we are currently experiencing an event that we believe others will ask us about later, or that we know we will need to remember later, we tend to pay attention to other features of the environment. When parking the car, we may look for a sign, trees, or other distinctive stimuli near to where the car is parked. When at an important family event, we may take photos, talk to others who are present, text friends, or post about it on social media. These additional associations with the original stimulus or event will aid later remembering (Fryling & Hayes, 2010). While some of these associations are created without much thought, some we deliberately create at the time that the stimulus to-be-remembered occurs to aid later remembering, so-called *acquisition strategies* (Delaney & Austin, 1998). For example, when being introduced to a new person, we might try to connect their name to some aspect of their appearance, so that when we see them again, we are more likely to remember the associated name—*B*elinda has *B*londe hair, for example. Note that the association does not need to be thought of as residing in any kind of memory store: The stimuli are associated in the environment.

During the process of classical conditioning, pairing an unconditioned stimulus with another stimulus creates an association between the two stimuli. If I say "sit" as my puppy sits, I will create an association between the spoken word "sit" and the behavior of sitting. The presentation of the, now-conditioned, stimulus ("sit") elicits the behavior (sitting) initially elicited by the unconditioned stimulus (whatever prompted the puppy to sit in the first place). In the same way, a stimulus associated at one point in time with a to-be-remembered stimulus can elicit behavior at a later time. Thus, just as a bell can become a conditioned stimulus eliciting salivation, or the word "sit" with sitting, the sight of Belinda's blonde hair acts as a discriminative stimulus prompting the response "Belinda." One way to enhance remembering, then, is to strengthen the associations between antecedent stimuli (Fryling & Hayes, 2010).

Mnemonic devices, as an acquisition strategy, involve deliberately constructed stimuli that are easier to recall than the stimuli that are likely to be needed in the future, and that serve as discriminative stimuli for these difficult-to-remember stimuli. For example, I learned in school the mnemonic "my very earnest mother just showed us nine planets" to aid the recall of the names, and order, of the planets that orbit the sun. (Of course, a new mnemonic will be needed now that we have lost Pluto as a planet!) Such mnemonics are quite effortful to learn, but there is evidence that humans can learn to develop their own mnemonic devices. Ericsson et al. (1980), for example, reported an analysis of a single person who became an expert at the digit-span memory task. This task involves presenting a sequence of digits (or words in the word-span task), at a rate of one digit per second and asking the subject to repeat the digits in the same order. If the list of digits is recalled correctly, one digit is added to the list. Ericsson et al.'s subject was initially able to recall seven digits—within the range of the average person's recall ability. However, after 2 years of training, the subject had increased the number of digits he could recall to 80. The subject was asked to describe his thought processes during each trial (the "thinking aloud" approach), providing insight into the learning process. Initially, the subject reported using only rehearsal strategies, but when rehearsal proved insufficient, he developed different mnemonic strategies, for example, by creating hierarchical groups of numbers, each group serving as discriminative stimuli for subsequent groups.

Belleza (1981) described many different types of mnemonic devices, which could be a helpful resource for practitioners seeking to teach clients how to use these devices, but they noted that evidence suggests it is better to encourage the client to develop their own mnemonic devices.

Training target groups in the use of mnemonic devices has been shown to improve their ability to remember information, not only in the short-term, but also more permanently. Mastropieri and Scruggs (1989) showed large and consistent effect sizes in a review of research where children with mild developmental delay were taught to use mnemonics to enhance their recall of academic content. An updated synthesis of 34 experiments concluded that the use of mnemonics for improving the recall of academic content is "extremely powerful" (Scruggs & Mastropieri, 2000, p. 170). A nice feature of mnemonic devices is that they can be an effective strategy for whole-class instruction, as the use of mnemonic devices has been shown to improve memory for academic content both for developmentally normal and developmentally delayed students in a classroom (Mastropieri et al., 2000). According to another meta-analysis, mnemonic devices also improve the memory performance of older adults (Verhaeghen et al., 1992), particularly when the training is delivered in a group setting.

Forgetting can occur when antecedent conditions or discriminative stimuli are either absent at the time of remembering, or when they become involved in new associations (Fryling & Hayes, 2010). For example, we may forget to take our medication when we are on vacation because the usual discriminative stimuli to prompt the behavior are absent. We might be unable to find the car in the carpark because different cars are now parked beside our car. A specific location may remind you of a person or event until it becomes associated with a new person or event. In such situations, to facilitate remembering, it may be wise to create associations with stimuli that are more independent of context, or to ensure that discriminative stimuli do not become involved in new associations. For example, when parking the car, it is not wise to use nearby cars as discriminative stimuli (Fig. 54.2), but rather immobile cues such as signs and trees that will still be there when you return.

In some cases, a therapist does not want to improve a client's memory, but rather to help a client forget something, for example, a painful experience (Fryling & Hayes, 2010). Exposure to the discriminative stimulus in the absence of the stimulus that caused pain, or pairing the discriminative stimulus with pleasant stimuli, can help weaken the association (such processes are known in behavior analysis as, for example, exposure therapy or systematic desensitization and counter-conditioning).

Antecedent or acquisition strategies, then, can help to improve remembering behavior by intervening prior to the need to remember, for example, by strengthening stimuli and events to-be-remembered, and by creating associations between to-be-remembered stimuli and other stimuli that can act as discriminative stimuli at the time of recall. How might we intervene to improve remembering in the absence of such antecedent strategies?

Behavior

Have you ever walked into a room and forgotten what you wanted in there? It is likely that you retraced your steps in the hope that it would help you remember. Stimuli in the place you return to will act as cues (discriminative stimuli) for the initial thought. You did not think, at the time you decided to move into the other room, to pay attention to stimuli in the first room, and yet, these stimuli have been associated in time and can therefore act as cues, even without the deliberate use of antecedent strategies. When asked to recall past events, then, contacting associated stimuli may aid accurate remembering (Shillingsburg et al., 2019).

As mentioned in the previous section, because stimuli-to-be-remembered are often associated with other stimuli and events, one way to achieve remembering is to contact the discriminative stimuli associated with the original to-be-remembered stimulus or event (Palmer, 1991). Such recall strategies work best in combination with acquisition strategies, whereby we attempt to create associations prior to the need to remember (Palmer, 1991). Some recall strategies are techniques that humans learn to engage in; that

Fig. 54.2 When taking note of your parking place, it is not very helpful to notice only the adjacent cars (left photo) as they may not be there when you return. A better approach is to take note of immobile stimuli, such as the 1b sign on the post (right photo)

is, the behavior is shaped over time by its consequences. For example, when trying to remember the name of an acquaintance, we commonly test out each letter of the alphabet in turn. Such a strategy often works because the sound of the letter is associated with the sound of the beginning of the person's name and acts as a discriminative stimulus to its recall. When using this strategy results in correct recall of the name, the use of the strategy is reinforced. Similarly, when asked what you had for dinner one night last week, you might first recall what other activities you were engaged in that day—recalling that you worked late, for example, you might recall that you did not have time to cook, so picked up a pizza that night. Again, if the strategy is successful, you will be more likely to use the same strategy in the future. Associative recall also occurs in the absence of a specific need or request for recall. For example, smelling a certain cologne on a passer-by may trigger the recollection of a man you knew who used the same cologne. During a visit to your hometown, you will spontaneously recall events from your childhood.

Forgetting can occur both when we do not encounter the necessary discriminative stimuli in the present time to elicit remembering behavior and when discriminative stimuli become associated with too many to-be-remembered stimuli (Fryling & Hayes, 2010). If every man wears the cologne, then smelling the cologne would not remind you of anyone in particular. If you do not pass by the store on the way home, you may forget to buy milk.

To help another person remember a stimulus or event, we might use *prompting*. For example, when a person is experiencing difficulty remembering, a practitioner may ask probing questions to help the person contact the discriminative stimuli associated with the stimuli or event-to-be-remembered. If a person cannot remember when they last saw their doctor, for example, we might ask whether it before or after Christmas, in the spring or summer, or before or after they engaged in some other memorable activity. Deliberate prompting is similar to the prompting delivered by our verbal community when we all learn to remember (as discussed above). Shillingsburg et al. (2017) argue that naturally occurring prompts may not be sufficient for children with ASD, however, the deliberate use of prompts with young children with ASD can improve their ability to recall past events (Shillingsburg et al., 2019), thus prompting may be a useful strategy for some clients.

Prompting can be arranged in the absence of a person to provide the prompts: that is, through the use of external aids that serve to prompt remembering behavior. Such prompts are also referred to as *reminders*. We learn to support our own remembering behavior by using diaries and calendars, and making shopping lists, for example, and, similarly, we can teach others to use external aids. These external aids serve as discriminative stimuli to prompt remembering behavior. Memory wallets are one example of an external memory aid to assist with retrospective remembering. Memory wallets contain personally relevant pictures and textual information depicting facts, people, or events that a person is having difficulty remembering (Bourgeois & Mason, 1996). Bourgeois and Mason (1996) investigated the efficacy of memory wallets with four people with dementia. Care workers created a book of photos and statements to use as cues to prompt conversation. They found some improvement in the clients' conversations—clients made fewer remembering errors, repeated themselves less, were more intelligible, and increased the number of factual statements they made. Half the family members reported that the clients were easier to talk to and care workers reported that their clients smiled a lot when they looked at the memory wallets.

Mobile phones can also deliver reminders to people with memory impairments. Unlike memory wallets, which are used to promote retrospective remembering, or reminiscing, mobile phones and other, similar types of reminders are more helpful for prospective remembering tasks. Wade and Troy (2001) found promising results for the use of a mobile phone app that reminds people to perform certain tasks. Other mobile phone apps, such as Google calendar, could be a useful tool for people with prospective memory problems (McDonald et al., 2011). In fact, a meta-analysis of prospective memory aids found a large overall effect size supporting the efficacy of portable prompting devices (Jamieson et al., 2014).

Consequences

If remembering is a behavior like any other, it should be possible to improve remembering performance by manipulating its consequences. Studies with non-human animals have shown that remembering performance is more accurate when reinforcer magnitude or probability is increased for correct remembering behavior (Brown & White, 2009) and reinforcing the accurate retrospective remembering of children with ASD improved their performance in a counting-span (Baltruschat et al., 2011a) and in a complex-span task (Baltruschat et al., 2011b). In another study, Baltruschat et al. (2012) found that not only did performance on working memory tasks (backwards span recall) by children with ASD improve but accurate performance also generalized to novel stimuli when correct recall was reinforced.

Prospective remembering outcomes are regularly rewarded and punished in society. For example, fines are imposed for forgetting to return library books, forgetting to attend an appointment, or paying bills late. Conversely, remembering a friend's birthday will be reinforced by your friend's happy response. Prospective remembering, then, should also be amenable to improvement through the use of reinforcement. Peisley et al. (2020) reinforced the correct responses of children with ASD as they played a computerized memory game called the Virtual Week (Rendell & Craik, 2000). Remembering accuracy increased for all children and was maintained for most children after reinforcement ceased. Children with traumatic brain injury (McCauley et al., 2009) and orthopedic injuries (McCauley et al., 2011) performed significantly better on a prospective remembering task when they were promised larger reinforcers for correct remembering ($1 per point) compared to children who were promised smaller reinforcers (1c per point). Thus, reinforcing correct remembering may be effective for some populations, and tangible reinforcers may lead to better outcomes for those who do not respond well to social reinforcement (e.g., children with ASD; Shillingsburg et al., 2017).

Another way to manipulate consequences is to make use of the *differential outcomes effect*, where different outcomes are arranged for different types of correct remembering responses. The differential outcomes effect is well-established in non-human animal research (White & Sargisson, 2015). In a delayed-matching-to-sample task, for example, animals see a sample stimulus (often a red or a green light) and, after a delay, choosing the stimulus that matches the sample is reinforced.

In a differential-outcomes delayed-matching-to-sample task, correct red responses might result in a larger reinforcer than correct green responses. White and Sargisson (2015) showed that arranging differential outcomes at single delays increased pigeons' remembering accuracy at those delays. The differential outcomes effect has also been demonstrated in remembering tasks with typically developing children (Estévez et al., 2003), older adults (López-Crespo et al., 2009), and persons with Alzheimer's disease (Plaza et al., 2012), among other populations. A recent meta-analysis found significant medium-to-large effects on overall accuracy, test accuracy, and transfer accuracy (generalization to novel stimuli) across 60 differential-outcomes-effect experiments with humans, with larger effects in clinical populations (McCormack et al., 2019). A practitioner could make use of these findings by reinforcing correct remembering behavior of one type with a different reinforcer to remembering behavior of another type to potentially maximize the effect of reinforcement on remembering outcomes.

Summary

While remembering has often been viewed from the cognitive perspective of fading traces and retrieval of copies from memory stores, behaviorists have argued that remembering is a behavior no different to any other behavior. Viewing remembering as a behavior enables a practitioner to apply behavioral principles to improve remembering behavior, and, indeed, in this review, I have shown that behavioral methods are successful for this purpose. Remembering is an important target behavior for practitioners given the global aging population, and the fact that remembering ability is linked to many other important behaviors.

One difficulty for practitioners in addressing the memory problems of their clients is that remembering is a covert process. The therapist or practitioner sees only the final remembering response, not the process that the person undertook to reach that response. One way to make the covert process of remembering overt is to ask the client to "think aloud" as they perform remembering tasks. Thinking aloud may allow the practitioner to identify strategies that the person is successfully using, and suggest others that could be taught. Once a baseline measurement of remembering behavior is established, the practitioner can apply any of the evidence-based behavioral techniques for behavior change. I have discussed a few here, involving antecedent, behavioral, and consequence interventions. However, a sophisticated behavior analyst should be able to adapt other behavioral interventions to assist their clients in coping with memory problems.

As published behavioral research on methods for improving the remembering behavior of target populations is sparse, I would encourage practitioners to track their progress as they introduce interventions, using robust single-subject research designs, and publish their findings to assist future behavior analysts in this fascinating area of behavior.

55 Picture-Based Communication

Rocío Rosales and Jack F. Blake

Introduction

One of the defining characteristics of autism spectrum disorder (ASD) is difficulty with social interactions and communication (American Psychological Association, 2013). These characteristics are manifested in many ways but may include challenges in understanding or responding to social cues (i.e., eye contact and facial expressions), back-and-forth conversation, and communicating basic wants and needs. These challenges in functional communication can result in the development of undesirable behaviors such as tantrums, aggression, and self-injury. Teaching communication of basic wants and needs is often referred to as "mand training" in line with B.F. Skinner's (1957) *Verbal Behavior* and is recommended as an early target in behavioral intervention programs (Sundberg & Michael, 2001).

In their seminal study on functional communication training (FCT), Carr and Durand (1985) clearly showed the relationship between self-harmful behavior and deficits in communication. Their research showed that teaching socially appropriate communicative acts resulted in the reduction of unwanted behaviors. The study included an assessment to find specific situations when unwanted behaviors of four students with developmental disabilities occurred. Following this assessment, participants were taught an alternative form of communication to request specific reinforcers related to the occurrence of the unwanted behavior. For example, if a participant emitted unwanted behavior during work situations, they were taught to vocally request teacher assistance (e.g., "I need some help"). The functional communicative response successfully decreased occurrence of each student's undesirable behavior.

Reviews of the research on FCT have continuously shown the efficacy of this teaching procedure for reduction of unwanted behaviors (Durand & Moskowitz, 2015; Heath et al., 2015). When individuals with ASD cannot communicate their basic wants and needs through vocal verbal behavior, a variety of augmentative and alternative communication systems (AACs) can be used to set up a functional communicative repertoire. AAC modalities include sign language, vocal output, or speech-generating devices (e.g., iPads and tablets), and picture-based systems. Importantly, FCT includes all modes of communication (Tiger et al., 2008) although the evidence to date shows slightly favorable outcomes for verbal and aided AACs (e.g., picture-based

systems and speech-generating devices) compared to unaided AACs (e.g., sign language; Heath et al., 2015).

Several variables should be considered in selecting a communication modality including the response effort required of the learner, learning histories correlated with presence of a specific communication modality, the likelihood that communicative acts will be reinforced in the learner's natural environment (Heath et al., 2015), as well as pre-requisite skills and learner preference (Valentino et al., 2019). To date there is little experimental research to guide modality selection by practitioners. Although more research is needed in this area, there is a large body of evidence to support the widespread use of picture-based systems for learners with ASD. This chapter will highlight the evidence base for this form of augmentative communication.

Picture Exchange Communication System

The Picture Exchange Communication System (PECS; Bondy & Frost, 2011) is a well-recognized picture-based communication system with robust empirical support. PECS was developed to teach learners to initiate communication and thereby promote independent communicative acts (Bondy & Frost, 1994). PECS is comprised of six phases that are taught in sequence. The goal of Phase 1 is to teach "how to communicate" by initiating an independent single picture exchange with an adult trainer who is deemed the listener or "communicative partner" (Frost & Bondy, 2002). The goal of Phase 2 is to teach "distance and persistence" and expands the use of single picture card exchanges to require the learner to travel first to the communication binder, and then to the communicative partner across various settings. Phase 3 teaches discrimination between picture icons primarily through error correction procedures. It is divided into two phases—Phase 3A teaches the learner to discriminate between a preferred and a non-preferred item, while Phase 3B teaches discrimination between two preferred items. Importantly, it is not until Phase 3 that multiple picture icons are presented to the learner on their communication book. Phase 4 teaches the beginnings of simple sentence construction; Phase 5 teaches the learner to respond to the question "What do you want?" and Phase 6 teaches commenting with various expansions such as use of attributes (Bondy & Frost, 2011; Frost & Bondy, 2002). PECS benefits from a robust line of research showing its efficacy in teaching an alternative form of communication for learners with ASD (Ganz et al., 2012).

Learner Outcomes

PECS was designed to be accessible to users who struggle with reliable pointing, imitation, and other behavioral basics of functional communication. The primary benefit for learners who successfully use PECS is development of these core functional communication skills. Ancillary benefits that have been noted in the literature to date include a reduction in unwanted behaviors, increase in *initiating* communication, development of simple sentence construction, spontaneous communication, generalization of responses, and increases in mean length of utterance (Bondy, 2001; Ganz et al., 2012). According to Bondy (2001) most children who start using PECS before age six and use the system for more than a year will develop speech (vocal verbal behavior) as their sole communicative modality with 80–120 icons; while other individuals need much larger icon representations before vocalizations begin to emerge.

An early comprehensive study by Charlop-Christy et al. (2002) taught three minimally verbal boys with ASD (aged 3–12 years old) all six phases of PECS. Participants showed proficient performance in all phases and several other functional communicative skills emerged including spontaneous speech (during Phase 4), imitation in play and academic settings, social-communicative behaviors (i.e., joint attention), as well as reductions in unwanted behavior (i.e., tantrums, grabbing, disruptions, etc.). The development of spontaneous speech is a particularly important outcome of this study. Other researchers have reported similar outcomes in vocal verbal behavior for learners who achieve proficiency in Phase 4 of PECS (Bondy & Frost, 1994: Ganz & Simpson, 2004; Tincani et al., 2006).

Tincani et al. (2006) examined the effects of PECS on the manding and speech development of two school-aged children with ASD. In this study, experimenters varied the training by delivering verbal feedback when the child emitted a vocalization in one condition, and no verbal feedback for child-produced vocalizations in a second condition. The verbal feedback condition resulted in differentiated outcomes for speech production (only following proficiency in PECS Phase 4). The increase in vocalizations following delivery of verbal feedback suggests this was a function of the explicit reinforcement provided by the experimenters in this study. These findings suggest that prompting and reinforcement procedures that target speech may be necessary to produce such increases, and without such procedures the increases in speech production may be less likely.

In a larger outcome study, Carr and Felce (2007) evaluated the impact on learner outcomes for 41 children with ASD (ages 3–7 years old) who received 15 hours of PECS instruction (Phases 1–3) compared to a group of children who did not receive PECS instruction. Results showed a significant increase in the persistence, spontaneity, and generalization of communicative initiations for the children who received PECS training. The generalizability of PECS outcomes (across objects, activities, environmental settings, and people) was a particularly noteworthy outcome of this study since reports of generalization are not widely reported in the literature (Ganz et al., 2012).

Carré et al. (2009) evaluated the generalizability of PECS Phases 1–3 from a training setting to classrooms and homes for three 5- and 6-year-old children with ASD. The participants received one-on-one PECS training modified to enhance generalization outcomes. These efforts to enhance generalizability included briefing sessions with teachers and teacher aides during regular intervals to ensure that all communicative partners understood how to respond promptly and consistently to picture symbol exchanges, as well as the importance of making communication materials accessible to children throughout the school day. Child participants of this study showed consistent use of PECS in the classroom, but minimal communicative acts in the home. There was also considerable variation in spontaneous PECS requests across both settings. Results of this study showed the need for intervention that incorporates features of a new communicative environment (e.g., typical communication partners and contexts) to systematically program for generalization.

Some recent studies have reported generalization outcomes including learners successfully using PECS to communicate access to items not directly trained (Marckel et al., 2006), in novel settings (Greenberg et al., 2012), and with novel communication partners (Tincani, 2004, Tincani et al., 2006). Greenberg et al. (2012) evaluated the effectiveness of a train and probe generalization assessment technique following each of the first four phases of PECS implementation. Specifically, generalization of use of PECS was measured across various settings (i.e., a center playroom area, a convenience store found in the nearby community, and the living room and other central in-home areas of each participant). The train and probe procedure was effective for three of the four participants included in the study. The researchers note procedural details of the generalization probes may have contributed to these positive outcomes. First, access to the highly preferred items was limited for the duration of the study. Second, the preferred items were visibly shown to the participants on a timed-interval schedule to evoke a response. Future research should evaluate these contextual variables that may contribute to positive generalization outcomes.

Peer Involvement Another important learner outcome of PECS is interaction with peers. Functional communication training directed at peers is a vital component of behavioral language interventions. This type of training gives learners an opportunity for social interactions that may lead to developing friendships. Training directly with peers is also important to address unwanted behaviors where peers are involved. For example, if another child is playing with a preferred item, the target child should be taught a socially acceptable response to request access to said item. In addition, pairing peers with access to preferred items may increase the reinforcing value of these social interactions and in turn condition peer interactions as reinforcers (Kodak et al., 2012).

Paden et al. (2012) evaluated the effects of a treatment package to increase peer-directed mands for preferred items using PECS among two boys with ASD. Once participants learned to use PECS with adults, requests directed towards adults were no longer reinforced, but participants were prompted to direct the same request to a peer who was prompted by the adult trainer, as necessary, using a least to most prompting hierarchy. Results showed an increase in frequency of peer-directed mands for leisure items, which also resulted in brief social interactions with peers (e.g., playing together with a toy). These results were replicated and extended by Kodak et al. (2012) who showed generalization of peer-directed mands to novel peers and to a novel setting. Doherty et al. (2018) further extended these results by evaluating the effects of a systematic prompt fading procedure on rates of independent peer-directed mands in six boys (ages 3–5 years old). The measures included some participants initiating communication and others responding appropriately to communicative bids by a trained peer. Generalization and maintenance probes showed overall positive lasting effects of this training.

Although these collective results are promising, more research is needed on the generalization and maintenance of peer-directed mands. As noted above, this line of research is important given the social validity and direct potential benefits of increased social interactions for both the learner and the peers learning to communicate with children with ASD. Future research on this topic should replicate and extend the procedures outlined in these studies. For example, demonstrations for peer-directed mands that expand into later phases of PECS (e.g., beyond Phase 4) are needed, as well as evaluation of the components necessary to support these skills in the absence of adult mediation.

PECS Adaptations A unique feature of PECS is its flexibility and adaptability for a variety of learners (Frost & Bondy, 2002). The developers of PECS outline many ways this communication system can be modified to meet the needs of learners with a variety of disabilities, but demonstrations of these adaptations have not been widely published. Malandraki and Okalidou (2007) report a successful adaptation of the PECS protocol for a 10-year-old with ASD and bilateral sensorineural profound hearing loss (i.e., deafness). Over the course of a 4-month intensive training program, the learner was taught to use PECS up to Phase 4, followed by a less intensive 4-month maintenance program and 6-month follow-up assessment. Modifications to the PECS protocol accounted for the participant's hearing loss and potential writing abilities. For example, he showed spontaneous writing once and finger-spelling of 31 words during an informal assessment, thus PECS picture cards were replaced with written cards. The participant emitted his first *spontaneous* vocalizations during the generalization of Phases 4 and 5; and follow-up probes showed the participant maintained spontaneous requesting and responding to requests in both written English and Greek sign language. Collateral responses included increases in eye contact, sitting with other children in a common-room, and interacting with other children during play.

Another demonstration of adaptation of the PECS protocol was reported by Lund and Troha (2008). These researchers used tactile symbols (i.e., three dimensional objects) to teach Phases 1-3A of PECS to three blind adolescents with ASD (12–17 years old). Referents included computers, rain sticks, and crash pillows represented with a combination of craft supplies (e.g., plastic, fabric, masking tape) and household items (e.g., grains of rice, marbles) and placed on 3 × 3 in. squares of cardboard. These items were then attached to a 4 × 8 in. Plexiglas board with Velcro to create the modified PECS communication board. Other modifications included limiting the instruction team to two individuals and the total daily number of trials for Phases 1 and 2 to account for time constraints and the unique obstacles presented by the participants' disability. One participant successfully completed all three phases of the modified PECS instructional program in under one month, while the other two showed notable improvement from baseline. All participants' rates of progress resembled those of sighted children using PECS. This demonstration suggests that tactile symbols can be incorporated into a PECS protocol to teach manding to children with ASD who are also blind.

Finally, Bracken and Rohrer (2014) assessed the effectiveness of an adapted form of PECS to increase independent requesting in deafblind adults with intellectual disabilities. PECS cards were created to accommodate the individual needs of each participant. This included use of enlarged photographs and swelled images created on raised line drawing paper. Participants were successfully taught to use PECS up to Phase 3 and generalized responding to different settings and with multiple communicative partners. Further research is needed to better understand the suitable AAC modalities and protocols for individuals with ASD and visual impairments or other forms of multiple disabilities.

Caregiver Implementation of PECS

In addition to learner outcomes, it is important to evaluate measures of treatment integrity for implementation of PECS. As a demonstration for the need to train caregivers on correct implementation of this popular augmentative communication system, Jurgens et al. (2012) asked 12 families to upload a series of videos on YouTube to show their in-home use of PECS for their child with ASD. Treatment integrity scores showed elevated levels of errors in several categories. For example, 61% of all observed exchanges included use of a vocal or gestural prompt by the communicative partner, an open hand prompt error, lack of timely reinforcement, and/or incorrect implementation of the 4-step error correction procedure during Phase 3 of PECS. These results highlight a need for specific training in the implementation of PECS. Fortunately, several studies have evaluated various training approaches for the implementation of PECS by parents (Alsayedhassan et al., 2016) as well as practitioners and education professionals who work directly with children and adults with ASD (McCoy & McNaughton, 2019).

Rosales et al. (2009) evaluated the use of a behavioral skills training (BST) package to teach implementation of the first three phases of PECS to two undergraduates and one graduate student with no prior training in the implementation of PECS. The training package consisted of written and verbal instructions, modeling by an expert trainer, practice with a confederate learner, and verbal feedback provided by the trainer until participants met a predetermined mastery criterion for each phase of training. Training sessions were conducted with a confederate and generalization probes were conducted with an adult with developmental disabilities that had no prior experience using PECS. All participants acquired predetermined performance levels on the implementation according to a treatment integrity checklist developed for the study. The overall effectiveness and efficiency of this three-hour training package provides trainers with a practical model for teaching individuals who have limited experience working with people who have ASD and other developmental disabilities. Results of this study were replicated by Homlitas et al. (2014) with three teachers who worked directly with young children with ASD.

Ganz et al. (2013) evaluated the impact of "instructional coaching" on implementation of PECS Phases 1–4 with three practitioners who worked with 3–4-year-old children with ASD and language delays. The coaching included a group workshop training (i.e., verbal explanation and review, practice, goal-setting, and guided implementation), as well as instruction to supply increased opportunities for clients to emit requests using PECS. Therapists showed an increase in providing PECS opportunities by ensuring the communication book was within 5 ft. of the child and enticing them with gestures or superimposition. Clients showed a corresponding increase in usage of PECS, but results did not generalize to a novel context. These results indicate a workshop alone may be insufficient in supporting the generalization of target behaviors in practitioners and their clients with consistent treatment integrity. Further research is needed to decide how direct training models can be modified for successful implementation and long-term maintenance.

Hill et al. (2014) taught PECS data collection and implementation (Phases 1–4) to three preservice teachers and staff with education and experience in special education but no prior direct experience with PECS. Researchers examined treatment fidelity in an extended school year (ESY) setting and student progress over the 4-week experiment. Training included modeling procedures across six 3-hour sessions with practice and feedback components, while implementation consisted of two teachers, one serving as the physical prompter and another as the communication partner, per student. Teachers showed successful communication using graphs of student progress with parents at the conclusion of the summer program. Follow-up observations in the three students' schools the following school year showed successful generalization of functional communication skills, though students progressed at uneven rates. These results show that teachers with no prior experience in PECS data collection or implementation can be taught both in a classroom setting with high fidelity through a practice- and feedback-based instruction program, and that their students can in turn make progress in their independent requesting in a short timeframe. Future research should incorporate more learner outcomes (i.e., measure of emerging vocalization and words, reductions of any unwanted behaviors, and spontaneous initiations).

Parent implementation of PECS is also vital to the ongoing maintenance of functional communication. Park et al. (2011) examined the effects of a mother-implemented PECS protocol for Phases 1–3B on the independent picture exchange of three children with ASD (2–3 years old). Each mother received 40- to 60-min training sessions that included written instructions, a video model of each phase to be trained, an opportunity to practice the role of communication partner, and feedback by the experimenter. All parent participants met or exceeded the criterion for correct implementation of PECS Phases 1–3B. Child participants increased their use of independent picture exchanges, generalized their use of PECS to different communication partners, and maintained the skills acquired for at least 1-month post-training. Notably, all mothers also reported high levels of satisfaction with the goals, procedures, and outcomes of the study. Researchers hypothesized that the children's rapid acquisition of functional communicative behaviors via PECS may be attributed to their training in naturalistic settings with familiar communication partners.

Recently, Alsayedhassan et al. (2020) investigated the effectiveness of a BST package (i.e., written and verbal instructions, modeling, role play, and feedback) to teach two parents to implement PECS with their 3- and 8-year-old children with ASD (one child per family). The researchers delivered formal PECS training to the parents in both university and in-home settings using a bug-in-ear device to deliver immediate verbal feedback; they then measured the parents' percentage of correct PECS implementation in Phases 1–3. Researchers also measured the percentage of correct exchanges by the children. Results of the study showed parents learned implementation quickly and the children mastered the respective levels of PECS in few sessions. Importantly, probes for generalization and maintenance also showed promising results for independent manding via PECS by the child participants.

The use of BST to train implementation of PECS is effective but can be time consuming in terms of the expert trainer supplying direct teaching to all participants. The demand for well-trained service providers who work directly with individuals with ASD calls for the development of efficient training methods as alternatives to face-to-face training. To address the limitation of the need for an expert trainer for all trainees, follow-up studies have evaluated the use of pyramidal training (Martocchio & Rosales, 2016), voice-over video modules (Martocchio & Rosales, 2017), and computer-based training (Rosales et al., 2018). The use of these asynchronous training methods helps to address the challenge associated with training methods that require the presence of an expert trainer and may also help increase accessibility to systematic training on the implementation of PECS and other behavioral intervention procedures (Gerencser et al., 2020). A review of asynchronous training methods revealed only one study (McCulloch & Noonan, 2013) that focused on "mand training" employed this form of training. Future research should focus on replications and extensions of the work that has been conducted using asynchronous training for various other behavioral intervention procedures as it can be adapted to teach implementation of PECS or other functional communication systems in general.

Comparison of PECS to Other AACs

Studies that have directly compared the use of PECS to other forms of AACs have reported mixed results. For example, Boesch et al. (2013) found no significant difference between PECS (Phase 1) and a speech-generating device (SGD; standard 5-button Logan ProxTalker) in terms of independent requests for edible items by the three elementary-aged participants with severe ASD. PECS was considered a more accessible choice given its portability and low cost, while the SGD offered enhanced durability with features including voice and dialect adaptability. In a similar study, Hill and Flores (2014) compared the independent use and effectiveness of PECS with Proloquo2Go AAC via the Apple iPad in three pre-school and two 9-year-old students with ASD and developmental disabilities. Results for this study were mixed whereby one participant acquired more independent initiations and independent requests using PECS, while another showed increased requesting behavior when the iPad was used. A potential confound with the use of a speech-generating device is that the auditory stimulus generated by the device may serve as a reinforcer for selecting an icon on a device. Two participants showed greater independent requests using the iPad and the final participant showed no significant differences in behavior, though she did begin saying words aloud during the PECS condition. These results suggest that low-tech intervention can be as effective as high-tech intervention during the first stages of communication development, though more research is needed to evaluate whether this transition from low-tech to high-tech is effective, and if so, when it should be implemented. Further investigation on graphic symbol iconicity, generalization across settings, and transitioning from PECS, the Logan ProxTalker, and other low and mid-technology to high technology such as the Apple iPad are also needed.

Caregiver and Learner Preference Some studies have systematically evaluated *preference* for picture-based systems such as PECS in comparison to other AACs. For example, Lorah (2016) recruited four teachers and paraprofessionals with no prior AAC training to conduct training trials using both a picture-based system (PE) and an iPad Mini with the AAC application (Proloqu2Go). Participants were exposed to a multi-component training package that included verbal prompting, time delay prompting, graduated guidance, and differential reinforcement. Measurements of teacher fidelity of implementation and acquisition of independent manding suggested no significant difference in treatment methods, but preference evaluations for students and teachers alike showed a general preference for the iPad-based SGD. While the positive reception of Proloqu2Go among elementary-aged students may simply be due to it being a well-liked consumer device overall, preference among teachers is especially important given their position as the stakeholders of this technology. In summary, the literature to date shows an overall preference for speech generating devices by caregivers, but the nature of these devices with appealing voice-output features and applications that serve functions other than communication need to be considered as potential confounds (Couper et al., 2014). A critical next step in this research is to focus on best practices for individualizing selection of AAC modality by incorporating learner preference.

Van der Meer et al. (2012) compared acquisition, maintenance, and preference for three AAC modalities (i.e., a speech-generating device, a picture-exchange, and manual signs) by four children with developmental disabilities. Participants were taught to mand for preferred snacks and toys using one of three modalities. Preference for use of a modality was evaluated and showed that three of the four participants selected the SGD most often, while one participant selected the picture exchange. LaRue et al. (2016) also evaluated learner preference for AAC modality (card touch, manual sign, or vocal approximation) and found that all three participants acquired labels most rapidly using their preferred modalities. Although the results showed a clear preference for a single modality and this preference corresponded with how quickly learners acquired use of the AAC modality (i.e., participants selected the modality they had acquired in the fewest trials), this study did not incorporate use of PECS, but rather taught a card touch. Finally, Valentino et al. (2019) examined the use of a brief prerequisite assessment to predict the effectiveness and rate of acquisition of mand training for three modalities (sign, picture exchange, and vocalizations) in 13 young children with ASD. In this study, PECS was the most effective and efficient modality for acquiring a rudimentary functional communication repertoire. Collectively, the results of these studies show that preference for communication modality may be idiosyncratic and thus should be evaluated during the preliminary stages of intervention.

Limitations of Research

As noted throughout earlier sections of this chapter, there is ample empirical support that shows the benefits of PECS for learners with ASD and limited vocal verbal repertoires. However, this research has largely focused on teaching the first three phases of PECS with few exceptions (e.g., Charlop-Christy et al., 2002). The paucity of research on implementation and outcomes for the latter three phases of PECS may be due in part to learners transitioning to electronic devices that have gained popularity and accessibility over the last decade. It is also likely that when some vocalizations start to appear, implementers of PECS shift focus to shaping vocal verbal behavior and pause the use of the aided AAC system, although this is not recommended or supported by research. Interruption of the use of PECS may lead to disadvantages in the development of increased length of utterances and complex verbal repertoires (Bondy, 2001, 2019).

In comparison to the evidence base of PECS with children with ASD, there is little research on adult learner outcomes. Hughes-Lika and Chiesa (2020) reviewed the literature of PECS implementation for adult learners and found only five empirical studies with a total of 18 participants (ages 19–52 years old). Importantly, the review showed only one participant with ASD in these studies, while the other participants had a wide range of disabilities including intellectual disability (ID), Down syndrome, and deaf blindness. Results of this review showed that PECS has the potential to teach functional communication skills to adults with difficulties in communication due to various disabilities, though further research is needed to explore such potential beyond Phase 3. Future research should not be restricted to ASD/ID in children and adolescents and instead evaluate the collateral effects and other unique aspects of PECS implementation in adults with various disabilities.

It is important to note that this paucity of research for adult learners is not unique to functional communication training or picture-based systems, but it is an area that needs to be further explored. The use of speech generating devices and the use of technology in general may be preferred for this age group, but there is limited research to show its efficacy. In addition, although voice-output devices may be *preferred* for adult learners, the transition to exclusive use of an electronic device should be done in a systematic manner. The next section of this chapter will outline recommendations for an optimal transition to electronic devices.

Use of Electronic Devices

There are many potential advantages of adopting the use of electronic devices as a form of functional communication for children and adults with ASD. Among these benefits is the decrease of social stigma that can be attached to carrying a picture board since much of the current population relies and carries at least one electronic device on their person. There are also potential disadvantages to teaching functional communication solely with the use of a voice-output device. The advantage of starting with a traditional tangible icon-based system is the step-by-step sequence for development of critical communication skills. Potential disadvantages to this system are that individual learners may acquire the functional use of hundreds of icons for their communication needs, which in turns demands a careful transition to electronic devices and other AACs without unethical skill degradation and loss of skills (Bondy, 2001).

When implementing PECS for individuals with a variety of communication problems, it is important to consider the practical and ethical risks present in distinct phases of intervention. While some learners who use PECS may develop vocal verbal repertoires, other learners may need several hundred picture icons for a complete functional communication system. Such repertoires may demand a transition to an electronic AAC. However, if the AAC leads to poor implementation, this puts at risk the communicative and social skills developed in earlier stages of training. Ethical and accessible intervention, however, holds many benefits (Bondy, 2012).

King et al. (2014) examined the acquisition of requesting skills in three 3–5-year-old children with ASD using the iPad application Proloquo2Go. Importantly, participants in this study were not taught using the PECS training protocol. Rather, after preferred items were identified via a formal preference assessment, training sessions started with a Proloquo2Go/iPad-modified PECS protocol. The AAC was effective in the development of requesting skills. All participants achieved proficiency in three of the five phases adapted from the original PECS protocol, and two of the three participants mastered the fourth phase as well. The emergence of vocal requesting in one participant and the increased frequency of vocal requesting in the other two participants also suggests Proloquo2Go can assist in the emergence of vocal verbal repertoires. These results suggest that PECS and other low-tech interventions can be adapted to high-tech applications to achieve target behaviors, as well as function as a speech-generating device.

Alzrayer (2020) also evaluated the effects of PECS Phase 4 protocol on the acquisition of spontaneous augmented requests with four children with ASD. During a natural play condition, the modified PECS protocol was used to teach participants to request access to preferred items by emitting a multisymbol message (e.g., I WANT + name of a preferred item) with an iPad as well as vocalizations. The results of this study suggest a modified PECS protocol can be successfully used to transition from a low to a high-tech communication modality. Similarly, Wendt et al. (2019) described an AAC that consists of PECS infused with the electronic SGD SPEAKall! This represents an accessible intersection between low- and high-tech intervention for the reliable development of requesting skills and of vocal verbal behavior.

Given the outcomes of these studies, the relevant question might be not whether electronic *should* be adopted, but at what point might the learner benefit from a transition to an electronic device. Bondy (2012) suggests this transition may be ideal during Phase 4 training, since this is usually also when vocal verbal behavior begins to emerge as a result of PECS. Alternatively, users may benefit not from a transition to electronic device as a sole form of functional communication, but a combination of the two modes of communication.

Alternative Picture-Based Communication Systems

Although PECS is a well-recognized communication system with robust empirical support, there are variations of picture-based systems that may also prove beneficial depending on unique learner characteristics. For example, although adaptations to the PECS protocol have been noted in prior research, learners with limited mobility in upper extremities may need to rely on eye gaze communication systems supplemented by pictures. In this case, eye gaze requires that the learner attend to a single picture or to shift eye gaze from one item ("yes") to another ("no") on a communication board or chart. Sigafoos and Couzens (1995) evaluated the effectiveness of eye gaze communication with photographs for a 6-year-old boy with multiple disabilities. The participant quickly showed spontaneous requests through eye gaze communication evaluated by the TARC Assessment Inventory (Sailor & Mix, 1975). Specifically, the participant learned to use eye gaze to select a missing item from a chart that was needed to complete a preferred activity. In the first phase of intervention, the participant was presented with a cassette tape and tape player with missing headphones. These items were supplied for 60 s only after the child requested the headphones by orienting to this item on the eye gaze chart. This procedure was repeated by omitting the cassette tape and requiring the child to request this item using the same procedure. Results of this study suggest that eye gaze can be targeted for instruction to accommodate learners with physical disabilities. There is limited research on this topic and some noted limitations to use of eye gaze for communication (e.g., cost, need for constant recalibration of the equipment, and restriction to a limited number of eye movements; Pai & Bhardwaj, 2019). Despite these limitations eye gaze technology is crucial for individuals with limited motor capabilities. A recently developed smart phone-based system known as Eye-based Alternative Communication Exchange (E-ACE; Pai & Bhardwaj, 2019) offers a promising alternative.

Other picture-based communication systems referenced in the published literature include SymbolChat (Keskinen et al., 2012) and Dynavox PCS (Nakamura et al., 1998). One of the main concerns and limitations of picture-based systems is that these do not require the learner to initiate communication with a listener (communicative partner) and this may limit *spontaneous* and *independent* communication. For this reason, an important variable to consider in deciding the efficacy of picture-based systems and other AACs is how well the system will transition to naturalistic settings. Nam and Hwang (2016) reviewed studies that evaluated the efficacy of mand acquisition using picture exchange-based and signed communication systems. Results of this review showed that children with ASD acquired picture-based systems more easily and rapidly than signed responses. Limitations of the picture-based systems noted above include required use of equipment, limited distance between listener and speaker/pictures resulting in lack of spontaneous communication or initiation, as well as difficulties with representation of abstract words.

Cultural Considerations and Adaptations

An area of recent interest for both the autism community and for applied behavior analysis practitioners is how best to adapt and accommodate ABA approaches for learners from culturally and linguistically diverse backgrounds (Lim et al., 2018; Wang et al., 2019). These adaptations necessarily apply to the use of AACs, including PECS. Yu (2018) evaluated the implications for bilingualism in the development and implementation of AAC interventions in children with ASD and reaffirmed earlier research that showed bilingual children with ASD perform on par with their monolingual peers on various language assessments that evaluated both listener and speaker behaviors, as well as social responsiveness, vocabulary size, age of first words and first phrases. Importantly, learning multiple languages is an asset beyond functional communication, including the development and maintenance of essential bonds with immediate and extended family members.

The flexibility of PECS allows for incorporation of multiple languages and the communication system has been implemented across the globe since its development (Al-dawaideh & Al-Amayreh, 2013; Hu & Lee, 2019; Odluyurt et al., 2016; Sulzer-Azaroff et al., 2009). Fahim and Nedwick (2013) examined how unique cultural and developmental circumstances of young dual language learners with ASD influence language acquisition skills and effective intervention plans. The authors distinguish between universal characteristics of ASD (e.g., poor joint attention and responding skills) from modes of communication that may be influenced by culture (e.g., gestures and facial expressions). Functional communication training can incorporate culturally relevant routines and bilingual AACs into young children's treatment plans. For example, intervention specialists may work with a child's family to incorporate words and phrases used in daily routines (e.g., greetings, bath time, mealtimes). Fahim and Nedwick (2013) discussed a case example of a family who incorporated Arabic songs, signs paired with both English and Arabic words, and verbal countdowns delivered in both English and Arabic by different family members into the intervention of a 3-year-old dual language learner with ASD. Although this paper does not specifically mention the use of PECS, integration of visual supports in two languages can be provided by including written labels in the home as well as the dominant language (e.g., English) to help promote generalization of the communication skills the child experiences across different environments (e.g., home and school).

Despite the flexibility of picture communication systems, there are features that require special attention and consideration. For example, Nakamura et al. (1998) discussed the difficulties of picture-based systems for Japanese speakers because these systems tend to be based on English sentence formation. These researchers evaluated the use of a computer-based version of the Dynavox Picture Communication Symbols (PCS) and discussed use of Bliss symbols as an alternative to the typical symbol-based sentence construction commonly used by English speakers. Chompoobutr et al. (2013) also described the importance of evaluating the choice of graphic icon symbols as these may have different meanings depending on the learner's cultural background. These authors evaluated the various semantic beliefs of graphic symbols used in the Thai picture-based communication system and in other AACs that use the Minspeak™ iconic encoding and language representative. Application among 65 Thai-speaking participants of varying educational backgrounds between the ages of 10 and 50 was assessed. Researchers emphasized the cultural factors that decide the efficacy of graphic symbols in AAC. For instance, apples are not traditionally consumed in Thailand; therefore, using an image of an APPLE to stand for a food concept can create unnecessary confusion to the learner.

Similarly, Dukhovny and Kelly (2015) outline basic guidelines for effectively designing and implementing AACs to multilingual and multicultural users with limited functional speech (e.g., age-appropriate picture symbols, gender- and language-appropriate voice options, and multilinguistic keyboards). The researchers evaluated the use of a simple phase-based application iWant™ for a Ukrainian-speaking 76-year-old man and another using the touchscreen communication aid Accent 100 for a 4-year-old Spanish-speaking boy. The success of these interventions suggests accessible and inclusive AACs include culturally relevant picture/symbol supports, a capacity for digitized speech, and multilingual synthesized voice options, keyboards, and grammatical support. However, the lack of Ukrainian grammatical support and Spanish-speaking intervention limited each participants' treatment options and long-term progress, respectively. For instance, the child's ability to generalize his English AAC skills to Spanish was limited, making his device less useful in a home setting than in an English-speaking classroom. The 4-year-old boy received AAC intervention services from exclusively English-speaking specialists. Bilingual support may aid in the successful use of the Accent 1000 device in both languages and settings. Instead, he often resorted to gestures and vocalizations to communicate with Spanish-speaking family at home. Suggestions for developing effective AAC with picture-based systems include the use of age-appropriate visuals and devices and gender-appropriate voice selection, especially for users like the elderly Ukrainian man in this case study, whose age and maturity are not often reflected in the design of AACs.

Overall, there is a need for more experimental studies to evaluate the variables that have been studied in descriptive and observational studies to date. In addition, there is a need for research on the development and implementation of AACs with age-appropriate visuals and devices as well as gender-appropriate voice selection, especially for adults with ASD and other developmental disabilities. This research will help to address optimal training strategies to implement functional communication with learners who come from diverse backgrounds. Findings from the literature to date suggest that ethical AAC practice demands informed practitioners who are capable of understanding, respecting, and collaborating with the wants and needs of their clients' families in developing more linguistically fluid and culturally relevant interventions.

Summary

This chapter reviewed picture-based communication systems with particular attention to PECS as an evidence-based AAC. This specific mode of functional communication has been shown to be an effective method for learners with ASD, although the research to date supports its use with children more so than adult learners. When compared to other modes of communication, PECS has not always been reported to be preferred by both caregivers and learners alike. Instead, the research to date shows speech-generating devices may be preferred by both groups. However, idiosyncratic results are reported in the literature and best practice suggests that an initial assessment should be conducted during the intake process to help find the ideal mode of communication for each learner (Valentino et al., 2019). Although there is a large body of support for PECS for learners with ASD, limitations of the existing research include a lack of systematic applications for all six phases of PECS, demonstrations of PECS with adult learners, and evaluation of the protocol with bilingual learners with ASD. Despite these limitations, picture-based communication systems should continue to be considered when learners with ASD do not have an established form of functional communication.

Teaching Foreign Language

Anna Ingeborg Petursdottir
and Juliana S. C. D. Oliveira

Global communication and mobility have characterized the twenty-first century, creating social and occupational advantages for those who can communicate effectively in more than one language. In the United States, demand for such workers more than doubled between 2010 and 2015 (New American Economy, 2017). In addition to enhanced employability, learning a foreign language positively affects cognitive functioning and increases cross-cultural awareness (for a review, see Fox et al., 2019). Around the world, vast numbers of students in elementary grades and beyond receive compulsory or optional education in languages other than those spoken in their home environments. Other people learn new languages outside of formal educational systems. In recent years, a flourishing market has appeared for interactive software applications that facilitate self-study of languages; for example, Duolingo®, Rosetta Stone®, and Babble® for adults, and Dino Lingo®, Rosetta Stone Homeschool®, and Gus on the Go! for children.

Behavior analysis has a long history of considering how behaviorally based teaching procedures may be applied to foreign-language instruction (Rocha e Silva & Ferster, 1966). Nevertheless, the behavior-analytic literature on this topic is small, and sustained, systematic programs of research have yet to emerge. In this chapter, we will consider the potential value of a behavior-analytic approach to foreign-language instruction, provide a behavioral analysis of foreign-language learning, and review existing behavior analysis research on this topic.

Learning a New Language: Concepts and Terms

We will begin by introducing terms to describe the language(s) in which a person can communicate or seeks to learn, followed by a brief overview of the different components of a new language that must be mastered for effective communication.

A *native language* (L1) is a language acquired to proficiency through natural environment exposure from birth or early childhood. A *second language* (L2) is acquired subsequent to L1, typically after the earliest years of childhood, but within an environment in which the language is widely spoken. L2 is not necessarily the second language a person learns; it can also be third, fourth, etc. (Gass & Selinker, 2001). L2 may be learned as a result of moving to a new country or region, or as a result of contact with a community of speakers in one's native region. In some cases, L2 becomes a person's predominant language and proficiency of use may approximate native speakers (Forsberg

& Fant, 2010), whereas in other cases, the L2 learner gains only limited command of the L2. Persons who speak two or more languages fluently, such as two L1s or an L1 and an L2, are referred to as bi- or multilingual. Age of acquisition and amount of exposure to L2 are influential factors in L2 learning outcomes (Peñaloza et al., 2019).

Learning a *foreign language* (FL), in contrast to L2, refers to learning a nonnative language outside of the natural linguistic community (Gass & Selinker, 2001). An FL, therefore, is learned primarily through classroom instruction or self-study, as opposed to immersion in a natural language environment. A language initially learned as an FL can later become an L2, and an L2 may be partially learned through formal instruction similar to an FL (e.g., in classes for immigrants). In contrast to L2 exposure, researchers have not consistently found advantages to starting formal FL instruction in early childhood (Baumert et al., 2020). Finally, the term *heritage language* is used to describe a language to which a person has a cultural or familial connection, but did not learn to proficiency in childhood (Valdes, 2005). For example, a heritage language may be the L1 of one or more immigrant parents or grandparents, or it may be an endangered ancestral language of an indigenous population.

In this chapter, we will focus on the potential application of behavior analysis to teaching a nonnative language, whether it is taught as an FL, an L2, or a heritage language. We will generally use the term FL to describe the target language of instruction, except in the context of studies that specify L2 or heritage language instruction as a goal.

Learning a new language is a complex task. In part, the problem lies in the large amount of information to be learned. Command of the 3000 most frequent words in a language is considered essential to everyday use (Nation & Waring, 1997), and at least 5000 words are needed to read for pleasure (Hirsh & Nation, 1992). Thus, *vocabulary* acquisition is an important and time-consuming aspect of FL learning. Vocabulary alone, however, is not sufficient for effective communication. FL learners often struggle with the *grammar* of the new language, which may differ from the student's L1 in both syntax (e.g., word order, sentence structure) and morphology (e.g., word inflection). For example, an L1 speaker of English learning Icelandic as an FL might struggle with the notion that nouns can take different forms (i.e., cases) depending on accompanying prepositions or verbs. The student also needs to master the *phonology* or sound system of the new language, which involves learning to both discriminate and articulate sounds that in some cases may not exist in the learner's L1. Other aspects of vocal speech, such as *prosody* (i.e., the pattern of stress and intonation), are perhaps less essential, but enhance the intelligibility of speech (e.g., Field, 2012). Because children immersed in an L2 environment are more likely than adults to master grammar, phonology, and prosody to the point of approximating native speakers, it has been hypothesized that critical (Lenneberg, 1967) or sensitive (Oyama, 1976) periods exist for these aspects of FL learning. However, data exist that contradict the notion of a biologically determined critical period (e.g., Hakuta et al., 2003), suggesting other factors (e.g., motivational) may play a role in the difference between the typical achievements of children and adults.

FL learners also need to master the writing system of the FL, which may be either similar to or very different from that of L1. For languages that use *alphabetic* or *syllabic* writing systems (i.e., systems in which each symbol roughly corresponds to a single vowel or consonant, or to a syllable, respectively), mastery of the writing system is closely tied to the phonology of the new language. For *logographic* systems, learning to read and write may be thought of as more closely related to vocabulary learning. Finally, relevant skills may include distinguishing between formal and informal speech, learning common idioms and expressions, and learning to choose words or expressions based on one's audience (e.g., children vs. older adults, or friends vs. colleagues).

What Can Applied Behavior Analysis Contribute?

A large literature exists on FL teaching and learning, with contributions from disciplines such as applied linguistics and psycholinguistics, educational science, and cognitive psychology. Topics of research include evaluations of teaching strategies and digital technologies (see, e.g., Golonka et al., 2014), strategies for addressing barriers to learning, such as anxiety (e.g., Dolean, 2016) and lack of motivation (e.g., Taskiran, 2019), age and gender differences in outcomes of language instruction (Baumert et al., 2020), and many others. Theoretical perspectives in the literature vary, but rarely include purely behavioral perspectives. According to Castagnaro (2006), the possibility of a behavioral approach to FL or L2 instruction has often been dismissed based on two faulty perceptions: First, a fictitious association between B. F. Skinner and the audiolingual method, a formerly popular method of FL instruction that has now fallen from grace, and second, "a demonstrably erroneous notion that operant psychology is too simplistic to effectively take up language issues" (p. 519). Castagnaro (2006) noted that contemporary behavior analysis is successfully engaged in the application of its theoretical system to teaching language skills to children with language delays, and suggested it was time to seriously consider its application to FL instruction.

Behavior analysis is well equipped to contribute to the literature on FL teaching and learning for several reasons. Behavior analysis offers a conceptual system that relies on well-studied learning processes and integrates language learning and human communication with all other learning and behavior. A long tradition exists for considering how this system may be applied to understanding human language as behavior (Hayes et al., 2001; Horne & Lowe, 1996; Sidman, 1994; Skinner, 1957), and to the design of language interventions (e.g., Hart & Risley, 1975; Sundberg & Partington, 1998). The twenty-first century has seen a surge of interest in areas of research of high relevance to FL teaching and learning; that is, verbal behavior (Petursdottir & Devine, 2017) and derived stimulus relations (O'Connor et al., 2017). Thus, a community of researchers and practitioners exists that may be well positioned to tackle topics in FL acquisition.

Some characteristics of applied behavior analysis may be particularly helpful in addressing the individual variability that characterizes outcomes of FL and L2 instruction (e.g., Ehrman et al., 2003). The emphasis placed on the role of reinforcement variables in behavior analysis may be helpful in addressing motivation as a barrier to student success. More generally, the emphasis on identifying functional relations at the level of the individual may be of value for identifying appropriate instructional modifications for struggling students.

Finally, behavior analysis has a long history of application to various problems in educational settings. Pioneering work on technologies that permit automated feedback on active student responding originated in behavior analysis (Skinner, 1958), and indeed, was applied to FL learning (Rocha e Silva & Ferster, 1966). Recent developments include the integration of programmed instruction with stimulus equivalence principles (Brodsky & Fienup, 2018); an area of research that may be highly applicable to educational software development in FL instruction. Existing, commercially available FL software applications bear an interesting similarity to the program described by Rocha e Silva and Ferster (1966), though we are not aware of a direct influence. These applications additionally incorporate many empirically based strategies (e.g., Settles & Meeder, 2016). However, we have not found evidence suggesting substantial influence from research on stimulus control, verbal behavior, stimulus equivalence, or derived stimulus relations. Application of these areas of research to FL instruction could potentially serve to inform effective software design in addition to classroom instruction.

Behavioral Analysis of FL Learning

From the perspective of Skinner's (1957) analysis of verbal behavior, target behaviors in FL instruction can be analyzed in terms of elementary verbal relations (Table 56.1) and autoclitic processes. Other behavior-analytic concepts of relevance to FL acquisition include functional equivalence (e.g., Dougher & Markham, 1994), stimulus equivalence (Sidman & Tailby, 1982), and parity (Palmer, 1998). Space does not permit a detailed analysis, but in this section, we will roughly outline how FL learning may be conceptualized from a behavioral perspective.

Vocabulary

Behaviorally speaking, an FL learner has acquired an FL vocabulary word or phrase when its emission (regardless of pronunciation) is controlled by the same variables that control native speakers' emission of the word or phrase. In Skinner's (1957) verbal operant taxonomy (Table 56.1), the learner emits the appropriate response as a *tact* controlled by a class of nonverbal stimuli, an *intraverbal* response controlled by a variety of verbal stimuli, and as a *mand* under relevant conditions of deprivation or aversive stimulation. The response does not need to be vocal; verbal operants can also involve written responses, hand signs (as in sign languages), or even pointing to written words or symbols.

According to Skinner (1957), tacts, intraverbals, and mands are functionally independent operants governed by different contingencies of reinforcement, and their presence in the learner's repertoire may be a product of separate reinforcement histories, as opposed to a single "word-learning" history. In FL learning, however, relations that already exist in the student's L1 repertoire may render it unnecessary to reinforce each novel FL response topography in the presence of multiple antecedents. An English-speaking learner of German, for example, can take advantage of the fact that "Hund" is controlled by much the

Table 56.1 Skinner's (1957) verbal relations applied to a subset of target behaviors in FL instruction

Verbal operant	Controlling antecedent	Example[a]
Tact	Nonverbal stimulus	Say "agua" as a result of seeing a glass of water
Intraverbal	Verbal stimulus	L1-FL: Say "agua" as a result of hearing "water" FL-L1: Say "water" as a result of hearing "agua"
Mand	Motivating operation	Say "agua" as a result of being water deprived
Echoic (duplic[b])	Spoken word that has the same sound pattern as the product of the spoken response	Say "agua" as a result of hearing "agua"
Copying text (duplic[b])	Written word that has the same visual pattern as the product of the written response	Write AGUA as a result of seeing AGUA
Textual behavior (codic[b])	Written word that bears point-to-point correspondence, but not physical similarity, to the spoken response	Say "agua" as a result of seeing AGUA
Taking dictation (codic[b])	Spoken word that bears point-to-point correspondence, but not physical similarity, to the written response	Write AGUA as a result of hearing "agua"
Relational autoclitic	Relationships between variables currently influencing the speaker's verbal behavior	Saying "agua fría" (as opposed to "fría agua") as a result of the relationship between the stimuli contributing tact control to the utterance

[a]Examples assume an L1 speaker of English learning a Spanish (FL) word. AGUA represents the printed word and "agua" represents the spoken word
[b]From Michael (1982)

same class of stimuli that control "dog" in L1. Learning to say "Hund" in the presence of a single exemplar of a dog (e.g., a picture of a Labrador Retriever) likely suffices to acquire "Hund" as a tact under the control of the entire class of stimuli (e.g., sights of dogs, sounds of dogs, smells of dogs) that control the tact "dog," exemplifying transfer of function within a class of functionally equivalent stimuli. Alternatively, learning to say "Hund" in response to L1 "dog" or even to say "dog" in response to "Hund" may suffice to establish appropriate tact control over "Hund" (e.g., Dounavi, 2014), as well as corresponding listener behavior, such as scanning the environment for a dog upon hearing "Hund" (e.g., May et al., 2016). In this case, establishment of a single intraverbal relation between an FL and an L1 vocabulary word produces tact and listener relations involving classes of nonverbal stimuli in the absence of any directly experienced relation between the FL word and the nonverbal stimuli. Exactly how to explain such effects is a matter of theoretical debate that will not be reviewed here. Operationally, however, they might be said to exemplify expansion of existing equivalence classes that include the various nonverbal stimuli and the L1 word (Joyce et al., 1993). Relations that emerge in this manner without being taught directly are usually referred to as emergent or derived relations.

Skinner (1957) suggested an adult's verbal (L1) repertoire contains vast numbers of intraverbal relations in which each verbal response form is controlled by many different verbal stimuli, and each verbal stimulus controls multiple intraverbal responses. Once equivalence relations are established between a multitude of FL and L1 words, intraverbal relations in L1 can likely transfer to the foreign language. For example, once "Hund" and "Katze" are related to "dog" and "cat," the learner might emit "Katze" as an intraverbal response to "Hund" or vice versa under conditions similar to those that evoke corresponding L1 intraverbal relations.

Of course, there are many instances in which an exact correspondence does not exist between controlling variables in L1 and an FL. An English-speaking learner of Icelandic, for example, will find the class of stimuli related to "kanna" to include both stimuli that control L1 "mug" and stimuli that control L1 "pitcher." Such non-correspondences may be even more prevalent in the case of abstract words that have no tangible referents. In these cases, the FL learner may rely on rules, or interactions with native speakers may gradually produce the appropriate stimulus classes via contingency learning. These processes may be slow and imperfect, however—the first author lived in an English-speaking (L2) country for many years before grasping the full range of vessels that control native speakers' emission of "cup."

Grammar and Syntax

Skinner (1957) provided an analysis of grammar and syntax that relied in large part on the concept of *autoclitic behavior*; verbal behavior that serves to adjust the effects of a speaker's other verbal behavior on the listener based on the strength or other properties of variables currently affecting the speaker. As an example, the "I think" in "I think I heard thunder" is a descriptive autoclitic that conveys weakness of control by the auditory stimulus that evokes "thunder." The verbal community reinforces inclusion of autoclitics in verbal utterances because they permit the listener to react more effectively to a speaker's verbal behavior. Applied to grammar and syntax, Skinner (1957) pointed out that these important characteristics of language may be thought of, in part, as serving autoclitic functions. The order in which verbal responses are emitted (i.e., syntax) is a relational autoclitic controlled by relationships between variables currently affecting the speaker's verbal behavior (Table 56.1), serving to fine-tune the effects of the verbal utterance on the listener. Similar functions are served by many instances of morphological inflections.[1] Skinner (1957) emphasized that whereas autoclitic control is the source of grammatical conventions, it need not be present in every grammatical utterance. With experience, responses like "the milk is in the refrigerator" may become functional units under tact or intraverbal control without an autoclitic component. Additionally, Skinner (1957) emphasized that although autoclitic functions are acquired through social reinforcement, it is not the case that every grammatical utterance must be a product of direct reinforcement. Instead, through reinforcement of multiple exemplars, we acquire autoclitic, grammatical *frames* of speech into which novel responses can be inserted as they come to strength (e.g., as tacts).

Numerous efforts have also been made to analyze grammatical behavior in terms of stimulus equivalence, functional equivalence, and contextual control over equivalence classes (e.g., Chase et al., 2008; Green et al., 1991; Mackay, 2013). For example, syntax acquisition has been interpreted in terms of transfer of ordinal functions (i.e., the order in which stimuli are placed) through equivalence classes that roughly correspond to grammatical categories like "subject," "verb," and "object" (e.g., Green et al., 1991).

In addition to the reactions of listeners as a source of reinforcement for verbal behavior, another source of reinforcement that has been proposed to explain the acquisition of some aspects of grammar and syntax (as well as other aspects of speech, such as pronunciation and prosody) is automatic reinforcement by *parity* (Palmer, 1998). Parity is detected when the products of one's own speech sound similar to that of other speakers, and serves as a reinforcing event. Learning to speak grammatically, from this perspective, is similar to learning to pick out a tune on the piano: Attempts that *sound right* are repeated and those that do not drop out. Reinforcement by parity has been used to explain findings such as the effects of modeling on children's grammatical utterances (e.g., Østvik et al., 2012). In the context of FL instruction, parity might be involved in the superior FL achievement observed among students who watch subtitled FL television and films in daily life, compared to those who watch material that is dubbed in L1 (Almeida & Costa, 2014).

Whereas behavior-analytic accounts of grammar emphasize the role of direct-acting reinforcement contingencies in L1 grammar acquisition, FL learning in formal settings likely relies heavily on rules that describe relations between grammatical constructions in the student's L1 and the FL under study. For example, L1 English speakers in a Spanish FL class may be exposed to the rule that in Spanish, the noun comes before the adjective, before they directly contact any social or automatic reinforcement contingencies involving Spanish word order.

Phonology, Reading, and Writing

Unlike the process by which L1 is learned, students learning FL in formal instructional settings are often exposed to reading and writing from the beginning of instruction. When learning languages that use alphabetic or syllabic writing systems, learning FL reading and writing is closely tied to learning the phonology of the FL and can be said to involve acquisition of *duplic* and *codic* (Michael, 1982) verbal relations (Table 56.1). In duplic relations, the product of a verbal response is a copy of the stimulus that evoked it. Duplic behavior includes the *echoic* (Skinner, 1957); in which the speaker vocally reproduces a prior stimulus. Although most FL students likely possess generalized echoic repertoires in L1, the phonology of an FL will in most cases include sounds that do not exist in L1 and the student may not be able to echo accurately without instruction. Another type of duplic repertoire is copying text. When an FL uses the same alphabetical writing system as L1, the FL student is likely to already have a relevant text-copying repertoire that can then be used for prompting additional written responses. However, learning a

[1] In some instances, according to Skinner (1957), morphological inflections may be under tact rather than autoclitic control, as when the presence or absence of the English plural -*s* ending is controlled by the number of objects perceived.

new writing system, such as when an English L1 speaker is studying Arabic, may necessitate practicing copying text. In codic behavior, the form of a verbal response is also under strict control by an antecedent stimulus, but instead of duplicating the stimulus, the response converts the stimulus to a different form. An example is *textual behavior* (Skinner, 1957), in which written text exerts precise control over the vocalizations of a person reading out loud. In FL classrooms, it is common to teach FL phonology in the context of textual behavior and letter-sound correspondences. Learning to spell FL words involves another codic repertoire of *taking dictation* (Skinner, 1957) in which the speaker converts spoken words to writing. Establishment of codic relations, of course, is only a first step toward reading an FL. Reading with comprehension (i.e., responding to text as a listener) also necessitates vocabulary and grammar.

Stimulus equivalence also may be thought of as contributing to acquisition of FL reading and writing. From this perspective, a written FL word ultimately enters an equivalence class together with the spoken FL word, the spoken L1 word, the written L1 word and, if applicable, the nonverbal referent. In a basic stimulus equivalence paradigm, each equivalence class member must be linked to at least one other class member through direct experience. However, once the FL student has acquired codic repertoires with respect to spoken and written words, it should be the case that only one FL stimulus (i.e., either spoken or written words) needs to be explicitly linked to an existing class member in order for both stimuli to join the class.

In the case of logographic writing systems, such as Chinese, learning FL reading and writing is similar to vocabulary learning. Ultimately the student must be able to tact each logogram in both L1 and the FL, and respond as a listener to L1 and FL spoken words by writing logograms. This process can also be analyzed in terms of equivalence class expansion, in which the logogram enters an existing equivalence class that includes L1 spoken and written words and may or may not already include the spoken FL word.

Behavior-Analytic Research on FL Teaching and Learning

As we have outlined, well-studied concepts that include elementary verbal relations, stimulus equivalence, and derived stimulus relations are available to support a behavioral analysis of FL acquisition. Other relevant concepts, such as autoclitic processes applied to grammar, are less well studied (Petursdottir, 2018). Nonetheless, substantial work has historically been done in applied behavior analysis on teaching L1 grammatical functions to children with neurodevelopmental disorders (e.g., Garcia et al., 1973; Guess et al., 1968). We will now turn our attention to the small portion of the behavior analysis literature that has explicitly addressed FL teaching and learning.

To our knowledge, Rocha e Silva and Ferster (1966) were the first to address FL acquisition from a behavior-analytic perspective. They evaluated an automated program for teaching grammatical functions of the German (FL) language to college students who spoke English as L1, drawing substantially on Skinner's (1957) verbal behavior analysis to articulate potential sources of strength for correct responses in each trial. Instruction was conducted in matching-to-sample (MTS) format and presented on a specialized teaching machine. In each trial, the student was presented with a sample consisting of a picture, German text, a spoken instruction in German, or a combination thereof. The student then selected a response from among several textual or pictorial comparison stimuli. Prompts were used when new content was introduced, and later withdrawn. The program began with basic vocabulary instruction and quickly moved to sentence construction, addressing grammar and syntax as new vocabulary continued to be introduced. Pronunciation was not taught directly, as it was assumed that automatic reinforcement by parity would be the primary influence on pronunciation development (p. 95). Progress through the program was, indeed, accompanied by increasingly accurate pronunciation, and after 14–18 h of instruction, the students were able to have simple conversations and write paragraphs of original text.

Roche e Silva and Ferster's (1966) study remains unparalleled as an evaluation of a comprehensive, behaviorally based program addressing essentially all components of FL learning. Subsequent research has focused more on isolated details of the learning process, such as the conditions under which FL tact and intraverbal relations emerge without instruction, and instructional variables in specific FL learning tasks. We will review this research in the sections that follow,[2] beginning with and devoting the most space to emergent relations in FL vocabulary learning, which has been the topic of a majority of all recent studies.

Emergent Relations in FL Vocabulary Learning

Studies on emergent relations in FL vocabulary learning have utilized both verbal behavior and stimulus equivalence frameworks to analyze teaching outcomes. We will begin by considering studies in which instruction has targeted specific FL relations, followed by assessment of the emergence of untaught relations and sometimes interventions to promote that outcome. Next, we will review studies that have examined how the type of directly taught relation influences emergent relations. Finally, we will consider potential benefits of capitalizing on emergent relations in FL vocabulary instruction.

Demonstrating and Promoting Emergent FL Relations

In the first study to examine derived relations in FL vocabulary instruction (Joyce et al., 1993), two English-speaking (L1) adolescents with memory impairment following traumatic head injury received computerized Spanish (FL) vocabulary instruction arranged according to stimulus equivalence principles. For each of 20 target nouns, five stimuli were included in assessment: A picture of the noun referent, the spoken and written L1 word, and the spoken and written FL word. Pre-assessment suggested the participants' L1 repertoires included relations between all nonverbal referents and the corresponding L1 spoken and written words. One participant was also proficient at matching written FL to spoken FL words. However, neither participant could match spoken or written FL words to spoken or written L1 words or to referent pictures. Instruction consisted of MTS conditional discrimination training. For one participant, FL written words served as sample stimuli and referent pictures (four per trial) as comparisons. For the other, pictures served as samples and FL written words as comparisons. Post-assessment revealed 90% or better accuracy for all relations among the five stimuli. This included performance in trials in which the spoken FL word was presented as an antecedent stimulus or requested as a vocal response from the participant, in spite of the spoken FL word not being included in training at all. Today, the approach exemplified in this study is often referred to as equivalence-based instruction (EBI).

In a similar vein, Petursdottir et al. (2008) taught Spanish (FL) nouns to five-year-old children who were native speakers of Icelandic (L1). Written words were not included in instruction; instead, each L2 target word was represented by relations between the referent picture, the spoken L1 word, and the spoken FL word. Although the aim of the study was to investigate emergent intraverbal responding in children, and not to address FL learning per se, we describe it here as a simple example of a study in which some of the trained relations involved vocal responding instead of MTS. Specifically, two of the four participants received FL tact instruction in which they were taught to vocalize each FL word when presented with the referent picture, whereas the other two received MTS listener instruction in which they were taught to select pictures given spoken FL words. All participants demonstrated

[2] To identify studies for review, we conducted a literature search using PsycINFO, Google Scholar, and websites of behavior analysis jurnals, using the keywords "foreign language," and "second language" combined with "behavior analysis" (except on journal webpages). We included all studies that directly addressed a topic related to FL teaching using behavior-analytic concepts and terms.

emergence of two types of intraverbal relations; L1-FL intraverbals (vocalizing the FL word in response to the L1 word) and FL-L1 intraverbals (vocalizing the L1 word in response to the FL word). However, the participants who received tact instruction responded with greater overall accuracy than the participants who received listener instruction.

Several other studies have employed similar methodologies to demonstrate derived relations in FL vocabulary learning, and extended this research to children for whom FL learning was a culturally important goal. May et al. (2016, 2019) taught Welsh (L2 or heritage language) nouns to children residing in Wales who spoke English as L1. In the first study (May et al., 2016), three preschool-age children were taught L1–L2 vocal intraverbal relations, and subsequently demonstrated emergence of L2 tacts and listener relations. In the second study (May et al., 2019), five- and six-year-old children received group-based L2 tact instruction. Three of six participants demonstrated robust increases in both L1–L2 and L2–L1 intraverbal responding, whereas results for the other three participants varied across stimulus sets. In a study by Haegele et al. (2011), participants were Native American pre-kindergarteners who spoke English as L1, but received classroom instruction in an endangered heritage language (Ojibwe for some students and Dakota for others). Computerized MTS instruction was used to teach the students to select both two-digit numbers and written number words in the heritage language when presented with spoken L1 words as samples. Emergent relations were then demonstrated between the numbers and the heritage language number words. Participants who received EBI substantially outperformed control participants from the same classrooms who, meanwhile, received classroom instruction in the heritage language as usual. No relations involving spoken words or vocal responses were tested, however.

Not all studies have shown such consistently positive results. Rosales et al. (2011) taught English (L2) nouns to four preschool-age children who resided in the United States but spoke Spanish as L1. Participants initially received L2 listener instruction in MTS format, following which they showed minimal emergence of L2 tacts, with variable improvement after additional, remedial listener instruction. Next, the researchers implemented multiple-exemplar instruction (MEI) to examine if directly teaching both L2 listener relations and tacts for several new L2 words would promote emergence of L2 tacts for the originally taught words. Although additional improvement was observed, it was not consistent across participants or stimulus sets. Petursdottir et al. (2014) similarly found FL listener instruction did not produce FL tacts and intraverbal relations to criterion for English-speaking (L1) children of preschool and kindergarten age who were taught Japanese (FL) nouns. In Experiment 1, collateral response training (CRT) was implemented as an intervention. CRT involved teaching participants to respond to spoken FL words by not only selecting the corresponding referent pictures, but also echoing the FL word and saying the corresponding L1 word as they pointed to each picture. CRT was followed by criterion-level performance in FL-L1 intraverbal probe trials, but not in FL tact or L1-FL intraverbal trials. Subsequently, direct instruction on all relations with some or all of the target words produced criterion-level performance. In Experiment 2 with three new participants, partial CRT implemented from the beginning of instruction did not increase emergence of tacts and intraverbals relative to listener instruction without CRT. In summary, therefore, both studies found limited effects of listener instruction on the emergence of vocal FL responding in young children, and intervention did not produce consistent improvement.

Teaching procedures in the aforementioned studies involved differential reinforcement of correct responses, combined with prompting and prompt-fading or least-to-most prompting. Other studies have demonstrated emergent FL relations as a result of instruction in which there was no active response requirement or contingency. First, Ramirez et al. (2009) demonstrated emergent Spanish (FL) tacts and listener relations in a child who had simply observed his sibling receive

FL listener instruction. Second, two studies have examined the effects of stimulus pairing procedures in which the teacher models FL tacts without requiring a response from the student. Rosales et al. (2012) used stimulus pairing to teach English nouns to Spanish-speaking (L1) preschoolers who, as in Rosales et al. (2011), were learning English as L2. The number of times each tact was modeled was yoked to the number of MTS trials implemented in the previous study (Rosales et al., 2011). Stimulus pairing increased correct responding in L2 tact and listener probes, and two of three participants reached mastery with some sets of words. Subsequent MEI produced criterion-level performance in most cases. Interestingly, the participants in this study performed better in L2 tact probes after stimulus pairing than did participants in Rosales et al. (2011) after listener instruction. Cao and Greer (2018) also used a modeling procedure to teach Chinese (FL) nouns to preschoolers who spoke English as L1. Tacts were modeled while the participants matched identical referent pictures to one another; however, although a contingency was placed on correct identity matching, there was no requirement to respond to the FL word in any way. Two hours after each session, participants were tested for emergent tacts and listener relations. The participants initially did not perform to criterion or performed to criterion only in FL listener but not in FL tact trials. The researchers then implemented an intervention that consisted of teaching the participants to echo FL syllables. After the echoic repertoire was mastered, performance improved substantially when new L2 words were modeled. Thus, the results suggested an effective FL echoic repertoire might be a prerequisite for novel FL tacts to emerge from modeling alone.

In summary, this literature suggests that for both young children of typical development, and for adolescents with neurological impairment, derived FL vocabulary relations tend to emerge after related relations are taught, with the possible exception that listener instruction has produced inconsistent effects on vocal responding (Petursdottir et al., 2008, 2014; Rosales et al., 2011). They also suggest that, at least with certain prerequisites or learning histories in place, even young children may demonstrate emergent FL vocabulary relations simply as a result of exposure to a model (Cao & Greer, 2018; Rosales et al., 2012). Nevertheless, other research suggests that differential reinforcement is an influential factor in FL vocabulary acquisition in natural contexts (Whitehurst & Valdes-Menchaca, 1988). Additional research may be warranted on the role of response contingencies in FL vocabulary learning for various age groups.

Comparison Studies on Emergent FL Relations

Following up on previous findings (Petursdottir et al., 2008), Cortez et al. (2020) formally compared the effects of FL tact and FL listener instruction on the emergence of L1-FL and FL-L1 intraverbals in children. Participants were of elementary school age, spoke Portuguese as L1, and were taught English (FL) nouns within the study. Each participant simultaneously received listener instruction with one set of stimuli and tact instruction with another. Trials to mastery were variable across participants and conditions. However, the results were consistent in that once mastery was achieved, all participants responded with substantially higher accuracy in intraverbal probes for items on which they had received tact instruction than for items on which they had received listener instruction. In a study with two five-year-old children, Petursdottir and Haflidadóttir (2009) similarly compared emergence of untaught FL relations following instruction that targeted FL tact, FL listener, L1-FL intraverbals, and FL-L1 intraverbals. Listener instruction did not produce criterion-level performance on any untaught relations for either participant, whereas outcomes of FL tact and FL intraverbal instruction were variable. The results of these studies are consistent with a broader literature demonstrating that listener instruction is less likely to produce speaker relations than speaker instruction to produce listener relations for children with neurodevelopmental disorders (see Contreras et al., 2020) and for children and adults of typical development (Connell & McReynolds, 1981).

A number of similarly themed studies have been conducted with adult learners. In a series of experiments with college students, Polson et al. (1997) and Polson and Parsons (2000) compared the effects of teaching L1-FL and FL-L1 intraverbals. The participants spoke English as L1 and were taught French (FL) vocabulary words using a computerized flashcard program. In Polson et al. (1997), the L1-FL intraverbal condition required participants to type the FL word when presented with the corresponding L1 word on the screen, whereas the FL-L1 condition required typing the L1 word when presented with the FL word. Across three experiments, each participant was taught half of the target words in each condition. Following mastery in both conditions, the L1-FL words were switched to the FL-L1 condition and vice versa. This reversal occasioned greater disruption of performance for words originally taught in the FL-L1 condition, suggesting L1-FL instruction produced a greater effect on the reverse FL-L1 relations than FL-L1 instruction on L1-FL relations. Polson and Parsons (2000) replicated this finding, in addition to comparing two different types of FL-L1 intraverbal instruction: topography-based and selection-based. The topography-based condition was identical to the previously described FL-L1 condition, whereas the selection-based condition involved MTS instruction in which an FL word appeared as a sample in each trial and four L1 words as comparisons. After the participants mastered one set of words in each condition, test trials presented words either in the same condition in which it has been taught, or in the opposite condition. All participants scored poorly in initial topography-based L1-FL test trials but with perfect accuracy in selection-based L1-FL trials, regardless of how the word had been taught. Thus, emergence of novel intraverbals depended on the mode of testing more than on the mode of teaching.

In another series of studies with adults, Dounavi (2011, 2014), and Daly and Dounavi (2020) compared emergence of vocal FL tacts and intraverbal relations following vocal tact instruction, L1-FL intraverbal instruction, and FL-L1 intraverbal instruction. Participants either spoke Spanish as L1 and were taught English (FL) nouns within the study (Dounavi, 2011, 2013) or spoke English as L1 and were taught French (FL) nouns (Daly & Dounavi, 2020). The results agreed with the previously described studies in that FL tact instruction and L1-FL instruction were more likely to produce derived relations than was FL-L1 instruction. Finally, W.-L. Wu et al. (2019) conducted a similar study with college students that additionally included an FL mand instruction condition, and tests for untaught FL mands. FL mand and FL tact instruction produced more untaught responding than did either form of intraverbal instruction, and for three of the four participants, mand instruction took the fewest trials to complete.

Overall, these studies suggest the extent to which derived verbal relations are observed in FL vocabulary instruction may depend on which relations are targeted for teaching, as well as on the format of testing. Overall, when vocabulary instruction is approached by selecting specific relations to teach and leaving others to emerge, the greatest degree of emergent topography-based responding may be seen when the taught relations involve participants responding by saying or typing the FL word, as opposed to the FL word simply being presented as a stimulus. Some studies suggest that specifically, tact or mand instruction may be more efficient than intraverbal instruction. Intraverbal instruction, however, may be easier to program for a wider variety of vocabulary targets, such as abstract nouns, prepositions, and conjunctions.

What Are the Benefits of Capitalizing on Derived Vocabulary Relations?

The emphasis on emergent relations in research on FL vocabulary acquisition is in line with an emphasis in modern behavior analysis on harnessing the power of derived stimulus relations to achieve efficiency in teaching (Critchfield, 2018). EBI and similar applications, which have flourished in recent years (Brodsky & Fienup, 2018), capitalize on the notion that teaching effort is saved when teaching a small number of relations generates a larger number of relations "for free." Interestingly, it is not clear from the existing literature if teaching fewer relations necessarily saves effort compared to teaching more relations. Comparisons of EBI with complete instruction (i.e., direct teaching of all possible relations) have favored EBI as the more efficient form of instruction (e.g., Zinn et al., 2015). However, laboratory research comparing stimulus equivalence procedures with complete instruction control conditions suggests efficiency may be influenced by training structure and type of mastery assessment more than by the number of relations taught (Oliveira et al., 2021; Petursdottir & Oliveira, 2020).

In light of these and other findings, it may be reasonable to ask how teaching, for example, FL tacts or L1-FL intraverbals, compares to instruction in which many types of FL relations are taught directly. In part, this information is of interest because the latter approach tends to characterize commercially available FL software applications. To date, only one study (Matter et al., 2020) has compared an EBI approach to FL vocabulary instruction with a complete instruction control condition. Preschool-age children who spoke English as L1 were taught sets of Spanish (FL) nouns through vocal FL tact instruction alone, and other sets through mixed instruction that included FL tact trials, FL listener trials, L1-FL intraverbal trials, and FL-L1 intraverbal trials. FL tact instruction reliably took fewer trials to complete for three of the four participants, whereas mixed instruction took fewer trials for the fourth. When post-tested on all relations, the participants performed just as well with words on which they had only received FL tact instruction as with those on which they received mixed instruction. Thus, capitalizing on derived relations may, indeed, increase the efficiency of FL vocabulary instruction. Additional research with adult learners might be of relevance to instructional software development, and should be extended to more complex networks of relations.

Other Research on FL Teaching and Learning

Besides derived vocabulary relations, several other topics in FL teaching and learning have been addressed in behavior analysis research. The remaining literature is small and scattered, but provides interesting examples of how different topics related to FL teaching and learning may be tackled empirically from a behavior-analytic perspective.

Procedures in Vocabulary Instruction

A number of studies have investigated the blocking effect in FL vocabulary learning with students of various ages. As an example, Solman and Chung (1996, Experiment 1) taught Chinese (FL) and French (FL) words to English-speaking (L1) children under two conditions: In a compound stimulus condition, trials were presented on flashcards that contained both the target FL word and the L1 word. In a spacing condition, the FL word was presented first, followed by the corresponding L1 word. Acquisition was enhanced in the spacing relative to the blocking condition. Other studies in this line of research (e.g., Adepoju & Elliott, 1997; Solman & Adepoju, 1995; Elliott & Adepoju, 1997) similarly suggest that simultaneous presentation of FL and L1 stimuli should be avoided during instruction.

In a study with high school students who spoke English as L1 and were enrolled in a Spanish class, Lloyd (1996) examined Spanish (FL) vocabulary acquisition under conditions of individual and group study with individual and group contingencies. Group study with group contingencies produced the best outcomes. In a more recent field study, Davidson and O'Connor (2019) evaluated the effects of morphological instruction as an intervention in vocabulary learning for elementary school students learning English as L2. Morphological instruction consisted of teaching the students to analyze words into morphemes in order to determine their meaning. The intervention increased all students' vocabulary scores, and generalization was observed to untaught words that shared morphemes with the taught words.

In a different vein, Duan and Cuvo (1996) taught adults who spoke English as L1 to tact written Chinese (FL) characters in English (spoken Chinese words were not taught). In a prototype condition, participants were taught the meaning of the prototype portion of each character along with the L1 translation of the word depicted by the character. For example, the authors explained that the character for "eat" contains a prototype component that has the meaning "mouth." In a rote condition, by contrast, participants learned only the L1 translation but not the prototype. Five of six participants learned faster in the prototype condition.

A number of studies additionally exist in which FL words were taught as examples of previously unknown instructional targets, but the researchers' primary interest was in some aspect of the instructional procedure rather than in FL learning per se. We will not provide a comprehensive review here, but to name examples, in Cengher et al. (2014), the amount of attention children received prior to FL teaching sessions affected the number of correct FL tacts they emitted, and in Haq et al. (2015), spaced learning opportunities produced faster acquisition of FL tacts for children than did massed learning opportunities.

Teaching Grammar and Syntax

Madrid and Torres (1986) taught Spanish negation to preschool-age children who came from homes in which both English and Spanish were spoken, but were not proficient in Spanish (L2). Two instructional conditions were compared with a control condition in a between-subjects design. In the simultaneous condition, trials alternated between L1 and L2 negation, whereas only the L2 trials were presented in the independent L2 condition. Results were in part dependent on the participants' L1 proficiency. Participants who were proficient in L1 acquired L2 negation while maintaining 100% correct responding in L1 trials, regardless of instructional condition. For participants who were not proficient in L1, both conditions increased correct responding in L2 trials, but no participant achieved mastery within the allotted instructional sessions. Additionally, participants who were nonproficient in L1 and received L2 without L1 trials showed a decrease in correct L1 negation responses in test trials as correct L2 negation responses increased.

Sigurðardóttir et al. (2012) used a stimulus equivalence paradigm to teach aspects of Icelandic (FL) grammar to adult and teenage participants who spoke different languages as L1. Participants were first taught a small vocabulary of feminine and masculine nouns. After learning to match both pictures and FL printed words to FL spoken words, conditional relations emerged as expected between the printed words and the pictures. The participants also passed tests in which plural forms of the spoken and written FL nouns were substituted for the original word forms, and pictures containing multiple items substituted for pictures of single items. Later they passed tests for matching singular nouns to pictures of single items, and plural nouns to pictures of multiple items. Contextual control was then established over matching based on gender or plurality. One contextual stimulus predicted reinforcement for matching singular to singular and plural to plural word forms, and another contextual stimulus predicted reinforcement for matching feminine to feminine and masculine to masculine nouns. All participants acquired contextually controlled matching by gender and plurality, with variable generalization to a card-sorting measure.

Teaching Phonology

Shimamune and Smith (1995) used discrimination training procedures to teach relations between written forms and pronunciation of English (FL) words containing consonants that can be difficult for Japanese L1 speakers to discriminate. One participant was first taught, via modeling and feedback, to pronounce FL words containing the target consonants when presented with printed words (i.e., textual behavior). Correct pronunciation increased to high levels, accompanied by a smaller increase in correct selections of printed words when presented with spoken words. The latter repertoire was then successfully taught. The other participant was taught to select printed words when presented with spoken words, and acquisition was accompanied by—indeed, preceded by—increases in correctly pronounced textual responses, even though pronunciation was not taught directly.

H. Wu and Miller (2007, 2012) developed a tutoring package to teach L1 speakers of English to pronounce Mandarin Chinese (FL); a tonal language in which pitch variations can alter meaning. Tutoring consisted of teaching participants to effectively respond to pinyin prompts (i.e., Chinese written in Roman alphabet with tonal symbols), using procedures that included modeling of lip and tongue placement, hand gestures to indicate changes in tone, feedback on pronunciation, and error correction in the form of repeated practice. In a similar vein, Cihon et al. (2013) used a visual phonics system to successfully teach correct pronunciation of printed Italian (FL) words to English-speaking (L1) college students preparing for a study-abroad experience.

Transfer from Classroom to Natural Environment

Washio and Houmanfar (2007) conducted a laboratory study with college students that modeled transition from an FL classroom environment into the natural environment. Stimulus features that tend to be present in instructional contexts (e.g., carefully articulated speech, simple sentence structures, unambiguous word choices) are often less salient in a natural language environment. Thus, to model the transition, the authors gradually decreased the salience of contextual stimuli that controlled the participants' matching of English (L1) and Japanese (FL) words that can have different meanings depending on context. As salience decreased, so did correct matching.

L1 Dominance over L2

In another laboratory study, Houmanfar et al. (2005) modeled L1 dominance over L2. No FL words were taught in this study; instead, nonsense syllables were used as stimuli. The procedure involved establishing contextually controlled equivalence classes in which pairs of classes shared a common member (the referent), modeling L1 and L2 vocabulary. L1 was overtrained relative to L2. L1 dominance was then demonstrated by showing that after exposure to equivalence class disruption, L1 resurged under extinction to a greater degree than did L2.

Future Directions

In summary, applied behavior analysis offers well-studied concepts and methods of relevance to FL teaching and learning, and the field has a long history of considering application in this area. The existing empirical literature is small and somewhat scattered, but provides (a) insights into the applicability of derived stimulus relations and EBI to FL vocabulary instruction, and (b) examples of successful application to various other topics.

Many topics related to FL teaching and learning would be of interest to explore further from a behavioral perspective. Additional research is needed on EBI applications in common language-learning contexts, such as FL classrooms and computer-based FL instruction. Such research additionally should be extended to scenarios that go beyond simple vocabulary learning in complexity, and address grammatical sentence construction and pronunciation, similar to existing commercially available applications. Existing behavior-analytic research on instructional variables in programmed instruction (e.g., Kritch & Bostow, 1998) could also be extended to FL instruction, along with further examination of optimal trial structures and contingencies. Further, understudied conceptual tools, such as autoclitic behavior and automatic reinforcement by parity, could be applied to grammar instruction, and interactions between rule-governed and contingency-shaped behavior might be examined in the context of FL grammar, pronunciation, and vocabulary learning.

In a different vein, the literature on anxiety and lack of motivation as barriers to FL learning might benefit from input from applied behavior analysis. In particular, attention might be given to identifying and resolving these and other acquisition barriers (e.g., faulty stimulus control) for struggling learners whose lack of progress may impede job mobility and earning potential (e.g., immigrant workers). Additional consideration might also be given to the applicability of behavior analysis to other problems of particular social significance, such as language revitalization efforts for endangered languages (Haegele et al., 2011).

Several recent developments in applied behavior analysis may predict a future increase in research and application to FL instruction. First, as previously mentioned, research interest in verbal behavior and derived stimulus relations is on the rise. Second, provision of services to bilingual children is receiving increasing attention in the field (e.g., Kornack et al., 2019), and engendering much-needed examination of how language of instruction—including when teaching language skills—affects acquisition and challenging behavior (e.g., León & Rosales, 2018; Neely et al., 2020). Third, increased emphasis on diversity and cultural competence in the training and practice of behavior analysts (e.g., Fong et al., 2016) may translate into increased interest in cultures, languages, and multilingualism. Because FL teaching and learning are already studied from multiple perspectives, behavior analysts breaking into these areas may need to familiarize themselves with new concepts and literatures. Such efforts, however, could ultimately be rewarded by meaningful contributions to FL and L2 teaching and learning.

57 Teaching Verbal Behavior

Alessandro Dibari, Chiara Caligari, Chiara Vecchiotti, Cristina Pavone, Cristina Citerei, Stefano Assetta, and Daniele Rizzi

A phenomenon may be investigated by varied scientific approaches which differ in the level of analysis chosen and/or in experimental procedures followed. These methods should be considered as parallel and assessed in a non-hierarchical way, that is, they are not mutually exclusive and that none of them can include others. The study of complex human behavior labeled as language also seems to follow this reasoning: there are different structural language classifications; it is possible to examine its shape by observing the smallest unit of sound (phoneme), the minimum linguistic unit with meaning (morpheme), the set of words and their relationships (lexis and syntax) and so on.

By considering, as the main reference text, *"Verbal Behavior"* by Skinner (1957), this chapter will outline the most important elements that represent the behavior analysis of linguistic interactions and the composite relationship between the speaker and the listener. The purpose, however, is not only to describe the systematic ordering of verbal events provided by the author but also to fully understand the revealing character of his work, also offering an examination of the experimental and applied work derived from it. It's the same Skinner who, before going into the presentation of his remarks, lists the traditional formulations that have analyzed the function of language and its learning: biological theories, according to which the language seems to be completely disconnected from environmental variables, such as reinforcement or stimulus control; cognitive theories, for which there is an internal mental activity determined and structurally connected to the perceptive system that accepts, classifies, and preserves verbal information. The new formulation proposed by the behavioral approach analyzes language through its function, avoiding hypothetical constructs that require further explications. Language is a learned behavior under the functional control of environmental contingencies. Verbal behavior is thus defined as any behavior reinforced through the mediation of another per-

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_57

son. This is undoubtedly a definition of verbal behavior of a "descriptive" type (Palmer, 2008): it does not aim to establish an immutable truth, but to discover other aspects of verbal behavior able to enrich its analysis. Therefore, the antecedent variables that stimulate and maintain it are the same that intervene on nonverbal behaviors. At the basis of the study of verbal behavior, there are not words, but *verbal operants*. The noun "operant" is essential: single responses occur only once and exclusively, that is, each is never equal to another, being able to change in form, intensity, energy, and so on. It is, consequently, of primary importance to refer to a principle that allows to associate responses that share some functional properties: the relationship that links responses to antecedent and consequent events. Thus, the operant is a class of responses that is marked by the effects they have on the environment. The consequences are, in turn, those environmental events that allow the identification and selection of a certain class of responses. From this point of view, as already mentioned, in the study of verbal behavior, the unit of analysis is not verbal response (understood as phoneme, word or phrase), but exactly the *functional relation* between the terms of contingency. After all, we can summarize by stating that verbal operants are a classification used to describe different antecedent and consequent conditions in which verbal behavior is emitted. Let's consider the following example of verbal behavior: a little girl does not play with her favorite doll that has been at grandmother's house for five days. She comes to grandma's house, sees the doll, and says: "Doll!," Grandma gives her the doll. The unit of analysis of this communicative episode is not only the word "doll," but a set of different elements: a motivation for the doll, the doll, and the grandma (they are nonverbal stimuli that indicate value and availability of the doll); the request of the doll (the word produced by the little girl) and the delivery of the doll (reinforcing consequence). It is clear that verbal behavior is well-structured. The verbal stimulus can be, alternatively, a response for the speaker and an antecedent for the listener.

The Echoic

Skinner's classification of verbal operants includes the identification of both formal and functional relationships. Formal relationships are determined by correspondence, within a verbal episode, among the constituent parts of the antecedent stimuli and those of the response. It must be taken into account that such a correspondence can vary along a continuum ranging from full form identity to possible degree changes. When the antecedent stimulus corresponds in all its parts (at the beginning, at the center and at the end) with the response, there is a *point-to-point correspondence*: "subdivisions or parts of the stimulus control subdivisions or parts of the response" (Michael, 1982). Moreover, when the stimulus and the response are in the same sensory mode (i.e., both visual and both auditory) and have a similar topography, they then present a *formal similarity*.

Because of many possible combinations with regard to relationships among different verbal behaviors and especially in order to provide a more specific categorization about the properties of verbal operants, Michael (1982) proposed the formulation of two new terms to describe the different relations among those verbal operants that present a point-to-point correspondence between antecedent stimulus and response: they are *duplic* and *codic*. The *duplic* is a verbal operant controlled by a verbal discriminative stimulus with point-to-point correspondence and formal similarity to the response. The *echoic* (vocal imitation), *mimetic,* and *copying a text* are part of the duplic relation. In the echoic relationship, the stimulus is auditory and the response makes an auditory product which is identical from a formal point of view. The echoic behavior is maintained by generalized reinforcement. A child says: "Apple" (or an approximation of it) after he has heard someone pronounce it. The "apple" stimulus said by an adult is the same in all its components to the "apple" response emitted by the child. Another important feature to define a response as echoic is the *temporal relation* between the stimulus and the response. The "later reproduction of speech," which bears a formal correspondence but is under a different stimulus control than the auditory stimulus, is not echoic (Skinner, 1957; Tsiouri & Greer, 2007).

Echoic is a verbal operant that is functionally present during daily conversation and serves an important *social function*, both in early development and in adult life (Ishikawa et al., 2019). Echoic is also called *vocal* or *verbal imitation* (Vladescu et al., 2018; Tarbox et al., 2009) and it plays a fundamental linguistic and academic developmental role, as well as being a very important tool in the attempt to teach verbal behavior (Tarbox et al., 2009; Cooper et al., 2019). Echoic is defined as a behavioral *cusp* (Cooper et al., 2019): if a person cannot echo, the probability of those responses to occur in other verbal operants is quite low (Sundberg & Michael, 2001). The echoic operant is very important for language acquisition, but forms of echoic relationships are also common in the linguistic repertoire of adults (e.g., one can repeat a religious formula pronounced by the priest during a Eucharistic celebration). Beyond that, as Skinner always suggests, echoic relations are also implicated in learning new words in an unknown language or when looking for rhymes or alliterations to write a poem.

Importance of Echoic in Language Acquisition

Echoic is an important target in every educational project, above all because achieving a well-established echoic repertoire can be the "building block" (Carr & Miguel, 2013) to facilitate the acquisition of other operant repertoires by using vocal modeling as a prompting procedure for mand, tact, and intraverbals (Williams & Greer, 1993; Vladescu et al., 2018; Tarbox et al., 2009; DeSouza et al., 2017; Rosales-Ruiz & Baer, 1997; Kodak et al., 2009; Sundberg & Michael, 2001). Getting a "generalized echoic" or a "generalized vocal imitation" (i.e., any vocal behavior in the native language frame that can hypothetically be imitated, Tarbox et al., 2009) can help clinicians to use echoic as a prompt to shape and teach vocal responses with a low-effort teaching procedure. Multiple exemplar training (MET, Young et al., 1994) is a teaching procedure used to systematically program for stimulus and response generalization (LaFrance & Tarbox, 2020) and it has been indicated as "an effective behavior-analytic procedure for teaching echoic repertoires" (i.e., generalized vocal imitation, Kymissis & Poulson, 1990); it has been well studied and "thoroughly disseminated in teaching systems for individuals with language impairment" (Carr & Miguel, 2013). MET allows the clinician to "train sufficient exemplars" (Stokes & Baer, 1977) to make the intervention efficient by determining a lesser number of targets to teach before generalization of untrained words occurs. Exemplars can be presented in a serial multiple exemplar training (S-MET, Eikeseth & Nesset, 2003; Aravamudhan & Awasthi, 2020a) where probes on untrained examples are conducted to test for generalization every time the mastery criterion is reached on the current trained target, or in a concurrent multiple exemplar training (C-MET, Wunderlich et al., 2014; Schnell et al., 2018, Schroeder & Baer, 1972), where more words are addressed at the same time. For example, to achieve the generalized articulation of the blend "sp" into words, the S-MET training is conducted on the word "spugna" (sponge in English), then a second word "spazio" (space in English) is tested, and if the word is correctly articulated, the training is stopped; otherwise, the word is taught and a third word, "spia" (spy in English), is tested; conversely, in the C-MET "spugna," "spazio," and "spia" are introduced at the same time. While MET is a training that presents a single operant at time (i.e., single exemplar instruction, SEI), multiple exemplar instruction (MEI, Greer & Ross, 2007; Guerra & Verdu, 2020; LaFrance & Tarbox, 2020) is a teaching structure where more operants follow each other within the same session, so that echoic instructions are presented mixed with other operants. Effects on echoic have been showed not only to increment accuracy and induce novel responses but also to establish joint control (LaFrance & Tarbox, 2020).

A second aspect is the role that echoic plays in daily conversations: "In a conversation a slightly atypical response is often picked up and passed from speaker to speaker. The two halves of a dialogue will generally have more words in common than two monologues on the same subject" (Skinner, 1957). Ishikawa et al. (2019) investigated the potential communicative function of four autism spectrum disorder (ASD) students' echoic. They taught, in person and through video modeling, a behavior they called "child's echoic conversational response" (also called intraverbal-echoic by Bondy et al., 2004), described as "an individual repeats a peer's topic word with appropriate prosody within 3 seconds." The target response was defined as "echoic" if it included at least the specific topic-related word (e.g., the speaker says "today is really cold," the word topic is "cold," so a correct conversational response may be "very cold"). This skill seems to be effective as a responsive ability during conversation, especially in individuals with high autism severity scores, with little interest in conversation with others: "Responding by echoic behavior permits speakers to react to it in other ways, especially in complicated conversations or directions to be followed […] asking for clarification or for expansion of what the speaker said, and acquiring echoic behavior should give the speaker another opportunity to initiate or react to the previous conversation" (p.2).

Third, echoic is important in establishing "parity" as reinforcing: "Achieving parity is a conceptually awkward sort of reinforcer. It is not a stimulus. It is a particular kind of response, a recognition that one has conformed. It is difficult to measure […]. But although difficult to measure, the reinforcement is real enough." (Palmer, 1996, p.290). When speakers have a good listener repertoire and know "what behavior should look like or sound like," they can detect whether they conform or deviate from typical verbal practices, given that conforming is reinforcing and deviating is punishing (Palmer, 1996). This ability can lead to a self-correction response, where people self-shape the responses that achieve parity with the auditory model.

Applications in the Assessment of Echoic

The echoic assessment goal is to collect information regarding the quality and the strength of the echoic repertoire (Sundberg & Michael, 2001) from small partial units (e.g., a single phoneme) to large units (e.g., a sentence), including non-speech properties such as intonation (Esch et al., 2010a). The assessment aims at establishing and sequencing a language intervention program according to typical language development (Cooper et al., 2019; Dyer et al., 2006; LaFrance & Miguel, 2014). In language development, "earlier" means "simpler" to discriminate and to produce in terms of motor control. An echoic program must be consistent with the current phonetic repertoire and phonological profile. An age-appropriate sound sequence has been proven to be more efficient in teaching vocal imitation to children with language delay and autism (Lim, 2016). Problems can be detected in the stimulus control (i.e., vocalizations are present but are not under the model stimulus control) or in evoking responses that share point-to-point correspondence and formal similarity with the model (Guerra et al., 2019), such as the sounds matching (i.e., the antecedent sounds and the response sounds are the same), the order of the sounds (i.e., the response sounds are in the same order as the antecedent ones), as well as other dimensions which could be overlooked, like co-articulation (i.e., sounds are co-articulated together and not separated), and lexical stress (i.e., the accent is in the correct position within the word). A starting point for those students who do not have echoic control is a *Vocalization Baseline* during *free operant vocal play* 30-sec interval (Esch et al., 2005) where the child is free to play and the clinician phonetically transcribes the quality and the amount of each sound that occurs during that interval (Carbone, 2005). For those students having some echoic skills, some—though few —structured tools (Esch et al., 2010a, b; Carr & Miguel, 2013), are available:

Early Echoic Skill Assessment (EESA, Esch, 2008) is a subtest for the VB-MAPP assessment (Sundberg, 2008) that evaluates speech production on a developmental base in terms of sounds (e.g., vowels, consonants), syllable combinations (e.g., diphthongs, 2-and 3-syllable words, short spoken phrases), and intonation (e.g., prosody of spoken phrases features, such as pitch, loudness and vowel duration).

Behavioral Language Assessment Form (BLAF, Sundberg & Partington, 1998) is a questionnaire asking to indicate, in a Likert-scale based range from 1 to 5, the number that best describes the learner's typical level of performance, among others, of vocal play and vocal imitation.

Kaufman Speech Praxis Test (KSPT, Kaufman, 1998) is "a norm-referenced diagnostic test assisting in the identification and treatment of childhood apraxia of speech," which registers and analyzes echoic responses to identify which sounds or sound combinations are particularly difficult for a child, pointing to a systematic course of treatment.

Motor and Vocal Imitation Assessment (MVIA, Aguirre & Gutierrez, 2019) tests echoic behavior (i.e., vocal play, canonical babbling, non-reduplicated speech, first words) in a hierarchical motor imitative context along with object imitation, body imitation, and facial imitation.

The Overall Speech Intelligibility Rating Scale (Koegel et al., 1998) aims to evaluate the child's production intelligibility and, therefore, how much the vocal productions are comprehensible and consequently can be reinforced by the community.

Echoic Trainings: Inducing and Expanding Echoic Repertoire

No single procedure presented in the literature has been demonstrated to be effective for all individuals. Cividini-Motta et al. (2017), after comparing three procedures (i.e., Vocal Imitation Training, Stimulus-Stimulus Pairing and Mand-Model), showed that the most effective procedure varied among the children involved in their experiment. Therefore, the authors suggested the importance of assessing what procedure is the most appropriate for each subject, also considering the subject's characteristics: "If the first strategy you select is not effective, attempt to use another strategy with the child until you determine what works best." Overall, according to Vladescu et al. (2018), it is important to attempt "to use one of the basic teaching strategies (i.e., Vocal Imitation Training, Stimulus-Stimulus Pairing, Mand-Model) before trying a more complex strategy that incorporates some of the basic strategies (i.e., Chaining, Rapid Motor Imitation Training)." Most of the authors presented interventions based on treatment packages where more than one procedure is concurrently implemented (Eikeseth & Nesset, 2003; Aravamudhan & Awasthi, 2020a). When a package is implemented, it is important to determine if all the components are essential to the intervention (i.e., detailed component analysis), and, if not, how to optimize the package by selecting only those really functional. Individual procedures and their clinical applications are described in detail below.

With students showing no echoic control (Cividini-Motta et al., 2017) and whose vocalization rate is too low to initiate echoic training (Shillingsburg et al., 2015), interventions are based on a strong *manipulation of antecedents*, such as Stimulus-Stimulus Pairing (SSP) and Operant Discrimination Training (ODT), or only on the *manipulation of consequences*, as with Direct Reinforcement and Differential Reinforcement of All Vocalizations, and Shaping.

Stimulus-Stimulus Pairing is a procedure used to "jumpstart vocal behavior" (LaFrance & Miguel, 2014) based on classical conditioning, a neutral stimulus (e.g., the sound "mmmm") produced at a low rate (Miguel et al., 2001) or a novel sound not produced at all (Sundberg et al., 1996), or both of a low rate and a novel sound (Yoon & Bennett, 2000) are repeatedly presented along, or just before, a reinforcer, both positive (e.g., a hug) and negative (e.g., changing the diaper). The neutral stimulus, the specific sound, being established as conditioned reinforcer (Shillingsburg et al., 2015; Sundberg et al., 1996) automatically becomes reinforcing (e.g., the child says "mmmm" also when alone even though nobody gives the child a hug). The effectiveness of the SSP procedure is still debated because results from studies are discrepant (Carr & Miguel, 2013; Shillingsburg et al., 2015), and authors have cautioned care in the clinical application of the SSP procedure. *Operant Discrimination Training* has been presented as an alternative to SSP in establishing sounds as conditioned reinforcers. The ODT procedure presented by Lepper et al. (2013) consisted of a discrimination training between target sounds and non-target sounds. The training teaches students to respond with a discriminative response (e.g., raising one's arm) only to target sounds, which become S^D for the reinforcement, and not to respond to non-target sounds, which become S^Δ. Results in this study suggest that ODT was effective in increasing the participants' target vocalizations, even though effects were similar to those of the SSP procedure. The SSP and ODT procedures through which new stimuli are established as conditional reinforcements, are of current interest for their possible clinical applications but need more research (Holth et al., 2009; Da Silva & Williams, 2020). Finally, the *Direct Reinforcing* of all vocalizations intervention aims to increase the frequency of vocalizations of appropriate speech sounds (Carbone, 2005) by the adult echoing speech-like sounds emitted by the child during play activities (e.g., jumping and singing) while delivering a reinforcement. The adult's vocal imitation, specifically the mother's, has been demonstrated to have a reinforcing effect on the infant's vocalizations (Pelaez et al., 2011a, b; Neimy et al., 2020), as it functions as a contingent social reinforcement. When associated with Differential Reinforcement, these interventions function as shaping procedures that select, by consequences, successive approximations to the final response topography (Lovaas et al., 1966; Marshall & Hegrenes, 1970). Progressive shaping can be slow in its effects (Skinner, 1957) if compared with modeling, especially for a child with a language impairment (LaFrance & Miguel, 2014).

With students who emit vocalizations but do not have echoic repertoire, procedures are essentially based on a manipulation of both the antecedents and the consequences, such as Vocal Imitation Training (VIT), Rapid Motor Imitation Antecedent (RMIA), Vocal Variability (VV) training based on a Lag reinforcement schedule. *Vocal Imitation Training* is the "basic intervention" to teach echoic control (Baer et al., 1967; Lovaas et al., 1966), consisting in the teacher's presentation of a vocal target, waiting for a defined amount of time for the echo by the child (e.g., 5 sec), and reinforcing the correct echoic. When VIT is not effective, other procedures can be implemented based on some behavioral principles, as is the case with extinction for the Lag schedule and behavioral momentum (Mace et al., 1988, 1990; Nevin et al., 1983) for the RMIA procedure. In the *Vocal Variability* Lag reinforcement schedule procedure, each trial began with the experimenter presenting a vocal model and reinforcing every child's vocal response only if different from the former one (i.e., in Lag1) or from a certain number of previous responses (e.g., Lag2, Lag3). This procedure aims at increasing vocal variability and, consequently, the phonemic repertoire, but does not reinforce parity with the model (Koehler-Platten et al., 2013; Esch et al., 2009). *Rapid Motor Imitation Antecedent* (Williams & Greer, 1993; Greer & Keohane, 2006; Ross & Greer, 2003; Tsiouri et al., 2012, Hansen et al., 2019) consists of a rapid and random sequence of three gross motor and three small motor actions (i.e., high-probability responses), with the sixth item always being a small motor action around the mouth (e.g., touch mouth, open mouth or show teeth), followed by the whole word or a pre-established approximation to the word to be echoed (i.e., low-probability response that is already in the child's repertoire, but at a low rate).

There are some other interventions that manipulate both antecedents and consequences and share the characteristic of teaching echoic simultaneously with other operants, as is the case of the Mand-Model (MM), the Echoic-to-Tact procedure, and the Natural Language Paradigm (NLP). The *Mand-Model* (Rogers-Warren & Warren, 1980) is based on EO manipulation to increase both the willingness of the child to participate in training sessions and the echoic behavior itself (Sundberg & Michael, 2001). During the MM training, the vocal target is the reinforcer name (e.g., the adult form of the word, a part of the word, an approximation), which it is echoically prompted to the child who attempts to gain access to it (Cividini-Motta et al., 2017; Drash et al., 1999). Stimulus control is shifted from the EO to the vocal verbal antecedent (Cooper et al., 2019). Similar effective results on vocal production have been achieved using a Mand-Model based on the picture exchange communication system (PECS) (Tincani et al., 2006; Tincani, 2004), on Manual Signs (Carbone et al., 2010), or on Speech-Generating devices (Gevarter et al., 2016; Gevarter & Horan, 2019) concurrent with prompt delay, vocal prompts of closer approximations, differential, and delayed reinforcement. When combined, these procedures have the advantage of safeguarding the communication function of the mand, while a vocal training based on echoic prompts is being carried out. Also, the echoic can be taught concurrently with the tact *(Echoic-to-Tact procedure)* by presenting the vocal model simultaneously with the related object and by reinforcing any vocal approximation response with a generalized social reinforcement and the functional use of the object to play (Löhr & Gil, 2015). Along the same lines, *Natural Language Paradigm* (Koegel et al., 1987; LeBlanc et al., 2006; Gillett & LeBlanc, 2007) is a parent-mediated intervention and consists in modeling the language naturally during play time sessions with preferred toys (Vladescu et al., 2018), thus directly teaching the echoic relation as well as the mand at the same time (LaFrance & Miguel, 2014).

With students that emit sounds under the control of a vocal model, but need to increase point-to-point correspondence, interventions are essentially structured on Modeling and Prompting. Procedures relying on modeling are Phonological Breakdown and Chaining of adult words. With Modeling, differently from Shaping, the clinician manipulates the vocal model (Lafrance & Miguel, 2014) by prompting a simpler form of the target word or by suggesting how to assemble echoic units, thus making the learning process faster (Skinner, 1957). In *Phonological Breakdown* interventions (Kaufman, 1998) what is known about children's natural phonological processes (Dyer, 2009) is integrated to select "word shells" that follow the developmental way (Ingram & David, 1989) through which infants and children learn to speak by moving from a simpler to a more complex form of sounds (e.g., for the target "mama" mm-ah>mah>mah-ah>mom-ah>mahmah> mama, example from Kaufman's Cards) and structures (e.g., for the target "potato" to>tato>potato) (Fee & Ingram, 1982) in order to achieve parity with the adult form of the words. Kaufman's method reduces the occurrence of errors (i.e., errorless instruction) and the response effort (i.e., stimulus demand fading) (Sweeney-Kerwin et al., 2006). In *Chaining*, a multi-syllable word is broken into smaller units such as phonemes, syllables, or group of syllables that are taught as chains (Tarbox et al., 2009; Sloane et al., 1968; Mallory et al., 2019). Tarbox et al. (2009) presented a chaining-like procedure consisting in modeling the first part of the word (e.g., "mun" for the word Monday), reinforcing the correct echo, promptly modeling the second part (e.g., "day"), reinforcing the correct echo, then rapidly modeling the entire word (e.g., "Monday") and reinforcing the correct emission. One possible limitation to these studies is the method used to break words into components. As the authors stated, "no formal rule was used for how to divide one-or three-syllable echoics into two components. Instead, clinicians judged which option sounded the simplest and least awkward" (p.903). Two problems may arise from the divisions the authors made: the first is that a single phoneme like "b," being a plosive phoneme, cannot be pronounced without adding a vowel-like sound (e.g., something like "bo," Gerenser, 2009), thereby altering the word sequence, which becomes something like "bo-all"; a second problem is that word prosody may be altered if the two parts into which the word is broken do not respect the lexical stress—e.g., for the word "Victoria," the correct position of the word stress is on the vowel "o" (i.e., Victória) and this word can be better divided into Vic-toria than Victo-ria. A proposal to investigate in the future could be a *Chaining method based on prosody* in which the word could be divided into two parts that preserve the main stress of the word. Stress is fundamentally based on vowel duration. To respect this rhythmic feature, the two words “patàta” in Italian and “potáto” in English have a stress on the second-to-last vowel; these two words could be preferably broken into “pa-tata” and “po-tato,” instead of “pata-ta” and “pota-to”; in contrast the two words “tàvolo”—table in English—and “yèsterday” have a stress on the third-to-last vowel and could be preferably divided into “tavo-lo” and “yester-day” instead of “ta-volo” and “yes-terday.” As suggested by Desouza et al. (2017, p. 242), “future research should compare the effects of backward versus forward chaining procedures in the acquisition of echoic responses involving one- to three-syllable words,” so it could also be interesting to experiment whether backward chaining may facilitate second-to-last stressed word acquisition (e.g., model “tato”> echoic “tato”> model “po-tato”> echoic “po-tato”> adult form “potato”> echoic “potato”), while forward chaining may result to be more effective for teaching third-to-last stressed words (e.g., model “yester”> echoic “yester”> model “yester-day”> echoic “yester-day”> adult form “yesterday”> echoic “yesterday”).

Procedures based on prompting use within-prompts, extra-stimulus prompts, and response prompts. Vocal imitation itself cannot be physically prompted (Hansen et al., 2019), which means that nobody can physically guide another person to echo. In general, the child who is attempting to imitate vocal sounds is helped by the ability to see the speaker’s mouth (i.e., a strong visual cue), while the speaker is speaking (i.e., the corresponding auditory information), as suggested by Imafuku et al. (2019), but no physical prompts can be helpful if students are not compliant with the request and do not attempt to produce an echoic by themselves. *Within-stimulus prompts* increase stimulus salience, thereby making that stimulus more discriminable. Within-stimulus prompts can include exaggerating some features of a difficult sound (Dyer, 2009; Aravamudhan & Awasthi, 2020b), by altering a distinctive trait (e.g., saying a more plosive “p” in the word “pasta,” a stronger “b” sound in the word “bolle”—bubbles in English), or a supersegmental dimension to increase the sound duration (e.g., saying a longer vowel “i” in the word “bici”—bike in English—“biiici”), as well as exaggerating the intonation or melodic patterns (Gerenser, 2009). Some methods use *Phonetic Hand Cues* (PHC), which are a codified system of hand prompts (i.e., gestures), studied to improve articulator precision when presented as an antecedent or simultaneous prompt (Strand & Debertine, 2000; Skinder et al., 1999). Hand cues are modeled by the clinician, paired with the production of a sound, and, in some cases, also executed by the subject (Kasper et al., 2018). Hand cues can be an example of *extra-stimulus prompts*. *Response prompts* involve the physical manipulation of the child’s articulators which are lips, mouth, and tongue (e.g., lip protrusion to say the sound “j” in the word “jeep”), toward the correct trajectory and movement (e.g., guiding the child’s jaw up and down when saying “mamma”—mama or mom in English-), and using some tools to help the articulators position.

With students who gain point-to-point correspondence, it is finally necessary to obtain fluency. Some authors (Aravamudhan & Awasthi, 2020b; Fabrizio & Moors, 2003) proposed intervention packages that involved *Precision Teaching* (i.e., an instructional approach that measures how the frequency of behavior changes in time by displaying data on a Standard Celeration Chart, Cooper et al., 2019) and *Frequency Building* (i.e., a stage of learning which aims to accelerate the performance rate of correct responding) to speed up the articulation rate and also obtain a fluency outcome.

The Mimetic

Many scholars agree that the first characteristic of the human being is his propensity to imitate the behavior of others (Girard & Doran, 2008). The action of imitating someone else’s gestures is a fundamental act for personal growth and for the evolution of the species, because it offers clear advantages in acquisition, especially in terms of time and energy. By imitating, one also learns the meaning of the context and results of the actions put in place by those who are observing.

Skinner talks about mimetic relation to imitate the non-vocal verbal behavior of another speaker through motor imitation. The antecedent stimulus is gestural (motor) and the response produces a gestural product (to imitate the movement shown): stimulus and response are identical, so the physical movement that constitutes the model to be imitated represents the control variable of imitative behavior. Imitation, however, is a complex act and is almost never governed (if not in the imitation of the simplest actions) by mechanisms of direct comparison between what is perceived and the motor scheme that is put in place. There are many mechanisms that support imitative actions: some of them refer to previous knowledge and/or abilities; others lead who imitates to analyze what does the model. The imitative repertoire also allows the acquisition of new behaviors, especially where communication and social skills are lacking.

Applications in the Assessment of Mimetic

The ability to imitate nonverbal behavior is an essential requirement in the acquisition of communication skills for which a part of mimetic assessment may include an assessment of motor imitation skill (Dequinzio et al., 2007). The main purpose of the evaluation should be to determine whether the child is able to copy the motor movements of others when required.

The first two levels of the VB-MAPP (Sundberg, 2008) allow the assessment of the motor imitation starting from the imitation of big motility with and without prompt, up to the imitation of fine motor movements and actions with more steps. The assessment results may provide important information to help determine whether augmentative communication is needed and what form may be most appropriate for a given child.

The *Motor and Vocal Imitation Assessment* protocol (MVIA) can also provide further information in the mimetic evaluation process, although not specific, as it is an assessment tool that includes tasks of imitating objects, imitation of body movements, in addition to imitation of facial expressions and vocal imitation (Aguirre & Gutierrez, 2019).

ABLLS-R (Partington, 2010) also offers 27 evaluation items of motor imitation skills. Many of the new abilities have been inserted to emphasize the importance of "paying attention to other people's behaviors" and thus assess the reproduction ability of these actions as a model.

Applications in the Teaching of Mimetic

Researches support the association between imitation and social communicative behavior (Ingersoll & Schreibman, 2006). Monitoring behaviors such as paying attention and imitating the behavior of the model form the basis of observational learning (Taylor et al., 2012). The ability to duplicate the actions of others plays a fundamental role in the acquisition of language, social behavior, and generative learning skills (Cooper et al., 2019). Motor imitation is essential to the acquisition of new verbal behaviors and teaching by imitation is one of the most important forms of teaching techniques (Michael, 2004). In addition, a conspicuous generalized imitative repertoire is a behavioral cusp, because it allows a child to easily learn new behaviors without direct teaching or reinforcing history (Rosales-Ruiz & Baer, 1996).

Motor imitation is a valuable tool for teaching sign language to people who are deaf or hearing but unable to speak. A strong imitative repertoire allows a student to immediately use sign language to learn quickly to communicate with others to get what he wants (Sundberg, 2008). Thompson et al. (2007) have shown that sign teaching can build the development of speech language by denying the belief that sign training is obstructive to early vocalizations. These results are also consistent with the results shown by Goodwyn et al. (2000). Two studies by Thompson and colleagues are very interesting: in the first (Thompson et al., 2004), the authors have implemented a sign training that includes delayed physical prompts and differential reinforcement and it was effective in producing independent signs in three children in less than four hours of intervention. In the second (Thompson et al., 2007), they inserted the model as a further prompt within the sign training to capitalize on the emerging imitative skills of participants and the results showed that the training has been effective both for the development of independent signs under new conditions both for the replacement of problem behaviors.

The Mand

In *Verbal Behavior* (1957), Skinner provided also an analysis of how motivational variables play a significant role in a human's acquisition of language and in later verbal functions. Particularly, in the second chapter, he identifies the independent variables in the review of verbal behavior, suggesting that motivation and emotions, as well as aversive situations, have a particular and distinct position with respect to other environmental variables. For example, in teaching a mand, "By reinforcing with candy we strengthen the response *Candy!* but the response will be emitted only when the child is, as we say, hungry for candy" ("Skinner, 1957 p. 31). Consequently, Skinner introduces the concept of mand: a verbal operant in which the response is reinforced by a specific consequence and is under the control of relevant conditions of deprivation or aversive stimulation. The influence of an antecedent stimulus on the response is not enough to evoke it in the absence of a learning history. Water deprivation (which is a motivational variable) will make the water (or other drinks) an effective reinforcement and will evoke some behaviors, such as the mand for water, if these behaviors in the past have produced water. Therefore, what defines a mand is the existence of a functional relationship among motivational operations, response, and a learning history. The specific form of reinforcement for the mand is directly connected with relevant motivating operation (MO), for this we can assert that a mand specifies its reinforcement and it is the only verbal operant that benefits the one who emits it.

There are also some mands which can't be explained briefly by asserting that responses of the same form have been reinforced in the past in similar circumstances: "The dice player exclaims *Come seven!,* for example, even though he has not asked for and got sevens anywhere" (Skinner, 1957 p. 47). According to Skinner these are accidental or superstitious mands: by referring to the previous quote, the dice player can state that there is no connection between his response and the behavior of the dice, but because of occasional consequences, the response retains its strength and he will continue to enunciate it.

Skinner's literary analysis among the pages of poets and writers is also very interesting: they seem to create magical mands that is born by analogy with those already used, but completely new. When a poet exclaims: "Milton, thou shouldst be living in this hour!" (Skinner, 1957 p. 48), this response (a vocative) in past history, has never brought anyone back to life, but with this mand, the speaker openly describes to the reader the appropriate reinforcement for his state of deprivation in that precise circumstance. This exemplifies a general principle: literature is the product of a special verbal practice, since it allows the issue of behaviors that would otherwise remain latent in the repertoire of many speakers.

Applications in the Assessment of Mand

The scientific literature has shown that this skill has a fundamental importance in the early stages of development: it makes the child a speaker, allowing him to control the environment. Mand can be evaluated through various assessment tools, such as the VB-MAPP (Sundberg, 2008), ABLLS-R (Partington, 2010), PEAK (Dixon, 2008), and the Essential for Living (McGreevy et al., 2012) (refer to the reading of Chap. 22, for more).

If the student has a weak vocal repertoire, however, it is important to choose an alternative communication system. *Essential for Living* (McGreevy et al., 2012) provides a system of comparison between skills and deficits in the student's repertoire (motor, visual, auditory skills); it also has specifics characteristics of each communication system and skills needed to use it (e.g., motor imitation in sign language) and some advantages that any alternative communication system retains of speech language (e.g., sign language retains the advantage of being a real language, but has the disadvantage of not having a wide audience). From the consideration of these three levels, it is possible to significantly increase the possibility that the alternative system of communication chosen will be the best for each student. Among the most widely used systems in clinical practice, we can mention the exchange of images (selection-based) and sign language (topography-based). Starting from the student's necessary requirements, Sundberg (1993) pointed out some advantages of topography-based systems over those based on selection. The latter necessarily require a skill of conditional discrimination on the part of the student, they are not portable everywhere and often fail to represent abstract concepts and do not have the characteristics to allow the development of the conversation.

Applications in the Teaching of Mand

One of the first applications to mand teaching is related to the reduction in problem behavior. Many students with autism with a weak repertoire of functional mand may show inappropriate behaviors (such as aggressions, self-injury), as such behaviors frequently lead to the obtaining of favorite objects or events (Hagopian et al., 2001). A specific methodology used for this purpose is *Functional Communication Training* (FCT): this intervention consists of teaching an appropriate communicative response (functional communicative response) with the reinforcements that maintain inappropriate behaviors (Tiger et al., 2008). For example, the child who in the past got the teacher's attention screaming is taught to require attention by calling the teacher's name: he will then be given opportunities to practice the skills and whenever the child calls the teacher by name, she will turn providing attention; on the contrary whenever the child screams the teacher will not provide attention.

The strategies of intervention for the mand teaching must necessarily take into account the critical importance of the motivating operation (MO), because the mand training can be carried out only when the student is motivated for something. Sundberg and Michael (2001) further highlight this concept, emphasizing the need to establish what are termed "pure" mand or responses evoked exclusively by motivating operations and maintained by specific reinforcements, so that the response is under the control of the correct stimulus. In the mand teaching, it is therefore essential that the caregiver is prepared to have control of the motivating operations. This is not always easy, as MO is not fixed, but may vary at different times depending on the levels of deprivation and satiation, but also on the basis of competition with other MO or with the required instructions (Alling & Poling, 1995). To overcome this difficulty, it is useful to use an evaluation of the MO, by observing the free operant behavior in order to *capture* the natural changes in the value of the MO. A further strategy is to manipulate the environment in a way as to alter the value of a consequence and at the same time to *create* an MO for that specific consequence such as an adult presenting to the student a jar of sealed Play-Doh and conditioning as a reinforcing event the opening of the jar. Sundberg and Partington (1998) point out that only after the MO has been contrived, the practitioner can start teaching using prompting strategies to evoke the target response and deliver the corresponding reinforcement after the child has emitted the mand.

In mand training, it is particularly important to teach in the natural environment. In addition to the motivating operations in place, the practitioner can use a nonverbal S^D (e.g., the presence of the desired item), or a verbal S^D, for example to ask: "What do you want?" The prompting strategies may vary depending on the communication system used by the student, for example, echoic prompts for vocal students. It is important, however, to fade the prompt as soon as possible in order to avoid a dependency, while reinforcing differentially the independent responses and providing opportunities for generalization (Cooper et al., 2007).

Indirect Approaches an important part of the literature has provided to more details related to teaching strategies aimed at establishing emerging mands. Among principal currents, there are Stimulus Equivalence and Relational Frame Theory.

Stimulus equivalence: several authors have pointed out the importance of the expansion of verbal repertoires through the formation of derived stimulus relations. Rehfeldt and Root (2005) for example, investigated the presence of derived mand as a result of conditional discrimination training on students with severe disabilities. The AB relation (spoken word-corresponding image) and AC relation (spoken word- written word) were taught to students who requested using the PECS system (Frost & Bondy, 1994). At the end of the training, participants derived the ability to request by selecting the written word corresponding to the desired object. In addition, the ability to match image-word (BC) and word-image (CB) has also emerged in all students and one participant has shown emerging tact skills of images and reading skills of words.

Relational frame theory: The RFT, in its proposal for an analysis of verbal behavior, raises some questions as to how to define mands to obtain new stimuli. Referring to the definition of Skinner (1957), Barnes-Holmes et al. (2000), state that the presence of the valuable stimulus is not necessary for the response to be shown, but it is necessary that in the past the stimulus has consistently followed previous instances of mand. However, this described above does not happen in the case of a mand for a new stimulus, in a condition that excludes generalizations of stimulus, inductions of response, and conditioning processes. A concrete example is provided by the authors themselves, comparing the case of a child who, following direct teaching, learns to say "car" within a toy shop, when he is motivated to get a toy car, with the case of a child who is taught to say "game" in the presence of a multitude of toys, thus building a category, and at the same time learning to require at least one (e.g., after learning that the car is a game, when the adult asks him: "What game do you want?," the child uses the mand "car"). In the second case, unlike the first, the child will not need a direct mand training to make the request for each specific game, as the "toy function" brings together all the stimulus that are part of a coordination frame. Such merging would thus allow generalizing the skill to new stimuli and would be what allows defining the mand as derived. In this context, the authors of the RFT emphasize how the emission of "pure" mand, whose importance has been highlighted, as previously explained, by Sundberg and Michael (2001), is in reality rather rare.

The Tact

In all verbal behavior under stimulus control, there are three important elements to take into account: a stimulus, a response, and reinforcement: it is the well-known three-term contingency. Let's now analyze, in more detail, the verbal response controlled by an antecedent nonverbal stimulus, the *tact*. Consider the following examples: a child pronounces the word "ball" in presence of that object and his mum says: "Yes, it's a ball. Good for you!"; a student gives a name to the relation between two objects of different sizes identifying it with the expression "bigger" and the teacher says: "That's great, right." Although the verbal form of responses takes on in these examples, different aspects, all are united by the presence of nonverbal stimuli as antecedents and by a generalized reinforcement as a consequent event. The word tact, from a terminological point of view, has many elements of contact with what in the common language is defined *to label* or *to name*, provided that the response is emitted in the presence of the object named. In fact, we can pronounce the word "apple" in the presence of the fruit as in its absence, but only in the first case we can speak of tact. For Skinner the tact is a "behavior that *"makes contact with"* the physical world" (Skinner, 1957, p.81). The characteristic that marks this operant is precisely in the presence of a nonverbal variable that acts as discriminative stimulus for the emission of a verbal response. It should be noted that the tact differs from the mand not only because the response is under control of an antecedent nonverbal stimulus, but also because the consequence is not specific, that is, it has no correspondence with the object of the tact itself. While the topography of a mand and a tact may be similar, Skinner confirms that the function of each operant is different and independent. A large number of stimuli may become part of this verbal relationship as antecedents: objects, people, animals, actions. Some tacts are general and have antecedents belonging to very large classes of stimuli (men, animals, plants); other tacts have antecedents belonging to more restricted classes (such as a person's own name). Moreover, the discriminative stimulus which controls the issue of a tact may be represented by physical characteristics of an object (the shape, the color) and by the relation among objects: the word "red" may be pronounced in the presence of a red light, a ruby or a wine; similarly, the placement of two objects on top of each other controls the verbal response "under/over." A response in a tact may be also controlled by less perceptive and culturally elaborate stimulus characteristics, such as when we recognize a writer by his literary style, or we recognize a guitarist by his executive expression. The tact may even be controlled by variables that only the speaker feels such when you have feelings of pain or happiness. A person learns to describe what she perceives and in the presence of a certain sensation (discriminative stimulus) can pronounce the phrase: "I have a stomach ache." The verbal community teaches and maintains the correspondence among environmental events and the expression that describe them: even in the absence of direct access to what a person feels, the correspondence between private events and language is modeled on the basis of other publicly observable events. Skinner refers to the metaphors as extended tacts: metaphors describing internal states commonly refer to properties and events of which everyone may have experienced or are of common observation: "An example of metaphorical extension is provided by the child who, upon drinking soda water for the first time, reported that it tasted like my foot's asleep." ("Skinner, 1957 p.92). It is therefore evident that what Skinner calls tact is a fundamental operant for the acquisition of those processes defined by the author himself as abstraction or learning concepts.

Applications in the Assessment of Tact

The assessment of a child's tact repertoire is primarily for discrete trials. The purpose of the assessment is the analysis of the degree of stimulus control exerted by the nonverbal stimulus on the tacting behavior. As the stimuli become more complex (settings with more stimuli, property of objects, spatial relations between objects), it is possible to observe a stimulus control weakness on the student's response. The purpose of the evaluation is to identify the basic level from which tact teaching can begin. The tact assessment can be conducted through various tools including VB-MAPP (Sundberg, 2008) and ABLLS-R (Partington, 2010).

The VB-MAPP proposes 15 subtest tact milestones organized in three levels of increasing complexity, starting from the tact of a reinforcing object, to possess a repertoire of 1000 tacts including nouns, verbs, and adjectives in the last level.

The "denomination" section of the ABLLS-R (Partington, 2010) proposes 47 objectives starting from the tact of reinforcing objects to arrive at more complex skills such as spontaneously tacting social interaction behaviors (e.g., a child says "Marco is fighting" while watching Marco and Antonio discussing each other) and events (e.g., a child during the party says "this is Marco's birthday"). Among the evaluation objectives are included the tact of emotions and private events of themselves and other individuals.

Applications in the Teaching of Tact

The ability to label objects, actions, property of objects, relationships, and private events is essential to living in society satisfactorily (Hall & Sundberg, 1987). One of the easiest strategies to implement in the teaching of tact is to exploit the repertoire of other verbal operants such as the use of a strong echoic repertoire. The teacher presents the nonverbal stimulus (a car) together with the echoic prompt ("car") and provides differential reinforcement when the student repeats "car"; then, she will proceed with the prompt fading until the stimulus control transfer is completed. Another method of teaching (Barbera & Kubina, 2005) consists in the use of the transfer of stimulus control from matching to sample (to show an example of the item and to ask the student to match, choosing the same item from a group of many items) to the echoic (the student labels vocally after the teacher shows the nonverbal S^D and appoints it vocally) up to the tact (the student labels the nonverbal stimulus vocally).

Braam and Sundberg (1991) comprehensively illustrated the difference between a pure tact and a tact under multiple control. In their study, they examined two procedures for the functional teaching of a tact repertoire to young adults with severe intellectual disabilities and limited verbal repertoire. Tact teaching included verbal prompts ("What is this?"), the correct response model, and one of two types of reinforcement: "specific" and "non-specific." In the condition of "specific reinforcement," participants who properly emit food image tact receive the corresponding edible as reinforcement by placing the response under multiple control (mand/tact). In the condition of "non-specific reinforcement"participants receive an edible other than the stimulus of which they properly emit the tact acquiring the response as pure tact. From the emerged results, the two conditions were equally effective in both acquisition rates and extinction resistance; however, the "specific" strengthening condition produced less latency in the responses, a higher percentage of mand compliance in probe sessions as well as the fact that all participants have shown that they prefer this condition. Teaching verbal operants under multiple control may result in higher compliance and be more rewarding than teaching pure operants, without sacrificing the speed of acquisition and strengthening of the student's response repertoire (Sautter & Leblanc, 2006). In a recent study, degli Espinosa et al. (2020), investigated the effectiveness of a multi-component approach in establishing generalized tacting controlled by multiple sources on two children with autism. In the first condition, an echoic priming has been used to establish the intraverbal control of the fixed term (e.g., "color") on the variable term (e.g., "green") of some autoclitic frames (e.g., "*color* green," "*number* 3," "*it is a* dog"). In the second condition students were taught to produce the tact of the object using an autoclitic frame, in which the fixed part had a formal relation with the antecedent verbal stimulus ("What *color* is it? *Color* green"). In the third condition, discrimination was established in the tact of stimuli with the respective autoclitic frame. Following the intervention, the response of both students was generalized to new members of the stimulus classes and, for a child, to a new stimulus class.

In the literature there are numerous procedures aimed at the development of generative responses involving different verbal operants as well as responses of the listener. Some of these can fall into the categories of interventions multiple exemplar training and multiple exemplar instruction (see Chap. 22 for more).

Stimulus equivalence: Procedures derived from stimulus equivalence theoretical framework are used to produce a wide range of new behaviors without direct teaching. A study in this area is that conducted by Sprinkle and Miguel (2012) which evaluated the use of conditional discrimination (listener) and tact training (speaker) in establishing equivalence classes containing spoken words, images, and printed words with children with autism. During the listener training, relations were taught in the following order: AB (to select image [B] in the presence of the spoken word [A]), AC (to select printed word [C] in the presence of the spoken word [A]) and trials are presented in a mixed way AB-AC. During the speaker training, the following relations were taught: BD (label [D] images [B]), CD (read [D] the printed word [C]) and trials are presented in a mixed order BD-CD. The results of the intervention show the emergence of untaught stimulus classes. While listener training did not necessarily lead to the emergence of speaker skills (BD and CD) and to formation of equivalence classes (BC and CB), speaker training led to the emergence of both the skill of the listener (AB and AC) and the equivalence class (BC and CB). It is possible that during speaker training the auditory stimulus produced by their own response may have acquired discriminative control over the orientation toward the image, which is a form of behavior of the listener.

Naming: Horne and Lowe (1996) define naming as a *higher order operant*, in which the same individual acts as speaker and listener in a bidirectional relationship. An example of naming reported by the authors is that of a child who sees a shoe and labels "shoe" (as a private or public event), therefore he hears himself saying "shoe" and emits a behavior of the listener (e.g., orienting toward the shoe or touching it).

Miguel and Kobari-Wright (2013) conducted a study to determine whether tact training leads to the emerging acquisition of the ability to categorize and whether naming is necessary for acquiring the ability to categorize. The results support previous research (Miguel et al., 2008) and confirm how tact training leads to the emergence of the ability to categorize (matching pictures accordingly to their category). Furthermore, after the tact training (tacting the category of an item), the participants selected the correct image according to the name of the category requested (e.g., the child selects the picture card "elephant" when instructor asks: "Touch an animal"), demonstrating a clear transfer from the speaker to the listener behavior (naming). A participant, however, failed to categorize, acquiring the ability only after requesting the tact of the samples, suggesting that he may not have made the tact of the samples. Based on the analysis of naming, during the task of categorization the student must emit the tact of the sample in a private or public way, so as to produce a discriminative stimulus for the selection of the correct comparison stimulus. The results of the study confirm that categorization depends both on naming, that is, the interaction of the listener's and the speaker's behavior.

Relational Frame Theory: a relational frame analysis of tacting behavior distinguishes between derived and directly taught tacts in the following way. Imagine that a square occasions the response "square" because, in the past, the response has been reinforced in the presence of squares. This is very different from a derived tact, for which no explicit history of reinforcement is required for the tact relation to emerge. In derived tacting, a child may respond with "square" in the presence of a square box, for example, because the box participates in a relational frame with the word "square" and other square objects and explicit reinforcement has never been provided for the tact "square." Imagine, for instance, that the child was taught to tact a box (by saying "cereal box" or "box") and was then told that a box is often square (the word "box," the word "square" and actual square boxes now participate in a relational frame of coordination). As a result, when presented with a square box and asked: "What is this?," the child may produce a derived tact by responding with "square," rather than the explicitly reinforced tact ("box" or "cereal box"). In the natural environment, "box" was explicitly reinforced as tact, but on a subsequent occasion the tact "square" was emitted in presence of a box. Distinguishing between derived and directly taught tacting will help to predict and to control these apparently unexpected behavioral outcomes (Barnes-Holmes et al., 2000).

The Intraverbal

Not all verbal relationships which present a verbal antecedent are characterized by the correspondence described above. Take as example the verbal behavior of a man repeating the alphabet or that verbalizes the address of a person after hearing her name. Skinner calls this kind of verbal relation *intraverbal*, where there is no point-to-point correspondence between the response and the discriminative stimulus that evokes it. A student could say "Rome" when his teacher asks him: "What is the capital of Italy?." An intraverbal response produces a generalized conditioned reinforcement. Skinner provides many examples of intraverbal behavior including word associations (dream, bed, pillow, rest, yawn could be appropriate responses to the verbal stimulus “sleep”); social responses under the control of verbal stimuli (“How are you?” “Fine thanks”); responses that manifests themselves as parts of a chain: (“Ready, set……” “Go”); metaphors (“He is the light of my eyes”) and translations.

Michael et al. (2011) describe how intraverbals result from a history of differential reinforcement and state that, like all verbal behaviors, these responses are not under stimulus control until they are reinforced. The first time a person hears “Ready, set…” and says: “Go!,” the response is not an intraverbal. It will become so after the response “Go” will contact the reinforcement in the presence of the stimulus “Ready, set…”.

Therefore, intraverbal behavior allows the development of a more complex verbal repertoire, because if with the acquisition of mands and tacts the speaker learns respectively to ask questions and to show verbal behavior on an object or event that is present, thanks to the intraverbal he is able to answer questions and talk (or think) about objects and events that are not present. Moreover, intraverbal can create additional opportunities to contact reinforcement through interactions with peers and adults. That is why this verbal operant is a critical component of many other aspects of human behavior, such as memory, thought, problem solving, creativity and other academic skills.

Applications in the Assessment of the Intraverbal

The *VB-MAPP Intraverbal Assessment Subtest* (Sundberg & Sundberg, 2011) is an assessment tool based on the typical development of intraverbal behavior and consists of the presentation of tasks with increasing difficulty. The assessment starts from the evaluation of simple stimulus, as for example to give some animal sounds (e.g., “the cat says…”); next comes verbal conditional discrimination (VCD). The latter becomes progressively more complex, with the addition of qualifying verbal stimuli (modifiers) such as adjectives, prepositions, pronouns, conjunctions and more articulated concepts (e.g., negation, time, position).

Sundberg (2016) classifies verbal stimuli that evoke intraverbal behavior in four different types of discrimination. In *simple discrimination* a single verbal component evokes a response (e.g., a speaker says “meow” after hearing “a cat says…”). In *compound verbal discrimination* several antecedent verbal stimuli independently evoke behaviors. When, however, these S^D are presented in the same configuration of the previous stimulus, they assume a different function (e.g., a speaker says “blue” after hearing “red, white and…”). In *verbal condition discrimination*, the antecedent consists of two verbal stimuli, in which one S^D alters the evocative effect of another S^D (e.g., a speaker answers “spoon” after hearing “*What* do you *eat* with?). Finally, in *verbal function altering discrimination*, a verbal stimulus alters the function of another stimulus or MO (e.g., “when I call your name, sing your part”) (Schlinger & Blakely, 1994).

Applications in the Teaching of the Intraverbal

To avoid intraverbal behavior from becoming a “rote” response, there are a variety of prerequisites that the students must have before starting with teaching, such as tact and listener (Sundberg & Sundberg, 2011). Among the numerous proposals for teaching intraverbal behavior, Aguirre et al. (2016) confirm the effectiveness of stimulus control transfer procedures in the intraverbal teaching in a direct way and their effect in facilitating emerging intraverbal repertoires in people with and without disabilities.

Direct Teaching the guidelines for direct teaching of intraverbal behavior involve the use of stimulus control transfer strategies (Ingvarsson & Le, 2011; Goldsmith et al., 2007; Kisamore et al., 2013). Prompting and prompt fading strategies that can be used in teaching, include the use of verbal operant already present in the student's repertoire, such as tact, echoic or textual. Some authors (Ingvarsson & Le, 2011), compared three types of prompts in order to verify which could be more effective. Although participants show better performance using an echoic prompt, the results can be considered inconclusive, as they disagree with another similar study by Ingvarsson and Hollobaugh (2013). A possible explanation for this is suggested by the authors of the articles themselves and corroborated by Coon and Miguel (2012), who confirm that, in all probability, there is no hierarchy of effectiveness between types of teaching prompts. What is really important would be familiarity with a given prompt, namely having had greater exposure to it in one recent learning history. A further factor to emphasize in the intraverbal direct teaching is the passage from acquisition to fluency. On the basis of the principles of precision teaching, in fact, Johnson and Layng (1996) say that some skills, including especially the intraverbal, must necessarily be fluent, in order to lay solid foundations on which to build more complex skills. Emmick et al. (2010) confirm this theory through the demonstration that an intraverbal training condition with the addition of fluency training is more effective than simple intraverbal training in the maintenance and acquisition of new responses.

With the increase in the complexity of the intraverbal training, Ingvarsson et al. (2016), finally suggest the effectiveness of block trials procedures, especially when other types of approaches fail. This procedure involves the presentation of stimuli in blocks of trials, in which the same question is asked (e.g., "What do you eat?," "What do you eat with?") until the criterion is reached (e.g., 4 blocks of trials with a maximum of 2 errors per blocks). Afterward, the trial blocks are reduced (e.g., from 10 to 8 consecutive correct answers) until the presentation of the questions in a random order.

Indirect Teaching indirect approaches include all those currents that have developed teaching strategies aimed at ensuring that intraverbal behavior emerges in a derived way from other training. It is possible to distinguish three main currents: that of stimulus equivalence, that of bidirectional naming and that of relational frame theory.

Stimulus equivalence: Sidman defines stimulus equivalence as a direct result of the reinforcement contingencies (Sidman, 2000) in those specific cases where there are conditional stimuli, that is, where the type of contingency present is at least four terms. The stimulus equivalence paradigm provides for the teaching of a small set of stimulus-stimulus relationships that led to the *emergence* of relations not directly taught between the stimuli in question (Zaring-Hinkle et al., 2016). The strategy used in teaching aimed at bringing out derived responses is called Equivalence-Based Instruction (EBI). Through this tool the potential of teaching increases exponentially, on the basis of the principles of reflexivity (A equals A), symmetry (If A equals B, then B equals A) and transitivity (If A equals B and B equals C, then A equals C). From the direct teaching of at least two relationships between stimuli can be obtained many more in a derived way. Thus, time and effort are reduced. In teaching intraverbal behavior this approach has made a great contribution, as it lays the foundations for the construction of a generative repertoire.

Widely validated results come from that part of literature that has used the prerequisite of the tact within EBI strategies aimed at bringing out intraverbal responses. The procedure provides that, after learning the correct response based on a conditional stimulus between the AB and AC relationships, derived intraverbal responses emerge (May et al., 2013; Ordonez, 2019). For example, after teaching to respond in the presence of the image of a tree and in the presence of the conditional stimulus "in the English" with the response "tree," and in the presence of the same image and the conditional stimulus "In French" with the response "arbre," the result is a series of emerging responses, such as the "arbre" response to the question "what do you call tree in French?." In agreement with May et al. (2013) it is evident how the fact of including in the educational sequence all three experimental stimuli (in the example: [A] image, [B] tree and [C] arbre), facilitates the emergence of new responses beyond those directly taught.

A new current of research has instead applied the approach of EBI to the emerging teaching of intraverbal responses through the use of other intraverbals. This implies all stimuli that make up the equivalence class are vocal stimuli (Zaring-Hinkle et al., 2016). In one study (Perez-Gonzales et al., 2008, as cited in Zaring-Hinkle et al., 2016), the vocal stimuli included were related to states, cities and parks. Two intraverbal relations between these stimuli have been taught directly, for example, "Buenos Aires is a city of Argentina" and "El Botanico is a park of Buenos Aires," from which all the other intraverbal relations could emerge in a derived way, for example, "El Botanico is a park in Argentina."

The emergence of so derived intraverbal relations has been further supported by the achievement of positive results not only through *Linear Series* strategies (LS), that is, by teaching the AB and BC relationships, as in the example shown, but also trough *One-To-Many* strategies (OTM), that is, teaching AB and AC and *Many-To-One* (MTO), teaching BA and CA (Zaring-Hinkle et al., 2016).

Carp and Petursdottir (2012) have pointed out the importance of some prerequisites necessary for such a strategy to succeed, such as those of the multiple control of the stimulus. The authors showed how the use of an exemplar training (e.g.: "Tell me one State; tell me another") and a category training (e.g., "What is Buenos Aires?"), where this ability is lacking, is necessary and sufficient for the emergence of derived intraverbal relationships, when these don't come up on their own. In addition, DeSouza et al. (2019) confirm the importance of some prerequisite skills already described by Sundberg & Sundberg (2011), for the emergence of convergent intraverbals (e.g., "A mammal from the savanna is…"): multiple tacts (e.g., "Name it," "it is a…," "this is from…"), multiple listeners (e.g., "point to all mammals"), intraverbal categorization (e.g., "Tell me some mammals") and listener compound discrimination (e.g., "Point to the mammal from the savanna").

Intraverbal bidirectional naming: Horne and Lowe (1996) define naming as a higher order operant behavior, consisting of a bidirectional relationship between the speaker's and listener's behavior. The teaching of only one of these components is sufficient to acquire both. Intraverbal bidirectional naming (Horne & Lowe, 1996), is a type of naming in which *matching to sample* (MTS) training contingencies can establish bidirectional intraverbal relationships among specific names. The latter, in turn, mediate the correct response on a subsequent test of stimulus equivalence. For example, when a student is taught to select an image of a triangle in the presence of a star, he can intraverbally connect the stimuli by saying: "The star goes with the triangle." In subsequent trials, the responses of the participant to the MTS test can be verbally mediated when he labels the sample saying "star," a response that automatically will evoke the previously learned relationships, namely that the star goes with the triangle, that controls the behavior of selecting the correct comparison (e.g., image of triangle) (Santos et al., 2015).

Santos et al. (2015) assessed whether intraverbal training is effective in performing MTS tasks in college students. In the first experiment, it was assessed whether the participant were able to match arbitrary visual stimuli (AB) after learning to tact the two classes (A and B) and connect them intraverbally (e.g., "A goes with B"). Following tact training and intraverbal training, all participants carefully matched the stimuli and emitted the taught intraverbals, showing how the conditional relationship between A and B can only be established trough intraverbal naming. In the second experiment, it was evaluated whether the same training would produce the bidirectional intraverbal in the form of "B goes with A" and MTS performance consistent with the principle of symmetry (BA). The results showed that intraverbal training AB (A goes with B) is sufficient to produce new intraverbal bidirectional (B goes with A), but also to perform MTS performance consistent with the principle of symmetry (BA). Hence, stimuli that are intraverbally linked can be replaced by others, such as when seeing or hearing one member evokes the other's selection or tact.

Relational frame theory: RFT uses multiple exemplar training (MET) extensively in order to offer broad opportunities for generalizing skills that require an increasing discrimination of the stimulus, ultimately useful for conversation development. RFT revisits the subject of arbitrary relations and highlights that these relations are based not only on equivalence relations but also on non-equivalence ones. The equivalent relations, in fact, as the word itself emphasizes, are based on the concept of similarity, but in reality, a large number of stimulus relations are based on non-similarity (Barnes-Holmes & Hayes, 2003). Therefore, in considering all types of relationships derived indirectly from experience, the RFT proposes an extension of the vocabulary in place for the description of the same (Hayes & Wilson, 1993). Then, it includes the concept of symmetry within a wider class defined as *mutual entailment*, which incorporates all emerging relations of a bidirectional, similar, opposite, comparative, space-time or casual type. Relations of mutual entailment result both those derived after learning that A is equal to B and therefore B is equal to A, but also those derived from learning that A is different from B and B is different from A. Even more interesting are those derived relations of comparative type, which are necessarily configured as asymmetric. For example, learning the concept that a tree is taller than a bush, the emerging bidirectional relation will be that a bush is lower than a tree. Even the concept of transitivity is inserted within a class called *combinatorial entailment*, in which the relations emerging from the link between two stimuli with a third stimulus in common cannot be based only on the concept of similarity or interchangeability. For example, once you have learned the concept that the word "employment" and the word "work" are the opposite of the word "rest," it emerges, in a combinatorial way, that "employment" is equal, not different from "work." In addition to this reclassification of existing derived relations, the authors of RFT also point out the importance of reconsidering the *transfer of function* process, characteristic of the equivalent classes, classifying it as a specific case of the wider process of *transformation of stimulus function*. In the previous example, we can easily deduce that if "employment" and "work" can acquire the same function, the word "rest" will assume exactly the opposite function, by virtue of the type of relationship between such stimuli.

The relationships described, although they define different types of what Hayes calls "relational frames" do not explain the process, but only the outcome. The relational frames are in fact real "generalized operants," the construction process of which is represented by the whole history of reinforcement contingencies that have led to the formation of certain relational responses that are under contextual control (Hayes et al., 2001). Unlike Sidman, however, the relations derived as a result of this process are not a "side effect" of the implemented teaching, but the main goal. As a consequence of the principles set out above, this alternative perspective proposes the distinction for each operant described by Skinner between verbal and nonverbal responses, where among *nonverbal* there are all those learned by direct teaching in an isolated way, whereas *verbal* responses include all those that, at different levels, involve a transformation of the function of the stimulus in accordance with a specific relational frame (Barnes-Holmes et al., 2000). In the context of intraverbal behavior, the RFT therefore makes a clear distinction between what is defined as nonverbal and verbal intraverbal. When any intraverbal response is taught in isolation and then separated from other words or specific events, in fact, it does not become part of any relational frame. Consequently, it is configured as an intraverbal response that has no point-to-point correspondence or necessary formal similarity with the antecedent verbal stimulus, but is not verbal. On the contrary, when an intraverbal response is connected with other words or with specific events, it automatically becomes part of a set of relationships that allow that same response to be defined as verbal (Barnes-Holmes et al., 2000). For a clearer understanding, we refer, in conclusion, an example reported by the above-mentioned authors: a parrot is taught to respond to the instruction "count up to three" with the response "one, two three," with direct reinforcement. In this case the response is separated from any relational frame and is therefore configured as nonverbal. The same identical response becomes verbal when connected not only to the antecedent stimulus in question, but also to a series of other stimuli that make the response part of a specific relational frame. In our example, the numbers one, two and three can be part of a comparison frame that including the concept that two comes after the one and before the three.

The Codic: Reading Text

After fully defining the echoic behavior, Skinner introduces *textual behavior*: "a familiar type of verbal stimulus which controls verbal behavior is a text" (Skinner, 1957 p.65). More commonly, the printed text is the visual control variable of text behavior, called simply reading. According to the same author, the reader is "a speaker under the control of a text."

Michael introduces the term *codic* to refer to responses controlled by a verbal stimulus with presence of point-to-point correspondence in the absence of formal similarity between stimulus and response, including precisely the reading and the behavior of writing under dictation. In reading, in particular, the stimuli that control behavior are visual (in a sensory mode), while the response is auditory (in another sensory mode), but the auditory response corresponds to visual stimuli.

A text can also be presented in the form of images and in that case the reading will simply consist of emitting an appropriate vocal form for each image; or we can have pictograms, hieroglyphics, phonetic symbols or Braille. Moreover, in reading, printed stimuli can be explicitly named or "covered" (silent reading). If the stimulus control is not accurate, there will be faulty textual behaviors, which is an incorrect reading.

Application in the Teaching of Reading

In the application area there are several approaches based on experimental methods, although unfortunately there is not much research. DeSouza et al. (2009) developed a research program, based on a variation in the matching-to-sample procedure, which starts with teaching simple words with sequences of consonants and vowels (bad, fan, nap), followed by the teaching of more complex word sequences (breads, chair, snake); at the same time the children also learned to read the same words. Always starting from a matching to sample procedure, Miguel et al. (2009) first taught some children with autism to select printed images and words, and then the participants, without further instructions, were able to read the written words aloud.

These studies show that textual behavior can be established indirectly through educational procedures that promote derived relations between printed words, images and dictated names; this is especially important when one of the goals is to optimize the time spent teaching. On this subject a study by Hopewell et al. (2011) uses a treatment package based mainly on the use of direct instruction together with flashcards, to increase reading skills in two primary school students with severe behavioral problems. Results showed that the independent variable led to an increase in the correct student responses and improved fluency and compliance with teachers (thanks in part to the application of the token economy), beginning to consider reading an easier task to accomplish.

The Duplic: Copying a Text

Until now we have only considered the vocal verbal behavior in which the speaker produces an auditory response that is reinforced when it has an effect on the listener as an auditory stimulus. But according to definition of verbal behavior that we explained initially, when a speaker produces a visual response with similar effects, the behavior in question is also verbal. Since writing can also be counted as verbal behavior, another relationship between antecedent stimulus and the response must be considered. Skinner calls it "copying a text," translated more simply as *copying*: the antecedent stimulus is visual (the text to be copied), the response is written (the copied text) and the reinforcement is generalized. The same author explains this verbal operant in a meaningful way, through two comparisons that also involve echoic behavior: "just as echoic behavior approaches mimicry, so what we may call copying approaches drawing" (Skinner, 1957 p. 70). The final reinforcement always depends on the correspondence between the response and the stimulus, but in copying could lack the correlation among the motor acts that reproduce the text and those that generated it, just as there could not be the correspondence between the two graphic signs. On this subject, Skinner states that the repertoire of behaviors required to copy a text can produce different visual forms from the antecedent stimulus.

Teaching Applications to the Copying

The verbal operant of copying a text, although is one of the most important skills, has been the subject of little research from an applicatory point of view. In one study, DeSouza et al. (2009) implemented matching to sample procedures to teach copying skills. In detail, in the mentioned study, a group of letters ("A," "B," "D," "R," "C"), was presented to the subject at the same time as the sample stimulus (the written word CAR) and then asked to "build" a word identical to the sample. Obviously at the time when the stimulus was represented by a printed word, the task required was essentially to copy.

Typically, in the context of education, having a repertoire that allows you to copy a text is a basic skill in text writing or rather is precisely a precursor behavior of independent writing. More specifically, in the process of teaching/learning a foreign language, copying a text has probably been one of the most used strategies in the past and its effectiveness has been the subject of several studies. Some authors (Uda & Sasaki, 2010) argue that copying a text in L2 (a language that is learned after the acquisition of mother tongue) can allow improving spelling in general, acquire new communication skills and learn basic vocabulary. In today's teaching method, however, hand-copying has often been replaced by the use of multimedia tools within an e-learning teaching, in which students and teachers communicate within a collaborative virtual environment. It seems, therefore, that there is a gap between manually copying and the exclusive use of multimedia devices to improve learning.

A very interesting study (Miyake & Owoku, 2012) demonstrated that it is possible, within an e-learning teaching method, to introduce the verbal behavior of copying a text, with positive results, regarding the learning of a foreign language. Some Japanese students were asked to manually copy what was proposed on the screen of a laptop, related to the lexicon and some aspect of English grammar. It has been shown that by copying by hand, students have acquired more easily words or phrases in L2, the percentage of correct responses has increased compared to the acquisition obtained copying not by hand but typing to the laptop. It must be said that it was not measured if the effectiveness of copying a text has changed depending on the language ability of the students.

Undoubtedly this verbal operant also becomes in the domain of application a strategy to be used to achieve additional goals and skills, such as the understanding of a text: copying a text can represent the first educational step to comprehend what we read, especially in the presence of specific learning difficulties.

The Behavior of the Listener

The listener is an important part of the contingency that governs verbal behavior. Skinner defines the listener as a discriminating stimulus for the speaker who constitutes an audience for his own verbal behavior.

> The listener is again a discriminating stimulus. He is part of an occasion upon which verbal behavior is reinforced, and he therefore becomes part of the

> occasion controlling the strength of behavior. [...] We may speak of him as the audience. The audience, then, is a discriminating stimulus in the presence of which verbal behavior is characteristically reinforced (Skinner, 1957 p. 172)

The effects of listener behavior on the speaker's behavior can be multiple: for example, if the listener constantly looks at the speaker, nodding or praising him, he will undoubtedly be a social reinforcer; on the contrary, if he constantly shakes his head looking elsewhere, it will have a punitive effect; the listener who answers to the speaker's requests will act as the mediator of the reinforcement. A verbal discriminatory stimulus can evoke echoic, intraverbal, and textual responses even in the listener who becomes a speaker in his turn.

Applications to the Teaching of the Listener Behavior

The use of a taxonomy of verbal behavior, based on Skinner analysis, has emerged in the planning of interventions for children with autism or other intellectual disabilities since the 2000s. Historically, even within the behavioral analysis, language was distinguished into *receptive* or *expressive*. The first curricula of intervention based on the UCLA model (Lovaas, 1977, 1981), suggested as a priority the intervention, starting with the teaching of the receptive language before inserting a formal training for the expressive language on the same targets previously taught (e.g., learn first to touch the image of a dog and then to name it). Although these recommendations are part of some operational manuals of intervention (Leaf & McEachin, 1999; Lovaas, 2003; Taylor & McDonough, 1996), the results derived from the literature suggest instead how starting from the teaching of listener skills does not necessarily encourage the development of responses as a speaker and how it is more likely that it is the acquisition of speaker responses to facilitate the emergence of listener responses (Contreras et al., 2020; Cuvo & Riva, 1980; Petursdottir & Carr, 2011; Delfs et al., 2014). Teaching programs of listener skills, based on a Skinner's analysis of verbal behavior, suggest instead to start from teaching answers as speakers (e.g., mand, tact, or intraverbal) and then to assess the issue of listener responses, or possibly teach the listener skills along with the responses as a speaker on the same stimuli (Barbera, 2007; Greer & Ross, 2007; Schramm, 2006; Sundberg & Partington, 1998). One of the first skills usually included in an ABA intervention program for children who have not acquired responses as a listener contacting natural environmental contingencies (e.g., attention from the audience as conditional generalized form of reinforcement for the behavior of following simple instructions) concerns responding with a nonverbal behavior to verbal S^D presented by a speaker (e.g., touching a ball when someone asks "where is the ball?"). In the literature there are mainly two ways to establish these first responses as listener: the simple-conditional method and the conditional only method. A *simple discrimination* is characterized by a three terms contingency: antecedent, response, and consequence. Responses contact the reinforcement if they are emitted in the presence of the antecedent stimulus and not in its absence (Green, 2001). An example of a simple discrimination is to follow simple instructions (e.g., to respond as a listener to the instruction "raise" or to touch the image of a ball when it is the only image present and after receiving the instruction "ball"). A *conditional discrimination* (also called manded stimulus selection, Michael, 1985) requires a four terms contingency: a sample stimulus, the presentation of comparison stimuli, a nonverbal response, and a consequence (Grow et al., 2011). An example of conditional discrimination consists in selecting an object (e.g., a glass) in the presence of other objects (e.g., a plate and a spoon) and of a verbal stimulus (e.g., "reach me the glass?"). The verbal stimulus presented momentarily makes one of the objects an S^D and other objects S^Δ.

Using the *simple-conditional method,* we start with the teaching of simple discriminations through mass trials. For example, in a set of three images, initially the correct answer is to select always the image 1, while images 2 and 3 never represent the correct answer; then the correct response always requires the selection of image 2 and not of images 1 and 3, and finally the selection of image 3. In the following phases of the intervention, we arrive at a conditional discrimination among the stimuli identified as targets, with all three stimuli that in rotation represent the correct response (Leaf et al., 2017; Lovaas, 2003). With the *conditional-only method*, instead, you start directly teaching a conditional discrimination (also called auditory-visual conditional discrimination) presenting two or more nonverbal stimuli (e.g., images or objects) which in rotation represent the correct response and a specific verbal stimulus for each target (called auditory conditional discriminative stimulus) to evoke the correct response (Kodak et al., 2015). The reader is suggested to read Chap. 15 for more information.

Comparing the two modes of teaching, the conditional-only method is easier to promote the acquisition of responses under correct stimulus control and reduce the probability that patterns of errors may develop during the acquisition phases, resulting also a more efficient teaching method when compared to the simple-conditional method (Green, 2001; Grow et al., 2011, 2014; Vedora & Grandelski, 2015; Lin & Zhu, 2020). Given the relative complexity of showing answers that provide for an auditory-visual conditional discrimination, it may be advisable to evaluate the presence of other simpler skills that can be characterized as pre-requirements for acquiring this response class. For example, Kodak et al. (2015) investigated the correlation among matching skills, visual discrimination (touching one between two images produces reinforcement, touching the other image does not produce reinforcement), auditory discrimination (to show a specific response in the presence of a sound and not in its absence), imitation of pointing, and scanning on the acquisition of responses from listener that required conditional discrimination. In seven of the nine participants in the study, the authors found a correspondence between the presence of these skills and the acquisition of responses as a listener. Despite proper teaching of these skills, additional curricular changes or training may be required to allow the acquisition of target responses under the control of the correct environmental variables (see Grow & Leblanc, 2013 and Lamarca & Lamarca, 2018, for a review).

For example, it is possible to insert a differential observing response (DOR) in the early stages of teaching (Dube & McIlvane, 1999), asking the student to show a response that demonstrates the sensory contact with the sample stimulus (e.g., after receiving the instruction "Touch the house" the child repeats "house" as echoic or mimetic). Another important part of the teaching to be carefully controlled is the prompting and fading mode, since the way in which the prompt is supplied, such as the tone of the voice used or inadvertently looking at the object to be selected, could lead to the development of faulty stimulus control (over selectivity). For example, in a study on the identification of the best strategies to establish an initial repertoire of auditory-visual conditional discriminations, Fisher et al. (2019) used an identity-match prompt (an image identical to the correct comparison) as a prompt to increase the probability that participants respond to the correct comparison. After the presentation of the antecedent stimulus ("touch the apple") and after having requested a DOR (e.g., "repeat apple"), in case of error in the selection, the experimenters showed an image identical to the correct image to be selected (e.g., image of an apple) to evoke the target response.

During the intervention, the complexity of the stimuli controlling listener responses is gradually increased by requiring increasingly specific responses for different configurations of the preceding verbal stimulus. For example, a greater difficulty of responses is required in the presence of antecedent *compound verbal stimuli*, that is, when the same response is controlled by two or more antecedent stimuli or by more elements of the same stimulus, as in the selection response of an empty container during a work activity within a supermarket, in response to the instruction of a work colleague "pass me an empty container" (Eikeseth & Smith, 2013). This type of response is under convergent multiple control exerted by all components of the antecedent stimulus, which together control the selection response (Michael et al., 2011). To issue the correct response, it will be necessary to respond as a listener to both parts of the verbal S^D, with a discriminative response controlled by the salient characteristics of the antecedent stimuli (full or empty container). The training usually involves initially the isolated teaching of listener responses for the different antecedent stimuli in isolation (e.g., responding as listener to the antecedent "container" and separately to the antecedent "empty") and then the presentation of the compound stimulus. The complexity of the previous stimuli is gradually increased by inserting more components into it (e.g., "Pass me a small yellow empty container"). A further level of complexity is given by listener responses for which a conditional discrimination is needed, where the presence of one or more verbal stimuli alters the function of other verbal stimuli (Catania, 2007; Michael et al., 2011; Eikeseth & Smith, 2013). Skinner (1957) uses the phrase "If your name is Charlie, stand up!." In this example, the first part of the verbal stimulus (if your name is Charlie) alters the function of the second part of the verbal stimulus (stand up) transforming it into a S^D or a S^Δ based on the listener's learning history (i.e., if he is called Charlie or in a different way). The literature has shown how it is possible, through specific intervention procedures, to teach responses as listener that require a verbal conditional discrimination l (e.g., "Find a sea animal" vs. "Find a savannah animal") and how the acquisition of such responses can facilitate the emergence of other verbal responses under multiple control (e.g., intraverbal or tact control) (DeSouza et al., 2017, 2019).

Despite the currently available teaching technology, it is impossible to teach explicitly and with discrete trials all possible components of the language. The research investigated the possible mechanisms underlying the emergence of untaught responses and generative language (Greer & Ross, 2007). Over the years, three different theoretical currents have developed to identify the possible mechanisms responsible for the generative language: Stimulus equivalence (Sidman, 1971), Naming (Horne & Lowe, 1996) and Relational Frame Theory (Barnes-Holmes & Roche, 2001). From these three different conceptual currents, united by the attempt to explain the same process, different strategies of intervention have derived. For example, the presence of Naming is demonstrated when, from the direct reinforcement of a listener response, as the behavior to bring a chair to an adult in response to S^D "Bring me a chair," also emerges a response as a speaker (a tact) of the same stimulus, such as the response "it is a chair" to S^D "What is that?," together with the presence of the chair, without the same response being directly reinforced. In the same way it is possible that direct reinforcement of responses as a speaker produces the emergence of responses as listener. More recently, the term Bidirectional Naming (BiN) has been used to identify the integration of both listener and speaker behavior (Miguel, 2016). During typical interactions between a child and his caregivers there are frequent opportunities to respond with listener behavior to verbal stimuli. For example, a mother can indicate a bird to fly and say: "Look there's a bird!." The child will then orient himself toward the bird receiving attention (a conditioned social reinforcement) from the mother. With the emergence of echoic responses and after a generalized reinforcement learning history for such responses, it is possible that the child will show, overtly or covertly, echoic responses in response to the speaker's verbal stimulus and in the presence of the nonverbal stimulus that controls the listener's response (the bird), thus also showing a speaker's response (the tact of nonverbal stimulus "bird") that will contact generalized reinforcement because shown in the same episode with the response as a listener. As a result, nonverbal stimulus can become an S^D for a response as a speaker (tact) (Miguel, 2018). Likewise, when the mother asks the child, "Do you know what this is?" indicating a dog, the child will show the tact of the nonverbal stimulus ("It is a dog"!), but at the same time also a listener response, moving toward the stimulus. Several studies have shown that the BiN can be established through teaching procedures that provide for the use of multiple exemplars (MEI), favoring the emergence of responses not taught directly (Lowe et al., 2002, 2005; Gilic & Greer, 2011; Greer et al., 2005, 2017; Olaff et al., 2017;

Delfs et al., 2014). It has also been suggested that it is necessary, for the development of BiN, that the child's behavior is sensitive to sources of conditioned social reinforcement (e.g., comments and smiles) (Greer & Du, 2015). In clinical practice, it may be useful, when such sources of control are not established by natural contingencies, to use specific procedures to make social responses conditional reinforcements (Olaff & Holth, 2020). A further possible clinical indication during the teaching of the first skills as listener during the DTT could consist, for example, in requiring a collateral echoic response (or DOR) of the salient component of the verbal stimulus presented by an instructor (e.g., to ask the child the echoic response "ball" as part of the instruction "touch the ball") and in requiring the same response when selecting the correct image (e.g., to issue the vocal response "ball" while selecting the image of a ball) (Horne et al., 2004; Miguel & Petursdottir, 2009; Petursdottir & Carr, 2011). Then you could test the emergence of responses as speaker after teaching direct responses as listener.

Similarly, Lowenkron (1984, 1988) suggested that the presence of responses of mediation may encourage the emergence of complex responses and how such responses are often under multiple control by different stimuli. For example, a listener response can be emitted under the simultaneous control of two different sources of stimulus control and then emerge as an effect of joint control exercised by the interaction between tact and echoic responses. The listener response will then be issued through the mediation of verbal responses. Imagine a child who has to respond for the first time to a complex instruction like "Go to your room and get your backpack and your jacket!." It is possible that the child shows, overtly or covertly, echoic responses of the salient parts of the instruction received (e.g., backpack... jacket...). When these self-echoic responses are shown in the presence of the corresponding nonverbal stimuli (e.g., the child repeats backpack and jacket in its presence) and then issued as a tact of the same nonverbal stimuli, an increase in response strength, or "saltation," (Palmer, 2006, 2009) occurs as a result of the introduction of the second of the two discriminative stimuli. The control exercised by the jump in the strength of the response establishes nonverbal stimuli such as S^D by evoking the response of selection (the child takes the backpack and the jacket). In accordance with a mediated stimulus selection account, as described by Joint Control, it is possible to explain the emergence of listener responses for which there is no past history of direct reinforcement and therefore to encourage the emergence of new responses without the need for formal teaching. Several studies have assessed the effect of teaching procedures using Joint Control as an independent variable (see Ampuero & Miklos, 2019 for a review). For example, Causin et al. (2013) used procedures based on the joint control analysis to teach selection responses (select multiple pictures from a larger set) mediated by verbal responses without the need for formal teaching for the specific selected target. Vosters and Luczynski (2020) used similar procedures to teach three children with ASD to complete novel two-step instructions to generalize and maintain acquired skills. In addition, these authors performed a component analysis of joint control to demonstrate how both sources of joint stimulus control and verbally mediated responses are needed to explain the results obtained, in line with previous results of transnational researches on the same topic (Clough et al., 2016; Degraaf & Schlinger, 2012; Gutierrez, 2006; Sundberg et al., 2018).

Skills as a listener, of course, are not limited to following a simple instruction or discriminating a simple command. The role of the audience within a verbal episode is much more complex, as the listener mediates reinforcement for the speaker's behavior, determining the future probability of a given response. For example, the use of a technical language will be more likely if you speak to professionals or the use of the Italian language will be more likely in the presence of people who speak Italian. In addition, within a conversation, the listener exchanges his role with the speaker, becoming in turn speaker and showing verbal behavior mediated by the audience present at that time (Michael et al., 2011).

Listener behavior may be affected by the speaker (Palmer, 2005, 2007; Schlinger, 2008). Let's take as an example the behavior of buying the latest album of a new rock band because a friend of ours told us that they play great music. This listener behavior (later transformed into a speaker behavior at the time of purchase) is not explainable by direct contingencies that could increase the probability of buying the new album (the rock band album has never been heard before). A possible hypothesis is that the speaker's verbal behavior has transformed the function of some stimuli (music store, new album) into discriminative stimuli and reinforcements and that such stimuli have entered equivalence classes with other stimuli (e.g., the new album with excellent music) bypassing direct reinforcement contingencies (Schlinger & Blakely, 1987; Sidman, 1994; Hayes et al., 2001). It is also conceivable that the listener is not "passive" agent within the verbal episode, but instead shows an active role as a covert speaker (Palmer, 2005, 2014) through possible mediation responses composed, among others, by echoic responses and responses under intraverbal control of the speaker's behavior, which allow discriminatively to respond to both verbal and nonverbal stimuli (Dugdale & Lowe, 1990; Miguel et al., 2008; Randell & Remington, 2006).

In recent years, researchers have investigated the underlying mechanisms of acquiring skills from complex listeners and proposed specific teaching strategies, taking into account skills such as to respond properly in the presence of metaphorical language (Persicke et al., 2012) or sarcastic (Persicke et al., 2013), to respond to implicit requests (Najdowski et al., 2017) or to respond to a disinterested listener during a conversation (Peters & Thompson, 2015). Among these more advanced abilities is also included the ability of perspective taking or "Theory of Mind" (see Peters & Thompson, 2018 for a review of applied studies and Schlinger, 2009 for a theoretical account). These new areas of research show that the contribution of the Skinner's analysis of verbal behavior is fundamental not only to explain relatively simple phenomena but also extremely complex responses without the need to use conceptual explanations from other disciplines.

The Autoclitic

So far, we have seen how it is possible to outline a taxonomy of verbal relationships on the basis of the environmental events that precede and follow verbal behavior. However, not all of them fall into the categories described: there are complex verbal relationships in which linguistic expressions are ordered in precise sequences or base themselves on the possibility of transforming such sequences into others, thus changing the effect that a sentence has on a listener. This particular relation of transformation and organization of the verbal event is defined autoclitic by Skinner: according to him, it is not a unique class of verbal relationships, but illustrates the functional characteristics of five subclasses that he calls descriptive, qualifying, quantitative, manipulative, and relational autoclitics. The event that controls the emission of descriptive autoclitics may be part of or coincide with that which controls the emission of the primary response, like the word "I hear" in the phrase "I hear Dad coming"; or originate in the subject's private sphere or emotional state as "I'm happy to...." *Descriptive* autoclitics arise from the discrimination of one's verbal behavior and for this reason they are probably implicated in what we call self-awareness (Catania, 1980); *Qualifying* autoclitics modify a tact or an intraverbal to alter the intensity or direction of the listener's behavior. In this category, Skinner includes terms that indicate affirmation or negation (Yes! No!) or the term "as" used in similarities. *Quantitative* autoclitics include article and undefined pronouns. Autoclitics can fulfill their function of changing the behavior of the listener as a function of obtaining a specific response from the listener, because they offer the speaker the possibility of manipulating a sentence in such a way as to relate precisely the elements that compose it: Skinner identifies in the *manipulative* and *relational* autoclitics such verbal relationships. The first ones include correlation expressions as if....then, or vice versa, while in relational autoclitics there are many grammatical mechanisms, such as gender distinction (masculine/feminine) and number distinction (singular/plural).

Autoclitic behavior is defined as secondary verbal behavior that depends on primary verbal operants (e.g., mands, tacts, echoics, and intraverbals) (Skinner, 1957). Within a verbal episode, the presence of autoclitics has the function of "clarify or alter the effect of verbal behavior upon the listener' '(Skinner, 1957, p. 332). For example, in the phrase "I am sure that Alessandro is bald," the part "I am sure" (descriptive autoclitic) describes the force of the primary verbal operant, (the tact "Alessandro is bald") modifying the listener's reaction accordingly, with a greater tendency to consider as certain the statement of the speaker when compared to the phrase "I think Alessandro is bald." The source of reinforcement for the autoclitic response will be an increased communicative effectiveness (Carr & Miguel, 2013).

When autoclitic responses take on a constant structure through several examples of verbal responses, we talk about *autoclitic frames*, or *intraverbal autoclitic frames* (Palmer, 2017). In autoclitic frames some parts of the statement remain constant, while other parts vary at the same time depending on environmental variables, which control the speaker's behavior. For example, in a relation "X is larger than Y," the autoclitic frame "is larger than" remains constant while the two terms in comparison vary. When autoclitic frame is controlled by different stimulus conditions and used in different verbal episodes, contributes to the generative language and to the use of verbal forms that do not need formal teaching.

Given that autoclitic behavior depends on other verbal behavior and is not emitted in isolation from the primary verbal operants, during a teaching program it is necessary that the latter are acquired before using strategies that encourage the emergence of autoclitical responses and usually the same responses are not taught directly. For example, Cengher et al. (2019) have favored the emergence of autoclitic responses by exploiting extinction-induced variability in their teaching procedure, not reinforcing simple mand (without autoclitics, such as "cookies") in favor of mand with autoclitic frames (e.g., "I want cookies please"). Luke et al. (2011) have used procedures based on multiple exemplar instruction (MEI) to promote the abstraction of spatial autoclitic frames (e.g., under, over, and on top) in children with autism and language disabilities. Speckman et al. (2012) have operated similar strategies to induce abstraction of the frame "-er," such as "bigger" or "happier" as comparative forms of "big" and "happy." Other studies have investigated the use of modeling for passive voice teaching (Wright, 2006; Østvik et al., 2012; Dal Ben & Goyos, 2019).

In their study on establishing generalized multiple controlled tacting to children with ASD who showed responses under restricted stimulus control, degli Espinosa et al. (2020) have used autoclitic frames matching the verbal antecedent stimulus, teaching a specific frame for each specific verbal antecedent (e.g., responding with "It's a X" to the verbal antecedent "What is it?" or with "Color x" to the verbal antecedent "What color is it?" for the same nonverbal stimulus).

Autoclitic frames could also be used for teaching very complex skills such as perspective taking, in order to facilitate the discrimination between the source of control of own behavior and the behavior of a third person specifying the sensory mode through which you enter or do not enter into contact with a certain stimulus (e.g., I know information because I see/feel/touch it while a third person does not know it because he does not see/feel/touch it).

In addition, autoclitic frames play an important role in the development of grammatical structures within a language, representing the fixed part of a sentence or verbal form, while other sources of motivational, contextual, or audience variables control for the variable part of verbal behavior (Palmer, 2014, 2017). These combinations of fixed and variable parts of the language are also practiced and acquired through automatic reinforcement and automatic shaping of the speaker's verbal behavior, which can set and modify its verbal behavior to match the verbal behavior of the verbal community (see the concept of achieving parity, Palmer, 1996).

In conclusion, it seems that the possibility of a human being to fully participate in his community life is directly linked to the development of his verbal behavior. Communicating one's needs, describing one's external and internal environment, and imitating and responding as a listener to the verbal behavior of others are inextricable behaviors in the development of every human being. Skinner's analysis of verbal behavior (1957) makes this clear and the scientific evidence confirms it. Similarly, the role of verbal behavior in complex behaviors such as remembering, problem solving, making inferences, responding to nonliteral forms of language such as irony and sarcasm and more seems central. The corpus of scientific research that demonstrates it is growing and Skinner's analysis is still and will be a source of guidance and inspiration for current and future trends.

Acknowledgments We thank Dave Palmer, Vincent Carbone, and Nicole Rodriguez for their helpful suggestions in the preparation of this chapter.

58 Vocational Skills for Individuals with Autism and/or Intellectual and Developmental Disabilities: Implications for Behavior Analysts

April N. Kisamore, Noor Y. Syed, Todd A. Merritt, and Lauren K. Schnell

Much behavior analytic research has been directed toward early intervention of individuals with autism spectrum disorder (ASD) and less emphasis has been placed on preparing individuals with ASD and intellectual and developmental disabilities (IDD) for the workforce (Hurlbutt & Chalmers, 2004). Many adults with ASD and/or IDD remain underemployed or unemployed after completing high school (Howlin & Moss, 2012; Shattuck et al., 2012; U.S. Department of Labor, 2020; Winsor et al., 2018). When these individuals are employed, their job quality and earnings are often lower than that of their neurotypical peers (Burgess & Cimera, 2014; Howlin 2000; Howlin et al., 2004; Winsor et al., 2018). Behavior analysts have the skills to create meaningful changes in the lives of individuals with ASD and/or IDD by better preparing them for employment and supporting them in these employment activities. Employment not only allows an individual to contribute to the community but also allows for greater autonomy. Individuals who are employed can contribute to their own financial support (Cimera & Burgess, 2011; e.g., buying their own groceries, paying their own bills) and pursue their own interests (e.g., going to the movies, dating, buying video games). In this chapter, we will guide readers through each stage of workforce development and readiness, speak to the law regarding vocational training and services for adults with ASD and/or IDD, provide an overview of research related to teaching necessary workplace skills, and make recommendations for clinical practice and future research.

Transition from Childhood to Adulthood

As students with ASD and/or IDD progress through the educational system, they and their caretakers may face challenges beyond that which neurotypical students and their families face. To assist with these challenges, the United States Department of Education (U.S. DOE) enacted the Individuals with Disabilities Education Act (IDEA, 2004). The IDEA (2004) is a law that ensures all children with disabilities receive a free and appropriate education (FAPE) and emphasizes access to special education and related services designed to meet their unique needs and prepare them for further education, employment, and independent living. Although many neurotypical students and students with disabilities may not seek out vocational opportu-

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_58

nities while in school, IDEA (2004) mandates that "transition services" are a part of a student's Individualized Education Program (IEP). Transition services, as outlined by IDEA (2004), refer to a coordinated set of results-oriented activities for a student with a disability that are focused on improving the student's functional achievement with the goal of facilitating movement from school to post-school activities (e.g., vocational education and integrated/supported employment). IDEA (2004) further stipulates that transition planning is based on the individual child's needs, taking into account their strengths, preferences, and interests and includes instruction, related services, community experiences, the development of employment, and other post-school adult living objectives and, when appropriate, functional vocational evaluation. Although IDEA (2004) does not specify how this planning is to be implemented, it does mandate that appropriate measurable postsecondary goals, related to training, education, employment and independent living, be based upon age-appropriate transition assessments. Planning must be started no later than the first IEP meeting that occurs once the child turns 16 years old.

In an effort to provide further guidance around the transition planning process, the U.S. DOE (2017) published "A Transition Guide to Postsecondary Education and Employment for Students and Youth with Disabilities." This guide states that a student's IEP must be developed by a team that includes the student's parents, at least one special education teacher/provider, a representative of the public agency, and, whenever appropriate, the student with a disability. Additionally, states and school districts, along with the student and the student's family member or representative, are to determine the most appropriate types of transition assessments based on a student's needs (U.S. DOE, 2017). The National Technical Assistance Center on Transition (NTACT, 2016) recommends the use of informal and formal transition assessments that involve some combination of paper and pencil tests, structured student and family interviews, community or work-based assessments (situational), and curriculum-based assessments. The NTACT also recommends that transition assessment information be gathered in the following four categories: (a) academic, (b) self-determination, (c) vocational interest and exploration, and (d) adaptive behavior/independent living. Additionally, the assessment process seeks to answer the following questions.

- Who am I?
- What are my unique talents and interests?
- What do I want in life, now and in the future?
- What are some of life's demands that I can meet now?
- What are the main barriers to getting what I want from school and my community?
- What are my options in the school and community for preparing me for what I want to do, now and in the future?

Following completion of the transition assessment process, the student's team is responsible for developing measurable postsecondary goals. Mazzotti et al. (2009) recommend person-centered planning for beginning the process of developing these goals. Members of the planning team need to be well-informed about the student's abilities, needs, and available services (U.S. DOE, 2017). To help facilitate the person-centered planning process, all members of the team should practice compassionate care, which includes interpersonal skills such as active listening, collaborating with caregivers, understanding a family's culture, being kind, asking open-ended questions, avoiding technical jargon, and caring for the entire family (Taylor et al., 2019). Through the person-centered planning process, the team should consider three questions:

1. Where is the student going to work or engage in productive activities after graduation?
2. Where and how is the student going to continue to learn and/or develop skills after graduation?
3. Where is the student going to live, and how are they going to access adult services, participate in the community, and have fun after graduation?

Measurable postsecondary goals are observable, describe an explicit skill or task for the individual to complete, and occur after high school graduation (Mazzotti et al., 2009).

After the measurable postsecondary goals have been identified, transition services that will help the student achieve these goals must be considered (Mazzotti et al., 2009) and may include a particular course of study, related services, community experiences, and possible instruction in daily living or other life skill domains. Lastly, the team develops annual IEP goals that align with the postsecondary goals and relate to the student's transition service needs, including how to access or complete the transition services.

Workforce Readiness: Post-21

As mentioned previously, it is critically important to engage in transition planning while completing secondary education. It is also vital to continue support of workforce readiness skills with transition-aged individuals. Research suggests that only 53% of youth with ASD worked after high school, holding at least one job between high school and their early 20s, compared to 63% of those with intellectual disabilities, and 89% with emotional disorders, learning disabilities, and speech-language needs (Roux et al., 2020a, b; Winsor et al., 2018). Hiersteiner et al. (2016) reported that only about 15% of adults with IDD were engaged in integrated and paid employment in the community and about 20% were engaged in paid facility-based work; the majority of adults (nearly 44%) participated in unpaid facility-based activities. In addition to underrepresentation in the workforce, data indicate that the majority of individuals diagnosed with IDD tend to work in part-time, entry-level positions with lower income compared to their neurotypical peers and have more limited access to benefits (National Core Indicators, 2017). However, data support that individuals with IDD, estimated to be about 2.5 million Americans (Equal Employment Opportunity Commission [EEOC], 2013) 19.1, express a desire to fully participate in the workforce with a growing expectation to be gainfully employed following formal education (Winsor et al., 2018).

The Americans with Disabilities Act (ADA, 1990, 2008) is a U.S. federal law prohibiting discrimination against individuals with disabilities, such as those who have impairments that significantly limit major life activities, have a history of a significantly limiting impairment, or are regarded as having a disability. Title I of the ADA covers employment under state and local government employers, as well as for private employers with 15 or more employees. While this section will review protections under ADA, it should be noted that Section 504 of the Rehabilitation Act and many states have additional protections, some of which may pertain to private employment with fewer than 15 employees.

The task of enforcing employment protections under ADA falls to the Equal Employment Opportunity Commission (EEOC), which oversees when an employer asks an applicant, employee, or family member questions about IDD, types of accommodations, and safety concerns. The EEOC is also concerned with how employers ensure no harassment in the workplace based on disability. All individuals who qualify should be made aware of their rights and protections. Some of these are as follows.

During the application process:

- An employer may not legally ask a job applicant about their medical conditions, if they have taken any special education classes, or if school records indicate a disability. Employers may ask whether the applicant can read and organize in a systematic manner (i.e., alphabetically or numerically).
- If an applicant discloses they have a disability, the employer may ask if accommodations are needed.

After an employment offer is given:

- An employer may now ask questions about health and disability, and they may require a medical examination, so long as all applicants for the same position are treated equally.

- A job offer may not be withdrawn if the applicant is able to perform the essential functions of the position.

During employment:

- Should performance problems appear and there is a reasonable belief that essential employee functions are not being met, an employer may ask for medical information including whether the employee has previously been diagnosed with a disability.

Accommodations:

- Applicants and employees are entitled to reasonable accommodations in the application and interview process, as well as during employment. These may include reallocation of marginal tasks, modeling, vocal verbal rather than written prompts, allowing additional time, task analyses, and visual prompts. Documentation may be required if an accommodation is requested; employers are not required to grant every accommodation request but must make a reasonable effort to accommodate at least some. In a scoping review, Khalifa et al. (2020) found successful accommodations to include reducing noise, outlining predictable job responsibilities, and minimizing distractions.

Safety:

- An employer may refuse to hire or terminate an employee with IDD if the employer believes they pose a direct threat, defined under ADA as posing a significant risk of harm to the individual or others that cannot be addressed through reasonable accommodations. The employer is required to collect objective, factual evidence of threat.

It should be noted that employers are required to keep all medical information confidential and must actively engage in practices to prevent harassment and discrimination. Should any of these rights be violated under state or local governments, or within a private organization, individuals with IDD, or a third party, must file a charge of discrimination with the EEOC by mail or in person typically within 180 days from the date of the alleged violation. If the violation occurs under the auspice of a federal government, the individual should contact an EEO counselor within 45 days from the date of the alleged violation.

Research strongly suggests that building trust between an employer and employee from the onset of the working relationship is critical for success in the workplace for individuals with IDD (Khalifa et al., 2020; Migliore et al., 2018). Additionally, training employers about ASD and IDD might increase interest in hiring and maintaining employment of individuals with ASD and/or IDD (Khayatzadeh-Mahani et al., 2020). Accommodations should be flexible and vary in intensity as needed; finding tasks or jobs that are the right fit for one's interest are also vital in building support.

Assessment Information

Assessment plays an integral role in the evaluation of an individual's current level of functioning and serves to assist in the selection of functional skills related to successful job performance. More so, assessment may assist in identification of appropriate vocational placements for adolescents and adults with ASD and/or IDD. Similar to the ways in which assessment aides clinicians in identifying academic skill deficits (e.g., Verbal Behavior-Milestone Assessment Placement Program; VB-MAPP, Sundberg, 2008), function of behavior (e.g., Functional Analysis, Iwata et al., 1994), or hierarchies of preferred items (e.g., Multiple Stimulus Preference Assessment; MSWO, DeLeon & Iwata, 1996), *functional-skill assessments* can be used to aide in identifying specific strengths and individual preferences required to be successful in job placements. Results of these assessments can be used in setting objectives and developing curriculum linked to terminal goals required for individuals with ASD and/or IDD to perform at their jobs.

Functional skills that are important for vocational success include independent problem solving, how to log in and out of a work clock, and performance on job-related tasks (e.g., lifting heavy objects, answering phones, following directions). Functional-skill assessments are typically indirect assessments involving interviews with caregivers, surveys completed by the individuals with ASD and/or IDD themselves, and direct observation of performance of job-related tasks. The *Assessment of Functional Living Skills* (AFLS; Partington & Mueller, 2012) serves to evaluate functional skills among adolescents and adults with ASD and/or IDD (LaRue et al., 2016).

The AFLS, is a criterion-based assessment tool, tracking system, and curriculum consisting of six assessment modules designed to evaluate an individual's performance of functional skills across *Basic Living Skills, Home Skills, Community Participation Skills, School Skills, Vocational Skills, and Independent Living Skills.* The AFLS is designed to be administered by caregivers and/or clinicians and information is typically obtained through direct observation of the individual in the natural setting, caregiver report, and contrived performance-based measures (LaRue et al., 2016).

In addition to the AFLS, practitioners interested in administering functional-skills assessments can also search their statewide agency for *vocational-rehabilitation assessments.* These vocational-rehabilitation assessments are typically administered by *Vocational Rehabilitation Counselors,* with the goal of providing supported employment to individuals with disabilities. Although the discussion of each of these statewide vocational-rehabilitation assessments is outside the scope of this chapter, we do recommend the reader see their *Vocational Rehabilitation Office* for more details (Employer Assistance and Resource Network on Disability Inclusion; EARN, 2020).

Weaknesses in *job-related social communication skills* (e.g., asking for help, notifying a supervisor when a task is completed, responding correctly to feedback) constitute an additional barrier to employment for individuals with ASD and/or IDD. In fact, research suggests that problems with job-related social communication skills may be an even greater barrier to employment than job-specific skills such as those mentioned previously (Chen et al., 2015). With this in mind, Lerman et al. (2017) employed an assessment to identify job-related social communication targets for intervention in the workplace. The assessment consisted of presenting a variety of job-related social communication skills and measuring whether participants engaged in those skills. The requirements included *confirming statements to an initial task instruction, asking for help, asking for a missing item to complete a task, responding to corrective feedback,* and *notifying the supervisor of task completion* when the environment was arranged to evoke these responses (e.g., unlearned tasks were presented, therefore requiring the participant to ask for help). The results of Lerman et al. demonstrated that most of the participants showed difficulty with one or more of the targeted skills. These results suggest that assessing and teaching job-related social communication skills is a necessary component to job planning.

Practitioners must also consider individual and family values which may ultimately lead to job satisfaction. This index, referred to as *social validity* (Wolf, 1978), measures the satisfaction of individuals and their families surrounding job choice and placement. When focusing on job placements, social validity can be measured by evaluating individual preference, family preference, and indices of satisfaction at the job setting. More so, ensuring adolescents and adults with ASD and/or IDD access jobs in accordance with their preferences represents person-centered planning in vocational training (Everson & Reid, 1997; Reid et al., 1999) and is considered a requirement in the employment legislation for individuals with disabilities (Reid et al., 1999).

Person-centered planning is an ongoing problem-solving process used to help people with disabilities plan for their future, or in this case, plan for their job-related future (Reid et al., 1999). A significant part of that planning is matching job tasks with work preferences (Reid et al., 1999), typically through the use of preference assessments (e.g., Cobigo et al., 2009;

Lattimore et al., 2003; Parsons et al., 2001). Along these lines, Parsons et al. (2001) used a paired-items preference assessment in which job tasks were repeatedly paired with each other to determine which tasks were selected most frequently across pairings and they used this as an indicator of job preference. Similarly, Lattimore et al. (2003) evaluated use of a multiple-stimulus preference assessment for predicting job preference among adults with disabilities. Results of both studies offered support for predicting preference.

Ultimately, assessing and programming for job success in individuals with disabilities requires systematic planning and customized employment services. The use of functional-skills and vocational-rehabilitation assessments in combination with social-validity assessments (e.g., measures of preference, choice, and satisfaction) ensures that individuals are in desired job placements where they can be most successful. Researchers should continue to develop and create varied forms of reliable functional skill-based assessments. For example, Chen et al. (2015) suggested that future assessments geared toward employment for individuals with disabilities incorporate resources such as the *World Health Organization's International Classification of Functioning, Disability, and Health (ICF)*, which provides an understanding of the variables that impact an individual's employment in a functional way. Furthermore, research on the development of valid, reliable, and efficient employment preference assessments for use with individuals with ASD and/or IDD is necessary. Results of these preference assessments can be used to further evaluate the ways in which preference influences skill performance on the job.

Vocational Skills Training

To prepare clients for the workforce, not only do we need the results of assessments to help us identify preferred jobs, necessary job-related skills and skill deficits, but we also need to identify effective strategies for teaching these skills. Vocational skills can be categorized into two main areas: *essential prevocational skills* and *employment skills*. In this section, we will share behavior analytic research related to essential prevocational skills and employment skills and we will provide recommendations for future research.

Essential Prevocational Skills

Much of what behavior analysts do to prepare individuals for the workforce occurs within the boundaries of the educational system. For the most part, this involves prevocational training. Prevocational training provides learning and work experiences that include volunteer work, where the individual can develop several general, non-task-specific skills that will increase the likelihood of employability in competitive and paid integrated community settings. These essential skills include the ability to behave independently (e.g., follow directions, follow a schedule, tell time, attend to work tasks for an extended period of time), communicate effectively with supervisors, co-workers, and customers (e.g., ask questions when necessary, seek help, answer questions adequately), solve common work-place problems and make decisions, engage in leisure skills during breaks, select and wear appropriate attire for the job, navigate the community (e.g., prepare their own lunch or order and pay for their own lunch while in the community, take public transportation), and engage in general workplace safety.

Increased Independence

Acting independently and following directions are often cited as important for employability (Agran et al., 2016; Hendricks, 2010; Ju et al., 2012). Activity schedules include pictures or words that cue an individual to engage in a sequence of tasks or activities independently. Activity schedules have increased independence in individuals with ASD and/or IDD across a variety of activities including leisure (e.g., MacDuff et al., 1993), social (e.g., Krantz et al., 1993; Krantz & McClannahan, 1998), and vocational tasks (e.g., Johnson & Miltenberger, 1996; Sances et al., 2018; Wacker & Berg, 1983). Sances et al. (2018) used activity schedules and contingent reinforcement to increase the number of independent beekeeping steps completed by an adult with ASD. Interestingly, the participant had a keen interest in bees and his interest played a role in his job selection. This is noteworthy as Hendricks (2010) noted that appropriate job placements for individuals with specific, restricted interests may produce successful employment outcomes. Additional research is necessary to address the role restricted interests play in job success.

Researchers have also evaluated the use of technology for increasing vocational independence among individuals with ASD and/or IDD across a variety of tasks including using a visual assistant program to teach time management and personal scheduling (e.g., Davies et al., 2002); using computer-based video instruction to teach the completion of multiple step, job tasks (e.g., watering plants, delivering mail, changing paper towels; Mechling & Ortega-Hurndon, 2007); and using video prompting or video modeling to teach meal preparation (e.g., Bereznak et al., 2012; Mechling et al., 2009b; Rehfeldt et al., 2003; Van Laarhoven et al., 2012), using a microwave (Sigafoos et al., 2005), loading a dishwasher (Van Laarhoven et al., 2012), using a washing machine (Bereznak et al., 2012), using a copy machine (Bereznak et al., 2012), recycling at a restaurant (Van Laarhoven et al., 2012), and janitorial tasks (Van Laarhoven et al., 2009). Several of the prior studies evaluated video-based instruction. Video-based instruction can include video modeling and/or video prompting. Video modeling involves showing a video in which someone models a behavior for a viewer such that the viewer might imitate the behavior in an appropriate context (Catania et al., 2009). Video prompting involves viewing a video of a model performing a task, but in this case, it is not necessary for the viewer to watch the entire video, rather they can watch specific steps of the tasks, as needed (Cihak et al., 2006). For example, Bereznak et al. (2012) evaluated the effects of a video prompting procedure on the independent completion of several essential prevocational skills (i.e., using a washing machine, making copies, making noodles). The videos were readily available on an iPhone®. Participants could watch and rewind the videos to prompt their own behavior, as necessary. Results of this study showed that the video prompting procedure was effective at increasing independent performance to mastery level and that responding maintained, when the iPhone® remained available. Although the authors did not assess social validity, they reported that the caregivers were thrilled their children were using the same technology as their siblings and the participants reported to have interest in obtaining iPhones® of their own.

Self-management has been used to teach a variety of essential prevocational skills including independent performance of individuals with IDD (Lagomarcino & Rusch, 1989) and time-management skills (Newman et al., 1995; Sowers et al., 1980). Self-management is the personal application of behavior change tactics that produce a desired improvement in behavior (Cooper et al., 2020). Newman et al. (1995) sought to transfer control from an instructor, who indicated when it was time to switch activities, to three individuals with ASD by teaching them to identify transition times. A classroom activity schedule was present throughout the study and included the time of day each activity was to occur. A digital clock was present and in view of all participants. Participants were also taught to self-reinforce successful transitions. All participants learned to transition at appropriate times and self-reinforcement increased with the intervention but was variable. Responding maintained at 1- and 3-month post-intervention and self-reinforcement remained high for two of the participants.

Social-Communication Skills

Social skills are often noted as a primary factor for obtaining and maintaining employment (e.g., Agran et al., 2016; Chen et al., 2015; Ju et al., 2012; Lerman et al., 2017). These include knowing when to seek help when an instruction is unclear, notifying a supervisor when assistance is needed, responding appropriately to critical feedback, and interacting well with coworkers and customers (e.g., Baldwin et al., 2014; Herbert & Ishikawa, 1991; Hurlbutt & Chalmers, 2004; Müller et al., 2003). Individuals with ASD often have difficulties with social interactions, perspective taking, understanding sarcasm and humor, using and understanding figurative language, and with lies and deceit (see Kisamore et al., 2019 for a review of the literature in these areas). Few researchers have evaluated strategies for teaching job-related social skills. Those who have done so have used video modeling to teach adults with IDD how to make coffee, serve coffee, and sit down beside a peer (Bidwell & Rehfeldt, 2004), used prompts and reinforcement to teach teamwork with activity schedules to individuals with ASD (White et al., 2011), and used behavioral skills training (BST) to directly teach job-related social skills (Grob et al., 2019). BST involves instructions, modeling, rehearsal, and feedback in which training continues until the trainee acquires the skill and demonstrates the ability to perform it independently (Parsons et al., 2013). BST begins with some form of instruction (e.g., written, verbal, video) provided to the trainee on the target behavior. This step is followed by a demonstration of the target response either in-vivo or through a video model. The trainee is then given the opportunity to rehearse the response while the practitioner provides feedback until mastery is demonstrated. For example, Grob et al. (2019) evaluated the efficacy of a treatment package that consisted of BST and stimulus prompts with three individuals diagnosed with ASD. Their results showed that the procedure resulted in an increase in job-related social skills, but that stimulus prompts were necessary for generalization. They did not see generalization across social skills underscoring the importance of carefully programming for generalization.

Problem Solving Skills

Another skill that is particularly valuable on the job is problem solving (Agran et al., 2016; Ju et al., 2012). Problem solving occurs when an individual is presented with a problem for which they have no immediate solution; thus, they must engage in mediating or precurrent responses (e.g., looking in a variety of places for a missing stapler, obtaining paper towels to replace an empty roll) that increase the likelihood of emitting a successful response (e.g., finding the stapler, cleaning spilled water on the floor; Skinner, 1984). Being able to problem solve increases the likelihood of identifying a correct response and might decrease maladaptive behavior of individuals with ASD and/or IDD (e.g., engaging in stereotypy or disruptive behavior). A variety of problem-solving skills have been taught in prior vocational skills research including training adolescents with ASD how to approach an instructor, describe a problem, and request assistance (Dotto-Fojut et al., 2011), training individuals with IDD to solve common workplace problems using self-instructions (Hughes et al., 1996; Hughes & Rusch, 1989), teaching adolescents with IDD rules for problem solving social situations in the workplace (Park & Gaylord-Ross, 1989), teaching individuals with ASD and/or IDD a decision-making framework on an iPad to problem-solve common work tasks (Van Laarhoven et al., 2018), and teaching adolescents with ASD to independently problem solve common workplace problems using textual/pictorial activity schedules (Lora et al., 2020). For instance, Lora and colleagues (2020) identified three types of common workplace problems (e.g., missing, broken, mismatched items) and they created an activity schedule that contained textual stimuli to cue the participant to engage in a series of mediating responses (e.g., identify the missing, broken, or mismatched item; go to the location where the item is kept; get the item; return to your room; finish your work). To ensure differentiated responding, the researchers presented both establishing operation (problem present) and abolishing operation (problem absent) trials. The researchers programmed for generalization by teaching to multiple scenarios within each category of problems and they assessed generalization with novel scenarios in each category. The researchers used reinforcement systems similar to those established in each participant's school programming to reinforce successful problem solving. Their results showed that the problem-solving procedure was effective, that participants demonstrated differential responding, that responding generalized to novel scenarios, and that responding maintained.

Leisure Skills

Although most people do not directly equate leisure skills with work-activities, employees do get breaks from work and require leisure skills to keep entertained during these breaks. Prior research in this area has focused on teaching individuals with IDD generalized use of vending machines (Sprague & Horner, 1984) and teaching individuals with IDD to listen to music on an iPod Touch (Kagohara et al., 2011). Kagohara et al. (2011) used video models presented on the iPod Touch® to teach three individuals with IDD how to find and listen to music on the iPod Touch®. Participants were instructed to watch the video and after viewing the video, they were given the iPod® and the experimenter asked the participant to complete each step of the "listening to a song" task analysis that included eight steps. The video was removed following successful performance with the video model. Responding for all participants increased to mastery level following introduction of the video model and responding maintained between 4 and 10 weeks for all participants even though participants did not have access to the iPod Touch® in the interim.

Self and Community Care

It is important to teach individuals with ASD and/or IDD how to take care of themselves while at work or in the community. The ability to successfully navigate transportation, pay for food, prepare food in advance, and heat food at work is one more area in which individuals with ASD and/or IDD should demonstrate some, if not total, independence. Researchers have evaluated strategies for teaching individuals with IDD how to navigate public transportation (Davies et al., 2010; Price et al., 2018; Stock et al., 2013), training individuals with ASD and/or IDD to use cell phones or to respond to a pager and share a communication card when lost (e.g., Hoch et al., 2009; Purrazella & Mechling, 2013; Taylor et al., 2003; 2004), teaching individuals with IDD to count change (Borakove & Cuvo, 1977; Lowe & Cuvo, 1976) and make change (Cuvo et al., 1978a, b), teaching individuals with IDD to prepare meals (Rehfeldt et al., 2003), and teaching individuals with IDD to use a microwave (Sigafoos et al., 2005). For example, Price et al. (2018) evaluated the effects of teaching four individuals with IDD how to use the Google Maps® application on a smart device via a total-task chain to take the bus to locations around a college campus and the community.

Workplace Safety

Employers have also rated workplace safety an important job skill for employees (e.g., Agran et al., 2016; Ju et al., 2012). Workplace safety includes avoiding inappropriate touching of others, avoiding problem behavior (e.g., arguing, aggression, self-injury, use of inappropriate language), and responding appropriately to job-related emergencies. Researchers have addressed problem behavior of individuals with IDD during vocational tasks (e.g., Barker & Thyer, 2000), trained individuals with IDD how to handle broken material (Winterling et al., 1992), and also taught individuals with IDD how to extinguish cooking-related fires (Mechling et al., 2009a). Mechling et al. (2009a) evaluated the effects of video models for teaching three individuals with IDD three fire extinguishing behaviors (i.e., scooping and releasing flour, placing a lid on a pot or pan, using a fire extinguisher). The researchers programmed for generalization of fire extinguishing behavior across a variety of stimuli (e.g., skillet, double boiler, stop top burner, microwave oven, fire pit, deep fryer) and assessed generalization of fire extinguishing behavior with novel stimuli (i.e., trash can, toaster oven, wok). Their results showed that the video modeling procedure was effective at teaching fire extinguishing behavior to all participants and results generalized to novel stimuli. Additionally, extinguishing behavior maintained from 22 to 52 days.

Employment Training

When behavior analysts work with individuals post-21-years-old, we might still dedicate some time to prevocational training, but we are also likely to assist individuals as they engage in sheltered and supported employment.

Sheltered Employment

Sheltered employment can involve *transitional employment programs* in which the goal is to provide training in non-integrated settings with the goal of increasing necessary skills for successful integrated employment. Some of these necessary skills might include learning how to type, file, answer the phone, and write down messages for a clerical position or how to clear a table, wipe the table down, wrap silverware, fill salt and pepper shakers, and set tables for a restaurant position. Sheltered employment can also involve *extended employment programs* in which the goal is to teach individuals to use their existing skillsets (trained in prior prevocational or transitional employment programs) to earn wages in non-integrated environments.

Supported Employment

Supported employment entails helping a learner obtain and maintain competitive or customized compensated employment in an integrated or general work setting. This might include job placement and development in which the behavior analyst (a) uses assessment results to target jobs available in the local labor market that are consistent with the learner's interests, abilities, and work goals, (b) negotiates with a prospective employer and educates the prospective employer about the benefits of hiring individuals with ASD and/or IDD, (c) assists the learner in the development or improvement of job seeking skills (e.g., resume development, interview skills, networking, completing applications), (d) engages in training and systematic instruction directly with the learner (e.g., teaches job-specific skills), and (e) conducts job coaching with the learner.

Development of Job Seeking Skills

When seeking an appropriate and desired job, the individual should begin by preparing a resume that speaks to their specific skill sets. Then the individual can begin the job search (with or without assistance). If the individual is expected to do this independently, they will need basic computer skills (e.g., using a mouse, using a search engine) and more advanced search skills including identification of relevant job ad sites, how to navigate such sites, how to identify relevant jobs, how to complete the job application, how to create a cover letter that speaks to their interest in the job and how they are uniquely qualified, and uploading a resume. Research on how best to teach these skills to individuals with ASD and/or IDD is warranted.

If contacted by a potential employer via email, the individual must respond with proper email etiquette including using a proper salutation, writing in full sentences and responding to any questions in the body of the email, using an appropriate closing, and signing their name. Some necessary skills here include typing, reading comprehension, and writing. Cihak et al. (2015) evaluated the effects of total task chaining on teaching four individuals with IDD how to access email, respond to email, and send an email. The researchers programmed for generalization using sequential modification across three devices (i.e., desktop, laptop, iPad). Results showed that the training procedure resulted in acquisition of the email task, but that training was necessary for mastery level performance across all three devices. Responding did maintain at 9 weeks for all participants. It is worth noting that the participants were allowed to continue accessing, responding to, and sending emails during the 9-week interim.

When invited for a job interview, it is important that the candidate prepare to answer standard job interview questions and dress appropriately. On the day of the interview, the candidate should arrive on time and adequately answer questions. Some skills necessary for success here include general interview skills, tolerating dress clothes, selecting appropriate attire, conversation skills, self-management, navigating transportation, and time management (Zalewska et al., 2016). Several researchers have evaluated teaching interview skills to individuals with ASD and/or IDD using virtual reality (Burke et al., 2017; Smith et al., 2014; Walker et al., 2016), selection-based responding (O'Neill & Rehfeldt, 2014), video modeling (Hayes et al., 2015), and BST with (Rosales & Whitlow, 2018) and without (Brazeau et al., 2017; Hall et al., 1980; Kelly et al., 1980; Mozingo et al., 1994; Roberts et al., 2020) video-based feedback. Roberts et al. (2020) evaluated the effects of BST for teaching three types of interview behaviors (i.e., asking questions, answering questions, appropriate body language) to three individuals with ASD. BST was sufficient for two of the participants to reach mastery level responding and the third participant was successful with the addition of textual cues and reinforcement. They programmed for generalization by incorporating multiple interviewers into training and assessed generalization of interview skills with a novel interviewer. Their results showed that the skills generalized to a novel interviewer. The researchers also assessed social validity of their findings by having community members rate the interviewee behaviors from pre- and post-training videos. Overall, the raters scored the post-training videos higher.

Task Engagement

Task engagement is often cited by employers as an essential skill (e.g., Ju et al., 2012). Difficulties in task engagement have been reported in individuals with ASD (e.g., Hume & Odom, 2007; Shields-Wolfe & Gallagher, 1992). Desired task engagement behaviors include attending to task materials, using task materials in the manner for which they were designed, and engaging in appropriate, task-related behavior. There are only a few studies that have evaluated strategies for increasing task engagement with adults with ASD. These include delivering specific instructions (Bouxsein et al., 2008), offering choice in activity order (Watanabe & Sturmey, 2003), and BST (Palmen & Didden, 2012). Watanabe and Sturmey (2003) noted the importance of choice for adults with ASD and they evaluated the effects of choice-making opportunities that were embedded within activity schedules combined with contingent praise on task engagement with three adults with ASD. Their results showed that participants' task engagement was higher during the choice opportunities compared to the no-choice opportunities. Additionally, task engagement maintained for all participants.

Training and Systematic Instruction

Following (or sometimes concurrently with) the acquisition of prevocational skills, job-specific skills are also trained. Job-specific skills might include those necessary for specific positions (e.g., clerical positions: reading, writing, typing, filing, answering the phone and taking messages; restaurant positions: removing dishes and silverware, wiping tables, wrapping silverware, filling salt and pepper shakers or adding individual packets to silverware wrappers, setting tables). These skills can be taught in transition programs or in supported employment environments. A variety of strategies have been used to train and provide ongoing instruction to individuals with ASD and/or IDD.

BST Research evaluating the effects of BST for teaching job-specific skills has included teaching individuals with IDD how to stamp a return address on envelopes (Schepis et al., 1987), teaching restaurant skills to an individual with ASD (i.e., setting up and running a commercial dishwasher, polishing and rolling silverware, bussing a table, cleaning the bathroom; Morgan & Wine, 2018), training individuals with ASD how to deliver a fire safety program as a mascot (Burke et al., 2010), training individuals with ASD behavior technician skills for working with children with ASD (Lerman et al., 2015), and teaching an individual with ASD basic computer skills (Sump et al., 2019). Sump et al. (2019) evaluated the effects of BST on acquisition of basic computer skills using Microsoft Word®, Microsoft Excel®, and Microsoft PowerPoint® by an individual diagnosed with ASD. Their results showed that BST was effective for teaching the individual how to use basic functions within the three programs and following the intervention, the participant was able to use the programs to independently complete schoolwork.

Video Modeling/Video Prompting Video modeling and video prompting have been used to teach a variety of job-specific skills to individuals with ASD and/or IDD including mascot tasks (Allen et al., 2010a, b); gardening (English et al., 2017), phone skills (Rausa et al., 2016), clerical skills (e.g., Bennett et al., 2013a, b), washing dishes (Sigafoos et al., 2007), chained job tasks (Goh & Bambara, 2013; Heider et al., 2019), and multiple-step tasks (e.g., folding multiple sizes of towels, sort recycling, prepare a buffet table with serving stations; Mechling et al., 2014). Allen et al. (2010a) evaluated the effects of video modeling to teach individuals with ASD nine target skills to entertain customers and promote a product in a retail setting while they were dressed as the product mascot. They assessed generalization from the training setting to an actual job opportunity and generalization was observed. Additionally, participants reported they enjoyed the work and their supervisors made positive comments about the experience.

Prompting and Chaining Procedures Prompts are supplementary antecedent stimuli used to occasion a correct response and behavior chains are a sequence of responses leading to a terminal outcome in which the response for one part of the chain serves as the conditioned reinforcer for that response and the discriminative stimulus for the next response in the chain (Cooper et al., 2020). Chaining, linking specific sequences and responses to form a new behavior, is one strategy to use to teach a complex skill. Researchers have evaluated backward chaining, in which the last response in the chain is taught to mastery before preceding responses (Cooper et al., 2020), to teach cleaning tasks (e.g., cleaning a sink, cleaning a locker) to individuals with ASD (Kobylarz et al., 2020) and they have evaluated guided compliance for teaching a variety of skills to individuals with IDD including janitorial skills (Cuvo et al., 1978a, b), mending skills (Cronin & Cuvo, 1979), and researchers have also incorporated instructive feedback into guided compliance procedures for teaching laundry skills (Taylor et al., 2002). Instructional feedback is the presentation of additional targets during antecedent or consequence portions of learning trials (Reichow & Wolery, 2011). These additional targets are not directly taught or reinforced but are assessed to determine if responding to these targets emerges as a result of exposure to them. For example, Taylor et al. (2002) used guided compliance to teach individuals with IDD how to wash and dry laundry. They also embedded nontarget, functional sight words on the appliances and the products used by the participants. Their results showed that participants not only learned how to wash and dry laundry but also responded appropriately to the sight words following the intervention.

Sometimes it is difficult to know what to teach or prompt before an individual is behaving in the work setting. Parsons et al. (2009) trained support staff to implement a least-to-most prompting strategy (say, wait and watch, act out, touch to guide) with reinforcement in the natural environments as a means for addressing these “in the moment tasks” that needed to be trained. Their results showed that there was an overall increase in independent completion of tasks by the participants and that overall, results maintained up to 33 weeks.

Job Coaching Job coaching involves on the job prompting and reinforcement for completion of vocational tasks. It can be somewhat stigmatizing for individuals to have someone beside them providing prompts and reinforcement, covert strategies such as the use of a “bug-in-ear” or covert audio coaching (CAC) might decrease some of this stigmatization because several people walk around with Bluetooth devices and/or headphones in their ears on a regular basis. CAC consists of a two-way radio system in which the individual who is giving feedback is able to do so from a distance and the person receiving feedback is privately able to hear via the earpiece. With the advent in Bluetooth technology for headphones and microphones, it is now also possible for the feedback recipient to respond and ask questions to the coach or instructor. Bennett et al. (2010, 2013a, b) have evaluated the effects of CAC for delivering feedback during vocational tasks. For example, Bennett et al. (2010) examined the use of CAC to deliver performance feedback with three employees diagnosed with ASD and/or IDD. Feedback took place at the individuals' job sites and was delivered for performance on the tasks of sweeping, cleaning windows, and stacking crates. Results indicated an increase in accuracy in task completion for all participants.

Self-management Self-management is also a valuable skill in the workplace. Employers prefer employees who can manage their own time and complete tasks efficiently. Researchers have primarily evaluated strategies for increasing self-management in the workplace as a means for increasing production rates (e.g., Christian & Poling, 1997; Moore et al., 1989). For example, Christian and Poling (1997) evaluated the use of a self-management strategy on the productivity of two individuals diagnosed with IDD. The self-management strategy included self-instruction, self-monitoring (with a timer to ensure speed of performance and written notes in a notebook), and self-reward (with individualized reinforcement). Tasks included weighing and bagging individual servings of various frozen foods, setting tables, and rolling silverware. Throughout the study their productivity was assessed and compared to their coworkers. While the results did show some improvement in productivity and participants were completing tasks at the same level of productivity as their coworkers, the most meaningful part of this study is that the participants reported they liked the procedures and both maintained their jobs. One participant even earned a raise.

Research Recommendations: Training Vocational Skills

Although there is a growing body of research on strategies for teaching essential prevocational skills, additional research is needed in all areas. For example, there are a handful of studies that have evaluated teaching problem-solving skills for the workplace, but those strategies are simply scratching the surface. Additional research is needed on teaching more complex problem-solving strategies (e.g., seeking a supervisor when there is a problem, what to do if the supervisor is not available, how to continue working when there is a problem) and using other strategies (e.g., mnemonics, flowcharts) to teach problem solving to individuals who have more limited language repertoires.

We are familiar with only one study that evaluated a strategy for teaching individuals with ASD and/or IDD to select clothing that matched popular fashion (Nutter & Reid, 1978). Although some jobs might allow for wearing of fashionable street clothes, most people have "work clothes," "leisure clothes," and "social clothes." Additional research is needed that addresses how to teach individuals with ASD and/or IDD to select and wear work-appropriate attire. This is considered an essential prevocational skill because workplaces often have dress codes and violations of those dress codes might result in feedback and/or termination. Researchers might evaluate teaching differential responding (e.g., I wear scrubs to work, I wear jeans at home) and problem solving for appropriate attire (e.g., it's raining, I should wear my raincoat). Additionally, research is necessary on teaching mask wearing while at work in some settings and adhering to social distancing guidelines in the workplace. Researchers might evaluate the effects of discrimination training (e.g., this is 6 ft. away, this is less than 6 ft. away, you do not wear a mask while eating lunch, you do wear a mask while at your desk).

Individuals with ASD are more likely to end up in sheltered employment than supported employment due to their behavioral difficulties, cognitive functioning deficits, and restricted interests (Hendricks, 2010; Müller et al., 2003; Richards, 2012; Taylor & Seltzer, 2011). However, with adequate supports, individuals with ASD can progress from needing moderate and intensive levels of support to needing minimal levels (Brooke et al., 2018; Ditchman et al., 2018). Barriers to successful employment for adults with IDD include problem behavior and interpersonal problems (Lemaire & Mallik, 2008). These findings support the need for continued research on effective prevocational and employment training procedures.

Increased use of technology to guide the day-to-day movements and activities of neurotypical individuals gives rise to additional training possibilities in which we can incorporate technological supports for individuals with ASD and/or IDD without stigmatizing them. Most people use Google and YouTube for supports as they attempt to complete tasks (e.g., clean a coffee maker, change the oil in a car). As noted above, technology can be used to share video models or video prompts with individuals in the community and the use of personal smart devices does not make them stand out from others in the community. Additional technological supports include applications that can be downloaded on personal smart devices to guide navigation (Price et al., 2018), assist in self-management (e.g., calendar applications, reminders), and help ensure that tasks are completed on certain days and by particular times (e.g., reminders, lists; Gentry et al., 2012). Additional research is needed to fully identify the ways in which we can incorporate technology into the lives of individuals with ASD and/or IDD.

Although there is an increased emphasis on the use of higher technology or "high-tech", such as iPads and other tablets (Bennett et al., 2013a, b; Bereznak et al., 2012; Mechling et al., 2014; Van Laarhoven et al., 2018), it is still important to consider teaching toward acquisition with lower technology or "low-tech" tools, such as picture and written prompts or less sophisticated software, as higher technology tools may break, lose power, or simply might not be a good fit for the individual.

Generalization and Maintenance

Much of what behavior analysts do to support employment of the individuals we work with occurs within the boundaries of the educational system and day habilitation programs. For the most part, this involves prevocational or transition program training in which we train the aforementioned skills in analogue settings. Because many of these skills are trained in analogue settings, it is important to program for and assess generalization and maintenance.

Generalization

According to Stokes and Baer (1977), a therapeutic behavior change is demonstrated only when behavior occurs over time, persons, and settings, and the effects of the change must spread to a variety of related behaviors. Individuals should be taught the types of vocational skills noted here and strategies should be used to promote the generalization of these responses across time, persons, settings, and also to promote varied topographies of responding. Clinicians and researchers can maximize the potential for generalization by incorporating common stimuli into training, teaching with multiple exemplars, ensuring skills contact natural consequences, reinforcing generalized responding, and teaching strategies to mediate generalization (Stokes & Baer, 1977). Training that requires varied response forms helps to ensure the acquisition of varied responding and also increases the likelihood that untrained topographies will emerge (Cooper et al., 2020).

Johnson and Miltenberger (1996) evaluated the effects of picture prompts and self-instruction (covert or overt verbal prompts generated by oneself to prompt specific responses or behaviors) on vocational task performance with three participants who were diagnosed with IDD. Participants were requested to overtly state four prompts consisting of the task sequence (i.e., "look at the picture," "point to the picture," "do picture" and "next picture") while pointing to or looking toward the targeted picture prompt. The authors used sequential modification to program for generalization. Results of the study indicated an increase in accurate task completion following training in using both picture prompts and self-instruction. Additionally, generalization was also observed in two of the three participants.

Wacker and Berg (1983) also investigated the effects of picture prompts on the completion of complex vocational tasks, which included packaging in addition to valve and circuit board assembly with five young adults diagnosed with IDD. Picture prompts were presented in a bound book and consisted of pictures of the parts to be selected and how the parts fitted together. They programmed for generalization by teaching to multiple exemplars. Results indicated each participant mastered the vocational task and that the skills generalized to two novel tasks.

Maintenance

In addition to generalization across environments and behaviors, it is important that we think about how we can create lasting changes in behavior, otherwise, the intervention is not truly effective (Baer et al., 1968). Self-management strategies might prove useful for enhancing generalization and maintenance (Ninness et al., 1991) of vocational skills. If behavior change does not maintain, it is important to ask if the new behavior is being supported in the environment outside of the intervention (Kennedy, 2002). If support is not present, it is necessary to determine if the target behavior is of importance to the individual and others in the environment. Kennedy (2002) suggested that maintenance of skills might be used as an index of social validity. When skills are used regularly (due to multiple opportunities in daily life), they are more likely to be maintained than skills that are used rarely.

Fluency training, or teaching behaviors to a rate criterion, might also be an important consideration in promoting maintenance. Lee and Singer-Dudek (2012) examined the effects of fluency versus accuracy training on the completion of vocational tasks (e.g., assembling a doorknob, assembling an object hanger) by individuals with IDD. Accuracy training consisted of the instructor modeling each step while providing vocal verbal directions and delivering verbal feedback after each attempt made by the participant to complete the step; to move on in the sequence the participant was required to accurately complete previous steps. In the fluency training condition, continuous modeling and step-by-step vocal verbal prompts were given for how to complete a different targeted behavior chain than taught in the accuracy condition. A timer was placed within the participant's view, the participant was informed that the duration of the task completion would be recorded, and encouragement was given for fast completion. Praise was delivered when the participant completed the chain of behaviors accurately as well as when the student performed the task faster than their previous record. If an error was made, a correction was provided for the missed or inaccurate step and the instructor continued providing prompts for the remaining tasks. Post-training assessments were conducted following both training conditions and consisted of 20-min sessions observed two days after criterion was met with training as well as 40-min time periods observed 6 weeks after training. During post-training assessments, participants were given a task to assemble independently. Results of the study indicated three of the four participants completed a higher number of correct fluency-trained tasks than accuracy during 20-min sessions and all four participants demonstrated better performance during 40-min assessments for fluency-trained behaviors.

Research Recommendations: Generalization and Maintenance

While research supports implementation of fluency training on the success of academic skills (Johnson & Layng, 1994; Singer-Dudek & Greer, 2005), limited investigations have been conducted on the use of fluency training to teach vocational skills. Although the findings from Lee and Singer-Dudek (2012) are promising, additional research is needed to assess implementation of fluency training for vocational and workforce readiness skills.

It can be difficult to identify common stimuli, relevant exemplars, natural consequences, appropriate and inappropriate contexts for behavior, and appropriate topographies of responses. One way to identify these variables is by using a general-case analysis (Cooper et al., 2020; Ducharme & Feldman, 1992). It is important to note that with the general case model, you plan for and program for generalization from the beginning of training rather than after some set criterion is met (O'Neill, 1990). Steps in the general case analysis include (a) defining the instructional universe (identifying where, with whom, and with which stimuli the behavior should occur), (b) defining the range of relevant stimulus and response variations within the instructional universe (determining variability desired in conditions under which the behavior occurs and variability in the types of responses made; including exceptions), (c) selecting examples for teaching and testing (ensuring that examples represent the variability noted in b), (d) sequencing teaching examples (using multiple exemplars, teaching to opposing examples, reviewing previously taught exemplars, teaching exceptions last), (e) teaching the examples (use techniques demonstrated effective in the literature), and (f) testing for generalization with novel examples (Horner & Albin, 1988; Horner et al., 1986; Horner et al., 1982; O'Neill, 1990). The only study we identified that relied on a general case analysis was conducted by Sprague and Horner (1984). The authors evaluated training in three conditions: Condition 1 involved training to a single vending machine, Condition 2 involved training to three similar machines, and Condition 3 involved training to a variety of vending machines that sampled the range of stimulus and response variations that might be present in the class of vending machines. Their results showed that Condition 3 (the one that relied on a general case analysis) was the most effective for obtaining generalization. Considering that vocational skills are often trained in analogue settings with the desire for them to occur in real-world work settings, it seems that general case analysis would prove useful for assisting in producing this desired generalization. We recommend that researchers keep this in mind in the future.

Social Validity

Wolf (1978) noted that as applied behavior analysts, we strive to solve problems of social significance. In order to achieve this goal, Wolf said that researchers must determine if: (1) the goals of our research and practice are socially significant, (2) participants, caregivers, and others find the treatment procedures acceptable, and (3) all parties are satisfied with the results. Hanley (2010) suggested that indirect measures of social validity should be combined with measures that are direct and objective (e.g., concurrent chains arrangements, measure allocation of time spent) in order to better assess social validity with young children. These procedures might also be useful for assessing social validity with individuals who are preparing for vocational training. For example, researchers and clinicians might design a concurrent chains arrangement (see Hanley et al., 1997; Hanley et al., 2005; and Luczynski & Hanley, 2009 for examples) to directly assess the preference for procedures related to teaching vocational skills. The researcher or clinician might expose the learner to rehearsal and feedback opportunities with an experimenter or instructor and rehearsal and feedback opportunities with a peer and then ask them to choose which format they would like to experience prior to each subsequent teaching session. In addition, Kennedy (2002) suggested that maintenance of skills might be used as an index of social validity. When skills are used regularly (due to multiple opportunities in daily life), they are more likely to be maintained than skills that are used rarely. This notion supports our previous recommendation regarding more thorough follow-up information.

In order to directly assess social validity at a societal level, researchers might follow the four-step social validation process used by Minkin et al. (1976). For example, to assess social validity regarding work-related behavior a researcher might: (1) gather samples of appropriate and inappropriate work-related behaviors by sampling the verbal and nonverbal behavior of neurotypical adults, (2) show the samples to potential employers and have the potential employers rate the samples, then develop operational definitions of the behaviors that are correlated with the subjective ratings compiled by the potential employers, (3) teach the target behaviors to the learners, and (4) have the potential employers rate the new behaviors.

Applications of Organizational Behavior Management to Vocational Skills Training

Within the field of applied behavior analysis (ABA), there is a sub-discipline of organizational behavior management (OBM) that refers to the application of behavior analytic principles to organizational settings (Bucklin et al., 2000). OBM contains three sub-fields: behavior-based safety, behavioral systems analysis, and performance management. Specific to an employee's performance, the sub-field of performance management focuses on the analysis of antecedents and consequences operating on the behavior of employees and employers and the development of interventions designed to affect these variables to change employee performance (Sigurdsson & McGee, 2015). When a performance deficit is identified in the workplace, a staff-level functional behavior assessment (FBA) may be used to identify the barriers to the employee's performance. The completion of a staff-level FBA prior to identifying and implementing interventions may lead to the development of function-based interventions that result in quicker-acting and longer-lasting effects than non-functional interventions (Austin et al., 1999).

A variety of staff-level FBAs have been developed within the sub-discipline of OBM. The PIC/NIC Analysis is a framework developed by Daniels and Daniels (2006) that hypothesizes antecedent and consequent events operating on an individual's behavior. It is called a PIC/NIC because it specifies whether the consequences are *P*ositive, occur *I*mmediately or in the future, are *C*ertain or uncertain, or are *N*egative. Information may be gathered through interviews or observations and, through completion of this analysis, the practitioner is able to identify and, subsequently, modify environmental conditions to increase or decrease a behavior of interest. Similarly, Austin (2000) presented the Performance Diagnostic Checklist (PDC), which is an informant method of functional assessment for use in an organizational setting to address employee performance problems. The PDC provides a series of questions that a practitioner answers by interviewing the employees' supervisor(s) and directly observing employee behavior. Through the completion of the assessment, the practitioner identifies variables maintaining a performance problem and uses this information to develop an intervention to ameliorate the employee's performance issues.

Although the PDC has been successfully adopted in various settings to address performance problems, more recently, it has been revised to better align with specific settings and performance problems. Martinez-Onstott et al. (2016) developed the Performance Diagnostic Checklist—Safety (PDC-Safety) that was specifically designed to examine the environmental variables that affect safe and at-risk performance. Similarly, Carr et al. (2013) revised the PDC to better align with the unique needs of a human services setting, where employees are responsible for providing care to others (e.g., schools, clinics, group homes, employment settings for individuals with disabilities), and developed the Performance Diagnostic Checklist—Human Services (PDC-HS). The PDC-HS has been implemented in a variety of human service settings to address various employee performance problems (Wilder et al., 2020). To date, there is only one published study that demonstrates the effectiveness of the PDC-HS with people with IDD. Smith and Wilder (2018) used the PDC-HS with two supervisors with IDD to increase the accurate pricing in a thrift store of two supervisees with disabilities.

Research suggests immediate performance feedback and goals may also have a positive impact on workforce skills. In a study with 36 neurotypically developing employees split into four groups, Goomas et al. (2011) found that productivity in a large retail distribution center increased by a mean of 10.25% across all groups compared to baseline when goals were set, and group-based immediate feedback was delivered. The authors hypothesized that employees should be given guidelines focused specifically on their roles and job tasks and should receive training in standards and expectations for their responsibilities; these recommendations are aligned with reasonable and successful accommodations for individuals with IDD described by Migliore et al. (2018). Betchel et al. (2015) further assessed the effects of temporal placement of feedback with 45 undergraduate-level students. They found that any feedback was strongly preferable to none. Data further indicated that feedback before performance (i.e., feedback given after one task but before the next in a sequence) was more desirable than feedback following the full completion of a behavior chain.

Increasingly, individuals with ASD and/or IDD are calling for increased support in the workplace. Winsor et al. (2018) found an increased expectation of higher paying positions following formal education with job satisfaction linked to the type of employment (e.g., individualized competitive careers). Research outside of the field also suggests that focus on the strengths of employees and encouragement of self-efficacy, which might be behaviorally defined as the covert reinforcement for meeting job expectations, are of high import in job satisfaction (Lorenz et al., 2016). While the literature described here gives some sense of how we might implement OBM principles to address workforce readiness and productivity, potentially leading to increased job satisfaction for individuals with IDD and ASD, a significant need for these investigations exists as OBM research has been heavily predicated with those who implement behavior analysis (Gravina et al., 2018) rather than with individuals diagnosed with disabilities.

Future Implications

Individuals with disabilities are estimated to make up at least 15% of the world's population, which equates to roughly 1 billion people (World Bank/World Health Organization, 2011). However, as discussed earlier in the chapter, few of these individuals are in paid, integrated employment positions within the community (Hiersteiner et al., 2016), suggesting that a significant number of individuals with ASD and/or IDD are without employment.

Research suggests that barriers for employment for individuals with ASD and/or IDD mirror barriers experienced by other minority populations, including negative attitudes and stereotypes that impact access to skill development (Krzeminski et al., 2019), inequity in assessment procedures for potential employees (e.g., a written exam taken by someone who may need an accommodation for written prompts; Sumner & Brown, 2015), and lack of training for human resource personnel and other professionals in the workplace (O'Connor et al., 2007). Other barriers may include performance-based criteria that are inequitable, inadvertent discrimination against employees who are neurodiverse, requiring training for which accommodations and alternative pathways to learning are not given, and hesitancy to share one's diagnosis for fear of discrimination (Sumner & Brown, 2015). While these barriers certainly exist, there are advantages for employers who hire individuals with ASD and/or IDD. These include increases in positive public relations, employees who have the ability to focus intensively on one task, opportunities to learn about illogical systems that require change, and the ability to hire employees who have strong interests, knowledge, and expertise in specific areas (Krzemisnki et al., 2019; Pisano & Austin, 2016).

For those with ASD and/or IDD, sustainable, integrated employment may have a strong impact on quality of life, cognitive functioning, and overall mental health, including reduced anxiety and depression and improvements in peer relationships (Walsh et al., 2014). These outcomes underscore the importance of educating potential employers on the advantages of hiring more neurodiverse employees and ensuring that accommodations (e.g., training and systematic instruction) are available in the workplace such that workplace environments are equitable (Wilczynski et al., 2013). As part of this process, it is also important that we consider how to best teach potential employees about job protections (e.g., minimum wage, health coverage, employment-based discrimination).

Moving forward, there is an impetus for behavior analysts to take a broader role in creating better pathways for employment of individuals with ASD and/or IDD (Lombardi et al., 2018). This includes an increased awareness of social justice issues, including race discrepancies in disability employment, which suggests that more White than Black individuals who have ASD and/or IDD are gainfully employed (Landa & Migliore, 2019). The behavior analytic literature reflects that typical employment for individuals with ASD and/or IDD commonly consists of menial jobs such as cleaning bathrooms, sweeping floors, and packaging materials. Individuals with ASD and/or IDD have expressed a strong desire for more meaningful employment (Winsor et al. 2018) rather than low-paid, entry-level positions (Hedley et al., 2017). Self-determination and person-centered planning (Bannerman et al., 1990; Zalewska et al., 2016) are of vital importance in meeting the needs of those with ASD and/or IDD. We call upon the behavior analytic field to help meet the growing demand for integrated employment by teaching toward, and researching, higher order vocational skills and the varied essential prevocational skills required for sustained, competitive employment.

A Review of Behavioral Intervention for Treating Tics

Keelin Norman-Klatt and Kevin P. Klatt

A tic is defined as a sudden, rapid, recurrent, nonrhythmic motor movement or vocalization and can be categorized as simple or complex (American Psychiatric Association, 2013). Simple tics are short in duration (i.e., less than a second) such as a quick shoulder shrug or facial grimace (motor) or sniffing (vocal). Complex tics usually involve more than one muscle group and can even look like the person is engaging in the tic to obtain attention. Examples of complex tics include making a tic-like obscene gesture (motor) and repeating their own or others' words (phonic). There is no current diagnostic test to objectively diagnosis a tic disorder, and therefore diagnoses are made by observation and verbal report using criteria in the Diagnostic Statistical Manual of Mental Disorders (5th ed.; American Psychiatric Association, 2013).

Tics are separated into four related but different diagnostic categories. The first three disorders include an onset before age 18, and the tic cannot be attributable to the physiological effects of a substance or another medical condition. The tic disorders are hierarchical in order, starting with Tourette disorder (TD). This disorder includes multiple motor *and* at least one vocal tic (not necessarily concurrently with the motor tic), and the tics must have persisted for more than a year since the onset of the first tic. Someone who does not meet these criteria might meet the criteria for the second tic disorder, persistent (chronic) motor, or vocal tic disorder. This disorder includes single *or* multiple motor or vocal tics, but not both motor and vocal, and the tic(s) must have persisted for more than a year since the onset of the first tic. The third tic disorder, provisional tic disorder, includes single *or* multiple motor and/or vocal tics. In this case, the tic(s) have been present for *less* than 1 year since the first tic onset. Both persistent (chronic) motor or vocal tic disorder and provisional tic disorder can only be diagnosed if the person has never been diagnosed with TD. If the criteria cannot be met for the three tic disorders, a diagnosis could be made of other specified tic disorder or unspecified tic disorder.

The occurrence of isolated and transient tics range between 11% and 20% for school-aged children, with males much more likely than females to be diagnosed. There is a wide range of prevalence estimates for TD and all tic disorders in general, likely due to different sample sizes and assessment methods. An estimate of prevalence for TD in school-aged children is likely to fall between 4 and 8 cases per 1000 (Scahill et al.,

2014). The occurrence of tics often coincides with other medical and psychiatric conditions. For example, both attention deficit hyperactivity disorder and obsessive-compulsive disorder are particularly common. Tics have been reported as early as age one, but usually start around age five, and often increase in frequency and intensity until about age 10 (Leckman et al., 1999). Many individuals with a tic disorder experience alternating increases and decreases in frequency of tics over time, with a peak often in the early teens (Woods et al., 2008a). Most individuals diagnosed with TD report an "urge" to engage in a tic. These internal subjective somatosensory sensations are usually referred to as "premonitory urges," and they usually precede tics (McGuire et al., 2016). Engaging in a tic then appears to temporarily reduce the urge to tic. In one study, adults reported an average of eight to nine distinct urges over 1 week (Leckman et al., 1993).

Treatments

Several behavioral interventions have been investigated to treat tics. Many of them, however promising, have not been investigated in enough studies and with the experimental control necessary to recommend as a sole treatment for tics, and therefore are not discussed in this chapter. Some of these treatments include massed practice (Yates, 1958), relaxation therapy (Turpin & Powell, 1984), self-monitoring (Billings, 1978), acceptance and commitment therapy (Franklin et al., 2011), and contingency management (Himle et al., 2008). Several behavioral treatments that have been shown to successfully treat tics and are discussed in this chapter include habit reversal (HR), comprehensive behavioral intervention for tics (CBIT), and differential reinforcement of other behavior (DRO). In addition, functional behavioral assessment (FBA) has been used in identifying contextual variables affecting tics that lead to behavioral intervention and is a key component of CBIT.

Habit Reversal

The most effective treatment for tics researched to date is habit reversal (HR), sometimes referred to as habit reversal training (HRT). The purpose of HR is to teach participants to become aware of their tic(s), self-monitor the tic(s), and learn to engage in a competing response either before or right after a tic occurs. Habit reversal is a training package that has included various procedures across studies. In the original study, HR was used to treat motor tics and nervous habits (Azrin & Nunn, 1973). The treatment consisted of first teaching the participant to become aware of the tic. Awareness training was conducted by beginning with a response description procedure. This required the participant to describe the movement of the counselor while the counselor modeled the tic. Then a response detection procedure was implemented whereby the counselor taught the participant to detect each instance of the tic by pointing out whenever one occurred. Following these two procedures, an early warning procedure was implemented requiring the participant to practice detecting the earliest sign of the tic.

Following these three procedures, a competing response was identified and taught. A competing response included a specific response pattern that was incompatible with the tic. The participant was instructed to engage in the competing response for about 3 min following either the temptation to perform a tic or the actual occurrence of a tic. The incompatible response was designed to be the opposite of the tic and capable of being maintained for several minutes. An attempt was made to make the incompatible response unnoticeable and easily completed within ongoing activities. A fifth awareness training procedure, situation awareness training, required the participant to recall all situations, persons, and places where the habit was likely to occur and describe how the tic was performed in these situations.

In addition to the five awareness procedures, three motivation procedures were implemented in an attempt to help the participant decrease their tic. The first motivation procedure was habit inconvenience, requiring the participant to review the inconveniences and embarrassment that resulted from the tic. In addition, social support procedures were added whereby family and friends commented favorably on progress and gave reminders to practice the competing response. Finally, generalization training was promoted using a symbolic rehearsal procedure that required the participant to imagine common situations where the tic occurred. The participant then imagined both detecting a tic and engaging in the competing response. The results of this study showed rapid reduction in tics and habits, although the study had some limitations. These included having participants self-report tics, presenting the data as a mean percentage change across the 12 participants, and using a non-experimental comparison design.

Subsequent studies using the HR procedure also showed a reduction in tics. For example, Azrin et al. (1980) compared habit reversal to negative practice using a larger number of participants, a greater variety of tics, and a longer follow-up period. Although the study had methodology shortcomings, HR appeared to have an immediate and substantial effect on the occurrence of tics.

The HR procedure was also demonstrated to be effective in treating TD (Azrin & Peterson, 1988). In this study, three adult males exhibiting the diagnostic criteria for TD (two were diagnosed) were treated with HR. The HR procedure included awareness training, self-monitoring, relaxation training, and a competing response. The frequency of tics was drastically reduced for all three participants and for two of the participants, at both home and clinic settings. Although the results from this study showed that tics could be reduced using HR, there were several methodological shortcomings including the use of a comparison design. Moreover, it should be noted that self-monitoring and relaxation procedures were added to the original HR procedure in this study.

Another investigation of HR was conducted for six adult males diagnosed with TD (Peterson & Azrin, 1992). In this study, however, HR was compared to self-monitoring and relaxation training. Note here that habit reversal was now considered separate from both self-monitoring and relaxation training. The results showed a reduction in tics from all three treatments when compared to baseline levels. The average reduction in tics across all six participants was 32% for relaxation training, 44% for self-monitoring, and 55% for habit reversal. Despite these percentages, the HR procedure was most effective for only two of the six participants. The self-monitoring procedure was most effective for three of the six participants. Despite methodological shortcomings, the results from this study showed the effectiveness of both HR and self-monitoring.

The procedures included in the HR training package varied in these early studies. Despite the differences in the HR training package, four main components have been identified (Miltenberger, 2016). These four components include awareness training, teaching a competing response, involving family and friends in social support, and strategies to motivate the use of this package. In addition to these HR training procedures, a book on treating TD and tic disorders recommended teaching relaxation training to patients with tic disorders (Woods et al., 2007).

Although the procedures used in the HR training package have varied, some studies have revealed that tics sometimes can be reduced without using the all the main components. For example, Ollendick (1981) used only self-monitoring for one participant and a combination of self-monitoring and a competing response practice procedure for a second participant. The self-monitoring alone was enough to reduce tics for the first participant. The other participant's tics were moderately reduced with self-monitoring, but the combined procedures were necessary for further reduction. In another study, Miltenberger et al. (1985) compared HR with a simplified package consisting of only awareness training and competing response training. The five participants receiving the simplified package all had drastic reductions in tics that maintained across 15 weeks. The successful reduction in tics using two components of HR suggests that the full package might not always be necessary, perhaps reducing the time and expertise needed to implement the full package.

Wright and Miltenberger (1987) used only awareness training to treat muscle tics for a 19-year-old college student. The tics were reduced using only awareness training and generalized to another setting. Wiskow and Klatt (2013) used only awareness training to treat four motor tics for a 9-year-old boy diagnosed with Asperger syndrome, TD, and attention deficit hyperactivity disorder. All four tics were reduced to zero with only awareness training. Woods et al. (1996) used a sequential application of the main HR components including awareness training, self-monitoring, social support, and a competing response for four children. Their results showed that the components necessary to reduce tics varied across the children, and awareness training alone was effective for one of the four children. Another study investigated a simplified HR procedure by comparing awareness training and competing response training to a combination of awareness training, competing response training, and social support using a pre-post group design (Flessner et al., 2005). Although the researchers hypothesized the addition of social support would result in greater treatment effects, there was no significant differences between the two groups.

The results of these studies demonstrate that not all components of the HR package are always necessary to decrease tics. In some cases, tics are reduced with only awareness training or awareness and a competing response training. To determine whether the competing response needs to be topographically similar to the tic as usually recommended, a topographically dissimilar response was investigated (Sharenow et al., 1989). The application of a dissimilar competing response resulted in a reduction in tics for all three participants. The data from this study suggests, and partially confirms, the topography of the competing response might not be as important as engaging in some response contingent on the occurrence of a tic or the urge to engage in the tic.

The competing response procedure in HR has been historically taught to occur contingent on either a tic or the urge to engage in a tic. This contingency, however, was investigated to evaluate whether the competing response needs to be contingent or whether nervous habits would reduce if done noncontingently (Miltenberger & Fuqua, 1985). The results indicated that the noncontingent competing response was mostly ineffective while the contingent competing response greatly reduced the habits. The study was conducted on nervous habits, not tics, so further research needs to be done to determine whether it also applies to vocal and motor tics.

Habit Reversal Literature Review

The HR training package, including various procedures, has been demonstrated to be an effective treatment for reducing tics (and other related behaviors) for almost 50 years. Several reviews have discussed the merits of the HR procedures (e.g., Carr & Chong, 2005; Cook & Blacher, 2007; Himle et al., 2006; Miltenberger et al., 1998; Woods & Miltenberger, 1995). The results from these reviews have led to different conclusions regarding the effectiveness of HR. In one review, Carr and Chong (2005) used guidelines from the Division 12 of the American Psychological Association (APA) Task Force on Promotion and Dissemination of Psychological Procedures to determine the empirical support for HR. In their review of 20 studies, only 12 included appropriate experimental designs and objective measurement of dependent variables. These 12 studies were reviewed in relation to the APA guidelines that stipulate a successful treatment effect must be demonstrated with at least two between-subjects designs or nine within-subject designs and include a treatment manual. The results from the 12 reviewed studies met the criteria for both between and within-subject criteria. The 12 studies, however, did not include the guideline requirements of the use of treatment manuals. Moreover, the studies fell short of another APA guideline in not sufficiently describing participant characteristics. These shortcomings led Carr and Chong (2005) to conclude the HR procedure did not meet the criteria for *well-established* but rather for *probably efficacious*. Two years later another literature review was conducted that included five additional studies

(Cook & Blacher, 2007). In this review, a conclusion was made that HR met the criteria to be classified as a *well-established* treatment.

To address the HR literature since the last reviews of studies using single-subject designs (Carr & Chong, 2005; Cook & Blacher, 2007; Himle et al., 2006), a review of the literature was conducted by both authors of this chapter. Similar to Carr and Chong (2005), the terms habit reversal and tics or Tourette and competing response and tics or Tourette were searched (for titles only) in both PsycINFO and Medline databases. A total of 41 studies were identified, and the reference sections of each article were reviewed. Seven studies were eliminated because they were not published in English. The number of studies was further refined by eliminating studies using a between-subject design (comprehensive list of between-subject designs is listed in Table 59.2. One study prior to 2005 was included because it was not included in the Carr and Chong (2005) review. Unlike past reviews, studies were included even if no experimental design was implemented. This was done to give a more comprehensive view of what studies have been published since the previous reviews. A final list of 12 studies were included in the review and presented in (Table 59.1).

The 12 studies included in the review were evaluated for information across 14 categories. The first five categories included several participant characteristics including age, gender, diagnosis, motor or phonic tics, and the tic topography. The other categories included the study settings, independent and dependent variables, whether inter-observer agreement, procedural integrity, and social validity were assessed, and the experimental designs utilized. Finally, the last two categories included the reported results and whether a functional assessment was conducted.

The results from the literature review showed there were 22 participants included across the 12 studies. Only one participant was included in 7 of the 12 studies. The participants ranged in age from 7 to 49, with 19 males and 3 females. Motor and phonic tics were addressed in 9 studies, only motor tics in 2 studies, and only phonic tics in 1 study. The settings in which studies were conducted included school (4), clinic (6), home (5), and university program (1). The dependent variables were assessed for interobserver agreement in 8 of 12 studies, treatment integrity in 5 of 12 studies, and social validity was assessed in 3 of the 12 studies. An experimental design was used to assess the effectiveness of HR in 5 of the 12 studies. A functional analysis was conducted in 4 of the 12 studies. The full HR package, including awareness training, competing response training, social support and motivation strategies was not included in any of the 12 studies. A variety of combinations of the HR strategies was used across the studies. The results showed a reduction in tics was reported for 20 of the 22 (91%) participants. This conclusion, however, should be interpreted with caution given the number of studies that did not use an experimental design along with other methodological flaws.

This review of studies over nearly 20 years shows that HR procedures have been used in a variety of combinations. The procedures that comprise HR have differed across studies since its inception. Two procedures used consistently in HR, however, include awareness training and teaching a competing response. Where studies differ includes what other procedures constitute HR including social supports, relaxation training, and motivation strategies. The studies reviewed treated a variety of tic topographies across mainly three settings, including clinic, school, and home settings. Studies have not been conducted in community settings such as recreation or workplaces. The studies also primarily investigated HR with males at a ratio much higher than would be expected based on a diagnosis ratio between males and females. The results of these studies showed a reduction in tics for almost all the participants. This finding, however, is inconclusive due to major methodological shortcomings found across many of the studies. Close to 60% of the studies did not use an adequate experimental design to assess the effects of the HR components on the occurrence of tics nor checked treatment integrity. Interobserver agreement was not assessed in one-third of the studies. Only three studies used an adequate experimental design and assessed both interobserver agreement and

treatment integrity (Carr et al., 2005; Dufrene et al., 2013; Wiskow & Klatt, 2013).

Habit Reversal Summary

The HR treatment package appears to meet the "well-established" treatment given the number of between and within-group designs. There are now at least 13 between group studies showing HR effectiveness (see Table 2) and more than 20 single-subject studies with adequate experimental designs. Habit reversal is effective, rapid, and long lasting in treating nervous habits and tics, including those tics associated with TD. Moreover, various combinations of HR procedures have been successful in reducing tics in most cases. In fact, research has demonstrated that the two most important procedures in HR include awareness training and teaching a competing response (Miltenberger et al., 1985; Woods & Miltenberger, 1995).

Functional Behavioral Analysis

The cause of tics is unknown, however, there is evidence of dysfunction in the cortico-striatal-thalamo-cortical pathway that is a brain circuit that controls movement execution (Mink, 2003). In addition to this known neurobiological basis, research has also demonstrated that tics can be influenced by environmental conditions. For example, environmental factors that can affect symptoms of TD were investigated for 14 children aged 6–14 (Silva et al., 1995). Each participant completed a questionnaire and was interviewed to comprise the factors that had the most and least effect on symptoms. The results showed 17 factors affected symptoms, and the most common were events that made the participant upset or anxious. Examples of anxiety producing events included starting a new school year, waiting for test results, moving to a new location, and family arguments.

Environmental factors associated with tic occurrence also were investigated by examining the behavioral activity during tics for people with chronic tic disorder (O'Connor et al., 2003). Participants recorded the frequency of tics, intensity of urge to tic, and situations where the tics were most likely to occur for 10 days. The results showed the highest risk for tics included social activities such as being at a party, situations requiring waiting (e.g., in line to get something), and when in transit (e.g., going to an appointment). Although the study did not demonstrate these activities caused tics, it suggested environmental variables can affect tic occurrence.

Further investigation of environmental variables affecting tics was completed using a function-based assessment of tics (FBAT; Woods et al., 2008a) to describe the frequency with which various antecedent and consequence variables were reported to exacerbate tics in youth aged 9–17 diagnosed with a chronic tic disorder (Himle et al., 2014). The results from this study showed that all the participants reported at least two tic-exacerbating antecedents, and all but two participants reported at least one consequence. The most common antecedent was watching tv and playing video games, while the most common consequence was attention in the form of being told to stop the tic. This study demonstrated again that environmental variables might affect the occurrence of tics. Using indirect assessment of environmental variables potentially leads to treatments that can address antecedents that function as a signal for a tic and/or consequences that function as a reinforcer. This assumes that the assessment accurately identifies the correct variables affecting the tic. In one study, however, participants were asked to evaluate how specific contexts influenced their tics, after which they were observed in the situations to evaluate whether their reports were accurate (Barnea et al., 2016). The results showed their subjective assessments were often inconsistent with the data collected when they were directly observed.

In addition to the indirect assessments of variables affecting tics, direct assessment of environmental variables also has been conducted (i.e., functional analysis). By manipulating specific environmental variables that might affect tics, a functional relationship can be identified between the tic and the specific variable(s). A recent review of the literature summarized the results from 13 studies that experimentally manipulated consequences to identify reinforcers maintaining tics (Goldman & DeLeon, 2020). Although only 13 studies have been conducted to date, and therefore the results should be interpreted with caution, there are some interesting data. First, differences in tic function were found between participants diagnosed with an intellectual disability or communication impairment (ID/CI) versus those not diagnosed. The participants not diagnosed with ID/CI were much more likely to have an automatic function for their tics, where those with an ID/CI diagnosis had tics more distributed across automatic, attention, and escape functions. Second, looking at the number of datasets, participants with TD were less likely to also be diagnosed with an ID/CI compared to those not diagnosed with TD. Third, differences in tic function were found between the participants diagnosed with or without TD. Participants with TD were much more likely to have an automatic function for tics, and the non-TD participants were more likely to have an attention function, or to a lesser degree, an automatic function. Fourth, the tic topographies most commonly maintained by automatic reinforcement included throat clearing/coughing and arm movements. The topographies most maintained by social consequences included head movements and throat clearing/coughing.

The results of this review provide further evidence that although tics have a neurological basis, environmental conditions could affect the tics over time. The results also have an important implication for treating tics. That is, treatment for tics maintained by social consequences might be more effective when the particular social consequence is manipulated. For example, tics maintained by attention from parents might not completely reduce with habit reversal alone. In this case, treatment might be more effective if the parents are taught how to reinforce appropriate behavior rather than tics.

Comprehensive Behavioral Intervention for Tics (CBIT)

Researchers from the Tourette Syndrome Association's Behavioral Sciences Consortium developed a treatment approach called comprehensive behavioral intervention for tics (CBIT) and published both a therapist guide (Woods et al., 2008a) and treatment workbook (Woods et al., 2008b). The CBIT treatment package is comprised of habit reversal training, a functional assessment of tic reinforcement, and relaxation training (see Table 59.3). These behavioral interventions are used together to address TD in children at least 9 years old and adults in a 11-session package, perhaps as either an adjunct or an alternative to medication. The first phase in CBIT training consists of eight sessions delivered over 10 weeks. The second phase consists of booster sessions that occur once per month for 3 months to increase maintenance and generalization of the treatment.

The CBIT treatment was investigated in a randomized controlled trial for 126 children diagnosed with TD or chronic tic disorder (Piacentini et al., 2010). The CBIT treatment was compared to a control group receiving supportive psychotherapy and education. The study included eight sessions of 60–90 min each across 10 weeks. The results showed tics were significantly reduced in the CBIT group compared to the control group. Moreover, the magnitude of reduction in this study was comparable to results of controlled trials with antipsychotic medications for TD (Scahill et al., 2003). Overall, 53% of CBIT participants were rated as much or very much improved by independent clinical evaluators compared to 19% in the control condition. The tics in this study were also indirectly measured

using the Yale Global Tic Severity Scale (YGTSS; Leckman et al., 1989) showing a 31% reduction in the CBIT condition and 18% in the control condition. Despite using indirect measurement, the scope of this randomized control trial suggests that the CBIT treatment package can be effective in reducing tics for some children and perhaps as effective as some medications.

Another randomized trial comparing CBIT to psychoeducation and supportive therapy was conducted for 122 adults diagnosed with TD (Wilhelm et al., 2012). The study was similar in design to the first randomized control trial (Piacentini et al., 2010) except for adult participants. The results were also similar, with the CBIT treatment resulting in a significant reduction in tics. This study, however, found the treatment was less robust, with a positive response found for 38% of adults compared to 53% for children in the previous study.

The outcomes of these two large random controlled trials suggest CBIT is effective for many children and adults. The effectiveness of the CBIT treatment, however, has been limited to children aged 9 and older, presumably assuming younger children would be unable to engage in HRT because of limited awareness of tics and urges. Given the onset of tics often occurs at an earlier age, however, a recent study investigated an adaptation of CBIT for children 5–8 years old (Bennett et al., 2019). In this study, 15 children aged 5–8 with clinically significant tics received a modified version of CBIT. While the basic structure and components of CBIT remained, changes were made to make the treatment age-appropriate for younger children. For example, the HRT component was taught using “The Opposite Game” (TOG). This game was used to teach and assess each child’s awareness and control of bodily sensations and movements and to teach the concept of opposite body actions. Tics were then measured using the YGTSS, a parent questionnaire, and a treatment acceptability questionnaire. The results showed a significant decrease in tic severity as evidenced by scores on the YGTSS and the parent questionnaire. The improvements in the YGTSS scores also maintained at a 3-month and a 1-year follow-up assessment. The degree of changes in tic occurrence was found comparable to those found in the first CBIT trial (Piacentini et al., 2010). The treatment was also shown to be acceptable to the children and their parents. These results suggest that a modified CBIT for younger children is feasible and effective, although future studies need to be conducted.

Other modifications to the original CBIT protocol have been investigated. For example, concerns about the lack of qualified therapists and the length of travel distances to get treatment in some countries led to investigating a modified treatment length of CBIT. Recall in the original protocol, the first phase consists of eight sessions delivered over the course of 10 weeks (Woods et al., 2008a). Several studies have been conducted investigating different ways to shorten CBIT treatment from the original protocol. In one case study, a 25-year-old male diagnosed with TD was given a massed version of CBIT (Flancbaum et al., 2011). A total of seven sessions were administered in a 2 week rather than 10-week period. Reduced frequency for two tics were noted; however, several methodological flaws and lack of maintenance at a 5-month follow-up prevent concluding that a massed trial version of CBIT was effective.

In another study, two males aged 10 and 14 diagnosed with TD were given the CBIT treatment in an intensive outpatient program (IOP-CBIT) that included several hours of daily treatment across 4 days (Blount et al., 2014). Both participants had a reduction on the YGTSS assessment, reported treatment satisfaction, and maintained tic reductions at follow-up sessions (except one participant had some regression at a 6-month follow-up). A replication of this study was then conducted with a small sample of five children and adults diagnosed with TD and who had a wider range of tic severity (Blount et al., 2018). The IOP-CBIT protocol was administered in the same fashion and tics were again measured using the YGTSS. The results showed similar reductions in YGTSS scores.

To expand the availability of the CBIT treatment, non-therapist health care providers (i.e., nurse practitioners) were taught how to administer a modified CBIT (CBIT-NP) protocol (Ricketts et al., 2016b). The nurse practitioners were trained using a multifaceted training program intended to maximize treatment fidelity. Once trained, the nurse practitioners delivered CBIT-NP in six sessions or less, all under 25 min, across 6–8 weeks. Nine participants, average age 11.9, completed the CBIT-NP treatment. The results showed significant reductions in tic severity. Six of the nine participants were rated as having no tic-related impairment at posttreatment. In a posttreatment survey, nurse practitioners reported that the shorter session length was feasible but not preferable. Moreover, even though the CBIT-NP treatment was incorporated into their clinics, logistical barriers existed such as limited clinic space, billing, and poor patient attendance.

Another approach to providing CBIT training includes videoconferencing (VC) technologies. In a pilot study, VC was used to provide CBIT training to three children with TD (Himle et al., 2010). All three participants showed significant reductions in tic severity. In a follow-up study, 20 children were randomly assigned to receive CBIT delivered either through VC or traditional delivery (Himle et al., 2012). The results showed tic reductions in both groups, with no significant differences in mean reductions between groups. More recently, CBIT was provided using Voice over Internet Protocol telephony or web-based VC (Ricketts et al., 2016a). In the second of two studies, the feasibility, acceptability, and preliminary efficacy of delivering CBIT treatment with this technology were evaluated for four participants aged 10–13 diagnosed with TD. Families in this study were given a web camera during the study if needed and were helped in downloading Skype software. The results showed a 29.4% average decrease in YGTSS tic severity from pre to posttreatment. Moreover, parent satisfaction ratings were high and over 70% of sessions did not have any technology problems. There were some technology problems, however, such as a computer virus, variable sound quality, and keeping participant attention.

Finally, a randomized controlled trial was conducted investigating a modified four session CBIT treatment for 42 children and adolescents aged 6–18 (Chen et al., 2020). The participants in the treatment group received four sessions of CBIT over a 3-month period (rather than the eight sessions over 10 weeks). Both treatment and control groups received psychoeducation and 50 mg pyridoxine (standard treatment in Taiwan where study was conducted). Tics were measured using YGTSS scores. The results showed significantly reduced tic scores in the treatment group compared to the control group. This study was another demonstration that a modified CBIT treatment can be used to reduce tics.

The CBIT treatment protocol was initially developed using components already demonstrated to be effective (e.g., HRT). Several random control trials have been conducted demonstrating CBIT to be effective across children and adults. In fact, guidelines from the American Academy of Neurology now recommend CBIT as a first-line treatment when symptoms interfere with daily activities (Pringsheim et al., 2019). In addition, studies have demonstrated that CBIT can be modified to treat children younger than 9, the number of sessions can be reduced, sessions can be spread across time, the treatment can be provided online, and the treatment can be taught to and provided by nurse practitioners in clinical settings. Furthermore, the tic reductions maintained for most participants months after treatment ended.

Differential Reinforcement of Other Behavior (DRO)

Differential reinforcement of other behavior (DRO) is a procedure where a putative reinforcer is delivered contingent on the absence of a target behavior. The DRO procedure involves reinforcing the absence of the target behavior after a predetermined interval of time, and potentially involves several behavioral processes (see Cooper et al., 2020). In other words, reinforcement is delivered for not engaging in the target behavior (Reynolds, 1961). The reinforcer can be delivered contingent on the target behavior not occurring throughout intervals of time (interval DRO) or at specific moments of time (momentary DRO). Moreover, in both cases, the putative reinforcer can be delivered using a fixed or variable schedule of reinforcement.

The DRO procedure has been used to treat a variety of tics. For example, in an early case study, a boy aged 12 diagnosed with TD who engaged in inappropriate vocal and motor behavior was treated with an unidentified procedure (Rosen & Wesner, 1973). The procedure included an electric light being lit every 30 s period without the occurrence of vocal or motor responses. The boy was told that he would receive a piece of candy for every time the light came on. Although the procedure was not identified as DRO, the implementation meets the definition. The vocal and motor responses were reduced; however, other treatments were also implemented which prevented any conclusion on the effectiveness of the DRO.

In another study, a 5-year-old boy diagnosed with TD was treated for multiple motor and phonic tics (Miller, 1970). The boy was given two pieces of candy for each 1-min period that he was not making barking noises. The frequency of barking noises was reportedly reduced compared to the baseline rate. In this study, however, data were not reported, and there was not an experimental design. Moreover, neither a preference nor reinforcer assessment was conducted to determine whether the candy functioned as a reinforcer prior to the study. The procedure, however, meets the definition of differential reinforcement using a fixed-interval duration of time.

DRO Literature Review

The DRO procedure has been used in a variety of ways to treat tics. To evaluate these studies, a review of the literature was conducted by the authors. To conduct the search, the terms differential reinforcement of other behavior and tics or Tourette were searched in both PsycINFO and Medline databases. A total of eight studies were identified, and two were eliminated because they were not published in a peer-reviewed journal. The reference sections of each article were reviewed to obtain a total of 14 studies. Four studies were eliminated due to individual data not being reported. A total of 10 studies were identified to be reviewed (see Table 59.4).

The 10 studies included in the review were evaluated across nine categories. The first four categories included the number of participants, ages, gender, and diagnosis. The next three categories included the type of DRO (interval or momentary interval), whether the schedule of reinforcement was fixed or variable, and the length of the DRO interval. Given a reinforcer is delivered following time periods without tics, another category included whether a preference or reinforcer assessment was conducted to identify stimuli that functioned as a reinforcer. The last two categories included whether maintenance was assessed and the reported results (including the experimental design if utilized).

The results from the literature review showed 26 participants were included across the 10 studies (the 5 oldest studies were case studies each with 1 participant). The participant ages ranged from age 4 to 38, with 19 males and 7 females. Most of the participants were diagnosed with TD and engaged in both motor and phonic tics. All 10 studies delivered the putative reinforcer based on intervals of time (interval DRO). The intervals of time used appeared to be chosen arbitrarily or based on previous studies. The schedule of reinforcement was fixed across 8 studies. The fixed intervals ranged from 5 s to 5 min. In one exception, the schedule varied between 3 and 7 min (Wagaman et al., 1995). In the second exception, the DRO was implemented by providing a putative reinforcer (music) until a tic occurred. The music was removed and if no tic occurred for 1.5 s the music was returned until the next tic occurred. In effect, no occurrence of a tic for 1.5 s resulted in the music continuing until the next tic occurred. In this case, there was no predetermined set intervals (Barrett, 1962).

The reported results, supported by visual analysis, showed a reduction in tics for 23 of 26 (88%) participants. This reduction, however, included participants from studies without adequate experimental designs. Looking at only studies with experimental designs, 15 of 18 (83%) of participants had reductions in tics.

Table 59.4 Review of studies implementing differential reinforcement of other behavior (DRO)

Title	Author(s)	Year	Journal/book	*N*	Age and gender	Diagnosis	DRO (interval or momentary)	Schedule (fixed or variable)	DRO interval	Preference or reinforcer assessment	Follow-up assessed?	Results
Comparing fixed amount and progressive amount DRO schedules for tic suppression in youth with chronic tic disorders	Capriotti, Turkel, et al.	2017	*Journal of Applied Behavior Analysis*	4	16-F, 10-M, M-15, M-15	Tic disorder	Interval	Fixed	10 s	No	No	Tics were reduced for all four participants using both fixed and progressive-amount schedules of reinforcement using a multielement design
Comparing the effects of differential reinforcement of other behaviors and response-cost contingencies on tics in youth with Tourette syndrome	Capriotti, Brandt, et al.	2012	*Journal of Applied Behavior Analysis*	4	9-M, 10-M, 11-M, 13-M	Tourette disorder	Interval	Fixed	5 s	No	No	Tics were reduced in both DRO and a response cost condition compared to baseline for three of four participants using a multielement design
Evaluating the role of contingency in differentially reinforced tic suppression	Himle, Woods, et al.	2008	*Journal of Applied Behavior Analysis*	4	8-M, 9-M, 8-M, 10-F	Tourette disorder	Interval	Fixed	10 s	No	No	Tics were reduced more in the DRO condition than other conditions for three of four participants using a multielement design
Investigating the effects of tic suppression on premonitory urge ratings in children and adolescents with Tourette's syndrome	Himle, Woods, et al.	2007	*Behaviour Research and Therapy*	5	17-M, 14-F, 13-M, 10-M, 8-F	Tourette disorder and other diagnoses	Interval	Fixed	10 s	No	No	Tics were reduced for four of five participants using DRO in a withdrawal design

Table 59.4 (continued)

Title	Author(s)	Year	Journal/book	*N*	Age and gender	Diagnosis	DRO (interval or momentary)	Schedule (fixed or variable)	DRO interval	Preference or reinforcer assessment	Follow-up assessed?	Results
Creating tic suppression: comparing the effects of verbal instruction to differential reinforcement	Woods & Himle	2004	*Journal of Applied Behavior Analysis*	4	10-M, 10-M, 11-M, 9-F	Tourette disorder and other diagnoses	Interval	Fixed	10 s	No	No	Tics were reduced using the DRO procedure for all four participants, although the DRO condition always followed a verbal instruction condition
Brief functional analysis and treatment of a vocal tic	Watson & Sterling	1998	*Journal of Applied Behavior Analysis*	1	4-F	None reported; participant had phonic tic	Interval	Fixed, increased across sessions	15 s (increased to 300 s)	No, but FA done	Yes	Tics were reduced with DRO procedure; comparison design was used
Treatment of a vocal tic by differential reinforcement	Wagaman, Miltenberger, et al.	1995	*Journal of Behavior Therapy and Experimental Psychiatry*	1	9-M	Chronic vocal tic	Interval	Variable	3–7 min	No	Yes	DRO resulted in reductions for both phonic tics using a reversal design
Using behavioral interventions to decreases coprolalia in a student with Tourette's syndrome and autism: A case study	Earles & Myles	1994	*Focus on Autistic Behavior*	1	9-F	Tourette disorder and autism	Interval	Fixed	2 min	No	No	Tics were reduced in DRO condition but a comparison design was used
A behavioral approach to Tourette's syndrome	Rosen & Wesner	1973	*Journal of Consulting and Clinical Psychology*	1	12-M	Tourette disorder and brain injury	Interval	Fixed	30 s	No	No	Tics were reduced when procedure was used (a competing response was also used) but no experimental design
Reduction in rate of multiple tics by free operant conditioning methods	Barrett	1962	*Journal of Nervous and Mental Disease*	1	38-M	None reported	Interval	Neither	Duration between tics	No	No	Less tics occurred in differential condition, but no experimental design

Although no study included a preference or reinforcer assessment to identify stimuli that functioned as a reinforcer, that might be of less concern given the high percentage of participants with tic reductions. Whether the tic reductions maintained was assessed in only two studies. Tic reduction maintained for 6 months in one study (Watson & Sterling, 1998), and over 9 months in the other study (Wagaman et al., 1995).

The processes responsible for the reduction in tics using differential reinforcement were not investigated nor identified. Several possible processes could explain tic reduction. For example, a disruption in the response-reinforcer contingency could result in extinction. That is, if a tic does not occur, presumably the reinforcer maintaining the tic is not delivered. Only one study in this review, however, did a functional assessment to determine the reinforcer maintaining tics (Watson & Sterling, 1998). In this study, a coughing tic was found to be maintained by social attention. Then in the DRO procedure, attention was given for tic-free periods that increased from 15 s to 300 s. No longer providing the reinforcer (i.e., attention) for engaging in tics suggests extinction might be a process responsible for some tic reduction. This does not rule out, however, other potential processes that also could be responsible for tic reduction. For example, delaying access to reinforcement (e.g., gradual increase in the interval that must be tic free) could suppress tics through punishment. The processes involved in the DRO procedure need to be investigated in future studies.

The DRO procedure was also used in a study not included in this review (individual data not presented) to investigate tic suppression and the urge to engage in a tic (Spect et al., 2013). The DRO procedure was implemented by telling the 15 participants, aged 10–17, that a token exchangeable for prizes could be earned for every 15 s period with no tics. The frequency of tics was measured in baseline and DRO conditions within a reversal design. The data collapsed across participants showed a 72% reduction in tics in treatment compared to baseline conditions. This study, along with the 5 single-subject studies with experimental designs in the review, suggests the DRO procedure is potentially effective in at least a temporary reduction in tics.

Future research studies are needed to investigate whether DRO should be used in isolation or in combination with other procedures (e.g., HR). For example, a DRO could be implemented in HR by delivering a putative reinforcer during a no tic period while the participant practices the competing response. Studies are also needed to investigate guidelines for setting the DRO interval to ensure that participants not engaging in tics will contact reinforcement when the DRO is in place. For example, whether an initial short interval gradually increased across time would be more effective or result in more participant tic reduction needs to be investigated.

Summary

The occurrence of tics often begins in childhood, waxing and waning in frequency across time. Most cases of chronic tic disorders are mild and decline by the late teen years. Tics have a genetic and neurological cause but also can be affected by environmental conditions. Research has shown that motor and vocal tics can change in frequency, intensity, and form. This suggests that tics can be treated in part by identifying the environmental variables maintaining the tics and developing treatment plans that modify these variables.

Regardless of whether specific environmental variables are maintaining tics, they are treatable. There does not yet seem to be one best treatment for all cases of tics. Rather, treatment depends on several variables including age, severity, number of tics, and perhaps communication ability. In general, however, HR training and CBIT are the most researched and therefore best treatment options. At a minimum, treatment should begin with awareness training. This step alone has, in some cases, resulted in a reduction in tics. In most cases, however, a competing response should be identified and taught to the individual. Although these two steps sometimes result in tic reduction, treatment could be bolstered by including social support from friends and family members. Furthermore, treatment can include increasing motivation by planning when these strategies can be practiced and implemented in natural situations. In some cases, tics can be further ameliorated by teaching the individual relaxation procedures. These procedures also have been adapted to a variety of community situations, such as in environments with limited access to trained therapists or when there is reduced training time.

Although much research on tics has produced a robust treatment protocol, future research could be done to continue to identify procedures that might be more efficient and effective. More research is needed to determine what specific treatments, or treatment components, are predictive of tic reduction for individuals. Research is also needed to determine how to provide treatment in areas where services are limited or do not exist. For example, what are the best ways to treat tics in elementary schools or in rural areas where expertise on tic treatment protocols is often lacking.

Conflicts of Interest The authors declare no potential conflicts of interest with respect to the research, authorship, and/or publication of this article.

60 Stereotypy

Kara L. Wunderlich, Christina A. Simmons, Amanda N. Zangrillo, and Tracy L. Kettering

Stereotypy is a commonly occurring category of behaviors. They include a wide range of behaviors with repetitive, fixed movements being core observable features (Oakley et al., 2015). Many of you, while reading this chapter, are demonstrating similar responses, such as tapping your pen or pencil, twirling a lock of hair, or swinging your leg. Although these behaviors are present in many people's repertoires, deviation from a typical developmental course and sequence often draws additional attention from key stakeholders invested in a person's life or care, warranting consideration of additional assessment and intervention. In this chapter, we provide (a) a brief overview of the operational definition of stereotypy, prevalence, and course; (b) a discussion of ethical and social considerations when determining the applied value of intervention; (c) a description of assessment and treatment procedures; and (d) considerations when implementing treatment.

Overview

Stereotypy is an umbrella term describing a wide range of repetitive responses or activities with no apparent goal or purpose (Rapp & Vollmer, 2005; Singer, 2009). This collection of behaviors is sometimes colloquially referred to as "stimming," "stims," or self-stimulation due to the hypothesis that the responses most often produce a form of arousal reduction (e.g., escape from stimulation) or arousal induction (e.g., access to sensory stimulation). Table 60.1 presents a list of common topographies of stereotypy and considerations unique to each topography category.

For most young children, stereotypical behavior commonly occurs during the early developmental period and typically decreases in frequency and intensity as children develop language, functional play skills, and other adaptive behaviors into childhood, adolescence, and adulthood (Goldman et al., 2008). Although common for some topographies of these behaviors to persist in most individuals' behavioral repertoires, stereotypy doesn't commonly continue at a level, severity, or frequency that impacts daily functioning (e.g., nail biting, hair twirling).

Stereotypy becomes a clinical concern if frequency and intensity do begin to interfere with social interactions, language, daily living skills, and leisure activities. Clinically significant stereotypy disproportionately occurs in individuals with autism spectrum disorder (ASD), intellec-

Table 60.1 Common examples of stereotypy and considerations for each topography

Categories	Examples
Fine motor	Finger rubbing, hair twirling, head nodding
Gross motor	Body rocking, spinning, pacing, jumping
Vocal	Humming, singing, noncontextual laughter, echolalia
Object-directed	Spinning objects, page rubbing, object mouthing
Higher-order or complex	Lining up objects, routines/rituals, conversation topics

tual disability, certain genetic disorders, and other neurodevelopmental disorders (Bodfish et al., 2000). A review of the literature found the prevalence of stereotypy to be approximately 61% in individuals with developmental disabilities. Prevalence of stereotypy was highest (88%) among those with ASD (Chebli et al., 2016). Stereotypy is also very common in individuals with psychiatric conditions, such as OCD, or neurological conditions, such as Parkinson's Disease (Bodfish et al., 2000).

Restrictive and repetitive behaviors (RRBs) are one of the diagnostic criteria for ASD, and stereotypy is one subtype of RRB. Identification of the occurrence of stereotypy is often captured using the Repetitive Behavior Scale-Revised (RBS-R; Mirenda et al., 2010), the stereotypy subscale of the Problem Behavior Inventory (PBI-01; Rojahn et al., 2001), or the repetitive behavior score on the Autism Diagnostic Interview-Revised (ADI™-R; Lord et al., 1994). Because stereotypy may occur at a high rate, behavior analysts typically record stereotypic behavior using duration measures or discontinuous sampling procedures, such as partial interval recording or momentary time sampling (Matson & Nebel-Schwalm, 2007).

Although it is easy to label a response as stereotypy, one cannot determine if a response is *stereotypic* based on topography alone. A stereotypic behavior, by definition, has no social purpose; thus, a repetitive response hypothesized to access some sort of social reinforcement would not be considered stereotypy. Take, for example, a child that repetitively licks objects. This behavior could be considered stereotypy if it serves no functional social purpose, or is maintained by automatic reinforcement. However, if this behavior occurs in order to gain access to social attention, then it would not qualify as stereotypy. The only way to make this determination is, of course, through functional behavioral assessment, described in the Functional Assessment Section of this book (see section "Behavioral Interventions for Stereotypy").

Individuals can display stereotypy both with and without physical injury; however, for the purpose of the present chapter, we turn our attention to stereotypy classified as non-injurious. For a detailed description of repetitive behavior with self-injury, we direct the reader to Chap. 66. Although some other repetitive behaviors may share features with stereotypy, they are also better discussed separately due to their unique features. Therefore, a discussion of tics can be found in Chap. 63, trichotillomania in Chap. 64, and toe walking in Chap. 68.

Clinicians and researchers classify stereotypy in a number of different ways, including topography (e.g., motor or vocal), the hypothesized sensory function that may be obtained through the behavior (e.g., vestibular, auditory), or number of stereotypies displayed (e.g., simple or complex). Topographies of stereotypic behaviors can be vocal or nonvocal, include gross or fine motor movements, and be performed with or without objects.

Is Stereotypy an Appropriate Target Behavior?

Behavior analysts have developed a highly effective technology that can affect change on a wide range of behaviors. Function-based assessment and intervention have indeed revolutionized our field and allowed for much more targeted, efficacious interventions for decreasing problematic behaviors. However, the existence of such powerful behavioral technology does not automatically indicate that practitioners should readily apply such tools for any behavior deemed problematic by another individual. Behavior analysts must avoid selecting target behaviors for the sole benefit of non-client individuals or to normalize society (Behavior Analyst Certification Board, 2014).

Although practitioner accountability is relevant across all target behaviors, this accountability is particularly important when considering stereotypy as a target behavior. Individuals with ASD and intellectual and developmental disabilities are often subject to normalization attempts due to decreases in autonomy and increased prevalence of maladaptive behaviors. Normalization refers to "the use of progressively more typical environments, expectations, and procedures to establish and/or maintain personal behaviors which are as culturally normal as possible," (Wolfensberger, 1972, p. 28). Further, stereotypic behavior ranges greatly in topography and severity, raising ethical considerations of whether intervention is warranted across all situations.

Across the behavior analytic literature, multiple guidelines have been disseminated for selecting appropriate target behaviors (e.g., Bosch & Fuqua, 2001; Hawkins, 1984; Komaki, 1998). A common thread throughout all of these guidelines is the critical importance of identifying whether the change in behavior will meaningfully improve the individual's life. As behavior analytic practitioners, it is imperative that any target behavior we select for change must have direct or indirect benefits to the individual.

To help make this determination, practitioners may consider asking several questions when deciding whether to target stereotypy:

- *Does the behavior result in functional impairment?*
- *Can functional impairment be reduced by changing the behavior of others?*
- *Is there a potential for the behavior to become harmful to the individual or others?*
- *Are there other behaviors to target that result in a decrease in stereotypy?*

Does the Behavior Result in Functional Impairment?

When stereotypy is identified as a target behavior by stakeholders (e.g., parents, teachers, direct support providers), the behavior analyst must question whether intervention on the stereotypic behavior constitutes a socially significant change for the client. Practitioners are first charged with determining whether the persistence of stereotypy results in functional impairment for the individual. Potential sources of functional impairment may include, but are not limited to, cases in which stereotypy interferes with skill acquisition, interferes with task completion, results in adverse social consequences, is unsanitary, and/or results in property destruction.

In some cases, persistent stereotypy may interfere with skill acquisition or task completion due to incompatible responses (e.g., Dunlap et al., 1983; Lanovaz et al., 2013; Matson et al., 1997; Morrison & Rosales-Ruiz, 1997). For example, persistent motor stereotypy involving the hands, such as hand flapping, may make it nearly impossible for an individual to practice a new motor skill (e.g., matching objects) or to complete a vocational activity (e.g., washing dishes). Similarly, persistent stereotypy involving the entire body (e.g., spinning) may interfere with an individual observing a therapist's controlling prompt in order to acquire a new skill. Vocal stereotypy may be incompatible with acquisition of vocal behavior or vocal responses necessary for functional community participation (e.g., providing personal information).

Further, stereotypic behaviors may be determined to have adverse social consequences (e.g., Jones et al., 1990; Wolery et al., 1985). Persistent stereotypy may result in peer isolation and rejection due to social stigmatization or interference with appropriate social exchanges. Social consequences of stereotypy may impact employment opportunities and community integration. Certain topographies of stereotypic behavior may be deemed unsanitary or potentially harmful to others (e.g., potential for spread of harmful pathogens due to saliva play; Piazza et al., 2000). Finally, repetitive behaviors may have adverse consequences on the environment, such as property destruction. For example, the participant described in a study by Mace and Belfiori (1990) engaged in repetitive object touching that resulted in occasional damage to property in the home environment.

Practitioners and researchers alike should clearly document the applied value of targeting an individual's stereotypy (e.g., degrees of functional impairment, injury, harm) to justify the need for intervention. For example, Mace and Belfiori (1990) presented the following description of the impact of motor stereotypy on their participant, describing interference with task completion, social impairment, and resulting property destruction:

> Doris engaged in repetitive, stereotypic touching of objects and, occasionally, people. The stereotypy interfered with completion of household tasks and socialization with clients and staff. Occasionally, the touching resulted in physical damage to the home (e.g., broken lamps) and to other clients (e.g., scratching). (p. 508)

In another example, Piazza et al. (2000) presented the following explanation of functional impairment that describes both unsanitary consequences and social impairment:

> Windows, floors, furniture, walls, and toys in Brad's home were covered in saliva. His saliva play was unsanitary (increased the exposure of friends and family to saliva-borne pathogens) and limited Brad's opportunities for integration into the community (community members did not want to be exposed to his saliva and the risk of infectious diseases). (p. 15)

Both examples justify the need for behavioral intervention by presenting multiple reasons why stereotypy yielded negative consequences for the individual and the environment. Although both of these examples draw from published research, similar justifications should be provided in formulation, documentation, and reports of intervention goals in clinical endeavors.

Can Functional Impairment be Reduced by Changing the Behavior of Others?

Although the goal of practitioners should be to maximize access to reinforcers in the natural environment, an important consideration is *whose* behavior should change. Practitioners should consider whether we can educate others on stereotypic behaviors rather than attempting to change behavior that others do not understand or deem acceptable (i.e., normalization). Interviews and focus groups conducted with adults with ASD who engaged in stereotypy suggested that they objected to attempts to eliminate their stereotypic behavior through intervention. A common theme that arose from these interviews was that social acceptance of their stereotypic behavior could be increased through educating others (Kapp et al., 2019).

Research has suggested that elementary (Campbell et al., 2004; Magiati et al., 2002) and middle school students (Campbell & Barger, 2011) lack adequate knowledge of ASD and its related behaviors, such as stereotypy. Campbell and Barger (2011) discussed how peers may misinterpret atypical behaviors (e.g., body rocking), which may then contribute to social distancing and social rejection of individuals with stereotypy. Peer education has been shown to improve acceptance of children with ASD in general education settings (Rao et al., 2003). Peer education that provides accurate information about autism may not only rectify global misattributions of students' behavior but may also promote acceptance of individual differences, leading to social acceptance without requiring an individual to decrease their stereotypic behavior.

Similarly, research suggests that law enforcement officers have varied knowledge of ASD and its related features (Gardner et al., 2019). Promoting education of law enforcement officers regarding behaviors such as stereotypy may promote more appropriate and safe interactions and understanding of individual differences.

Is There a Potential for the Behavior to Become Harmful?

As previously noted, this chapter highlights considerations for specific forms of stereotypic behavior that do not produce injury to the individual. However, an additional consideration that practitioners should take into account is the additive effects of consistent and pervasive stereotypy. A single instance of a response, for example, may not pose immediate concern, but frequent repetition of a response could have a deleterious impact. Other concerns may include a response becoming self-injurious over time due to its frequency and intensity. For example, pervasive hand mouthing may be characterized as self-injurious behavior when it occurs at such a level that it causes tissue damage (Richman & Lindauer, 2005). Clinicians may collaborate with stakeholders and medical professionals to fully understand the long-term effects of repeated stereotypy to guide determination of the appropriate point of intervention and reduce risk of harm to the individual.

Are There Other Behaviors to Target That May Result in a Decrease in Stereotypy?

Practitioners should also note whether stereotypy occurs more frequently in certain contexts and under certain antecedent conditions. Through structured interviews or direct observation, a behavior analyst might detect that features such as a skill deficit may contribute to the presence of stereotypy and thus teaching an appropriate skill (e.g., appropriate social conversation exchanges) may result in a decrease in stereotypy. Some research has suggested that anxiety in children with ASD may increase levels of repetitive behaviors (Hallett et al., 2013). As such, appropriate treatment of anxiety may result in a concomitant reduction in stereotypy. For example, an individual exposed to aversive stimuli in a specific setting may engage in increased levels of stereotypy; thus, stereotypy may be reduced by systematically introducing the individual to the aversive context (e.g., environment with excessive social stimulation).

Once practitioners have undertaken the task of determining whether the topography of interest is of sufficient concern to warrant intervention, they are faced with two courses. One option is to proceed to intervention. The second is to proceed to continued monitoring and turn attention to skill development or behavior reduction in other target behaviors. Although the question of *how* to intervene is discussed below, we provide one final consideration for readers regardless of the path selected. Specifically, we strongly encourage practitioners to provide detailed documentation in supporting materials (e.g., functional behavior assessment, behavior intervention plan, individualized education program) of the course of action (i.e., to intervene or not on the specific behavior of interest) and justification for the decision. As noted above, careful consideration and documentation of level of impairment, influence of the environment, risk of harm, and presence of other collateral behaviors are critical components of the treatment plan.

Behavioral Interventions for Stereotypy

As with other topographies of problem behavior, interventions for stereotypy can be broadly categorized as either antecedent or consequent interventions and may or may not be informed by identified function. Because the specific automatic reinforcer (i.e., specific sensory contribution) is often difficult to identify, function-based interventions may be less possible for stereotypy relative to socially maintained problem behavior. Further, practitioners often must employ two or more interventions in a treatment package to achieve clinically significant reductions in stereotypy (e.g., Dickman et al., 2012; Falcomata et al., 2004).

Below, we discuss the most common behavioral interventions for reducing stereotypy, as well as specific considerations for the implementation of each intervention.

Antecedent Interventions

Antecedent Exercise Physical activity has appeared in the extant literature for several decades as an antecedent intervention for reducing stereotypy, as well as other maladaptive behaviors such as aggression and off-task behavior. In most antecedent exercise interventions, the clinician prompts the client to engage in walking or jogging for a period of time prior to an interval in which lower levels of stereotypy are desirable (e.g., jogging for 10 min prior to 1:1 instruction time). Although jogging is the most common form of exercise used in antecedent exercise interventions, the intervention has been demonstrated to be successful with activities as disparate as exergaming, martial arts, and trampoline jumping (Anderson-Hanley et al., 2011; Bahrami et al., 2012; Neely et al., 2015).

Despite the numerous studies on antecedent exercise, the minimum duration of activity that is required for the activity to be effective or whether certain topographical requirements of the physical activity must be met is unknown. Further, despite the intervention's efficacy, the mechanism by which behavior reduction is obtained is unclear. One hypothesis is that antecedent exercise produces fatigue, resulting in concomitant decreases in stereotypy. This hypothesis is somewhat contradicted, however, by evidence that not all behaviors decrease following exposure to antecedent exercise. Some adaptive behaviors, such as on-task behavior, have been shown to increase after physical activity (Neely et al., 2015). A second, more viable hypothesis is that antecedent exercise serves as an abolishing operation for stereotypy, reducing the value of the reinforcers produced by stereotypy and thus reducing the likelihood of stereotypic behavior (Neely et al., 2015). Practitioners should therefore carefully consider the duration of exercise used, as longer durations of exercise do not necessarily produce greater reductions in the target behavior. At present, it is also unclear if the topography and mode (e.g., aerobic or anaerobic) of the exercise are important, and for how long the effects of the intervention are sustained postexercise.

Noncontingent Reinforcement Noncontingent reinforcement (NCR) is often recommended as an intervention for stereotypy due to its ease of implementation, the lack of potential side effects (such as those common with punishment-based procedures), and the large number of research studies documenting success in reducing target behavior. In some examples of NCR, clinicians provide continuous access to several different, preferred items or activities; this approach might also be called "environmental enrichment." For other clients, a clinician might select one specific item or activity to provide continuously or on a time-based schedule to reduce the establishing operation for stereotypy. Usually, dense schedules of delivery are needed at the start of intervention, but it may be possible to fade the schedule over time (see Chap. 6 for a detailed discussion of reinforcer thinning).

Clinicians should carefully consider the stimuli selected for use in an NCR intervention. In some cases, an arbitrarily selected item, especially one that is highly preferred, can effectively compete with stereotypy. Often, though, finding items or materials that generate stimulation similar to the hypothesized sensory consequences produced by the stereotypy is most effective. Piazza et al. (2000) were some of the first researchers to evaluate the effects of items that produced stimulation similar to the sensory consequences hypothesized to be maintaining target behavior (i.e., *matched*) compared to items that produced unrelated sensory consequences (i.e., *unmatched*). This research and subsequent studies have demonstrated that NCR interventions that included matched items produced greater reductions in stereotypy (e.g., Love et al., 2012).

Table 60.2 provides a list of sample items to consider as competing stimuli, organized by hypothesized sensory reinforcement produced by the targeted stereotypy. For example, to match the sensory consequences for vocal stereotypy,

Table 60.2 Hypothesized sensory consequences and competing stimuli for sample stereotypy topographies

Hypothesized sensory consequence	Example topography	Potential competing stimuli
Vestibular	Body rocking, spinning	Rocking horse, sit-and-spin, trampoline, exercise
Auditory	Humming, singing, tapping	Music, white noise, recording of own stereotypy, sound toys
Tactile	Squishing objects, saliva play	Slime, stress ball, shaving cream, textured or "fidget" toys
Olfactory	Sniffing, inhaling, forceful exhaling	Deep breathing exercises, blowing nose
Visual	Peering, pushing on eyes, waving fingers in front of eyes	Light up toys, flash lights, spinning toys
Oral	Hand mouthing, shirt chewing, item licking	Chewing gum, chew tube

clinicians could use different forms of auditory stimulation. Noncontingent music has been demonstrated to reduce vocal stereotypy in a number of cases (e.g., Lanovaz et al., 2014). Saylor et al. (2012) found substantial reductions in stereotypy when they noncontingently played a recording of a child's own stereotypy. The authors also included a comparison to noncontingent music, with noncontingent access to music being slightly more effective in reducing vocal stereotypy and more highly preferred by the children and their caregivers. In a similar example, Rapp et al. (2012) employed a talking robot toy as matched stimulation for vocal stereotypy. Other examples of matched stimulation used in noncontingent reinforcement interventions include a chew object for saliva play (Luiselli et al., 2004) and a vibrating pen placed on the neck for head rocking (Wilder et al., 2000).

When identifying a stimulus that may compete with the stereotypic behavior in a noncontingent reinforcement intervention, practitioners can begin with a competing stimulus assessment (CSA; Haddock & Hagopian, 2020). Similar to a preference assessment, in a CSA a variety of items or activities are nominated by the practitioner or caregiver that are hypothesized to compete with the stereotypic behavior. The stimuli are then presented for brief periods of time (3–5 min). A no-stimulus control condition, similar to the no-interaction condition of a functional analysis, should also be implemented for comparison. Data should be collected on both the target behavior (i.e., stereotypy) and engagement with the item or activity. Practitioners should select stimuli that produce lower levels of target behavior and high levels of engagement to maximize efficacy of the NCR intervention.

Figure 60.1 displays hypothetical results from a CSA that could be conducted for vocal stereotypy. Based on the results from Fig. 60.1, exposure to a self-recording produced lowest levels of vocal stereotypy and highest levels of engagement relative to the control condition. Of note, practitioners may consider frequent reassessment of competing stimuli given the ease of implementation of the CSA to proactively prevent satiation, continue to reassess additional items that may contribute to further reductions in stereotypy, and address any decrements in treatment efficacy.

Similar to the evolution of the preference assessment literature, various modifications of the CSA are noted in the literature. For example, Brogan et al. (2018) described a free-operant variation in the CSA that provides information about competing properties of the stimuli and a more direct measure of relative preference. In addition, Hagopian et al. (2020) developed an augmented competing stimulus assessment (aCSA) that involves providing prompts to engage with the item or activity while blocking the target response.

Reinforcement-Based Interventions

Differential Reinforcement Differential reinforcement of other behavior (DRO) and NCR share common features in that both interventions reduce stereotypy by delivering a reinforcer at

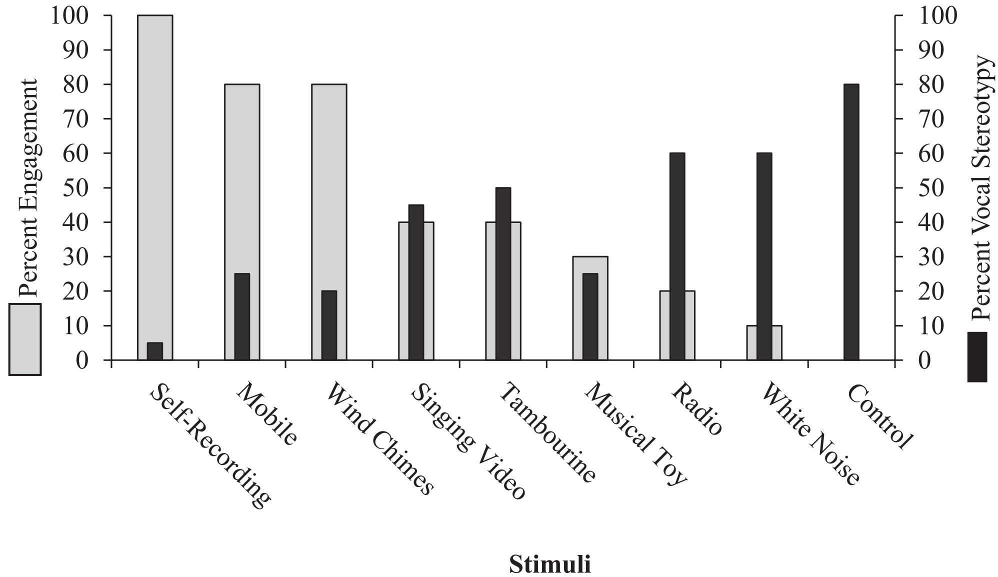

Fig. 60.1 Sample competing stimulus assessment

specified intervals; however, in DRO, the practitioner delivers the reinforcer contingent on the absence of stereotypy for a period of time rather than on a strictly time-based schedule. Although DRO is also generally most effective when the functional reinforcer is applied, nonfunctional reinforcers are often utilized in DRO procedures to reduce stereotypy due to the difficulty identifying and/or arranging contingent access to the functional reinforcer.

Practitioners should select short DRO intervals, or even better, select intervals that are based on response patterns of stereotypy. For example, if stereotypy occurs very frequently, practitioners should measure the time between bouts of behavior (i.e., inter-response time), and start with DRO intervals that are shorter than that interval (Rozenblat et al., 2009). As stereotypy decreases at short intervals, practitioners should systematically increase the DRO interval until reaching a schedule that is feasible to implement in the natural environment (e.g., Taylor et al., 2005).

In some circumstances, a practitioner may choose to implement differential reinforcement of alternative behavior (DRA) instead of, or in combination with, DRO to reduce stereotypy. In a DRA intervention, a practitioner reinforces the occurrence of a specific alternative behavior or behavior incompatible with stereotypy (Vollmer et al., 1994). For example, for a client who engages in vocal stereotypy, a practitioner may reinforce appropriate communication with access to a highly potent reinforcer. In a combined DRA and DRO, the contingency for reinforcement would be to engage in the alternative behavior while not emitting the stereotypic behavior. Researchers have shown that this combined contingency may be more effective than DRO or DRA alone (Hedquist & Roscoe, 2020).

Although not required, most applications of DRA include extinction for the target behavior (Vollmer et al., 2020). In the case of stereotypy, arranging extinction is often difficult or impossible. Therefore, most differential reinforcement interventions for stereotypy will not include an extinction component, and they may rely on delivering an arbitrary reinforcer (e.g., an edible item) rather than a functional one. In applications of differential reinforcement, practitioners should conduct a preference assessment or CSA to identify highly preferred items or items that compete with stereotypy (e.g., Taylor et al., 2005), or consider using access to stereotypy as a reinforcer as long as you are able to restrict its access to deliver contingently (Potter et al., 2013).

Sensory Extinction

In some cases, clinicians may be able to hypothesize the specific maintaining reinforcer for stereotypy. In applications of sensory extinction, the practitioner disrupts the response-reinforcer relationship by masking or preventing the sensory stimulation produced by the stereotypic action. For example, Rapp et al. (1999) hypothesized that one participant's hair manipulation was maintained by the tactile stimulation in her fingers. Wearing latex gloves modified the stimulation produced by the hair manipulation and effectively reduced this behavior.

When designing sensory extinction, practitioners attempt to mask the specific hypothesized sensory consequence maintaining stereotypy. However, even when a practitioner has a plausible hypothesis about the specific maintaining sensory consequence for stereotypy, this can be very difficult to validate. Thus, even when the implementation of sensory extinction results in reductions in stereotypy, it is often difficult if not impossible to attribute reductions to sensory extinction alone.

As with all extinction procedures, sensory extinction should be used in combination with reinforcement-based interventions. Sensory extinction should also not be attempted with all topographies of stereotypy. For example, if a hypothesized reinforcer for ear plugging is automatic negative reinforcement in the form of escape from aversive noises, it would not be ethical to arrange for sensory extinction such that aversive sound could not be minimized by the client without providing alternative access to automatic negative reinforcement. Extinction also comes with a host of side effects, such as elicited emotional responses and/or aggression that practitioners need to be aware of when they employ this procedure (Lerman et al., 1999).

Response Blocking Response blocking is a commonly employed intervention for gross motor and object-directed stereotypy (e.g., hand mouthing; Roscoe et al., 2013). In such cases, blocking is accomplished by the practitioner preventing the behavior from occurring through temporarily physically intervening in such a way that the entirety of the stereotypical response cannot be emitted. For example, if a clinician were to use response blocking to reduce hair pulling, then the clinician would prevent the client from placing their hands within a certain distance (e.g., 5 cm) of their hair; the client would otherwise be unrestrained and able move their arms freely. Because response blocking is performed by the practitioner and is not accomplished through manual or mechanical restraint, blocking is not an appropriate intervention for many topographies of stereotypy. For example, response blocking cannot be conducted with vocal stereotypy or behaviors such as posturing.

Research indicates that blocking may reduce behavior through extinction for some individuals, whereas it may serve as punishment for other individuals. Three studies have evaluated the mechanism by which blocking reduced automatically maintained self-injury, and the results collectively indicate that the effects of blocking are idiosyncratic (Lerman & Iwata, 1996; Smith et al., 1999; Wunderlich et al., 2017). This is likely also true for response blocking of automatically maintained stereotypy, although it has yet to be evaluated empirically. However, because it is possible that response blocking operates as a punisher for many individuals, appropriate safeguards and protections should be in place regarding the use of punishment whenever a blocking procedure is used (Behavior Analyst Certification Board, 2014).

Punishment

Response Interruption and Redirection Response interruption and redirection

(RIRD) is a punishment procedure in which the practitioner interrupts each occurrence of stereotypy by delivering a demand or a series of demands. Demands can be either matched to the topography of the stereotypy (e.g., asking a child to clap their hands instead of hand flapping) or unmatched (e.g., answering intraverbal questions instead of hand flapping) and can include one or multiple demands. Some practitioners require the client to both refrain from stereotypy and comply with demands before the demand sequence is terminated. More information on RIRD can be found in Chap. 16.

As first researched by Ahearn et al. (2007), RIRD is a promising intervention to reduce both motor and vocal stereotypy. However, more recent research has indicated that the data analysis procedures used in some RIRD research may impact the interpretation of treatment efficacy. It is possible that apparent intervention success in some studies may have been at least partially an artifact of the data analysis method rather than overall reductions in stereotypy (Carroll & Kodak, 2014; Wunderlich & Vollmer, 2015; DeRosa et al., 2019).

Response Cost Response cost as an intervention for stereotypy is most often implemented as the brief removal of a preferred item as part of a treatment package. For example, Watkins and Rapp (2014) implemented environmental enrichment for five individuals with problematic stereotypy by giving continuous access to a preferred item, but found no substantial decreases in the level of stereotypy. When researchers removed the preferred item for 15 s following each instance of stereotypy, behavior immediately decreased to low levels for all five individuals. Response cost has also been used to successfully reduce stereotypy with noncontingent reinforcement (e.g., Falcomata et al., 2004), differential reinforcement (e.g., Laprime & Dittrich, 2014), and differential reinforcement procedures within a token economy (e.g., Shillingsburg et al., 2012).

Other Punishers Other punishers, such as overcorrection, reprimands, and time out, have also been evaluated for use with stereotypy. Response blocking and sensory extinction procedures, described above, may also be better classified as punishment procedures depending on the mechanism by which they reduce stereotypy.

Because the effects of punishers are often idiosyncratic and the likelihood of side effects may be high, clinicians may consider using a punisher assessment to first determine what mild punisher is most effective and socially valid before implementing an intervention package containing a punishment component. Verriden and Roscoe (2019) describe a simple procedure consisting of a thorough caregiver interview and a multielement evaluation of several mild punishers (in combination with both NCR and DRA) to evaluate effects on both stereotypy and collateral behaviors. These procedures resulted in successful treatment of stereotypy with increased levels of appropriate behavior and low levels of emotional responding. Practitioners considering punishment procedures for stereotypy should review ethical safeguards and social validity measures, as well as intervention effectiveness.

Factors Guiding Intervention Selection

Practitioners should match the intervention for stereotypy to the hypothesized behavioral function whenever possible (Cunningham & Schreibman, 2008). We also recommend practitioners consider access to functionally equivalent sources of competing reinforcement (Rapp & Vollmer, 2005) or teach alternative behaviors that produce access to reinforcement. The contexts for intervention, plans for maintenance and generalization, and transition to naturalistic environments must all be considered carefully. Figure 60.2 displays considerations and potential contraindications for each of the intervention procedures described, and below we present

		Considerations				Potential Contraindications			
		Individual engages in adaptive alternative responses	May provide access to automatic reinforcement	Requires preference assessment or CSA	Stereotypy is prevented from occurring	May be effortful for implementer	Could result in emotional or aggressive responses	May not be feasible for individuals with physical limitations	May not be feasible for vocal stereotypy
Antecedent	Antecedent Exercise	X						X	
	Noncontingent Reinforcement		X	X					
Reinforcement	DRO		X	X		X			
	DRA	X	X	X		X			
Extinction	Sensory Extinction						X		X
	Blocking				X	X	X		X
Punishment	RIRD					X	X		
	Response Cost					X	X		

Fig. 60.2 Attributes and contraindications for stereotypy interventions

several additional practical recommendations to consider when selecting interventions for stereotypy.

1. *Define an appropriate treatment goal*
   After determining that stereotypy is an appropriate target for behavior reduction, practitioners should consult with the client and relevant stakeholders to determine the appropriate treatment goal. For some individuals, a decrease in the level of stereotypy across all contexts is the most appropriate goal. In other cases, clinicians may aim to reduce stereotypy only for specific periods of time or in specific circumstances. This is often the case when stereotypy is only a problem in certain environments or when stereotypy is problematic because it is interfering with access to other reinforcers. Such goals are essential to identify before choosing an intervention to implement.
   If the stereotypy is problematic due to the overall frequency (e.g., high levels of repetitive motor movement causing deterioration of joint tissue), then a reduction in the behavior throughout the client's day might be the most appropriate treatment goal and well matched with an intervention such as DRO. By contrast, if the behavior is problematic due to interference with specific contexts (e.g., learning opportunities), then teaching stimulus control should be a component of the intervention (see section on discriminative stimuli below), and the practitioner should select interventions that also support alternative adaptive behavior (e.g., DRA). For example, a teacher might request that a student's motor stereotypy be reduced, in level and/or intensity, during large-group instruction time but not during individual work time. If stereotypy is interfering with the ability to access reinforcers in social situations, then a prime goal for practitioners should be to select intervention components that prioritize social inclusiveness.
2. *Implement reinforcement-based approaches first*
   The Behavior Analyst Certification Board's Professional and Ethical Compliance Code for Behavior Analysts provides guidelines to practitioners to consider reinforcement-based approaches to intervention prior to punishment (Behavior Analyst Certification Board, 2014). More specifically, an adaptive and functional alternative behavior should be selected to replace stereotypy whenever possible. This obligation to reinforcement-based approaches is heightened for stereotypy as these behaviors may not produce immediate danger, may be more treatment resistant due to their persistence and likelihood of being maintained by automatic reinforcement, and may be more susceptible to normalization attempts.
   When the ethical application of punishment for stereotypy is justified (e.g., failure of reinforcement-based approaches, immediate danger), practitioners should only consider punishment in conjunction with reinforcement in line with ethical standards of the field. The application of punishment with individuals with developmental disabilities has been widely discussed and critically reviewed (e.g., Lerman & Vorndan, 2002; Matson & Taras, 1989). Those practitioners implementing interventions with vulnerable populations have an increased responsibility to comply with ethical standards (Pokorski & Barton, 2020).
3. *Consider Intervention intrusiveness and adherence*
   When selecting treatment approaches for stereotypy, practitioners should consider the intrusiveness for clients. We recommend consideration of degree of difficulty, degree of restrictiveness, level of autonomy, and preference when considering client characteristics that impact intervention selection. For example, although antecedent exercise is an effective intervention to reduce stereotypy for many individuals, such vigorous exercise may be especially burdensome to some clients or lead to increased frustration due to lack of coordination or muscle tone. In such circum-

stances, antecedent exercise would be contraindicated.

Practitioners should also devise interventions that maximize efficacy and durability while decreasing the likelihood of caregiver burnout. Special consideration should be provided to caregiver-specific barriers to intervention implementation (e.g., resources, education level, time). For a comprehensive review of factors impacting caregiver adherence, see Allen and Warzak (2000).

4. *Enhance Discrimination using signals*

   Practitioners may consider using unique signals to aid in discrimination of when certain treatment components are or are not in effect. Simple stimuli, such as colored cards or bracelets, can be paired with specific components of a treatment package (e.g., reinforcement, extinction, punishment). For example, Cook et al. (2014) used a red card to signal that reprimands would be delivered following each instance of stereotypy and a green card to signal that no social consequences would be delivered for stereotypy.

   Signaling periods of time in which interventions are in effect may also result in a desirable inhibitory effect when that signal is introduced in new contexts. For example, Tiger et al. (2017) reduced one child's toy car hoarding behavior with a blocking procedure. A specific-colored car was present during intervention to signal that blocking was in effect. The researchers then introduced the same car in two other contexts, and car hoarding immediately reduced without the need for blocking.

5. *Include only necessary components*

   In many cases, when approaching treatment of stereotypy, practitioners may opt to begin with isolated intervention components and build intervention packages if needed, depending on the resulting effects on behavior (e.g., Roscoe et al., 2013; Verriden & Roscoe, 2019). When an intervention in isolation does not produce the desired outcomes, practitioners might consider adding treatment components rather than changing treatment course altogether. In other situations, severity or intensity may warrant introduction of multiple interventions simultaneously in order to achieve a clinically acceptable and socially valid reduction in behavior. In scenarios such as these, we encourage practitioners to consider conducting a component analysis once successful behavior reduction has occurred to determine which intervention components are necessary to maintain low levels of behavior. Researchers have demonstrated that multiple treatment components for stereotypy can be systematically faded while maintaining treatment effects. For example, Athens et al. (2008) treated automatically reinforced vocal stereotypy with a treatment package including noncontingent attention, contingent demands, and response cost. Vocal stereotypy remained low after noncontingent attention was removed and the therapists' presence was faded.

6. *Develop interdisciplinary collaborations*

   Collaboration with caregivers and other practitioners is essential when evaluating treatment outcomes throughout the intervention process. In some cases, families may seek out medical or pharmaceutical interventions in addition to behavioral strategies. Although pharmaceutical interventions may not be an effective intervention in the treatment of restricted and repetitive behavior for many individuals (Yu et al., 2020), thoughtful and ethical collaboration with practitioners outside of behavior analysis will allow for the greatest benefits to our clients (Broadhead et al., 2018).

7. *Program for Generalization and maintenance*

   As with any interventions, behavior analysts should program for generalization and maintenance. Many studies evaluating interventions for stereotypy document immediate reductions in stereotypy but a lack of sustained treatment effects (e.g., Schumacher & Rapp, 2011). Generalization and maintenance of treatment effects are of particular importance as stereotypy often persists across contexts and is sometimes unresponsive to treatment. Thus, when efficacious interventions are identified, ensuring durability of those interventions is of great importance. For more information on methods to increase the likelihood of generalization, please refer to Chap. 15.

Conclusions

Stereotypy includes a wide range of behaviors, elusive maintaining variables, and is generally difficult to treat. It is critical to identify assessment and treatment strategies to produce meaningful change in the frequency and severity of the behavior and to improve the long-term outcomes for individuals displaying stereotypy. As highlighted in this chapter, behavior analytic approaches to the assessment and treatment of stereotypy can be a multifaceted and complex process. Thus, we aimed to provide practitioners with guidance on the importance of (a) understanding operational definitions of stereotypy, prevalence, and course; (b) ethical and social considerations when determining the applied value of intervention; (c) assessment and treatment procedures tailored specifically to stereotypy; and (d) considerations when implementing stereotypy treatment.

We urge practitioners and researchers to consider variables specific to their setting (e.g., available resources) and the target response (e.g., impact of multiple dimensions of the behavior) when employing the strategies outlined here to ensure appropriate and ethical conceptualization of intervention.

Self-Injurious Behavior

61

Adithyan Rajaraman and Joshua Jessel

The class of responses referred to as self-injurious behavior (SIB) are those directed toward oneself that pose imminent risk of harm. SIB is often conceptualized as a deliberate act of self-harm, which can take many forms, but is primarily defined by the capacity of the response to produce tissue damage (Winchel & Stanley, 1991). SIB is particularly problematic when it is chronic, seemingly intractable behavior that both inhibits one's daily functioning and is of concern to important people in the individual's life (Tiger et al., 2019). However, SIB is uniquely challenging to address because, depending on its form, a single instance of the response can result in significant injury to the individual (e.g., eye gouging, ingesting toxic substances).

SIB is heterogeneous; it describes a broad range of responses that lie along a continuum of severity, from minimally injurious (e.g., repetitive slaps to the body) to potentially fatal (i.e., suicidal; e.g., cutting wrists). It is important to emphasize that the occurrence of SIB is not limited to any diagnostic or demographic profile; SIB can be exhibited by individuals, of any age, with or without a psychiatric diagnosis. That said, compared to typically developing individuals, SIB is more likely to be observed among individuals with intellectual and developmental disabilities (IDD: Dominick et al., 2007; Maurice & Trudel, 1982) and is significantly more likely to be observed among individuals diagnosed with Angelman, Fragile X, Lesch-Nyhan, and Smith-Magenis syndromes (Huisman et al., 2018). Because the purpose of this chapter is to highlight the contribution of applied behavior analysis (ABA) to understanding and addressing SIB, our focus will be on that which has been most often reported in the ABA literature: Non-suicidal SIB exhibited by individuals with IDD, including autism spectrum disorder (ASD).

SIB is among the most often-researched types of problem behavior displayed by individuals diagnosed with IDD (Hanley et al., 2003; Minshawi et al., 2014; Shawler et al., 2019), despite not being a defining feature of any diagnosis under the IDD umbrella. Prevalence estimates suggest that about 30% of individuals with IDD engage in dangerous SIB (Cooper et al., 2009; Soke et al., 2016) and those same individuals are more likely to be hospitalized due to SIB-related injury than typically developing peers (Kalb et al., 2016). Although there are no defining topographical characteristics of SIB other than its capacity to produce bodily harm, some commonly observed examples include hand-to-head, head-to-object, hand-to-body, self-biting,

self-scratching, hair pulling, eye poking, and skin picking (Iwata et al., 1994c; Shawler et al., 2019). Head-directed SIB comes with a unique set of concerns related to the potential for concussion and neurological sequelae, whereas biting, scratching, and picking bring about concerns related to bodily fluid exposure (Minshawi et al., 2014). Individuals may also exhibit pica, a unique form of SIB wherein non-edible, sometimes toxic substances are ingested. Although not a traditional consideration of SIB, pica can result in intestinal blockage, poisoning, and death (Piazza et el., 1998).

The lives of individuals who engage in chronic SIB are negatively impacted in a variety of ways beyond the associated physical injury. The occurrence of SIB is likely to interfere with an individual's capacity to learn daily living, academic, and social skills, which may result in school-aged children falling behind their typically developing peers. If the nature of SIB is severe enough, it is likely that the individual will require a more restrictive learning environment relative to general education, including possible placement in long-term residential or inpatient medical care (Winchel & Stanley, 1991). In some cases, day-to-day management of SIB involves the routine use of physical, mechanical, or pharmacological restraint (e.g., three-person supine floor holds, arm splints that limit range of movement to prevent SIB; Fisher et al., 2013). Whether in inpatient care or not, chronic and dangerous SIB is likely to preclude an individual from participating regularly in community events and activities (Kormann & Petronko, 2004), the cumulative effect of which can hinder social and emotional development and integration. The occurrence of SIB is associated with increased stress and anxiety among caregivers, teachers, and other helping professionals. The resultant impact of increased stress on daily interactions with those displaying SIB is an overall decrease in quality of life for the individual as well as the important people in their life (Rojahn et al., 2007). Finally, it is worth noting that management and treatment of chronic SIB are expensive; families, school districts, and state governments often have to bear financial burden across many years (Cooper et al., 2009; Jones et al., 2008). In short, chronic SIB can be dangerous, highly restrictive, socially devastating, and extremely costly to those whom it affects. Approaches to the assessment and treatment of dangerous SIB require a great deal of sensitivity.

Understanding Why SIB Occurs

An important first step to treating SIB is to determine why it occurs. Several hypotheses have been put forth regarding the etiology of SIB because it can (a) take many forms, (b) be displayed by a diverse range of individuals, and (c) present as highly unusual and concerning. Understanding why SIB develops, occurs, and endures requires first prescribing to a conceptual framework through which to attribute its occurrence. To be clear, the occurrence of SIB is complex enough that there are likely multiple etiologies at play; however, a pragmatic, scientifically defensible approach to understanding SIB requires only that one understands enough about why the behavior occurs such that an effective treatment can be developed that yields socially meaningful improvements. Two frameworks that have fostered the most treatment-oriented research are biological (i.e., biomedical) and operant (i.e., ABA) conceptualizations of SIB (Shawler et al., 2019).

The biological conceptualization of SIB considers the physiological reactions that may be products of SIB—such as the release of endogenous opioids, endorphins, or hormones—to be primarily influential in the development and maintenance of the behavior (Cataldo & Harris, 1982; Huisman et al., 2018). Further, there is evidence to suggest that certain genotypes, namely, those associated with Lesch-Nyhan and related syndromes, may contribute to the development of SIB (Schretlen et al., 2016). Treatments developed upon the assumption that SIB is caused by some underlying, malignant biological process are pharmacological in nature. In other words, if SIB is considered to be caused by an aberrant biochemical process, some type of medication is presumed to intervene upon the malady and produce reductions in SIB. Indeed, individuals with IDD who engage in dangerous SIB are often prescribed psychotropic medication, sometimes in lieu of behavioral intervention (Hagopian & Leoni, 2017; Morano et al., 2017; Seigel & Beaulieu, 2012).

In contrast to looking inward for the cause of SIB, the operant conceptualization of SIB considers behavior to be primarily influenced by environmental variables external to the individual, namely, (a) reinforcing consequences; (b) the establishing operations (EOs) that momentarily increase the effectiveness of those consequences; and (c) the discriminative stimuli (S^D) that signal the opportunity for SIB to produce those consequences. The EOs, S^Ds, and reinforcers collectively comprise the *operant contingencies of reinforcement* that evoke, occasion, and maintain SIB (Carr, 1977; Iwata et al., 1994a; Tiger et al., 2019). Put another way, the operant conceptualization suggests that when SIB occurs, it produces important outcomes in one's environment that are the reasons why the behavior will continue in the future. Moreover, there are certain environmental contexts—those that temporarily increase the value (i.e., EOs) of those outcomes and signal their availability (i.e., S^Ds)—that quite literally determine the probability with which SIB will occur. Assessments informed by the operant assumption of behavior are called *functional assessments* in that they attempt to identify the important environmental changes surrounding SIB that may lead an individual to exhibit more SIB later on (Hagopian et al., 2013).

Consider a young child who does not have strong language skills and is often passively cared for in the periphery of a parent. Imagine that the child is deprived of stimulation and, one day, engages in head-directed SIB. The child's well-meaning parent, in an effort to mitigate the bizarre and concerning SIB, stops what they are doing and begins to coddle the child by enriching the environment with interactive games. The parent may find success in the momentary distraction; however, reinforcement informs that which will happen in the future and an operant interpretation may be predictive of a worsening in SIB that is now to come. In other words, a contingency has been established whereby that particular parent serves as a salient indication (S^D) that an improvement in the child's environment related to a particular state of solitude (EO) is available if SIB were to occur (reinforcement). The antecedent circumstances render SIB highly likely to occur if the child has experienced past reinforcement under similar conditions; the SIB responses are determined by environmental contingencies of reinforcement. This operant conceptualization has robust support in the ABA literature, to the extent that contemporary treatments for SIB are predicated on first identifying contingencies from those naturally occurring encounters (Hayvaert et al., 2014; Jessel et al., 2018; Shawler et al., 2019).

Toward an Operant Methodology for Understanding SIB

Schaefer (1970) provided an early empirical demonstration, albeit with a non-human primate, illustrating the manner in which SIB could be strengthened by reinforcement. Schaefer provided pieces of fruit contingent on the behavior of head-hitting with a forepaw to two male rhesus monkeys. The contingent delivery of fruit resulted in immediate and sustained increases in head hitting, and a reversal of this contingency led to extinction of the behavior. Schaefer further demonstrated that SIB in rhesus monkeys could come under the control of both S^Ds and EOs, as the responses were exclusively observed under conditions in which food had been deprived and when food reinforcers were signaled to be available contingent on SIB. This early demonstration not only validated but offered generality across species, to the account that SIB may be determined by its consequences.

Carr (1977) extended the earlier work by providing a cogent argument for why an operant conceptualization may yield pragmatic benefits in the treatment of SIB. Recall that the biomedical approach to understanding SIB fostered the development of medical interventions for SIB; however, evidence supporting their long-term effectiveness in engendering socially meaningful improvements in SIB remains somewhat scant (Siegel & Beaulieu, 2012). In synthesizing the literature on what was understood to be motivating SIB, Carr provided multiple operant hypotheses, ranging from influence by positive, to negative, to sensory reinforcement. In doing so, Carr amalgamated the biological and operant assumption to suggest that, regardless of an individual's psychiatric diagnosis or the topography of the SIB, the immediate outcomes of the behavior played the most important (causal) role in its future occurrence. It is worth emphasizing that the biomedical conceptualization of SIB; specifically, that SIB is strengthened because of its physiological consequences, is actually commensurate with the operant conceptualization. The notion that the release of endogenous opioids, for example, may serve as influential consequences that increase the future probability of SIB, is tantamount to suggesting that SIB is reinforced by "automatic" consequences (i.e., that the reinforcers for SIB are the sensory consequences inextricably linked to its emission; Cataldo & Harris, 1982). The primary contribution of the operant conceptualization has been a functional understanding of environmental consequences that can now be managed to support other more appropriate behavior.

If *functional assessment* is the broad term characterizing any approach to understanding the environmental events that influence one's SIB, *functional analysis* refers to the specific, experiment-oriented approach to determining which contingencies of reinforcement are responsible for SIB. In a functional analysis, contingencies suspected to influence SIB are manipulated systematically, across control (contingency absent) and test (contingency present) conditions in order to determine the extent to which they directly influence the likelihood of SIB (Hanley et al., 2003). A controlling contingency historically influencing SIB is identified when SIB occurs exclusively or at higher rates in a test condition relative to a control condition. Other chapters in this volume describe various procedures and considerations to be made in the functional analysis of problem behavior such as SIB, predicated on the assumption that, if behavior is occurring with regularity, it is being reinforced. Rather than reiterating those methods here, we articulate two special considerations regarding the functional analysis of SIB that warrant special mention in this chapter.

The first consideration when attempting to conduct a functional analysis of SIB is that it is possible, if not likely, that more than one reinforcing outcome has followed and has been functionally related to SIB in one's natural environment. There are dozens of studies suggesting that SIB may be reinforced, not only by one of the commonly reported contingencies responsible for problem behavior (e.g., attention, escape; Ala'i-Rosales et al., 2019), but by a combination of those contingencies as well as other, more idiosyncratic variables (Beavers & Iwata, 2011; Rajaraman & Hanley, 2021; Schlichenmeyer et al., 2013; Slaton & Hanley, 2018; Slaton et al., 2017). This may not be surprising to anyone who has spent time with an individual who engages in dangerous SIB; SIB is a highly effective and reliable way for an individual to change their circumstances—to get others to stop what they are doing, attend undividedly to the behaving individual, and to do whatever they can to thwart SIB. This may involve relenting on expectations, providing particular items or interactions, restoring environmental arrangements, resuming previous activities, providing uninterrupted opportunities to engage in certain behaviors (e.g., stereotypy), restraining the individual, or any combination therein. Those tasked with analyzing and treating SIB are most likely to derive information about the possible variables contributing to the maintenance of SIB by asking open-ended questions about such events to caregivers with intimate familiarity with the individual and the contexts in which SIB is most likely (Coffey et al., 2020b; Hanley, 2012; Hanley et al., 2014). Contemporary functional analyses take into account all of the possible variables of which SIB is a function, teaching behavior analysts not just about the specific functional classification of the behavior, but rather the variables functionally controlling the behavior in a manner that emulates the ecology of the individual's natural environment (Jessel et al., 2018, 2020).

The second consideration that warrants mention in a discussion of analyses of dangerous SIB is that the dangerous topographies of SIB need not be evoked during the analysis in order to determine the variables contributing to its maintenance. Over the past two decades, a great deal of research has been devoted to exploring strategies and tactics to promote safety in the analysis of dangerous problem behavior, including SIB (Bloom et al., 2011; Jessel et al., 2020; Smith & Churchill, 2002; Thomason-Sassi et al., 2011; Wallace & Iwata, 1999). One line of research, that which examines precursor or co-occurring responses, deserves special mention because it has allowed researchers and practitioners to infer the controlling variables for SIB without ever needing to evoke dangerous SIB in a functional analysis. Specifically, researchers have investigated less dangerous behavior—reported to precede or co-occur with SIB—and have consistently verified influence by the same contingencies of reinforcement (Borrero & Borrero, 2008; Dracobly & Smith, 2012; Fritz et al., 2013; Herscovitch et al., 2009; Hoffmann et al., 2018; Magee & Ellis, 2000; Richman et al., 1999; Schmidt et al., 2020; Smith & Churchill, 2002; Warner et al., 2020). In other words, if caregivers report that some less dangerous topography of behavior (e.g., elbow banging, stomping, body tensing) reliably precedes or co-occurs with SIB (e.g., head banging), there is insurmountable evidence to suggest that contingencies that yield differentiation of those less dangerous responses in a functional analysis are likely to be functionally related to the SIB in question.

The phenomenon of shared operant-class membership among responses clustered around dangerous behavior appears to have broad generality with respect to individuals who engage in SIB. This suggests that functional analyses of dangerous problem behavior can be conducted successfully without ever needing to evoke the dangerous topography because inferences about the function of SIB can be made by analyzing less dangerous behavior across multiple potential dimensions (see Fig. 61.1). Furthermore, there have been multiple accounts of functionally equivalent dangerous *and* non-dangerous problem behavior decreasing with a function-based treatment informed by the results of functional analyses of only precursor behavior (Dracobly & Smith, 2012; Hoffmann et al., 2018; Rajaraman et al., 2022). A proper interview with relevant caregivers is likely to reveal possible topographies of both dangerous SIB as well as co-occurring and preceding non-dangerous topographies of problem behavior, such that a functional analysis can be successfully conducted that results in the information necessary to develop a treatment—predicated on the operant assumption of SIB—that yields meaningful improvements in the behavior. Whereas the biological or biomedical approach to understanding SIB prescribes pharmacological treatments, the operant or ABA approach to understanding SIB prescribes function-based treatments that manipulate important environmental events endemic to SIB in order to support more adaptive, appropriate responses under the conditions that historically, counterintuitively supported SIB. When conducted with proper considerations, functional analyses of SIB have the potential to inform the design of interventions for problem behavior, predicated exclusively on reinforcement, that teach a complex repertoire of adaptive social skills that effectively replace SIB.

Function-Based Treatments of SIB

The treatment procedures used to reduce SIB differ depending on the results of the functional analysis. If SIB is found to be sensitive to socially-mediated reinforcers, it permits the behavior analyst to manipulate those environmental events and rearrange them in a way that no longer sustains the occurrence of SIB and possibly strengthens other alternative, appropriate behavior. Using the contingencies identified in the functional analysis to treat SIB is referred to as a function-based intervention in that the socially-mediated reinforcers manipulated are those identified as originally contributing to the SIB. This is juxtaposed with the manipulation of arbitrarily selected consequences that require the behavior analyst to make a large interpretative

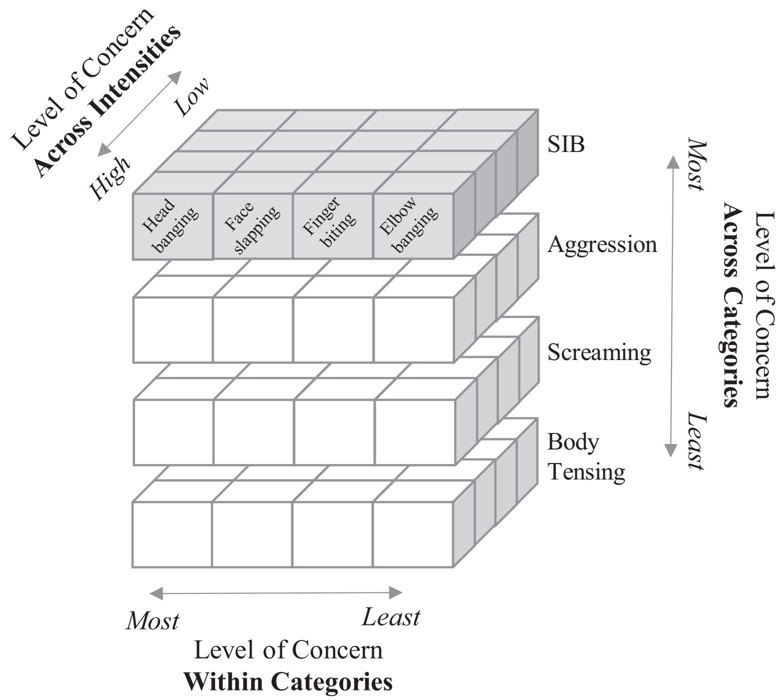

Fig. 61.1 Reinforceable dimensions of problem behavior. (Note. The behavior analyst is likely to be most concerned with reducing high intensity, dangerous topographies of SIB; however, insofar as multiple forms of problem behavior are reported to co-occur, a functional analysis targeting an open-response class of topographies and intensities of less concern can still inform effective treatment without creating an unsafe environment)

leap in determining if that treatment will be effective. The behavior analyst is making one of two potential assumptions when choosing to conduct an intervention with arbitrary consequences.

The first assumption is that the arbitrary reinforcers will compete with the functional reinforcers. Without an analysis identifying functionally relevant reinforcers, the behavior analyst cannot with any confidence interrupt the contingency between SIB and the reinforcers contributing to SIB. Therefore, the behavior analyst is left to hope that their arbitrarily chosen reinforcers strengthen other appropriate behavior that may effectively compete with problem behavior, knowing that the functional reinforcers continue to be producible by SIB. In other words, the behavior analyst may have to rely on powerful reinforcers or punishers to work as a sort of sledgehammer effect over the SIB.

The second assumption is that the behavior analyst, by chance, selected reinforcers that are, or closely align with, the functional reinforcers. This is one of the most dangerous considerations because some procedures can be contraindicative of treatment effects and may cause SIB to worsen (Iwata et al., 1994b). Therefore, arbitrarily selecting consequences without functional analyses is somewhat like a game of roulette and is not one a behavior analyst should consider when working with problem behavior as severe as SIB, especially given that function-based options are well documented (Heyvaert et al., 2014).

Function-based interventions for SIB maintain one singular unifying principle: The reinforcers identified during the functional analysis are systematically manipulated in treatment. How those reinforcers are arranged with respect to SIB is the distinguishing feature of each function-based preparation. For example, the behavior analyst could prepare a negative contingency if SIB continues to occur in the absence of socially mediated consequences. This has been defined as differential reinforcement of other behavior (DRO) and involves programming a specific interval of time in which problem behavior cannot occur if the reinforcers are to be delivered. There are multiple variations of the DRO arrangement (Jessel & Ingvarsson, 2016); however, all DROs program for problem behavior to result in a worsening in the environment (i.e., delay to reinforcement access).

The contingent relation between the functional reinforcers and the SIB could also be broken. Extinction is the process of discontinuing the presentation of reinforcers that previously strengthened SIB. Doing so ensures that problem behavior never comes into contact with reinforcement. Extinction alone is never recommended as an intervention as it is associated with a host of negative side effects (Goh & Iwata, 1994; Lerman et al., 1999) and because it creates a barren environment antithetical to ethical considerations of reinforcement-based therapeutic strategies. In addition, the contingency can still be eliminated without the complete removal of the functional reinforcers by presenting them on a time-based schedule. This arrangement is termed non-contingent reinforcement (NCR) and also has the ability to break the contingent relation between SIB and reinforcement while maintaining a relatively rich environment with continued access to the functional reinforcers. The essential element of the NCR arrangement is that SIB no longer impacts the delivery of the reinforcers.

Finally, the behavior analyst could prepare a positive contingency for some other alternative behavior. The differential-reinforcement-of-alternative-behavior (DRA) arrangement takes the reinforcers that historically strengthened SIB and provides them contingent on some alternative response. Therefore, unlike DRO that may promote docility or NCR that simply reduces the motivation to exhibit any behavior, DRA teaches an individual that their behavior can impact and improve their current circumstances. The alternative response is selected based on its appropriateness for the context and is intuitively intended to replace SIB by rendering it unnecessary for the production of important reinforcers. Moreover, DRA is commonly accompanied with extinction for problem behavior, such that reinforcers are exclusively provided contingent on the emission of alternative behavior. The alternative response may be selected based on its relation to SIB (i.e., if it is incompatible with SIB) but some form of communication is most commonly selected (Ghaemmaghami et al., 2021; Tiger et al., 2008). Behavior analysts tend to select a communication response to be strengthened using the functional reinforcers because language ability is often negatively correlated with problem behavior (Williams et al., 2018) and it enables the individual with the ability to appropriately ask for their wants and needs, a deficit skill for many individuals with IDD. Due to the contingent relation between the functional reinforcers and communication, this response has been termed a functional communicative response (FCR).

The specific DRA preparation that reinforces appropriate communication is called functional communication training (FCT; Carr & Durand, 1985). Although DRO, NCR, and DRA have robust evidence as function-based treatments for reducing problem behavior (Kahng et al., 2002; Petscher et al., 2009, Carr et al., 2009), FCT may be considered more socially acceptable among those tasked with addressing severe problem behavior. However, FCT alone is not sufficient for producing meaningful reductions in SIB and extensions to this treatment are required. FCT involves teaching a single, simple communicative response to earn the functional reinforcers on a dense, often continuous reinforcement schedule. This is merely a starting point to validate the efficacy of the reinforcers contributing to SIB identified during the functional analysis and ensure the initial success of the treatment by reducing response effort and increasing the richness of the therapeutic environment. For the treatment of SIB to be sustainable in the home or school environment, extensions must be conducted to improve the practicality of the procedures by reducing access to reinforcement (Ghaemmaghami et al., 2021).

Practical Extensions to Function-Based Treatments

First, the behavior analyst can focus on improving communication skills to extend the procedures of FCT. Caregivers are unlikely to accept the use of simple FCRs below an individual's current abilities. Shaping up more complex and developmentally appropriate language skills is likely to make communication more recognizable amongst an individual's broader community, thereby increasing the likelihood that it will be reinforced. Thus, the behavior analyst should begin FCT by teaching a simple response knowing the ultimate goal is to extend the treatment by teaching progressively more complex responses. Doing so involves the progressive extinction of previously strengthened FCRs and teaching of new, more complex responses. This often involves targeting a single omnibus mand (e.g., "My way") and building upon the sentence structure and response effort (e.g., "Excuse me, may I have my way?").

The construct of complexity can take many different forms and is specific to the individual and caregiver. For example, the complexity of the initial FCR can involve moving from a single word utterance to using a full sentence (Ghaemmaghami et al., 2018; Hernandez et al., 2007; Tiger et al., 2008). The initial FCR targeted in a treatment is unlikely to be considered socially acceptable. This is purposefully arranged to focus on the elimination of problem behavior. Once elimination is achieved, the behavior analyst can progressively improve the sentence structure to meet developmental expectations. Complexity can also be increased by requiring the individual to first obtain the behavior analysts attention before continuing with the request for her reinforcers (Hanley et al., 2007, 2014). This chain of responding establishes an added element of natural conversation and uses the context in which the functional reinforcer is delivered as a conditioned motivating operation. That is, the individual must first ask for and obtain the attention of the adult who controls the reinforcer delivery in order to be able to ask for and obtain the reinforcer. In another example, the individual could be required to specify those they are talking to or the item they would like returned (Ward et al., 2020). The complexity of the FCR now grows with the skeletal frames that incorporate multiple skills (e.g., knowing the names of adults the individual is addressing or the names of items to be requested). These strategies can also be combined to establish a seemingly more natural communicative interaction between a child and adult.

For example, Ward et al. (2020) taught three children diagnosed with an IDD who exhibited SIB to initially emit the simple FCR "My way" to have all reinforcers contributing to problem behavior at one time (i.e., an omnibus mand). The sentence structure of the FCR was expanded to require an initial request for attention (e.g., "Excuse me") and to reinforce the omnibus mand only if emitted after they had been acknowledged. Finally, in three consecutive steps the participants were then taught to ask for breaks from work ("all done"), access to leisure items ("stuff"), and interactive play with the adult ("play with me"). SIB was eliminated by the end of the study and the participants acquired multiple forms of communication including omnibus and isolated FCRs.

Regardless of the individualized specifications, the process for shaping complex communication skills remains the same: Begin with a simple response and progress the contingency to support intermediary responses until the terminal complex response is achieved. It is important that these intermediary responses are included to pace the building of the communicative repertoire because increasing the effort too quickly could result in the reemergence of problem behavior (Ghaemmaghami et al., 2018).

FCT and complexity training reduce SIB by replacing it with a developmentally appropriate form of communication that obtains the same reinforcer. However, this treatment is still limited to situations in which the reinforcer can be presented on a dense schedule (i.e., each instance of communication is reinforced). In essence, complexity training teaches new developmentally and socially appropriate skills while maintaining a sufficient reduction in problem behavior; however, the terminal goals of returning to the natural environment have yet to be met. The expectations of a teacher or caregiver often require some level of tolerance when those reinforcers are not immediately available. The second step to extending function-based treatment involves teaching tolerance to the denial of those reinforcers.

Caregivers will often present a verbal discriminative stimulus indicating that reinforcers are no longer forthcoming, referred to as a denial cue (e.g., “no you can’t have that”, “not right now; I am busy”). A specific history with denials will often leave them as conditioned aversive events that can evoke problem behavior in their own right. Denial is indicative of the end of the reinforcing context even if the individual asks appropriately. Interventions for SIB are likely to fail if this conditioning history is not addressed. In other words, tolerance training involves shifting the value of a denial to reinforcement from an S-delta signaling no reinforcement to an S^D signaling probabilistic reinforcement (Hanley et al., 2014). This is completed by including an additional response requirement before the functional reinforcers are delivered. The novel response that is taught, often referred to as a tolerance response or denial acknowledgement, is a form of awareness, acceptance of, and coping with the expectations that reinforcement may not be forthcoming. However, reinforcement continues to be presented on a rich schedule in the early stages of teaching the tolerance response to improve the efficiency of skill acquisition. For example, the chain is extended from asking and earning reinforcers to then asking, being denied, tolerating this denial, and then earning reinforcers. The delay to reinforcement is artificially extended during this time as the response chain continues to grow (i.e., it takes the individuals longer to earn reinforcers using multiple forms of communication) but continues to produce reinforcement at a level that cannot practically be maintained. Therefore, the delay to reinforcement needs to be actively thinned while maintaining a level of tolerance to the progressively less reinforcing environment.

The process for thinning reinforcement involves slowly and progressively reducing access to reinforcement with the ultimate goal being to meet social expectations or mimic proportions of reinforcement comparable to those experienced by typically developing counterparts. Similar to the variations in function-based treatments, behavior analysts have identified multiple procedures for thinning reinforcement (Hagopian et al., 2011). These procedures fall into two potential categories based on whether the return of reinforcement is irrespective of the individual’s performance (i.e., time-based progressive delays) or dependent on the individual’s performance (i.e., contingency-based progressive delays). Time-based progressive delays involve scheduling a period of time after which reinforcers are re-presented, whereas contingency-based progressive delays can fluctuate based on the engagement in targeted contextually appropriate behavior (e.g., doing homework, following adult instruction).

Time-based progressive delays simply introduce a period where reinforcement is not available, often referred to as a mixed or multiple schedules of reinforcement (Hanley et al., 2001). Therefore, the expectations are that the individual can tolerate delays to reinforcement without any additional skills being taught; SIB has no impact on the scheduled delivery of the reinforcer. These delays typically begin as brief (1 s, 5 s, 10 s) and eventually extend to more substantial durations (5 min, 10 min, 20 min). For example, a delay can be programmed in between a response and the reinforcer delivery (i.e., the reinforcer is not delivered immediately following a communication response but rather after 5 or 10 s). This is essentially fading in extinction as the delay between the contingent delivery of the reinforcer is extended following the communication response (i.e., the contingency is eventually broken). It is important to reiterate the limitations of extinction as this delay-fading procedure is likely to result in the elimination of the new communication skills learned and reemergence of problem behavior (Hanley et al., 2001). Multiple schedules can also be conducted using signaled periods of immediate reinforcement (often using a visible green card) and extinction (often using a red card) with the proportional period of extinction progressively increased. Beyond the limitations associated with the use of extinction alone, others arise when extinction is incorporated in a multiple schedule. First, the use of arbitrary signals makes it hard to integrate into the natural environment considering everyone (teachers, caregivers, therapists) has to consistently use and have access to those signals, which can introduce supplemental costs for materials. Second, an immediate contingency between the FCR and reinforcement remains in place during signaled reinforcement periods. That is, the multiple schedules arrange more of an avoidance of denials rather than a repertoire of tolerating them. Therefore, there are likely more benefits to employing contingency-based delays during reinforcement thinning (Drifke et al., 2020; Ghaemmaghami et al., 2016; Iannaccone & Jessel, 2021).

Contingency-based delays extend the performance requirements to the delay period. In addition to communication and tolerance skills, the chain to the return of reinforcement now introduces expectations of cooperation. Cooperation skills can be taught in one of two possible ways (Jessel et al., 2018). The instructions could involve engaging with available items or activities without exhibiting SIB if the individual has some alternative contextually appropriate behavior within their repertoire. In this arrangement, the functional reinforcers are delivered following the engagement in a socially acceptable task for a certain period of time with this time becoming longer as SIB remains low. This form of contingency-based reinforcement thinning is meant to emulate situations where caregivers are unavailable and the individual must independently engage with whatever is accessible. This may include not having TV available for a period of time while mom is working and having to play outside in the yard. This may also include being asked to put down the iPad to play an interactive game with siblings while dad is busy cleaning.

In other cases, the instructional requirement may involve direct supervision and teaching of the contextually appropriate behavior. Therefore, after the individual emits the tolerance response indicating their acceptance that reinforcement is not immediately forthcoming, the behavior analyst then begins to introduce instructions, the contingent completion of which results in the return of the reinforcers. The response effort remains low at first, such as providing minimal (1, 2, 3) gross motor instructions and progressively increases to larger ratios (20, 30, 40) and more difficult tasks (e.g., self-help skills, activities of daily living, academic instructions). Contingency-based reinforcement thinning with supervision allows the behavior analyst to provide reinforcers contingent on each discrete response. Thus, it can be applied in the classroom when the individual is expected to complete work, in the home when they are instructed to complete chores, or during any adult-led activities. It should be noted that the behavior analyst may want to eventually reduce the level of supervision, which could involve a combination of the two contingency-based strategies or momentary-based criterion for delivering reinforcement during scheduled supervision checks (Jessel et al., 2017).

Figure 61.2 provides a step-by-step guide outlining the interactions between the child who exhibits SIB and the behavior analyst throughout the entire treatment process teaching communication (top panel), tolerance (middle panel), and cooperation skills (bottom panel). It should be evident that, as the treatment progresses, an additional chain is added to the contingency to strengthen a comprehensive repertoire that is intended to replace SIB across a multitude of potential EOs and discriminative events that had previously evoked SIB. This includes the removal of positive reinforcers, the denial of returned access to reinforcers, and the presentation of instructions. Because of this focus on promoting skills using contingencies during every step of the treatment, the process that incorporates FCT, tolerance training, and contingency-based reinforcement thinning has come to be termed *skill-based treatment* and has been socially validated and replicated in its entirety on multiple occasions (e.g., Beaulieu et al., 2018; Coffey et al., 2020a; Ferguson et al., 2020; Hanley et al., 2014; Jessel et al., 2018; Rajaraman et al., 2022; Santiago et al., 2016).

Supplemental Treatment Procedures

In some cases, function-based treatments may not be sufficient to reduce SIB alone and behavior analysts must add supplemental procedures. It is important to point out that as the functional analysis technology continues to improve, the

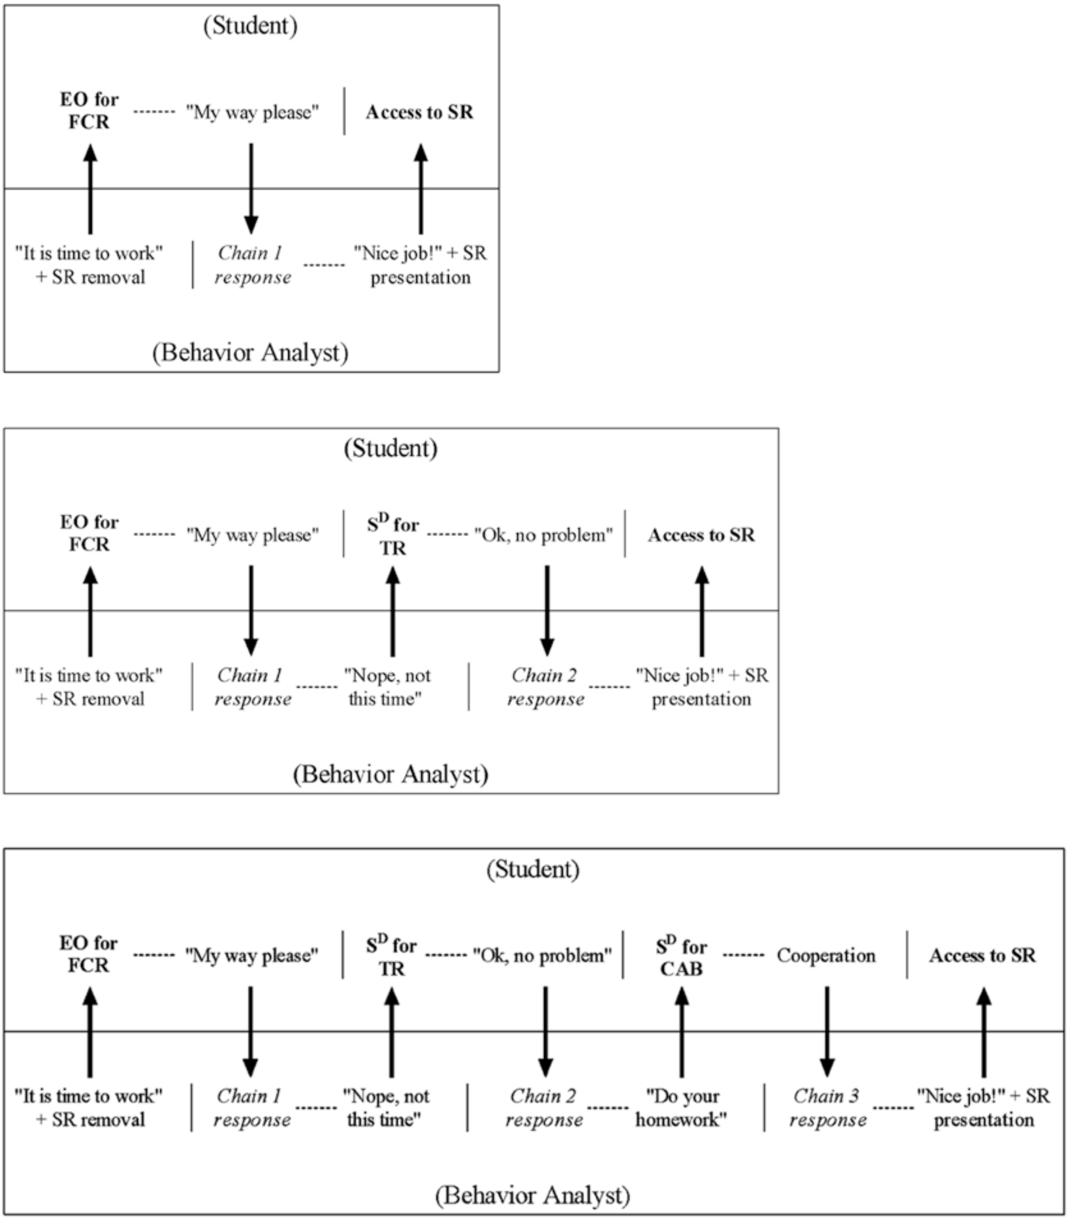

Fig. 61.2 Interactions between the student and behavior analyst when teaching communication, tolerance, and cooperation skills. (Note. EO establishing operation; SR reinforcers; S^D discriminative stimulus; TR tolerance response; CAB contextually appropriate behavior)

use of supplemental procedures beyond the function-based treatments appears to be diminishing (Hagopian et al., 1998; Jessel et al., 2018; Rooker et al., 2013). Nonetheless, the behavior analyst can include arbitrary reinforcers in a concurrent DRO, NCR, or DRA schedule when expected reductions in SIB are not achieved. For example, the child may earn the functional reinforcers of a break with a toy when exhibiting the target FCR and earn arbitrary preferred edibles every 30 s without SIB. In other cases where functional and supplemental reinforcement strategies fail, the behavior analyst may have to rely on punishment or restraint procedures to suppress SIB. However, punishment should only be considered if (a) reductions in SIB are not determined to be socially significant otherwise and (b) there is a pressing concern of safety with the continued occurrence of severe SIB. In addition, the appropriateness and acceptability of the punishment procedures should always be transparently addressed with caregivers before use.

Punishment procedures should be approached with caution and any stimuli and events selected to serve as punishers should meet rigorous criteria. First, punishers could be selected based on the outcomes of the functional analysis without the need of additional assessments (Lerman & Toole, 2011). This could be as simple as implementing the opposite of the reinforcement contingency when problem behavior occurs. The assumption being that stimuli that act as positive reinforcers when presented following appropriate behavior (contingent access to tangible items) will act as negative punishers when removed following problem behavior (contingent removal of tangible items). Similar reflexive properties are considered when negative reinforcers are removed following appropriate behavior (contingent removal of homework) and presented as positive punishers following problem behavior (contingent requirement of homework). In some cases, patterns in responding during the functional analysis could be indicative of a punishment effect. For example, if rates of SIB are found to be lowest in a condition where instructions and adult attention are contingently removed, then this may be indicative of timeout serving as a potential function-based punisher. On the other hand, adult interaction, such as reprimands, could also be deemed suitable as a punishment procedure when SIB is lowest in the functional analysis condition that includes contingent attention.

In a second set of criteria, aversive stimuli could be selected based on the results of an assessment conducted prior to evaluation in a treatment (Fisher et al., 1994; Verriden & Roscoe, 2018). Doing so could aid in the selection of the least aversive and most socially acceptable procedures while avoiding the use of arbitrary aversive events that may not serve to suppress problem behavior. Verriden and Roscoe (2018) briefly compared a selection of clinician-informed aversive stimuli and measured problem behavior, appropriate engagement with preferred items, and emotional responding as a comprehensive evaluation of potential punishers. In other words, if punishers are deemed necessary, they should reduce SIB without negatively impacting appropriate behavior or positive affect. In fact, a correctly implemented treatment package that includes rich reinforcement and punishment may even be preferred by the individual in some cases (Hanley et al., 2005).

Considerations for Automatically Reinforced SIB

Additional difficulties arise when SIB continues to occur in the absence of socially mediated consequences. This has often been referred to as automatic reinforcement because the behavior itself is said to produce some form of sensory stimulation that maintains SIB. Although SIB that is sensitive to automatic reinforcement is more likely to be resistant to treatment effects, there are potential procedural options. If the source of stimulation can be isolated, it would be possible to implement a function-based treatment using sensory extinction (Rincover et al., 1979). Sensory extinction involves eliminating the stimulation produced by the SIB using protective gear, response blocking, or medication. For example, protective wrist guards could be placed on the arms to reduce self-inflicted arm biting that is automatically reinforced (Luiselli, 1988). Attempts at identifying the specific type of stimulation could also be used to inform the selection of certain items that can compete with that source of reinforcement (Shore et al., 1997; Dowdy et al., 2020).

The competing stimulus assessment involves evaluating items that, when continuously available, reduce SIB by producing some form of substitutable reinforcement (Haddock & Hagopian, 2020). The assessment attempts to match stimulation produced by the SIB informing a treatment of NCR that will be more effective than including any arbitrarily selected preferred items. Therefore, the competing stimulus assessment is essentially an extension to preference assessments specifically designed to address automatically maintained SIB. For example, Piazza et al. (2000) conducted the competing stimulus assessment with a selection of items that appeared to match and not match sensory stimulation. Matched stimuli for hand mouthing included items that produced stimulation in the mouth (soft candy) or hand (hand massager) and unmatched stimuli included items that produced other sensory stimulation such as videos or musical toys. The authors obtained differentiated outcomes when implementing NCR, with the matched items producing more pronounced reductions in problem behavior across participants.

It may also be potentially beneficial to categorize SIB into multiple subtypes depending on the different patterns of responding that can be obtained during functional analyses the results of which indicate automatic reinforcement (Hagopian et al., 2015, 2017). The properties of automatic reinforcement may differ dependent on some biological underpinnings that influence how SIB responds to different contingencies. First, SIB could be sensitive to environmental stimulation and suppressed in a play condition when alternative forms of reinforcement are available. This has been identified as subtype I and suggests that reinforcement-based strategies are likely to be effective in reducing problem behavior. Second, SIB may be relatively insensitive to environmental stimulation and may occur across all conditions (i.e., subtype II). Subtype II is particularly resistant to reinforcement-based treatments and the behavior analyst may need to incorporate multiple treatment components including response blocking, punishment, and restraint. The presence of SIB that specifically includes some form of self-restraint across functional analysis conditions has been delineated as subtype III, which could inform the use of restraint procedures during treatment. Thus, delineating the different subtypes of SIB considers a pragmatic approach to assessment that helps to inform treatment selection and predict treatment efficacy even when SIB is historically influenced by automatic reinforcement.

Conclusion

Individuals who engage in intractable SIB run the risk of causing serious injury to themselves, to say nothing of the highly restrictive lifestyle that may be imposed by such behavior. Decades of research focused on the environmental determinants of SIB have fostered the development of an array of behavior analytic treatment approaches with strong evidence supporting their efficacy. A comprehensive approach to addressing socially-mediated SIB involves (a) conducting a functional analysis to identify the reinforcers of which SIB is a function; (b) teaching a simple FCR to empower an individual with a low-effort alternative response to produce said reinforcement, thereby rendering SIB unnecessary; (c) increasing the complexity of the FCR to a developmentally appropriate terminal topography; (d) teaching explicit responses to denials and disappointment; and (e) increasing the contextually appropriate behavior expected of the individual during periods of nonreinforcement. Special consideration should be given to SIB that is automatically reinforced, but reinforcement-based options such as providing competing stimulation should be considered prior to resorting to restraint or punishment-based procedures. A behavior analytic approach to treating SIB has the potential to yield socially meaningful improvements in behavior, minimizing an individual's risk and maximizing their opportunities to behave effectively in important environments.

62 Assessment and Treatment of Toe Walking

Ansley C. Hodges, David A. Wilder, and Hallie Ertel

Idiopathic toe-walking (ITW) describes a condition in which children walk with a toe-to-toe gait pattern in the absence of any known cause (Sala et al., 1999). ITW is also less frequently referred to as habitual toe-walking and congenital short tendo calcaneus. ITW is not considered pathologic for individuals 2 years of age or younger (Matthew & Sean, 2012); however, after 2 years of age, treatment is recommended.

While ITW may be exhibited by typically developing individuals, there is a growing body of research suggesting that it may be more common among those with disabilities (Accardo et al., 1992; Barrow et al., 2011; Ming et al., 2007; Sala et al., 1999; Shulman et al., 1997). It may be particularly common among children with autism spectrum disorder (ASD). Barrow et al. (2011) examined ITW in 324 children with ASD. These researchers found that 65 (20.1%) exhibited persistent toe walking and 39 (9%) had tight heel cords. Tight heel cords were defined as heel cords that do not reduce past 90° in dorsiflexion (backward bend). When these results were compared to typically developing children, data showed that persistent toe walking and tight heel cords were more common in children with ASD than among children with developmental diagnoses other than ASD.

When it does occur, ITW may also persist longer in individuals with ASD (Barrow et al., 2011). Persistent ITW can lead to a number of medical problems. For example, one common result of persistent ITW is a secondary motor deformity in which the heel cord is shortened so much that the foot can longer be dorsiflexed beyond 90°. Sobel et al. (1997) reported that 80% of "high-toe walkers" had an ankle equinus deformity. Ankle equinus occurs when the ankle joint lacks the flexibility necessary to move upward, which is a result of tightness in the Achilles tendon or calf muscle. Sobel et al. also reported that ankle equinus was more common in older children who toe-walked, and that range of dorsiflexion tended to decrease with increasing age. Other complications that may arise as a side effect of ITW include falling, in-toe gait (walking with toes pointing inward), pain, fatigue, flatfoot (arches on the inside of the feet are flattened), limping, poor balance, and bunions (Sobel et al., 1997).

Interestingly, Sobel et al. (1997) described a variety of toe-walking patterns. Some children were found to walk high up on their toes (labeled "high toe-walker"), some exhibited a pattern of heel-to-toe steps followed by toe-walking steps, some toe-walked only after long periods of time,

some toe-walked when adults were not observing, some toe-walked barefoot but not in shoes, and some toe-walked barefoot and in shoes. Thus, it is important for clinicians to assess and describe the specific conditions under which toe walking may or may not occur.

Measurement of Toe Walking and Its Effects

The first step in assessing and treating ITW is to accurately measure its occurrence. Research on ITW exhibited by individuals with ASD can be found in the pediatric (Barrow et al., 2011), orthopedic (Matthew & Sean, 2012), and behavioral literature (Wilder et al., 2020). Orthopedic assessments of ITW typically include a neurological evaluation to rule out any underlying neuromuscular issues (Barrow et al., 2011; Shulman et al., 1997). The neurological evaluation may include measures of muscle bulk, tone, strength, deep tendon reflexes, sensation, head circumference, and leg length. The assessment may also include testing of motor nerves and superficial sensory nerves. A podiatric measurement of ITW also typically involves measurement of dorsiflexion. A lack of dorsiflexion range of motion (ROM) is often referred to as a tight heel cord. Barrow et al. (2011) classified a tight heel cord as a heel cord that did not extend beyond 90° in dorsiflexion while in a seated position.

In behaviorally based studies, measurement of toe walking typically requires direct observation and counting of inappropriate and appropriate steps. This can be difficult, because the child may walk at a quick pace or even jump when walking. Accurate measurement may require obtaining video footage of the child walking, then watching and scoring the videos later. Inappropriate steps are often defined as those with a toe-to-toe gait, and appropriate steps are defined as steps with a heel-to-toe gait (Hodges et al., 2018; Wilder et al., 2020). The percentage of toe-walking steps is obtained by dividing the total number of steps by the number of inappropriate steps, then multiplying by 100. To date in the behavioral literature, most studies have measured toe walking by providing a percentage of appropriate or inappropriate steps taken based on a predetermined amount of steps required. For example, recent studies have required participants to take 1000 steps and have calculated the percentage of these steps with toe walking (Hodges et al., 2018; Wilder et al., 2020).

Assessment of Toe Walking

Behavioral assessment involves identifying environmental variables responsible for challenging behavior. There are three primary assessment methods: informant, descriptive, and experimental. Informant methods involve a series of questions presented to the caregiver and/or client. The questions are designed to isolate the specific conditions under which the target behavior is likely to occur. For example, standard indirect assessment tools include, but are not limited to, the Motivation Assessment Scale (MAS; Durand & Crimmins, 1992), the Functional Analysis Screening Tool (FAST; Iwata et al., 2013), and the Questions about Behavioral Functioning (QABF; Paclawsky et al., 2000).

Descriptive assessment requires recording variables contributing to the occurrence or nonoccurrence of the target behavior as they occur in the natural environment via direct observation. Finally, experimental or functional analysis (FA) involves systematically exposing individuals to specific antecedent and consequence events, while carefully measuring the target behavior (Iwata et al., 1982/1994). The functional analysis (FA) is considered the gold standard assessment tool to identify the variables responsible for challenging behavior.

Given the complexity and etiology of ITW exhibited by individuals with intellectual disabilities (ID), it is important to assess ITW properly. This process includes obtaining medical and development information, consulting medical providers, and ruling out any underlining medical conditions. One study found that among patients with ITW referred to neurologists by orthopedic surgeons, 62% of the patients had an underlying neurological etiology (e.g., cerebral palsy, neuropathy, ASD; Hayes et al., 2018). Therefore, it is essential for pediatricians, parents, and behavior analysts to collaborate during assessments and intervention development and evaluation.

Informant-Based Assessment Informant-based assessments of ITW are typically conducted with caregivers. Caregivers serve as historians for their child's developmental milestones and concerns regarding ITW. Medical records that include gait analysis or baseline range of motion (ROM) data are also vital. The ROM data often indicate the severity of ITW and provide baseline information, which can later be used to evaluate treatment. During the structured interviews, basic questions should include the age of onset of ITW, specific activities that evoke ITW (e.g., walking, running), and family history of ITW. Pomarino et al. (2017) developed an interview checklist to determine the family history of ITW in specific family members, the onset of ITW (i.e., at the onset of walking, X number of months or years after walking), and current ITW status.

Other ITW assessment tools provide additional information. For example, Accardo and Barrow (2015) created a heel cord ROM questionnaire to obtain historical data on ITW and ROM. This tool includes a 3-point Likert scale, which scores ITW as 0 = absent, 1 = present (longer than 3 months), 2 = intermittently present, and 3 = persistent. Similarly, a 3-point Likert scale is used to evaluate ROM (p. 607). Other assessment or screening tools are more involved and require direct observation.

Most of the existing behavioral intervention studies on ITW have included informal parent interviews (Hobbs et al., 1980; Hodges et al., 2019; Persicke et al., 2014; Wilder et al., 2020). These interviews typically include questions about the environmental conditions under which toe walking is most and least likely to occur. Questions on the severity and frequency of ITW are also included.

Descriptive Assessment Direct observation is often the next step in evaluating ITW. Observations by an occupational or physical therapist or a physician typically focus on analyzing the individual's gait, both walking and running. It is often advantageous to observe individuals when they are unaware of the analysis, as reactivity in the form of altered gait or increased anxiety may occur (Bishop, 2016). In addition to gait analysis, medical providers conduct a physical exam and typically obtain ROM data on the hip, knee, and ankle. These measurements are necessary because individuals who engage in ITW are three times more likely to have dorsiflexion ROM limitations (Pomarino et al., 2017). It is essential to ensure the direct assessment conditions capture the conditions under which ITW is likely to occur. Most observations occur at the time of medical visits; however, some studies have used pre-recorded videos to evaluate ITW (McMulkin et al., 2006). Unfortunately, assessing ITW, either in vivo or via recording, can be cumbersome and time-consuming. ITW assessment technology ranges from basic questionnaires to sophisticated technology measures.

Questionnaires are the most simplistic form of assessment for physicians and allied clinicians. Williams et al. (2011) developed a 28-item ITW questionnaire to screen individuals for underlying medical issues, guiding primary care physicians on referring to other specialties. This tool requires physicians to observe the patient walking directly (both on normal gait and on heels), standing up from a seated position, testing reflexes, and muscle tightness (i.e., hamstrings, hip flexors, gastrocnemius, and soleus). In Williams et al., six clinicians used the tool to screen patients from a pre-recorded assessment; all videos contained all information needed to screen each patient. Results indicated that all clinicians correctly identified all individuals with underlying medical conditions; nevertheless, this tool is not commonly utilized by medical professionals or reported in research.

Other researchers have created assessment tools to quantify ITW severity. For example, Alvarez et al. (2007) created a severity screening tool to classify ITW into three distinct categories: mild, moderate, or severe. The authors examined the heel strike upon initial contact, followed by when the heel is lifting off the ground, and ankle movement, including power and positioning. The severe group demonstrated the most restrictive ankle ROM.

Some individuals do not present with severe ITW during brief medical exams. Therefore, Pomarino et al. (2017) created an assessment tool that was more likely to capture ITW. Their assessment included various movement conditions to evoke ITW, in addition to ROM measures; they tested the assessment tool across 836 individuals with ITW compared to 55 participants with a normal gait in a control group. The spin test requires the physician to quickly spin the individual around in one spot, starting with one spin and adding a spin until they reach a maximum of 10 spins. After the spin, physicians instruct the participants to walk 10 steps and record the spin number during which ITW occurred. The test is considered positive once the participant engages in ITW. The next condition examines performance during heel walking and the adjustment made to achieve heel walking (i.e., a forward inclination of the trunk, ankle dorsiflexion ability). Any compensation in the torso position, knee, or ankle produces a positive result. ROM is assessed in different positions and requires a goniometer for measurement.

Technology can alleviate some of the challenges in measuring, monitoring, and assessing ITW. For example, Kim et al. (2019) assessed wearable sensors attached to participants' lower back (L5-S1) to measure ITW. The device differentiated ITW from heel-to-toe gait with 82% accuracy across 3 days for five participants. Other researchers have successfully assessed ITW with kinesiological electromyography (EMG) (Thielemann et al., 2019) and three-dimensional gait analysis (Hicks et al., 1988; McMulkin et al., 2006; Westberry et al., 2008). Unfortunately, this technology can be cost-prohibitive.

Some of the behavioral intervention studies also included descriptive assessment (Hodges et al., 2018, 2019; Wilder et al., 2020). Hodges et al. (2018/ 2019) conducted direct observations of participants walking with and without shoes. Additional gait analysis was obtained via video recordings. Similarly, Wilder et al. (2020) observed participants walking and playing in a room via an observation window. Persicke et al. (2014) reported that direct observation data were obtained before the study, but did not mention how they conducted the observations. Other behavioral intervention studies either did not conduct descriptive assessments or neglected to report the data (Hirst et al., 2019; Hobbs et al., 1980; Marcus et al., 2010).

Experimental Analysis Assessment-based interventions that address the cause of challenging behavior are often most effective. During an FA, the clinician systematically manipulates specific antecedent and consequent events to identify the conditions under which the challenging behavior is likely to occur (Iwata et al., 1994). FA methods have evolved and become less intrusive and more efficient (Lang et al., 2011). Behavior that occurs during all FA conditions or during the alone or no interaction condition of a FA is said to be maintained by automatic reinforcement. That is, when a behavior occurs in the absence of social consequences, the behavior is described as producing its own reinforcement. Often, the specific source of reinforcement for the behavior is a condition of the body: a feeling or sensation that is either produced or removed when the behavior occurs. Querim et al. (2013) created a screening assessment for behaviors likely to be maintained by automatic reinforcement that accurately predicted the function of challenging behaviors that occur in the absence of social consequences.

Only a few behavioral intervention studies on ITW have included FA's, and these studies utilized the Querim et al. (2013) screening assessment. For example, Hodges et al. (2019) used the pre-treatment screening analysis (Querim et al., 2013) to verify that ITW occurred independent of social consequences. This assessment included a series of 100-step sessions, both with and without shoes, in which the participant was alone. Multiple video cameras recorded walking sessions conducted across several days. ITW occurred during a mean of 94% of steps. In a similar study, Hodges et al. (2018) again utilized the same pre-treatment screening analysis. Procedures were identical to the previous study, but the assessment occurred across 2 days. ITW occurred on 96% of steps with and without shoes. In both studies, the authors did not control for gait speed but reported that ITW occurred during both walking and running at similar rates. The screening assessment identified that ITW was maintained by automatic reinforcement for multiple participants. Wilder et al. (2020) also used the pre-screening assessment; however, participants in this study were instructed to walk around an empty room for 5 min. The experimenter observed and collected data through an observation window. The three participants engaged in ITW for means of 89%, 98%, and 98% of steps. Overall, when FAs have been used, they have verified that ITW was maintained by automatic reinforcement.

Medical studies have examined other variables that may contribute to ITW, such as various gait speeds, flooring types, and vibration sensitivity thresholds. For example, Valagussa et al. (2017) conducted two experiments to assess the conditions under which ITW was likely to occur. The first experiment examined ITW during standing, walking, and running in 69 individuals with ASD. In the standing condition, participants stood in front of a table with multiple preferred toys. To assess ITW during running and walking, the experimenter instructed the participants to either walk or run 10 m three times across 3 days. The second study assessed the cumulative number of seconds allocated to (1) tiptoes, (2) both full feet support, (3) one full foot support on a hard surface (i.e., linoleum floor), and a soft surface (i.e., foam mat). Participants included 14 individuals with ASD (7 with ITW and 7 non-ITW). Exclusionary criteria included any participant who exhibited an ankle dorsiflexion ROM of less than 90°. Results show 10 participants (14.49%) engaged in ITW across all three conditions, four during walking and running (5.57%), and eight in the running only (11.59%) condition. Surface assessment results showed a higher occurrence of ITW on hard surfaces (78.77%) versus soft surfaces (37.30%) for participants in the ITW group; the non-ITW group never engaged in ITW. These findings have implications for potential interventions, such as modifying shoe type.

Fanchiang et al. (2016) also evaluated the effects of different surfaces (i.e., vinyl tile, carpet, pea gravel) on barefoot gait patterns in 30 participants between 4 and 10 years of age. Fifteen participants served in the ITW group and 15 typically developing individuals served as age-matched peers without ITW. Exclusionary criterion included participants with neuromotor or musculoskeletal disorders. Motion system analysis recorded gait measures as the participants walked across each of the four surface types. Results showed similar gait patterns across different surfaces for both groups and no significant differences across age. However, vinyl and carpet produced significantly higher early heel rise effects for the ITW group. Alternatively, pea gravel produced no initial toe-contact, which resulted in decreased ITW.

In summary, FA is a process that demonstrates that particular events or conditions are responsible for the occurrence or non-occurrence of behavior. Thus far, researchers have verified that ITW often occurs in the absence of social contingencies (Hodges et al., 2018, 2019; Wilder et al., 2020) and have identified multiple surface types that may influence ITW (Fanchiang et al., 2016; Valagussa et al., 2017). Additional research is needed to replicate surface assessment results and expand assessment to include alternative surfaces and shoes.

Medical Interventions for Toe Walking

Both medical and behavioral interventions have been evaluated to treat ITW. Medical treatments for ITW include surgery (Eastwood et al., 2000; Hemo, 2006; Jahn, 2009), serial casting (Brouwer et al., 2000; Eastwood et al., 2000; Fox et al., 2006; Stott et al., 2004), Botulinum Toxin A (Engström et al., 2010; Engström et al., 2013; Sätilä et al., 2016), orthoses (Caselli, 2002; Herrin & Geil, 2016; Stricker and Angulo 1998), and watch and wait (Davies et al., 2018; Stricker

& Angulo, 1998). Unfortunately, there is a paucity of research with proper rigor on treatment efficacy (Leyden et al., 2019). Medical treatment can be influenced by clinician training, treatment funding source, and inconsistent treatment evidence (Williams et al., 2010).

Several recent reviews (Caserta et al., 2019; Leyden et al., 2019; Valagussa et al., 2017; van Bemmel et al., 2014) have described medical treatment for ITW. These reviews classified treatments into two main categories: surgical and non-surgical interventions (Caserta et al., 2019).

Surgical Interventions Surgery is the most invasive and expensive ITW treatment. Surgeons aim to achieve at least 10° ankle dorsiflexion by carefully lengthening the Achilles tendon, which tightens due to toe walking (Hall et al., 1967). This procedure is often effective for individuals who do not respond to other treatment modalities (van Bemmel et al., 2014). However, treatment outcomes for individuals with ASD are less promising than for those without an ASD diagnosis. In fact, Leyden et al. (2019) found that 75% of individuals with ASD resumed ITW within 2 years of surgery. Unfortunately, individuals with ITW and ASD receive surgical treatment nearly three times more often than those who exhibit ITW but do not have an ASD diagnosis (Leyden et al., 2019). Other interventions (e.g., serial casting, orthoses) may be dismissed due to concerns about tolerating less invasive treatments. Thus, it is essential to educate caregivers and medical professionals on the treatment outcomes within this population.

Most surgical studies omitted comprehensive pre-operative gait analysis and direct measurements and only reported post-operative gait or range of motion outcomes. Thus, these studies make it difficult to compare pre- and post-surgical outcomes. McMulkin et al. (2006) was one of the first authors to report quantitative outcomes for pre- and post-surgical intervention for 14 individuals who underwent a Vulpius-type procedure (gastrocnemius lengthening) bilaterally or Achilles lengthening surgery. Measurements from the ITW subjects were compared to normative data of their non-ITW peers. After surgery, participants showed significant improvements in peak dorsiflexion in stance and swing, increased stride length, improved ankle dorsiflexion with the knee extended and flexed, reduced hamstring tightness, and increased hip rotation.

Unfortunately, surgery imposes a sedation risk as well as a recovery risk. Van Bemmel et al. (2014) reviewed 10 studies that compared surgery to casting, and six of these studies ($N = 180$ patients) provided data on complications (61 casts, 119 surgery). Follow-up data were reported at 2.5 years for the casting group and 4.1 years for the surgical group. Only 3.3% of the casting studies reported complications, compared to 6.7% in the surgery studies. The predominant complication associated with casting was ulcerations. Six of the eight surgically treated individuals experienced Achilles tendinitis, and one individual had an ankle fracture due to manual pressure during the lengthening process.

Hemo et al. (2006) conducted parent interviews post-surgery (M = 2.9, range = 1.1–6.0 years). Twelve parents reported that their child consistently walked with a normal gait post-surgery, and three parents said their child still occasionally engaged in ITW. One participant experienced Achilles tendonitis 6 years post-surgery and required casting to correct ITW. Three additional studies reported high levels of parental satisfaction post-surgery (Stott et al., 2004; Stricker & Angulo, 1998; van Bemmel et al., 2014).

Serial Casting Serial casting involves placing a patient's lower legs and feet in a series of plaster or fiberglass casts to continually stretch the muscles surrounding the ankle, which may inhibit toe walking (Pistilli et al., 2014). The interior lining of the cast is waterproof, allowing individuals to bathe. Rubber sole walking shoes with Velcro™ straps are used to prevent slipping over the cast. Casting duration is typically 4–6 weeks (Ruzabarsky et al., 2016), although some studies report casting duration of up to 10 weeks (Fox et al., 2006). Casts are changed roughly every 2 weeks. Initial casts restrict ROM and require individuals to walk on their heels. This treatment sometimes precedes surgical interventions in typically developing individuals; however, individuals with ASD are more likely to undergo surgical interventions before attempting serial casting (Leyden et al., 2019). When implemented alone, serial casting is often the most effective non-surgical intervention (Bishop, 2016; Engström & Tedroff, 2012; Fox et al., 2006); however, long-term follow-up data are needed. In a review by van Bemmel et al. (2014), ITW returned in 52.1% of individuals at follow-up (M = 3.5 years) who received serial casting. Additional gait analysis by Van Kuijk et al. (2014) reported that gait patterns failed to normalize post-treatment. Thus, research on serial casting outcomes is inconclusive.

Fox et al. (2006) examined the effects of casting on 44 individuals between 2 and 14 years of age without intellectual disabilities. Professionals replaced casts twice with at least 1 week between changes; the pediatric physiotherapist conducted follow-up exams at 3 months post-cast removal and then every 6 months after that for approximately 14 months. Two thirds of participants decreased or stopped ITW. In a separate analysis, Katz and Mubarak (1984) reported that casting significantly improved gait in five out of six participants. Conversely, Eastwood et al. (2000) found that casting was not was as effective as described in Fox et al. and Katz and Muburak.

More recently, Davies et al. (2018) conducted a retrospective study that examined the long-term effects of casting (n = 23) versus stretching (n = 20) in 43 participants ranging in ages 13–28 years. Follow-up exams were conducted approximately 13.4 years post-intervention. In the casting group, all participants' casts were changed every 3 weeks. Following casting, 17 participants wore ankle foot orthoses for 1-year post-cast removal. Results showed a statistically significant difference from baseline to follow-up in the casting group but no significant difference in the stretching group. Seventy-four percent (12/23) showed improvements, 26% were unchanged (6/23), and 52% (12/23) of individuals self-reported that ITW still occurred at follow-up. In the stretching group, 35% (7/20) improved, 55% (12/23) remained the same, and 10% worsened (2/20). Self-report data indicated persistent ITW for 45% (9/20) of participants at the follow-up exam. Unfortunately, long-term outcome data were obtained by the parent's verbal report and not verified with ROM. Thus, outcomes should be interpreted with caution.

Finally, Thielemann et al. (2019) examined serial casting in 10 participants with ITW. These researchers excluded participants with underlying neuromuscular medical conditions or those who received previous ITW interventions. Treatment consisted of serial casting, and casts were changed every 14 days. Nine participants met the dorsiflexion requirement of 20° after 28 days, and one participant required an additional 14 days to meet the ROM aim. Electronic gait analysis data were obtained from the sensors in the insoles. Assessments were conducted after the cast was removed and at a 6-month follow-up visit. Results showed a significant reduction in gastrocnemius stiffness and heel force. Treatment effects persisted during the follow-up exam. This study was the first to report that casting resulted in complete gait normalization. The generality of treatment effects needs to be tested with other populations. Moreover, long-term maintenance of treatment effects is unknown beyond 6 months.

Botulinum Toxin A Medical professionals inject botulinum toxin A (BTX) in the muscles to treat a variety of medical conditions (e.g., migraines, muscle stiffness, eye problems) and cosmetic enhancements (e.g., wrinkles, severe sweating). BTX is also commonly prescribed for motor disorders, such as cerebral palsy. Botulinum toxins are potent proteins derived from the bacteria *Clostridium botulinum* and inhibit acetylcholine, a neurotransmitter, resulting in temporary paralysis (Anwar & Zafar, 2013). Treatment effects are dose-dependent, and last approximately 3 months (Anwar & Zafar, 2013; Jacks et al., 2004). Hastings-Ison et al. (2016) found that BTX injections administered once per year were equally effective to those administered three to four times per year and reported to have less adverse effects. Recently, BTX has been used to treat ITW (Multani et al., 2019).

Engström et al. (2010) evaluated the effects of BTX injections on ITW in 15 participants (5–13 years) without ID. Three-D video systems were used to obtain gait analysis data during three different 10-m barefoot walks. Participants received BTX injections, 6 units/kg of body weight with a maximum of 400 units, into both calves at four different sites. The physical therapist instructed parents and participants to stretch five times per day and walk on heels for at least 50 steps a day. Gait analysis data indicated significant improvements during initial contact, in the swing phase, and in ROM with ankle dorsiflexion. Three of the 15 participants stopped toe walking, and parents reported favorable treatment outcomes.

Engström et al. (2013) conducted another randomized controlled, parallel group trial in Sweden with 47 participants that compared the effects of casting to casting plus botulinum toxin. Sixty-eight percent of participants reported a family history of ITW, and participants had no prior intervention history. ITW improvements were defined as more than 50% of the time walking using an appropriate heel-to-toe gait. Gait measures were obtained using 3-D video analysis at the onset of the study, 3 weeks post-BTX injection, and with post-treatment follow-up analysis at 3, 6, and 12 months. The casting group included 26 participants with equal gender distribution ranging in age from 5.4 to 13.6 years. The casting plus botulinum toxin A group consisted of 21 participants (male = 16, female = 5) between the ages of 5 and 14. The experimenter applied analgesic cream 1 h before injections. A maximum of 400 BTX units were injected into the calf muscle in four areas. After BTX injections, participants were encouraged to stretch five times a week and walk on their heels 50 steps per day. A single BTX injection significantly decreased ITW and improved ROM for 11 of the 12 participants at the 12-month follow-up exam. The experimenters contacted the parents 3–5 years post-follow-up to track progress. Two parents reported ITW ceased, three parents indicated that ITW occurred during less than 50% of steps, two parents reported surgical interventions were later needed, and one parent stated ITW ceased after BTX plus casting. Only two parents reported ITW occurred during 75–100% of steps post-BTX. Three parents disclosed adverse outcomes that included moderate pain for 2–3 days post-injection.

In a similar study, Sätilä et al. (2016) conducted a 2-year evaluation of the effects of BTX ($N = 16$) relative to a more conservative intervention (i.e., stretching, foot orthoses, or firm shoes) group ($N = 14$). Thirty participants (2–9 years) presented with normal development and never received BTX, casting, or surgical interventions. The control group wore firm heel cups daily, night splints at least five nights per week, attended physical therapy once a week and stretched five times per week for at least 10 min per day. The BTX group received a 16 U/kg dose in three injection sites in both legs. Stretching occurred after the injections to activate the BTX. Participants were recorded walking and playing for 15 min. Experimenters evaluated ITW severity from the videotapes using a five-point scale. Follow-up assessments were conducted at 6, 12, and 18 months. Both groups showed significant improvements, and ITW was no longer present at the 24-month follow-up for 100% of the BTX group and 85% of the conservative treatment group. ROM outcomes varied across participants with no significant differences between groups.

Ankle Foot Orthoses (AFOs) An ankle foot orthosis is a plastic support sleeve used to train individuals on proper heel-to-toe gait (Herrin & Geil, 2016). Unfortunately, AFOs are not intended for long-term use, and ITW often re-emerges shortly after removal. AFOs restrict ROM and prevent ITW, whereas foot orthoses (FO) are less restrictive. Both AFOs and FOs are less invasive interventions, and at least one hospital (The Cincinnati Children's Hospital) recommends AFOs as the preferred non-surgical intervention for ITW (Herrin & Geil, 2016). Unfortunately, long-term outcomes are not promising.

Herrin and Geil (2016) conducted a randomized controlled trial to evaluate the effects of AFOs ($n = 10$) to FOs ($n = 9$) on ITW in individuals without neurological conditions. Participants ranged in age from 2 to 8 years. Experimenters obtained gait data using electronic motion analysis during five different 10 m walks. Participants in the AFOs group demonstrated significantly more treatment effects than the FO treatment group; however, treatment relapse occurred faster in the AFO group than in the FO group. That is, as soon as the AFOs were removed, ITW returned to baseline levels. Both parents and participants preferred the FO to the AFOs.

Researchers have also conducted a variation of FO treatment. Michalitsis et al. (2019) conducted a randomized controlled trial to determine the effects of orthoses with high-top boots on ITW in 10 males between 4 and 10 years of age. Participants walked on a GaitRite™ mat that measured heel strike and ankle dorsiflexion under three different conditions: barefoot, wearing everyday footwear, and wearing carbon orthoses inside high-top boots. The heel-to-toe strike occurred most often during the combined orthoses and high-top boots (89%) condition relative to the barefoot (64%) and normal footwear (68%) conditions.

In addition to manipulating the types of FO and shoes, researchers have also examined FO with feedback. For example, Pollind et al. (2020) used customized insoles with two pressure points to provide vibration feedback to five participants with ITW between 9 and 17 years of age. All participants temporally decreased ITW; however, absent vibration feedback, ITW resumed for all participants (median = 13 s). Participants reported that the feedback helped alert them to the target behavior; note, however, that participants' language development is unknown. Thus, it is unclear to what extent this treatment would be useful for individuals with ID.

Although AFOs are a more conservative treatment, empirical research supporting their efficacy is limited. In addition, parents and medical providers should consider the limitations of AFOs and FO before recommending them for treatment. Custom FO are expensive, and AFOs are bulky, uncomfortable, and require special shoes. Furthermore, AFOs are visually unappealing and can result in unpleasant social attention (e.g., bullying) (Ruzabarsky et al., 2016). Professionals should consider individual preference, given that research on AFO and FO has reported similar outcomes.

Watch and Wait The most conservative medical intervention requires caregivers and medical professionals to evaluate ITW over time, sometimes referred to as the watch and wait treatment. Taussig and Delouvee (2001) reported that some individuals self-corrected and no longer engaged in ITW between 3 and 8 years of age. Similarly, Engstrom and Tedroff (2018) surveyed 63 Swedish parents whose children met the criteria for ITW and did not have any other medical issues. Parents reported the approximate percentage of time (i.e., 25%, 50%, 75%, and 100%) their child was toe walking at various ages. Seventy-nine percent of parents reported that ITW stopped without treatment when their child was 10 years of age. Unfortunately, this study relied solely on the parents' report. In contrast, other studies have reported little change in ITW over time. For example, Eastwood et al. reported that 88% of participants met ITW criteria after 3 years of observation. Stricker and Angulo (1998) reported similar results; these results indicated that 48 individuals with ITW made no significant improvements without treatment at a 3-year follow-up. To date, no studies have compared an ITW watch and wait treatment group to an ITW non-treatment group with long-term follow-up data.

Overall, a variety of medical interventions have aided in the assessment and treatment of ITW. Surgical interventions and serial casting interventions have effectively reduced ITW; however, surgery is invasive, and a months-long recovery period is often necessary before the patient regains the ability to walk normally. Unfortunately, many individuals with ID who have undergone surgery reverted to ITW within 2 years (Leyden et al., 2019). While less invasive, serial casting prevents the patient from engaging in many everyday childhood activities, such as running and playing sports. In addition, as with surgical interventions, individuals with ID often revert to ITW in less than 3 years post-intervention

(Leyden et al., 2019). Thus, parents and medical professionals should examine ITW treatment relapse, especially for individuals with ID. Unfortunately, results from a healthcare survey (*N* = 908) reported a significant disconnect between medical professionals understanding of common ITW treatments and a treatment consensus (Williams et al., 2020). The paucity of evidence-based interventions imposes additional treatment challenges, and the non-evidence-based treatments need further examination. Recommending non-evidence-based treatments or treatments lacking long-term effects for specific populations (i.e., ID, ASD) can impose tremendous financial burdens on families and the healthcare system (Williams et al., 2020). Perhaps the most effective treatments may include behavioral interventions or a combination of behavioral and medical interventions.

Behavioral Interventions for Toe Walking

Behavioral interventions focus on the manipulation of environmental events to teach appropriate walking and/or increase the motivation for the individual to walk appropriately. Most behavioral interventions for challenging behavior such as ITW are preceded by a functional assessment, as described above. The purpose of the assessment is to determine the reinforcement contingency maintaining the challenging behavior. Social positive reinforcement involves the presentation of a social stimulus (e.g., attention) contingent upon the challenging behavior; this stimulus results in an increase in the occurrence of the behavior in the future. Social negative reinforcement involves the removal of a stimulus (e.g., an unpleasant task or activity) contingent upon the challenging behavior; this stimulus results in an increase in the occurrence of the behavior in the future. In contrast to social reinforcement, automatic reinforcement occurs when a behavior produces its own reinforcement "automatically"; another person is not involved. Automatic positive reinforcement occurs when a behavior produces some type of stimulation and this stimulation results in an increase in the occurrence of the behavior in the future (e.g., when a self-massage, which produces a pleasant condition of the body, is repeated). Automatic negative reinforcement occurs when a behavior alleviates or reduces some type of bodily sensation and this reduction in stimulation results in an increase in the occurrence of the behavior in the future (e.g., when scratching an insect bite alleviates itching, so it is repeated). Most cases of ITW are likely maintained by automatic positive or automatic negative reinforcement, although it is certainly possible that social reinforcement also plays a role in some cases. Walking with a toe-to-toe gait may produce pleasant sensations on the feet or toes, or may enable avoidance of unpleasant sensations produced by heel-to-floor contact.

Although ITW may often be maintained by automatic reinforcement, as described above, few studies have verified this. Future research should conduct functional analyses before intervening to reduce toe walking.

Behavior maintained by automatic reinforcement is among the most difficult to treat, in part because it is difficult to identify the exact source of reinforcement. For example, as described above, toe walking could be maintained by the muscle contractions it produces in the toes, the absence of stimulation on the heel, or both. Even when it is possible to identify the specific source of reinforcement, it is often impossible to manipulate this source of stimulation or stimuli relevant to the source. For example, some cases of toe walking may be maintained by the tactile stimulation the behavior produces. However, manipulating that stimulation may be impossible. Thus, behavior analysts have largely evaluated non-function-based interventions to decrease toe walking. Nevertheless, future research should explore function-based options.

Specifically, behavioral interventions for ITW have included punishment-based procedures (Charlop et al., 1988), differential reinforcement procedures (Marcus et al., 2010), stimulus control procedures (Hodges et al., 2018), and even the manipulation of response effort (Hobbs et al., 1980). Punishment-based procedures have included overcorrection and the application of light pressure to the participant's shoulder so that the feet are flat. Differential reinforcement procedures have been used with and without other procedures. Stimulus control procedures have included the use of a multiple schedule represented by a wristband. The use of heavy boots to increase the effort required to toe walk has also been examined.

Hobbs et al. (1980) were the first to implement a behavioral intervention for ITW. They combined a pair of heavy boots (to increase the weight of each foot and therefore increase toe-to-heel steps) with a differential reinforcement of other behavior (DRO) procedure to decrease ITW by a young child. The researchers conducted their treatment evaluation across two settings (hallways in a school and a playroom) using a combination multiple baseline and withdrawal design. The boots and DRO were each assessed alone and in combination. The results suggest that the combination of the two procedures was more effective than either procedure alone, although even in the combined condition, ITW still occurred during about 40% of intervals. Nevertheless, the researchers told the participant's mother to use the combined interventions. The researchers conducted a follow-up telephone call with the participant's mother over 3 years after the conclusion of the study and noted that the mother reported no toe walking at that time. However, no formal follow-up data were presented. In addition, design flaws prevent firm conclusions regarding the effectiveness of the interventions.

This study is interesting for a number of reasons. First, it was the initial foray into behavior analytic interventions for ITW. Second, the researchers employed a response effort-based intervention (a weighted boot) to decrease toe walking, which appeared to be at least somewhat effective. Finally, the researchers implemented a DRO procedure using food and tokens with the participant, which appeared to be less effective than the weighted boots, but again, concluding anything about the relative effects of the two procedures evaluated in this study is difficult due to design concerns.

A year later, Barrett and Lin (1981) implemented another behavioral intervention to reduce ITW. These researchers evaluated a combined physical therapy procedure with positive practice overcorrection. The physical therapy involved four specific techniques focused on decreasing tendon rigidity and increasing ankle range of motion. These techniques were practiced across all phases of the study, including baseline. The positive practice overcorrection procedure consisted of a verbal warning followed by required toe tapping on cloth footprints for 30 s. During this tapping, the therapist held the participant's heel against the floor. At least 10 taps were required during each 30-s procedure. The therapist physically guided the participant to perform the taps, if necessary. This procedure was implemented contingent upon each instance of ITW and was effective to decrease toe walking to low levels. Moreover, once ITW decreased, the researchers implemented the verbal warning by itself. If the participant ceased toe walking contingent upon the warning, they did not implement the toe tapping procedure. During this phase, levels of ITW remained low. Finally, the researchers also conducted a follow-up phase during which they discontinued both the toe tapping procedure and the verbal warning. ITW maintained at low levels during this follow-up phase.

This study is interesting for a number of reasons. First, it included a physical therapy procedure; unfortunately, the extent to which the physical therapy component was responsible for the treatment effects is unknown. Second, the researchers conducted an impressive follow-up evaluation, and the results were favorable. Finally, although the behavioral intervention was punishment-based (i.e., they referred to it as a positive practice overcorrection procedure), the researchers note that requiring the participant to repeatedly practice touching his toes to the ground while his heel was on the floor may have also contributed to learning the correct movements involved when walking appropriately.

Charlop et al. (1988) compared the effects of varied presentation of three punishers versus presentation of a single punisher to decrease problem behavior exhibited by three children with intellectual disabilities. One of the children, a 6-year-old girl, exhibited ITW. The punishers in the varied punishment condition included a verbal reprimand, overcorrection, and a time-out procedure. The single punisher condition consisted of either a reprimand, overcorrection, or a time-out procedure. The varied presentation of punishers was more effective than any of the single presentation punishers to reduce ITW. Unfortunately, the researchers reported data across dependent variables, so it is difficult to determine the specific effects of the procedures on toe walking. These data suggest that, when a punishment procedure is necessary to reduce ITW, varied presentation of punishers may be more effective than the delivery of only one type of punisher.

Marcus et al. (2010) were the first to use auditory feedback to treat ITW. These researchers attached Gaitspot Auditory Squeakers™ to the heels of participant's shoes. Every flat-footed step produced a squeak. They then paired the squeak sound with edible items so that the squeak became a conditioned reinforcer. Next, the researchers added components of simplified habit reversal (SHR). They then evaluated this multicomponent intervention to decrease ITW exhibited by three children with ASD. The procedure was effective; all participant's ITW decreased to some degree, although the amount of reduction varied. The researchers were even able to fade the squeakers and test for maintenance in the absence of the squeakers. Intervention effects largely maintained even after the squeakers were removed.

Lancioni et al. (2012) provide a technology-based example of an intervention designed to address ITW exhibited by 32-year-old woman with encephalopathy and blindness. The researchers used a microprocessor-based control device connected to an MP3 which was housed in a backpack worn by the participant. Sensors were placed on the two extremities of the participant's shoes to detect shoe-to-ground contact. Contingent upon contact of the heel of the shoe with the ground within 1.5 s, the device played the participant's preferred music for 5 s. The music continued if the next step (from the other shoe) was also appropriate. Contingent upon ITW, all music ceased. The results of the study suggest that the procedure was effective; the percentage of appropriate steps increased to between 80% and 100% when the intervention was in place. In a subsequent study, Lancioni et al. (2013) replicated this procedure.

Although effective, the technology used in these studies was expensive. The researchers estimated that it cost about $1000, which makes it out of reach for many families, agencies, and service providers. The price may decrease in the future, however, and this approach appears promising. The researchers also noted that the settings on the device might be adjusted for other participants. For example, a different schedule of reinforcement (e.g., FR 10) might be programmed during a maintenance phase.

Persicke et al. (2014) evaluated a modified TAGTeach™ procedure plus a correction procedure to decrease toe walking in a 4-year-old boy with ASD. Specifically, the researchers evaluated two conditions: correction alone and correction with an audible conditioned reinforcing stimulus. In the correction alone procedure, the researchers placed their hand on the participant's shoulder and added slight pressure until his heels touched the floor each time he engaged in ITW. In the correction plus audible conditioned stimulus (i.e., TagTeach™) procedure, the researchers used the same hand on shoulder procedure, but produced an auditory clicking sound contingent upon each appropriate step made by the participant. To establish the sound as a reinforcer, the researchers repeatedly paired it with a preferred edible item. The correction alone procedure produced little to no decreases in ITW. However, the correction plus an audible conditioned stimulus (i.e., TagTeach™) produced low levels of toe walking.

After verifying that toe walking persisted in the absence of social consequences, Hodges et al. (2018) evaluated the use of a multiple schedule to decrease ITW. The researchers placed a wristband on the participant's arm which signaled the availability of praise for appropriate walking and reprimands for toe walking. No programmed consequences were delivered in the absence of the wristband. Once ITW decreased to acceptable levels with the wristband on, the researchers systematically increased the number of steps during which the participant wore the wristband. They also evaluated the procedure in the community, in addition to a clinic. Finally, they had the participant's mother implement the procedure. Throughout all conditions and both settings, the procedure effectively reduced ITW to low levels.

Hodges et al. (2019) used a contingent acoustical feedback procedure to reduce ITW exhibited by a young boy with autism. The researchers paired a clicking sound with a preferred item to establish the sound as a conditioned reinforcer. They then used a clicker to deliver acoustical feedback contingent upon appropriate walking. After thinning the schedule of clicker delivery, they conducted generalization probes in another setting. The procedure was effective to reduce ITW and increase appropriate walking.

Jowett et al. (2019) used differential reinforcement of other behavior (DRO), rules, and feedback to decrease ITW exhibited by a 5-year-old girl. Although the participant had no known disability or psychiatric diagnosis, her language skills were well below those of her same age peers. The researchers first presented an instruction to walk with flat feet, which was ineffective. Next, they added a rule, a goal, feedback, and a DRO. The rule specified the contingencies, which involved access to preferred items via a token economy. That is, the participant earned a smiley face on a chart for each interval without ITW. The DRO interval was gradually increased until toe walking did not occur for an entire session. Finally, the researchers had the participant's teacher implement the procedure. The results suggested that the procedure was effective; intervals with toe walking decreased to low levels and remained low during all DRO sessions. ITW during the teacher implemented session was also well below baseline levels, suggesting the procedure can be successfully implemented by others.

Wilder et al. (2020) extended Marcus et al. (2010) by further evaluating the use of Gaitspot Squeakers™. Marcus et al. included additional treatment components (e.g., simplified habit reversal) in their intervention, which may have been unnecessary. In addition, Marcus et al. did not examine if the auditory feedback produced by the squeaker could decrease ITW. Wilder et al. (2020) conducted a pre-treatment screening analysis to identify the function of toe walking, eliminated other intervention components, and evaluated the squeaker-produced auditory feedback itself on toe walking. Three children with ASD and a multi-year history of toe walking participated. The researchers found that the squeaker-produced auditory feedback did decrease toe walking to some degree for all participants. For one participant, the auditory feedback alone produced clinically significant reductions. For the other two participants, the delivery of preferred edible items, which had been paired with the auditory feedback, was necessary to decrease ITW to acceptable levels. Finally, for one participant, the researchers had to add a procedure in which they placed a hand on the participant's shoulder contingent upon a step with toe walking, similar to Persicke et al. (2014). The researchers were also able to thin the schedule of edible item delivery while maintaining treatment effects. Generalization to another setting was also evaluated; ITW remained low across settings.

Future Research on ITW

Future research on medical interventions for ITW should focus on identification of a hierarchy of least intrusive and most effective interventions. For many children, orthoses might be the first line of intervention, followed by serial casting, and, if all else fails, surgery. Future research should also focus on identifying sub-populations of toe walkers for whom surgery and other intrusive interventions are needed immediately.

Future research on behavioral interventions for ITW should also focus on identification of a hierarchy of least intrusive and most effective interventions. In addition, function-based interventions should be evaluated and compared to non-function-based procedures, such as the manipulation of response effort and punishment-based interventions. Finally, stimulus control-based interventions should be refined and the delivery of more immediate and precise feedback should be included as intervention components.

Finally, future research on ITW should combine medical and behavioral interventions. For example, researchers should examine the use of FOs combined with behavioral procedures. In addition, researchers should develop a hierarchy of combined medical and behavioral interventions. Since they are less intrusive, behavioral interventions might be the first class of interventions implemented in a hierarchy. If possible, function-based interventions might be implemented initially. If necessary, stimulus-control-based, DRO, or response effort manipulations might be evaluated next. If ITW is not reduced, medical interventions (orthoses, casting, and surgery) might be appropriate.

Using Reinforcement to Prevent Challenging Behaviors

Regan Weston, Holly Rittenhouse-Cea, Spencer Gauert, Madison Crandall, and Supriya Radhakrishnan

Challenging Behavior

What Is Challenging Behavior?

The term challenging behavior (CB) evokes varied imagery dependent on individual perceptions and experiences with behavior. According to Smith and Fox (2003), CB is a persistent behavioral pattern that impedes learning and social opportunities. These behaviors include tantrums, sleep disturbances, aggression, stereotypies, verbal outbursts, withdrawal, destructive behaviors, self-injury, noncompliance, and issues with eating. There are additional influences related to cultural beliefs and potential biases of the observer that factor into the identification of CB in children (Gilliam et al., 2016). CB ranges from mild to severe in nature, and when left untreated can cause long-lasting harm to the individual (Ogundele, 2018).

The prevalence of CB differs greatly across populations and age groups. Bowring et al. (2019) found that as many as one in five adults with intellectual disabilities (ID) receiving services engage in CB. In children with disabilities, ages 3–21, the prevalence ranges from 48% to 94%, with children with autism spectrum disorder (ASD) at the highest rate (Simó-Pinatella et al., 2019). The most commonly reported CB among individuals with disabilities are aggression (Newman et al., 2015), self-injury (Simó-Pinatella et al., 2013), and stereotypy (McTiernan et al., 2011). According to Alimovic (2013), the prevalence of CB among individuals with development disabilities (DD) is three to seven times higher than that of their typically developing peers. There has been a significant amount of research evaluating methods to address CB among various populations, including those diagnosed with intellectual and developmental disabilities.

Treatment of Challenging Behavior

Functional behavior assessment (FBA) is an array of evidence-based methods used to identify the environmental contingencies that are functionally related to CB. The reinforcer that the CB produces is commonly referred to as the function of the CB. Traditionally, there are four families or types of functions: attention, escape, tangible, and automatic, or sensory stimulation (Iwata et al., 1994a).

FBAs can consist of both direct and indirect methods of assessment. Indirect methods may include interviews with the individual of interest or with stakeholders who regularly interact with

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_63

the individual of interest. Direct methods include direct observation, descriptive analyses (such as correlational assessments), as well as experimental manipulation of reinforcement contingencies (i.e., functional analysis). A survey of practicing behavior analysts indicated that a majority of respondents primarily used interviews with stakeholders and descriptive analyses to identify the function of CB (Oliver et al., 2015).

Prevention of Challenging Behavior

The majority of CB interventions in the literature are reactive approaches (Fahmie et al., 2018). That is, the intervention is introduced following the development of clinically significant and severe levels of CB. Although effective in reducing CB, these intervention approaches can be resource intensive. For example, research has shown that the financial cost of caring for an individual with ID with comorbid CB is estimated to be $3 billion annually (Waddell et al., 2018). Moreover, there are several practical constraints in implementing a functional analysis methodology (Hanley, 2012; Iwata & Dozier, 2008). Implementing a functional analysis requires considerable time and expertise. Research has shown that a traditional functional analysis can take up to 3–4 days to implement, making it impractical to implement in most outpatient or educational settings (Iwata et al., 1994b; Tincani et al., 1999). These findings highlight the importance of identifying preventive or proactive strategies to decrease the likelihood of CB emerging in the first place.

Some ways to prevent severe CB are (a) reinforcing appropriate responses noncontingently, (b) placing less severe CB on extinction, and (c) teaching an appropriate response in situations that evoke the severe CB (Fahmie et al., 2016). Hanley et al. (2007) implemented some of these preventive strategies with typically developing preschoolers, who were at risk for developing severe CB due to the time spent in nonmaternal care. Appropriate social behavior (referred to as preschool life skills [PLS]), such as responding to name, tolerating a delay in reinforcement, and friendship skills (e.g., saying, "thank you"), were taught using a classwide approach, independent of the presence of CB.

Similarly, Luczynski and Hanley (2013) evaluated the acquisition and maintenance of self-control and functional communication skills in preschool children, who warranted more intensive CB and self-control interventions than their peers. However, instead of a classwide approach to teaching PLS as was used by Hanley et al. (2007), the authors implemented a small-group PLS program (Luczynski & Hanley, 2013). The authors also included a control group of participants who did not receive the PLS intervention. The study results demonstrated that all participants who received the PLS intervention successfully engaged in the target skills. Five of six participants continued to engage in the target skill during maintenance. Moreover, CB worsened for all participants who did not receive the small-group PLS intervention.

To further this research line, Fahmie et al. (2016) conducted a two-part study with an adult with developmental disabilities. As per the teacher report, the participant engaged in a minor but emerging CB when the teacher restricted access to tangible items. The purpose of Study 1 was to implement sensitivity tests, and the purpose of Study 2 was the evaluate the efficacy of a prevention strategy. The sensitivity tests, a variation in the trial-based functional analysis, were conducted to identify the establishing operations (EOs) that may create the occasion for the emergence of CB. During the control trials, the implementer provided noncontingent access to tangible items. During the test trials, the implementer conducted five test conditions, which might evoke CB maintained by access to tangible items (e.g., removed access condition). If the participant engaged in an appropriate response or severe CB (e.g., aggression or self-injury) during the test trials, the implementer removed the potential EO by delivering the tangible items. If the participant engaged in minor CB (e.g., body rocking), the implementer placed the CB on extinction. The sensitivity test results demonstrated that the participant engaged in only minor CB and no appropriate requests during test trials. These results allowed the researchers to analyze the preventive effects of the intervention in Study 2. In this study, the participant was taught a functional communication response (i.e., card exchange) in the presence of the EO. Subsequently, the implementer taught the participant to tolerate delayed reinforcement by waiting to access tangible items following appropriate communication. Finally, the implementer also taught the participant to tolerate denied reinforcement, in which the participant was told "no" following appropriate communication.

Although a research-based prevention model to address CB is relatively new compared to more prevalent reactive approaches, there are several evidence-based reinforcement strategies that have been shown to be effective in a variety of settings that could potentially reduce the likelihood of CB occurring. The remainder of the chapter will focus on strategies that can be used as preventative strategies for CB.

Reinforcement Strategies to Prevent Challenging Behavior

Differential Reinforcement

Differential reinforcement (DR) is a schedule arrangement in which reinforcement is provided for a specific response (or class of responses) and withheld when other responses are emitted. DR can be applied to various dimensions of a behavior including the frequency or rate of a behavior, the inter-response time (IRT) (i.e., the time that passes between two instances of a response), and the magnitude, or intensity of a response. Reinforcement can also be delivered noncontingently. One variation of DR that is not discussed here is differential reinforcement of other behaviors, which is discussed in another chapter.

Differential Reinforcement of Alternative Behaviors

Differential reinforcement of alternative behaviors (DRA) is a procedure in which interventions minimize or withhold reinforcement for undesirable behaviors and provide greater reinforcement for desirable behaviors relative to that offered for undesirable behaviors (Vollmer et al., 2020). Conceptually, DRA is a concurrent-operants schedule, where two independent reinforcement schedules are simultaneously in place for two different responses (Kunnavatana et al., 2018).

DRA can be considered a proactive strategy for addressing CB because its manipulation of reinforcement should alter future frequencies of CB. Further, developing the strength of the alternative response increases the future frequency of that alternative, socially valid response in the natural environment, where it can be met with reinforcement. In DRA intervention sessions, the establishing operation for the CB is in place. By manipulating reinforcement contingencies after the establishing operation is introduced, DRA theoretically increases the future frequency of alternative, more desirable behaviors in the environmental arrangements that tend to evoke CB and decreases the future frequency of CB.

DRA has been shown to be effective in decreasing a variety of undesirable behaviors in a wide variety of populations (MacNaul & Neely, 2018; Petscher et al., 2009). Although most commonly used for individuals with developmental disabilities (including ASD), DRA has also been successfully used for individuals with other disorders, such as schizophrenia, cerebral palsy, and feeding disorders, as well with those with typical development. DRA has been used to successfully reduce CB such as aggression (Athens & Vollmer, 2010), pica (Hagopian et al., 2011), property destruction (Durand & Carr, 1992), disruptive behavior (LeGray et al., 2013), elopement (Davis et al., 2012), food rejection/packing (Piazza et al., 2003), self-injury (Worsdell et al., 2000), inappropriate vocalizations (Kunnavatana et al., 2018), inappropriate sexual behavior (Fyffe et al., 2004), and tantrums (Carr & Durand, 1985). DRA has also been used to increase other desirable behaviors, such as appropriate vocalizations (LeGray et al., 2013), task completion and/or compliance (Athens & Vollmer, 2010), and food acceptance (Piazza et al., 2003).

When implementing DRA, practitioners should carefully consider what an appropriate alternative behavior might be. The behavior should be functionally equivalent to the CB targeted for reduction. While traditional thinking suggests the alternative behavior should be in the child's repertoire or should be easy to quickly prompt, pre-teaching the alternative behavior may improve therapeutic outcomes (LeGray et al., 2013). For learners who can understand verbal instructions, describing the behavioral contingencies can support learning (Schlichenmeyer et al., 2015).

Differential Reinforcement of Incompatible Behavior

One slight variation of the DRA procedure is differential reinforcement of incompatible behaviors (DRI). Procedurally, DRI is identical to DRA. The distinction is that the replacement behavior selected when implementing a DRI schedule is incompatible with, or cannot occur at the same time as, a target CB. To select an incompatible behavior, you must ensure that the replacement behavior cannot occur simultaneously with the target CB. Research evaluating the effects of DRI procedures oftentimes categorize the independent variable as a DRA procedure with the distinction that the alternative replacement behavior is also incompatible with the target CB (Schlichenmeyer et al., 2015). DRI has been shown to be effective to address pica and maladaptive behaviors displayed by adults with ID (Donnelly & Olczak, 1990; Datlow-Smith, 1987; Spira et al., 2004), idiopathic toe-walking and elopement in individuals diagnosed with ASD (Marcus et al., 2010), and appropriate mealtime behaviors in an elementary school lunchroom (Wheatley et al., 2009). DRI can be beneficial as it provides a competing schedule of reinforcement between a desired and undesirable behavior given that the two behaviors cannot occur at the same time.

Differential Reinforcement of Low or High Rates of Behaviors

One element of the behavior that a practitioner might want to alter using DR procedures is the rate or frequency of the behavior. Differential reinforcement of low rates of responding (DRL) and differential reinforcement of high rates of responding (DRH) are two DR procedures that might be selected when you are interested in changing the rate at which behavior occurs.

Select a DRL procedure when you are interested in reinforcing a lower rate of the target behavior compared to baseline rates, but it is not necessary for the behavior to stop occurring altogether. In addition to reducing the rate or frequency of a response you can also use DRL to decrease the intensity or magnitude of a response (Schmidt & Ulrich, 1969; Wilson & Hopkins, 1973).

On a DRL schedule, reinforcement is delivered if a predetermined number of responses is not exceeded within a set period of time, or when a minimum amount of time has passed between one instance of a response and the next response. Deitz (1977) described three distinct methods of programming DRL schedules: (a) spaced-responding DRL, (b) full-session DRL, and (c) interval DRL. In spaced-responding DRL, reinforcement follows a response when a predetermined inter-response time is met. In other words, a response is only reinforced if a minimum amount of time has passed between the current response and the previous response. A full-session DRL requires that the number of responses are at or below a pre-determined criterion in order for reinforcement to occur across an entire session of time. Essentially, the learner earns reinforcement when they do not exceed the maximum number of responses allowed across the entire period.

An interval DRL schedule requires a certain response rate to be met within a pre-determined interval; if the response rate is exceeded within the interval, the interval is reset, and reinforcement is delayed. This might sound similar to a full-session DRL; however, the intervals used in this schedule require that the entire session is divided into a series of equal intervals of time. Consider a 2-h treatment session; for full-session DRL, the practitioner would record whether a certain number of responses was met (and not exceeded) across the entire 2-h period. Using an interval DRL, the same 2-h period might be divided into eight, 15-min intervals and a certain response requirement must be met (and not exceeded) in each interval.

To select the initial interval prior to implementing a DRL procedure, it is recommended that practitioners review baseline response rates. To determine the inter-response time (IRT) for space responding DRL, the practitioner should determine how often the target response occurs within a set period of time in baseline. For example, if a behavior occurs, on average, six times within a 30-min interval, an IRT of 5 min between responses would be appropriate. In other words, reinforcement would only be delivered if 5 min elapsed between one instance of the target response and the next response. Similarly, the average response rate within a set period of time can be used to determine the interval for an interval DRL procedure. For the behavior that occurs six times per 30-min interval, a response requirement of no more than one response per 5-min interval would be appropriate.

When using full-session DRL, the practitioner should identify the average number of responses emitted within a time period and set the response requirement slightly lower than that number. For example, if a student were to engage in 15 instances of talking out per hour for teaching attention, you would want to set the criterion for reinforcement at 15 responses per hour or lower.

Using baseline data to select the target response rate, IRT, or interval will help to ensure that the learner is capable of meeting the target rate of responding is more likely to access reinforcement for doing so. DRL has been used to reduce the frequency of question-asking and inappropriate social behaviors by adults with ID (Otalvaro et al., 2020; Singh et al., 1981), children's requests for teach attention (Austin & Bevan, 2011; Becraft et al., 2017), the rate of off-task or disruptive behavior in a classroom (Deitz & Repp, 1973, 1974), as well as to increase pro-social behaviors related to employment during transition to adulthood for individuals with ASD (Taylor & Seltzer, 2011).

A variation of the DRL schedule is DRH. This schedule can be used when you are interested in increasing the rate at which a target behavior occurs. Girolami et al. (2009) used a DRH procedure to increase the pace of self-feeding in a 9-year-old boy who was gastrostomy tube dependent. Not only did the DRH procedure increase the number of bites consumed during mealtime, but the average duration of each meal decreased during treatment from 35.5 min on average in baseline to 25.3 min on average in treatment. DRH can be an effective strategy to employ when you are interested in increasing the rate of a target behavior.

Some questions that have been presented in the literature regarding the effects of DRL/DRH schedules include whether the schedule affects non-targeted behaviors during the intervention. For example, Otalvaro et al. (2020) observed a decrease in the number of questions asked by adults with intellectual and developmental disabilities at an adult day treatment workplace when a full-session DRL was implemented. They also measured the duration of task engagement to determine whether a reduction in the number of questions asked by participants resulted in an increase in the duration of task engagement. Their findings were difficult to translate directly into an increase of work productivity and the authors suggested that future researchers might measure the rate or number of tasks completed rather than duration of task engagement to evaluate the effects more clearly.

Additionally, it is not clear how a DRL/DRH procedure affects the target behavior in non-intervention environments. When utilizing interval-based schedules of reinforcement, the length of the interval could decrease the effects of the intervention if a delay to reinforcement is an issue. In such cases, it is important to examine whether an intervention is successful using a shorter interval or appropriate schedule thinning procedures are used.

Given the nature and expected outcomes of a DRL schedule, this procedure should not be used to target self-injurious or dangerous behaviors. Additionally, DRL should not be used when you are interested in rapid behavior reduction. When it might be appropriate for the target behavior to be reduced to zero, you could select a full-session or interval DRL, as reinforcement can be delivered even if there are no instances of the behavior.

However, when it is important that the behavior remain in the learner's repertoire to some extent, it might be more appropriate to select a spaced-responding DRL, as reinforcement is delivered following an occurrence of the behavior.

Noncontingent Reinforcement

Noncontingent reinforcement (NCR) is an empirically supported treatment that has been used to increase a large number of appropriate, pro-social behaviors while simultaneously preventing the occurrence of CB (Richman et al., 2015). Vollmer et al. (1993, p. 10) described NCR as a "response-independent or time-based delivery of stimuli with known reinforcing properties." NCR consists of the delivery of reinforcement on a fixed interval or fixed time schedule of reinforcement. In other words, to implement NCR, a practitioner should provide learners access to stimuli that have known reinforcing properties on a fixed time schedule, noncontingent on the occurrence of target behavior. There are three primary assumptions as to why NCR is effective in changing behavior. The first assumption is that NCR results in a manipulation of the establishing operation of the target behavior (Vollmer et al., 1993). Rescorla and Skucy (1969) discuss the possibility that it could be a result of a disruption of the response-reinforcer relation or extinction. Finally, NCR may result in behavior changes because reinforcement occurs following responses other than CBs (Carr, 1996).

There are some characteristics of NCR that should be considered prior to implementing an NCR schedule. First, you must consider the interval by which you will deliver reinforcement. NCR has been implemented using many variations of basic schedules of reinforcement (i.e., fixed time, variable time), with or without schedule thinning, and with or without extinction (Carr et al., 2009). Second, you must consider the reinforcer presented. Richman et al. (2015) coined procedures that included functional reinforcers as NCR whereas procedures that included nonfunctional reinforcers as NCN. Although there was a small difference between outcomes when using functional and nonfunctional reinforcers, the results of the metanalysis conducted by Richman et al. (2015) do suggest functional reinforcers (or utilizing the maintaining variables for CB) are preferable over nonfunctional reinforcers.

Considerations of Differential Reinforcement Procedures

With Extinction For practitioners who determine that quick elimination of a dangerous behavior is needed, a DR procedure with extinction may be the most prudent choice (MacNaul & Neely, 2018; Petscher et al., 2009). Indeed, Petscher et al. (2009) noted several instances of learners who did not demonstrate acceptable levels of CB until a DRA with extinction procedure was introduced.

An additional consideration when choosing to use extinction is if the behavior can be safely placed on extinction. For example, behaviors that are attention-maintained, but result in serious injury to the learner or others, may not be placed on extinction. Additionally, in some environments, such as schools, extinction of CB may not be permissible, or even achievable (e.g., behavior that is maintained by peer attention).

A second consideration is the degree to which resources afford near-perfect procedural fidelity, as extinction by definition requires zero rates of reinforcement. Errors of commission (accidentally reinforcing CB) have been shown to be counter-therapeutic (Pipkin et al., 2010; Vollmer et al., 2020). In a study explicitly manipulating treatment integrity errors in DRA with extinction procedures, Pipkin et al. (2010) documented decreased rates of alternative behaviors and increased rates of CB when errors of commission were committed.

Without Extinction Practitioners might consider implementing a DR procedure without extinction for several reasons. First, certain settings and behaviors do not allow for extinction to be used. Legal constraints, safety of peers and adults in the environment, or size of the client relative to the size of the therapist all are variables that may prohibit extinction from being achievable (Vollmer et al., 2020). Additionally, behaviors that are dangerous to the learner or others and are attention-maintained may not be blocked without providing reinforcement (i.e., attention; Vollmer et al., 2020). In these instances, DRA without extinction is an acceptable alternative.

Interventionist factors also might make DRA without extinction most practical. If the therapist is physically weaker than a learner, response blocking may not be possible (Vollmer et al., 2020). Further, if the interventionist is an indigenous implementer, such as a parent or teacher, it may not be reasonable to expect them to perform with complete procedural fidelity. DRA without extinction may not be as sensitive to the counter-therapeutic effects of errors of commission in a DRA with extinction intervention. This is an additional way DRA without extinction may serve as a preventative measure for future CB.

Finally, practitioners who wish to use DR without extinction should consider if reinforcement can be consistently manipulated in some dimension, and if the learner is sensitive to changes in reinforcement along that dimension. Because sensitivity to manipulations of reinforcement dimension varies across learners, practitioners should consider testing learner sensitivities to those dimensions first (Kunnavatana et al., 2018). Further, practitioners should carefully document the variation in the selected reinforcement dimension and monitor the procedural fidelity of how those manipulations are delivered.

The most common dimensions of reinforcement that can be easily manipulated are quality, magnitude, and immediacy. When manipulating quality, practitioners can offer a highly preferred reinforcer for the alternative behavior and a lower-preferred reinforcer for the CB. For example, Kunnavatana et al. (2018) provided access to a highly preferred item after mands but provided access to a low preferred item in response to CB. Magnitude (in other words, intensity or duration) of reinforcement may be altered across the two schedule components. For example, Kunnavatana et al. (2018) offered 90 s of access to a preferred tangible contingent on undesirable behavior, and 15 s of access to the same tangible contingent on desired behavior. Immediacy of the delivery of reinforcement may also be altered such that the delivery of the reinforcer for the desirable behavior is more immediate than it is for the CB. For example, Horner and Day (1991) provided immediate escape contingent on alternative behaviors and delayed access to escape contingent on CB for an individual with escape-maintained self-injurious behavior and aggression.

Schedule Thinning An additional consideration when implementing a DR procedure is the gradual thinning of the schedule of reinforcement for the desired behavior. Reinforcement is often not delivered as consistently or immediately in the natural environment as it is in a tightly controlled intervention environment (Drifke et al., 2020) and it may not be reasonable to reinforce requests for desired stimuli on a FR1 schedule. Thus, in order to prevent future re-emergence of CB when these delays occur, schedule thinning should be included in a DR intervention plan.

Schedule thinning may be introduced once the target CB has been decreased to acceptable levels and an alternative response has been acquired under the original, denser reinforcement schedule for the appropriate response. Then, learners are taught to tolerate a delay between the appropriate response and delivery of reinforcement. "Tolerance" can be most simply defined as the absence of CB. The number of tasks required for completion before reinforcement is delivered can then be gradually increased, thus also gradually increasing the delay to reinforcement. Teaching learners to engage in an alternative response during delays to reinforcement has been shown to produce more desirable treatment outcomes (i.e., low levels of CB and repeated mands for reinforcement during delays, but maintained levels of mands when appropriate) than simply teaching learners to wait during the delay (Drifke et al., 2020).

Reinforcement-Based Intervention Packages

The following intervention packages are based on the assumption that all behaviors are responding to the environment in which it occurs. As such, by providing reinforcement for appropriate and desirable behaviors, the requirement to engage in CB to access reinforcement is minimized.

Functional Communication Training

In a review of the research on DRA, Petscher et al. (2009) found that 70% of the included studies used procedures that could be categorized as Functional Communication Training (FCT) interventions. FCT is a function-based DRA behavior intervention in which a CB is replaced with an appropriate verbal response. For example, individuals who engage in severe aggression reinforced by access to attention might be trained to say the phrase “play with me please” as a replacement. This intervention reduces CB by providing a socially acceptable replacement behavior (verbal response) that is reinforced instead of the CB. FCT was first codified by Carr and Durand (1985), who drew from prior research that suggested that CB occur when reinforced by attention or escape from difficult tasks. By training an appropriate verbal replacement response (i.e., a functional communication response, or FCR), CB is reduced. As FCT provides a more appropriate, functionally equivalent behavior to the CB, effective FCT requires that the verbal response functionally replaces the target response. Therefore, to implement FCT, it is essential to first determine the function of behavior (Durand & Moskowitz, 2015). Once the function of the target behavior is identified, a verbal replacement behavior can be identified. When selecting an appropriate verbal behavior, it is important to ensure that the verbal behavior is appropriate for the individual. Therefore, if the client is verbal and capable of speech, it is possible to select a socially valid mand (e.g.., “I would like to play, please”). However, if the client is nonverbal, minimally verbal, or otherwise presents with a verbal deficit such as a stutter or speech impediment, it is important to select an alternative response that is appropriate for the client’s verbal repertoire. Some alternatives to lengthy mands include brief mands of one or two words (e.g., “play please”), or a visual communication system such as picture exchange or communication board. The verbal response selected must be at strength within the participant’s repertoire as the greater the difficulty of response, the more likely the client is to default to the initial CB. Repeated pairings between the verbal response and access to the functional reinforcer serve to reduce CB by providing alternative access to reinforcement. This is most effective if extinction between the CB and reinforcement is implemented, allowing access to the reinforcer only contingent on the FCR.

FCT has wide ranging use and is appropriate for most clients at different ages and functioning levels. FCT should always be considered when the target CB is clearly functionally related to a specific reinforcer or reinforcement class, or even when a behavior might be multiply maintained (Falcomata et al., 2013). FCT is not appropriate to use in situations where clients are unable to independently emit a verbal response of any kind (including picture exchange systems). FCT is also not appropriate in the treatment of behavior that is automatically maintained, as these responses cannot be functionally replaced by an FCR (Gerow et al., 2018). FCRs should be selected with an eye towards social acceptability, as well as feasibility. Training an FCR that will be acceptable in a wide variety of situations (e.g., “help me please”) will allow the response to contact reinforcement under a wide variety of potential conditions, as well as receiving reinforcement from novel populations without the need for training. Further, choosing a socially valid FCR provides the learner access to the verbal community, where the response will likely be reinforced regardless of context. However, overly general FCRs (such as the above example, “help me please”) do not functionally replace behavior, and thus might not serve to replace behavior in all instances. Consider that a behavior such as aggression maintained by access to a tangible object (striking another child in order to access a favorite toy) is not functionally equivalent to asking the child, or a teacher, for access to that same toy. In this example, the likely outcome of the FCR is not access to the tangible item, but rather attention from the peer or teacher. Access to the tangible is thus necessarily more delayed (and potentially denied) as it requires mediation by a third party. In cases where the behavior is maintained by a consequence other than attention, the use of an FCR such as "help me please" provides reinforcement for that behavior only incidentally, and at far less consistency than an FR1. Thus, when access to the functional reinforcer after the FCR is unreliable, resurgence of CB is likely to occur.

Considerations When Implementing FCT

Establishing Operations Prior research in FCT implementation suggests that the presence of the establishing operation (EO) during training can have a large effect on the occurrence of CB. DeRosa et al. (2015) and later Fischer et al. (2018) demonstrated that longer periods of exposure to the EO resulted in greater rates of CB. Their research suggested that restricting the presence of the EO during FCT can reduce overall CB. Thus, if rates of CB are a concern, they recommend restricting the presence of the EO when conducting FCT.

One concern in regard to EOs and FCT, however, is that the presence of an EO is necessary for FCT to be possible. FCRs will only occur when they provide access to functional reinforcers, and thus require the presence of deprivation in order to be valuable. Shillingsburg et al. (2013) demonstrated that FCRs only occurred when an EO (in this case, physical blocking of access to a reinforcer) was present. Without the presence of the EO, no FCRs occurred. In addition, McGill (1999) noted that FCRs are not functionally related to the EO. They modify only the response that occurs in the presence of the EO, but do not change the EO itself. Manding for "help," for example, does not provide access to the functional reinforcer, it merely provides the opportunity for another person to provide the reinforcer.

Resurgence and Schedule Thinning One special concern for implementation of FCT is resurgence of CB. When implementing FCT, a sudden decrease in CB occurs as the FCR comes to provide alternative access to the functional reinforcer. However, resurgence of CB will always occur as CB retains its strength due to prior history of reinforcement. Resurgence is least likely to occur when FCT provides access to the functional reinforcer on an FR1 schedule. However, for long-term maintenance of behavior, it is not feasible to provide certain consequences at such a dense schedule of reinforcement. For example, an individual reinforced by escape from work tasks might have a functional replacement behavior for aggression in the FCR "I need a break please." While implementation of this FCR will likely reduce CB and serve as an appropriate functional replacement, such a dense schedule of escape from work tasks is not appropriate in school or work settings as it disrupts the individual's ability to engage in necessary activity.

Therefore, it is essential to train schedule thinning in order to allow for the FCR to retain strength even when it is reinforced at a less dense schedule of reinforcement (Durand & Moskowitz, 2015). However, this leads to fairly obvious problems. As parents, teachers, and other non-behavior analyst individuals are ultimately responsible for delivering consequences after clinical intervention concludes, the FCR is likely to be overtaken by CB in cases where it provides faster or more reliable access to reinforcement. Thus, it is necessary to effectively train for tolerance of delays and/or denial of reinforcement in response to the delivery of an FCR.

Prior research has been conducted on methods that increase the speed of schedule thinning and reduce the occurrence of CBs during the transition from dense, FR1 schedules of reinforcement to schedules that include delays and/or denial of reinforcement in response to FCR (Austin & Tiger, 2015; Falcomata et al., 2013; Hagopian et al., 2005). In general, schedule thinning resulted in an overall reduction of CB during the extinction condition, as well as increased responding. These may be considered when concerns arise that CB will prevent effective schedule thinning.

Positive Behavior Supports

Positive Behavior Supports (PBS) is a widely used, evidence-based technology that is conceptually and scientifically grounded in applied behavior analysis, with additional contributions from developmental and social psychology (Sailor et al., 2008). The key features of PBS include FBA (Dunlap et al., 1991), the rearrangement of environmental variables to prevent CB (Carr & Sidener, 2002), focus on teaching functionally equivalent replacement behaviors (Carr & Durand, 1985), and providing appropriate consequences for both desirable and undesirable behaviors (Koegel et al., 1996). PBS aims to improve the quality of life of recipients by addressing academic and social-emotional challenges of individuals and systems through thoughtful arrangement of the environment and the addition of other variables, such as reinforcement to increase appropriate behavior, coupled with the removal of environmental factors that promote CB (Carr & Sidener, 2002). Data collection is a defining element of PBS, and the importance of tracking both treatment fidelity and individual outcomes is emphasized (Horner & Sugai, 2015).

Positive behavioral interventions and supports (PBIS) is the most widely recognized application of PBS. PBIS was adopted by schools to improve student behavioral and academic outcomes, and school culture, by reducing or eliminating the use of often ineffective punitive practices (Horner & Sugai, 2015). PBIS is federally mandated for use with individuals with disabilities according the Individuals with Disabilities Act (IDEA), with specific emphasis on function-based assessment and intervention, and the use of positive approaches to behavior management (IDEA, 2004).

PBIS offers an alternative to reactive, punitive practices that were historically implemented in schools and other social systems. It requires a commitment to systems change and encourages scaling-up evidence-based behavioral interventions (Tincani, 2007). The interventions take place in the natural environment and are designed to produce long-lasting behavior change (Sugai & Horner, 2008). PBIS is a proactive approach that uses a tiered framework, as symbolized by Fig. 63.1, which was originally derived from the field of public health (Sugai et al., 2000).

Teams are established in order to develop specific plans for tiered supports, track and review data, and make decisions regarding effectiveness of intervention. These teams have varying focus dependent on the level of support provided to the individual. At the tier 1 level, teams meet regularly for planning and tracking effectiveness of the program. They monitor system-wide data to ensure that individual access to supports is equitable, strive to build foundational relationships with families, and attempt to gain cultural knowledge for individually relevant supports (Horner & Sugai, 2015). At tier 2, the teams increase training and professional development opportunities for staff, improve communication efforts with families, and continue to gather and analyze student data. Teams at the tertiary level are developed to conduct assessments, design intervention, more closely monitor student outcomes, and provide training and feedback to interventionists (Horner et al., 2010a).

Tier 1 is focused on universal prevention of CB. Creating supports at this level involves establishing behavioral expectations, providing operational definitions of behaviors and intervention procedure components, specifically training skills using modeling and feedback, delivering reinforcement contingent on the engagement of appropriate behaviors, utilizing interruption and redirection contingent upon the occurrence of CB, and systematic data collection to inform decision making (Horner et al., 2010b, 2014; Sugai & Horner, 2002). Tier 1 supports are designed for all members of the population, therefore, these components are embedded naturally into the environment and become part of the daily routine. The types of supports presented in Tier 1 include offering choice, providing prompts, the good behavior game (Barrish et al., 1969), utilizing visuals, social skills instruction, frequent contact with families, differentiation of

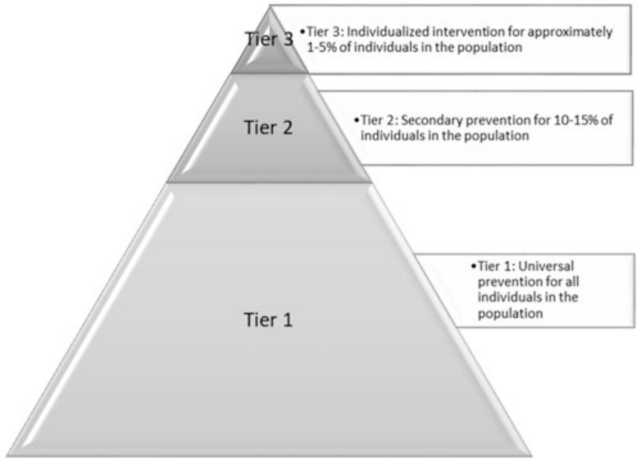

Fig. 63.1 PBIS tiered prevention model

instruction based on interest and readiness, flexible seating, and goal setting.

Approximately 10–15% of individuals do not respond to Tier 1 supports and require Tier 2 intervention. Tier 2 supports are supplemental to those of tier 1 and seek to prevent the need for more intensive intervention. Tier 2 interventions are often planned in advance and ready to be utilized quickly upon recognition of need, making them efficient and minimally time restrictive for interventionists. They are implemented in similar fashion across students, or in small groups where individuals have related behavioral, social-emotional, or academic needs. Supports at this level can include parent training, conflict resolution training, social-emotional skill groups, mentoring programs, check in check out (CICO; e.g. Todd et al., 2008), time management training, mentoring programs, self-regulation training (Horner et al., 2014), organization and study management training, visual supports, task analyses, self-monitoring, small group instruction, individual or group counseling, increased opportunities for access to reinforcement, and multicomponent intervention programs (Sugai & Horner, 2008).

Tertiary supports are reserved for the approximately 1–5% of individuals who do not respond to tier 1 and 2 supports, and whose behavior necessitates intensive, individualized intervention. Individualized support teams are developed to conduct FBAs, develop function-based behavior intervention plans (BIP), closely monitor fidelity and outcome data, make changes to interventions when data indicate, and evaluate for potential individualized education programs (IEP).

Since its inception PBS has evolved from a practice for specific use with individuals with disabilities (Carr & Durand, 1985), to a well-established system that has many applications. The technology has documented success in K-12 schools (Horner & Sugai, 2015), early intervention programs (Fox et al., 2003), Head Start and other early childhood programs (Voohrees et al., 2013), juvenile facilities (Kumm et al., 2020), and foster care systems (Crosland et al., 2008).

Considerations of PBS

While PBS has a history of well-documented success, there are several areas that still need to be explored. Future research could look toward the long-term impact of PBIS on youth outcomes in secure juvenile facilities and developing more honed tools for measurement (Kumm et al., 2020). In child welfare, more research is needed on the use of behavioral intervention across all child welfare services, the application of Behavior Analysis Service Program (BASP) type programs outside of the state of Florida, and in the area of prevention of abuse and neglect, as suggested by Stoutimore (2008).

Summary

The reinforcement strategies and treatment packages just discussed can contribute to a prevention-focused model of CB. Establishing an environment where desirable behaviors are intentionally reinforced, potential risk factors for CB are monitored via continuous data collection, and specialized interventions are implemented to address these behaviors before they become significant can contribute to more effective outcomes for learners in all environments.

DR and NCR procedures have been well-documented as effective strategies for increasing appropriate alternatives to CB in a variety of populations. In order to achieve the most desirable therapeutic outcomes, characteristics of the setting, implementer, and behavior should be considered to determine which specific reinforcement strategy would be most appropriate. DRL or DRH schedules can be selected when the frequency, duration, or magnitude of a behavior should be changed, but not necessarily completely eliminated. While FCT is extremely effective at reducing CB and has a great degree of acceptability within participating populations, the strength of FCT relies on its ability to be implemented universally in novel contexts. This relies on FCRs being effectively reinforced and maintained in generalized settings. Doing so will help the individual learner be more resistant to delay and disruption in reinforcement, as reinforcement of FCRs might be delayed or ignored during normal daily activities.

Interventions based on reinforcement succeed best when reinforcement for the preferred alternative is availably continuously. However, when reinforcement is inevitably withheld (intentionally or otherwise), problem behavior will almost certainly resurge. Just as no plan survives contact with the enemy, no reinforcement-based intervention survives exposure to real-world environments that often prefer extinction and punishment-based alternatives to behavior control. Programming for failure becomes necessary if interventions are ever to maintain outside of carefully controlled laboratory settings. Interventions that seek to utilize these methods should plan for schedule thinning, as well as programming resistance to extinction and punishment of target behaviors.

From its emergence almost four decades ago, PBS has grown and evolved into a comprehensive approach for addressing social-emotional and behavioral needs across a number of disciplines. PBS promotes a positive and safe environment where individuals are encouraged to meet their full potential. With its broad growth and expansion over time, it is reasonable to assume that the application of PBS will be extended even further to reach new individuals in areas that do not yet have access to this powerful technology.

Reinforcement-based strategies and interventions packages for problem behavior work by providing alternative ways of obtaining reinforcement. When approaching treatment of a CB, it is important to remember the axiom that learners naturally respond to the contingencies of their environment. To approach the treatment of problem behavior from a purely reinforcement-based experience is to acknowledge that the environment has selected for such behaviors. Consequentially, it is important to re-arrange the environment to promote a more desirable repertiore.

Creating an environment that uses supportive structures to promote desired behaviors often requires helping parents, teachers, and staff rethink and reprogram their environments. Interventions such as PBS strive to help create a more enriching environment in which to support reinforcement-based strategies of behavior modification. However, interventions such as DR, and especially FCT, help our clients to bridge this gap by providing novel skills that allow for access to reinforcement in their environments. Giving our clients access to appropriate replacement behaviors and/or access to the verbal community sets them up for success in environments that previously shaped and maintained CBs. Thus, the best outcomes stem from being able to both create an environment that supports the kinds of behaviors we want to see, and to promote behaviors in our clients that provide access to better outcomes.

Currently, the majority of CB treatments are initiated following the occurrence of severe levels of CB. However, there is a growing body of research on preventive treatment strategies. These research studies have implemented effective strategies that have prevented the emergence of CB or have prevented its development into severe topographies, such as aggression and self-injury (e.g., Fahmie et al., 2016; Hanley et al., 2007; Luczynski & Hanley, 2013). These strategies include: (a) teaching appropriate skills in situations CB is most likely to occur; (b) providing reinforcement for appropriate skills noncontingently, and (c) placing less severe topographies of CB on extinction. Although still in its early stages, the existing literature provides a promising start to this line of research.

Autism

64

Ana Luiza Roncati and Andresa A. De Souza

Autism spectrum disorder (ASD) is a developmental disorder characterized by (a) deficits in social communication skills and social interactions across different contexts; and (b) restricted interest and repetitive behaviors (DSM-5, 2013). According to the Center for Disease Control (CDC, 2020), 1 in every 54 children in the United States of America has an ASD diagnosis. Furthermore, data show that ASD affects four times more boys than girls.

The term *autism* was used for the first time in the literature by Eugene Bleuler in 1911 (Evans, 2013). Bleuler employed the term to refer to some characteristics commonly observed in individuals diagnosed with schizophrenia such as loss of connection with reality and impaired communication (Stotz-Ingenlath, 2000). Later, Leo Kanner (1943) used the word when referring to 11 children with behavior manifestation, differentiating their condition from that of individuals with a diagnosis of schizophrenia. These children described by Kanner were socially isolated from others and presented repetitive behaviors and speech. One year later, Hans Asperger (1944/1991) also used the term autism in his descriptive study involving children with similar characteristics as those identified by Kanner.

Although references to autism were observed early in the previous century, it was only around the 80s that the condition was characterized in the way we currently understand it (Kamp-Becker et al., 2010). The DSM-5 characterizes autism as a neurodevelopmental disorder and distinct from other personality disorders. The new classification elucidates the presence of different manifestations of the disorder and the need for recognizing the different levels of support that individuals with this diagnosis might need across their life.

Interventions Based on Applied Behavior Analysis

ASD is a disorder that will be present in the entire life of the individual. Fortunately, there has been substantial evidence showing that effective and timely interventions can mitigate the deficits and negative behavior manifestation characteristic of ASD (Roane et al., 2016). However, to guarantee that an individual with a diagnosis of ASD can benefit from specialized interventions, it is very important these interventions are evidence-based.

The term *evidence-based practice* was first used in the medical field (Sur & Dahm, 2011), but it has been adopted by different fields in

human care including mental health (Frank et al., 2020), and education (e.g., Hempenstall, 2006). According to the American Psychological Association (APA, 2008), evidence-based practice involves the combination of practice with strong empirical support of evidence, implemented by a trained professional, taking into consideration the client's characteristics, values, and cultural background. In response to the need for evaluating and informing service providers, educators, and parents of evidence-based practice for the intervention of individuals with ASD, the National Autism Center (NAC, 2009) conducted and published the National Standard Report with the objective of providing information about the levels of scientific evidence of several behavioral and educational interventions implemented with individuals with ASD.

The NAC (2009) was a systematic literature review of studies published from 1957 to 2007 involving intervention for individuals with ASD. The report was conducted in consultation with subject-matter experts and a panel of reviewers who collaboratively developed criteria for evaluating the scientific rigor of published studies (i.e., *Scientific Merit Rating Scale* [SMRS]), the effect of the intervention, and the level of confidence about the effectiveness of a specific intervention (i.e., *Strength of Evidence*). Out of the 38 interventions identified in the report, 11 were classified as established interventions (i.e., intervention which had enough empirical support to be considered as evidence-based). In 2015, the Phase 2 of the NAC was published with similar results from 2009. The NAC (2015) concluded that the overwhelming majority of the interventions identified as "established" were developed in the behavioral intervention literature including applied behavior analysis (ABA). In fact, ABA research involving interventions for individuals with ASD has been robust for the last decades (Roane et al., 2016; Smith, 2013). Several studies have evaluated procedures to address specific behavior deficits as well as the enhancement of already established intervention technologies for children with ASD.

ABA-based interventions focus on addressing behavior concerns that might otherwise interfere with the quality of life of individuals with ASD. ABA interventions rely on observable behaviors and clinical decisions based on reliable data and can be implemented at home, clinic, school, or community to address a variety of behaviors. The goals and objectives of the intervention are guided by the outcomes of behavior assessments evaluating the individual's skills deficits and behavior excesses (Fovel, 2002). These assessments provide information that will guide not only the selection of behaviors that will be addressed during the intervention but also the selection of the optimum service model. ABA-intervention for individuals with ASD and other developmental disabilities can be classified into two broad models: Comprehensive interventions and focused interventions (Smith, 2013; Steinbrenner et al., 2020).

Comprehensive Interventions

Comprehensive intervention models involve a service approach aimed to address a broad aspect of behaviors and conditions associated with ASD (Odom et al., 2014). In these models, the focus is not only on the individual's behavior deficits across a range of domains but also on the improvement in the family's quality of life. According to Odom et al. (2014), interventions following into this model are characterized by the following criteria: (a) the intervention model has been described and the description has been published; (b) a written guide of procedures or a manual is available; (c) the model follows a distinct conceptual or theoretical framework (e.g., behavior analysis, developmental); (d) it promotes changes in several developmental domains (e.g., language, communication, social); and (e) it is delivered for more than 25 h/week for a minimum of 1 year. There have been several comprehensive interventions documented in the literature (Odom et al., 2014). Two ABA-based models are early intensive behavioral intervention (EIBI; Lang et al., 2016) and the Early Start Denver Model (ESDM; Dawson et al., 2010).

Early Intensive Behavioral Intervention

The goal of early intensive behavioral intervention (EIBI) is to promote, early in life, changes in several domains of a child's development and daily-living aspect. Intervention procedures within this model are designed based on the principles of ABA and are delivered for several hours per week (Lang et al., 2016). Typically, the intervention would focus first on the development of the child's early communication (e.g., making requests, labeling items, and responding to simple questions), learning skills (e.g., attending to adults, following commands, scanning objects, imitation), and pre-academic skills (e.g., matching pictures and selecting items on command; Sundberg & Partington, 1999). Goals related to basic social skills such as joint attention and looking at and following peers might be addressed at this time (Sundberg, 2014). As these foundational skills are acquired, the intervention might involve complex skills building on existing repertoire and setting the basis for early academic skills (e.g., recognizing letters and numbers; writing). It is common for age-related, daily-living objectives to be incorporated throughout the intervention such as toilet training, dressing and grooming, and independent feeding (Partington, 2006). Behaviors that can hinder learning (e.g., escape-maintained challenging behavior, stereotypes) or that are harmful for the child and individuals around (e.g., self-injurious behavior, aggression) should also be addressed in EIBI (Sundberg, 2014).

According to Green et al. (2002), studies implementing EIBI as an intervention for children with ASD typically have the following features in common: (a) These interventions were comprehensive, with individualized goals addressing most if not all of skill domains; (b) several procedures based on principles of behavior analysis were employed to promote acquisition of functional skills and reduction in maladaptive behaviors; (c) there was at least one service provider who had advanced training in ABA and experience working with children with ASD; (d) intervention goals and objectives were defined based on typical child development; (e) parents had an active role in the delivery of intervention; (f) intervention was initially delivered in a one-to-one format and then transitioned to learning occurring in small groups and, finally, in large groups when appropriate; (g) intervention was initially implemented at home and then transferred to other environments and settings including school classrooms; (h) intervention involved structured activities which were programmed for 20–30 h per week plus unstructured opportunities for learning and practice of skill throughout the child's waking hours; (i) it was common for children to receive intervention for a minimum of 2 years; and (j) children started intervention at age of three or 4 years old (Green et al., 2002).

EIBI was first developed by Ivar Loovas for the intervention of children with ASD (Roane et al., 2016). In 1987, a seminal study conducted by Lovaas brought attention to its applications for children with ASD. Lovaas (1987) compared the effects of different dosage of intervention based on ABA intervention in children with an ASD. Participants were assigned to one of two groups: Experimental group received 40 h of ABA intervention per week and the control group received 10 h of ABA intervention per week. Participants were children younger than 46 months of age with a diagnosis of ASD. Both groups received intervention at a clinic-based setting for two or more years. The first year of intervention focuses on decreasing challenging behavior, the establishment of compliance, and the development of imitation and basic play skills. During this year, families became heavily involved in their child's intervention. During the second year, the intervention emphasized the acquisition of expressive and advanced language, and social skills. Finally, in the third year of the intervention, teaching involved the development of complex language such as the expression of emotions, basic academic skills (i.e., reading, writing, and arithmetics), and higher-order behaviors such as observational learning. The outcomes of behavioral (i.e., direct observation of participant's behavior) and cognitive (e.g., Stanford-Binet Intelligence Scales) assessments were compared pre- and post-intervention across both groups. Results showed that 47% of participants from the experimental group demonstrated pre-academic and academic skills similar to same-age, typically-developing peers versus 2% of participants from the control group. Although Lovaas (1987) study has received much criticism in particular to the weakness of his experimental methodology (Gresham & MacMillan, 1997), it continues to be the hallmark of the development of EIBI for children with ASD.

Since then, there have been several studies demonstrating the effectiveness of EIBI to address the core and co-occurring conditions of children and adults with ASD. Eldevik et al. (2009) conducted a meta-analysis of studies employing EIBI for children with ASD. The authors reviewed 34 studies including nine controlled designs involving a comparison or a control group. A test of homogeneity and publication bias was conducted to assess if the populations of the selected studies had the same distribution and the presence of bias in publications. Furthermore, the authors measured differences in effect size for any or both of two parameters conducted pre- and post-intervention: a full-scale measure of intelligence (e.g., Wechsler Intelligence Scale for Children–Revised) or a standardized assessment of adaptive behavior (e.g., Vineland Adaptive Behavior Composite). Eldevik et al. results demonstrated that the population sample of the selected studies was reasonably homogeneous and no publication bias was identified. Mostly important, the results showed a large effect size for measures of IQ and a moderate effect size for measures of adaptive behavior assessments before and after the EIBI. Eikeseth (2009) conducted a literature review of comprehensive psycho-educational interventions for children with ASD. His review included 25 studies published in peer-review journals, involving comprehensive intervention in children less than 6 years old at intake with reported outcome data. Selected studies were evaluated by their scientific merit and the magnitude of reported results. Children who underwent ABA-based comprehensive interventions were more likely to demonstrate significant gains in standardized measures when compared to children receiving other interventions. Finally, the NAC (2015) has included and classified EIBI as an established intervention for children with ASD between the ages of 0–9 years old.

Whereas Loovas' EIBI model relied heavily on discrete trial teaching (DTT) as the main teaching strategy with many presentations of the target skill and strong control of antecedent stimulus (Roane et al., 2016), contemporary ABA-based comprehensive interventions favor a combination of DTT and natural environment teaching (NET) to promote acquisition of skills, in particular language skills (Sundberg & Partington, 1999).

Early Start Denver Model

The Early Start Denver Model (ESDM; Rogers & Dawson, 2010) is a multidisciplinary, developmental approach for the intervention of young children with ASD recently incorporated as a type of ABA-based intervention (Roane et al., 2016; Vivanti & Stahmer, 2020). The ESDM was created from the early work of Sally Rogers out of the University of Colorado Medical Center in Denver and Geraldine Dawson (Rogers, 2016). The conceptual basis of the ESDM and its intervention approach follows a developmental framework taking into account the concept of normal child development and their "readiness" for the acquisition of skills (Rogers & Dawson, 2010). Moreover, the model takes into consideration the characteristics of learning and the importance of a conducive environment for infants and toddlers to develop their early milestones, in particular, communication skills. The model favors a naturalistic approach where the adult follows the child's interest during the intervention procedures (Rogers, 2016).

According to Rogers (2016), the ESDM integrates three areas of science: developmental including communication development, relationship-based, and applied behavior analysis while focusing on individualized intervention and the adult-child relationship. The child intervention plan is developed by a multidisciplinary team containing experts in different aspects of child development. Direct services are delivered by a trained therapist and overseen by a team leader. The child's progress is assessed every

12 weeks and the intervention plan is updated based on the outcomes of the assessment. Furthermore, parents are coached in promoting learning opportunities for their child during everyday activities and routines (Rogers, 2016). Services can be delivered in a variety of settings including clinical, at home, pre-school or day-care, or via parent coaching. The major areas of intervention involve skills related to imitation, joint attention, play including pretend play, and language and social communication. According to Rogers (2016), these skills can set the foundation that will allow the child to learn within her natural environment and in the interaction with others.

Dawson et al. (2010) conducted the first randomized, controlled-trial study evaluating the effects of ESDM intervention for young children with ASD. Participants were 48 children between ages of 18 and 30 months with a diagnosis of ASD and related developmental disorders. Participants were randomly assigned to the ESDM group or the assess-and-monitor group. Children in the ESDM group received (a) 20 h/week of ESDM intervention delivered by trained therapists in the University of Washington autism clinic; (b) 5 or more hours/week of ESDM intervention delivered by parents; and (c) any other community services parents chose. Children in the assess-and-monitor group received intervention from community providers in the greater Seattle region. Children were evaluated before the start of the intervention, after 1 year, and either after 2 years or at 48-month-old by experienced examiners who were naive to the study phase at the time of the evaluation. Several standardized measurements were utilized to evaluate intervention outcomes (e.g., Mullen Scales of Early Learning; Vineland Adaptive Behavior Scales; Repetitive Behavior Scale). Results demonstrated more robust intervention effects for children in the ESDM groups as compared to children in the assess-and-monitor group. According to Dawson et al. (2010), the gains demonstrated with the ESDM model in terms of IQ scores, language development, and adaptive behavior were greater than it had been shown before by any other developmental behavioral approach. The authors suggested the ESDM offers an effective model for young children with ASD with an intervention approach that focuses on a rich and engaging relationship between the child and the implementer.

In the last 10 years, several empirical studies have demonstrated the effectiveness of the ESDM for young children with ASD (e.g., Contaldo et al., 2019; Vivanti et al., 2014). Most recently, Fuller et al. (2020) conducted a meta-analysis to evaluate the effectiveness of ESDM for young children with ASD. The meta-analysis included 12 published studies that met the following criteria: (a) participants were children younger than 6 years old with a diagnosis of ASD; (b) the main intervention evaluated was the ESDM; (c) the intervention group was compared with a group who did not receive ESDM (e.g., treatment as usual, waitlist control); (d) included participant's outcome; and (e) the study had a group design including randomized control trial and quasi experimental design. The authors extracted the data from included studies and calculated the standardized mean difference effect size of participants' outcome measurements. Overall, results of the meta-analysis suggested a moderate but statistically significant effect size favoring children who received ESDM intervention as compared to control groups.

ESDM is a promising intervention (Waddington et al., 2016); however, more research is still needed to consolidate the intervention as an evidence-based practice for children with ASD. Baril and Humphrey (2017) conducted a broad systematic review to evaluate the evidence of ESDM for children with ASD. The authors examined the quality of 14 published studies using a method for evaluating and determining the level of evidence in intervention approaches (Reichow et al., 2008). Results demonstrated high levels of variability across studies in terms of methodology, characteristics of participants and the intervention implemented, and research rigor. Baril and Humphrey concluded that although there have been compelling demonstrations of the effectiveness of ESDM for addressing behavior concerns in children with ASD, additional research is still needed including replications of previous studies by independent researchers.

Focused Interventions for Core Skills

In contrast to the comprehensive model, focused interventions are individually designed practices to teach a specific skill or address a specific behavioral concern of individuals with ASD (Steinbrenner et al., 2020). These practices are typically carried over for a shorter period of time as compared to comprehensive interventions or until the goal of the intervention is reached. They are typically evaluated using single-subject research designs and data collection of specific target skills or behaviors (NAC, 2015). Evidence-based focused intervention are those behavioral and educational practices that have enough empirical support of being effective in addressing the different core and comorbid conditions of individuals with ASD (Steinbrenner et al., 2020).

Several focused practices have been identified as evidence-based interventions by previous literature reviews, scientific reports, and intervention manuals (ONTABA, 2017). Whereas comprehensive interventions take into consideration specific age groups (Odom et al., 2014), focused interventions will be determined by the behavior domain addressed. The National Clearinghouse on Autism Evidence and Practice extended a systematic literature review of studies published between 1990 and 2017 evaluating interventions for individuals with ASD (Steinbrenner et al., 2020). The results were summarized in terms of type of intervention, behavior domain addressed, and age for which it has been shown to be effective. Out of 28 focused practices identified in the review, 23 had a behavioral framework and are regularly included in ABA-based studies and ABA-based interventions (e.g., antecedent-based interventions, differential reinforcement, discrete trial training, extinction, functional behavior assessment and functional communication training, reinforcement). Based on the existing literature, each of those intervention practices should be implemented to address specific behavior issues for individuals in specific age groups as prescribed by literature reviews and intervention manuals.

Language and Communication

Goals related to language and social communication skills in individuals with ASD are a very important part of the intervention as they provide the basis for complex repertoire such as social and academic skills (Sundberg & Partington, 1999). Furthermore, deficits in functional communication skills can lead to the development of challenging behavior ranging from mild to severe (Sundberg & Michael, 2001). When addressing language and communication skills in individuals with ASD, behavior analysts approach it from a functional rather than a topographical perspective (Carr et al., 2000). Skinner (1957) established the behavior analytical approach to language and focused on identifying the function of the communicative response rather than its form or shape. In other words, behavior analysts are interested in the environmental conditions that foster language development, and specifically, the environmental antecedents, consequences, and setting events that are functionally related to language development (Sundberg & Michael, 2001). Skinner called this communication repertoire *verbal behavior* referring to responses which are reinforced by the mediation of another person's behavior. This assumption implies the presence of a speaker (the one who emits the behavior) and a listener who mediates the consequences for these behaviors. Skinner (1957) developed a taxonomy of verbal behavior and referred to the different functional responses as *verbal operants*. Sundberg and Michael (2001) suggested that researchers and clinicians should employ Skinner's taxonomy of verbal behavior when teaching language to children with ASD to ensure that learning opportunities are designed taking into consideration the appropriate antecedents and consequences for each of the verbal operants.

Focused ABA interventions for children with ASD typically target each verbal operant individually and build up on complexity as the child expands his verbal repertoire (Sundberg & Partington, 1999). The goals of the intervention are commonly informed by behavior skills assessments such as the Verbal Behavior Milestones Assessment and Placement Program (VB-MAPP; Sundberg, 2014) or the Assessment of Basic Language and Learning Skills-Revised (ABLLS-R; Partington, 2006). These assessments provide information about the child's verbal strengths and deficits and will guide the selection of intervention goals. The verbal operants commonly addressed in focused interventions are the mand, the tact, the echoic, and the intraverbal. The mand and the tact have received the most attention from the scientific community, followed by the intraverbal and the echoic (DeSouza et al., 2017).

The mand is potentially one of the first verbal operants to be addressed in language interventions for children with very limited verbal repertoire. Mands are essentially requests for items, attention, information, and removal of unwanted stimulus. It provides the child with some control of the environment and access to social and nonsocial reinforcement while promoting the foundations for the speaker and listener roles which are essential for the development of more complex verbal skills (Sundberg & Michael, 2001). One essential aspect of mand training is the manipulation of motivating operations (MOs) to ensure that the verbal response is under the control of relevant antecedent stimulus (Sundberg, 2004). Sweeney-Kerwin (2007) manipulated the presence of the preferred edibles to transfer the control of mands from the discriminative visual stimulus (i.e., edible item) to the establishing operation (i.e., item deprivation). Two children with ASD who would mand in the presence of the item but not in its absence participated in the study. The therapist would give a small portion of the item to the child, put the rest of the item away from the child's view, and wait for 2 min for a mand. If the child emitted a mand, the therapist delivered the time. If the child did not mand for the item, the therapist presented the item again and restarted the procedure. Both children were able to request the item under the control of the EO when items were absent.

Others strategies have been developed to ensure that the mand being taught is in fact under the control of relevant EOs. One strategy commonly used during mand training is behavior chain interruption (Carnett et al., 2017). The behavior chain interruption strategy consists of identifying a chain of behavior and interrupting it to create an EO for the emission of a mand that would result in continuation of the chain. Albert et al. (2012) used the behavior chain interruption strategy to teach mands to three children with ASD. Children were first taught to complete a behavior chain for access to a preferred item (e.g., sandwich). Then, while making a sandwich, the experimenter removed an essential item (e.g., toaster) and prompted the child to request for the item after a 10-s delay. The behavior chain interruption strategy has also been used to teach mands for information using “where?” (Carnett et al., 2020), “who?” and “which?” (Shillingsburg et al., 2014), and “how?” (Lechago et al., 2013).

A large number of studies have evaluated procedures to teach tact to children with ASD (DeSouza et al., 2017). Skinner (1957) called tacts those behaviors of labeling and describing stimuli in one's environment. Most studies have examined tacts of visual stimulus (e.g., pictures or items; Bak et al., 2021), although there has been a growing body of study which has evaluated procedures to teach tact of stimuli in other modalities. For example, Hanney et al. (2019) taught two children with ASD to tact auditory stimuli; Dass et al. (2018) taught three children with ASD to tact olfactory stimuli; and Rajagopal et al. (2021) taught three children with ASD to tact private events of tactile stimulation in different parts of their bodies. Interventions involving tact training typically employ vocal prompt, prompt delay, and differential reinforcement to teach the tact of target responses (DeSouza et al., 2017).

There have been only a few studies evaluating procedures to establish echoic repertoire (vocal imitation) in children with ASD (DeSouza et al., 2017). A few studies have used the stimulus-stimulus pairing procedure which consists of presenting a reinforcing item along with therapist vocalizations to increase the child's vocalizations (Miguel et al., 2002), and then bringing these vocalizations under the control of a vocal stimulus (Carroll & Klatt, 2008). Chaining is another procedure that has been used to increase echoic responses by breaking down target words into smaller units and then teaching each unit in a chain until the child could echo the whole word (Tarbox et al., 2009). When deficits in echoic responses present as a compliance issue rather than a repertoire issue (i.e., the child demonstrates high levels of vocalization but would not respond to a request to engage in vocal imitation), the intervention should focus on bringing these responses under instructional control. For example, Hansen et al. (2019) used the high-probability (high-p) instruction by presenting a sequence of several motor imitation requests followed by a vocal imitation request to increase echoic responses in a child with ASD.

The intraverbal has been receiving increasing attention from researchers for the intervention of children and adolescents with ASD (DeSouza et al., 2017). Some behaviors classified as intraverbals are responding to questions, making comments, telling stories or past events, singing along, and engaging in back-and-forth conversation. According to Sundberg and Sundberg (2011), most of a person's verbal interaction involves intraverbal responses and the acquisition of complex intraverbal fosters the development of cognitive, academic, and social skills in children. Several studies have demonstrated the effectiveness of different prompt procedures such as textual prompts (e.g., Vedora et al., 2009), echoic prompts (e.g., Ingvarsson & Hollobaugh, 2011), and tact prompts (e.g., Kodak et al., 2012) to teach intraverbals to children with ASD. Recently, Roncati et al. (2019) showed that the effectiveness of prompts used to teach intraverbals depends mostly on the child's history of reinforcement with the specific prompt.

Considering the extent of an intraverbal repertoire, it is unrealistic to assume that a child could be taught every possible intraverbal relation through direct teaching. Therefore, understanding the prerequisites necessary for facilitating the emergence of novel verbal responses without direct teaching is critical to the development of complex language repertoire. In the last two decades, a number of studies have demonstrated that instructional conditions can be arranged to facilitate the emergence of untrained skills in children with ASD (Gibbs & Tullis, 2021) and, therefore, reduce the amount of direct teaching needed for a child to acquire language skills. In other words, emergent responding approaches seek to identify the set of skills that once taught will promote the acquisition of novel intraverbal responses. DeSouza et al. (2019) demonstrated that teaching the sequence of skill determined by Sundberg and Sundberg (2011) to be the prerequisite skills for complex intraverbal responses facilitated the emergence of intraverbal under divergent control in four children with ASD.

For those individuals whose vocal language has not emerged to a functional level, one option is the use of augmentative and alternative communication (AAC; Shane et al., 2012). AACs are intervention strategies used to compensate for the lack of speech and replace or augment the individuals' social communication skills (Ganz et al., 2012). Two types of AAC strategies commonly used with individuals with ASD are picture-based such as the Picture Exchange Communication System (PECS; Bondy & Frost, 1994) and speech generating devices (SGDs; Tincani et al., 2020). With the PECS, individuals communicate by exchanging with a communication partner a laminated picture representing their communicative responses. SGDs are typically implemented with the aid of tablets and smartphones (Tincani et al., 2020) and require a specific device application. With SGD, individuals would select pictures of their communicative response by touching the screen in the device. Rather than exchanging a picture card as one does while using PECS, with SGD the device generates an automated speech that matches the communicative response selected by the individual. A meta-analysis conducted by Ganz et al. (2012) demonstrated that AAC interventions had a large effect on target behavior outcomes such as making requests, spontaneous social initiations, and spelling. Furthermore, results demonstrated that SGDs had larger positive effects when compared to the effects of PECS. Although these are promising results, further research is still needed to evaluate the effectiveness of these intervention technologies to supplement the communication across different domains of individuals with ASD as well as guidelines for the selection of the most appropriate AAC modality given the need to the individual learner (Ganz, 2015).

Social Skills

A defining feature of ASD is impairment in social interaction skills. According to Mendelson et al. (2016), individuals with ASD are more likely to experience social isolation and peer rejection than their typically-developing peers. Moreover, social skills deficits do not resolve with age and development (White et al., 2007); the summative effects of social skills deficits across the years hinder the acquisition of other skills that, for typically-developing children, are shaped and reinforced through interactions with peers (Bellini, 2006). Social skills deficits in individuals with ASD can be perceived at young ages as lack or inappropriate eye contact, failure to attend to others, and reciprocal and shared enjoyment. As the child ages and acquires language, these deficits can be observed as failure to initiate and engage in reciprocal conversations with others. Older children or adults might experience difficulties in identifying and adapting to others' emotions, making and maintaining friendships, and demonstrating communication skills needed for securing and maintaining employment (Klaiman et al., 2015).

ABA interventions have employed a variety of procedures to teach social skills to individuals with ASD (Flynn & Healy, 2012). Early social skills have been taught using differential reinforcement, shaping, and prompting. Fonger and Malott (2019) used a shaping procedure to teach sustained eye contact (minimum 3-s duration) to three children with ASD. In the first part of the intervention, the therapist reinforced any eye-orientation to any part of the therapist's body and later only to the therapist's face. Next, reinforcement was delivered only for eye contact with the therapist for specific durations (1-s, 2-s, 3-s). Finally, the therapist incorporated instructions into the procedure and reinforcement was delivered only if participants made eye contact in between high-probability instructions. Taylor and Hock (2008) used differential social reinforcement and least-to-most prompt to teach three children with ASD to respond to bids for joint attention by looking at the direction of an item, making a comment, and looking back to the adult. The researchers taught the same children to initiate bids for attention using differential social reinforcement and most-to-least prompt.

Social play skills are also typically impaired in children with ASD. Several studies have used an activity-schedule to teach and increase social play between children with ASD (e.g., Betz et al., 2008) and between children with ASD and typically developing peers (e.g., Akers et al., 2018). An activity-schedule involves a sequence of words or pictures that can serve to prompt someone to engage in specific behaviors (McClannahan & Krantz, 2010). Another strategy to teach social play involves video-modeling in which the participant watches a video-recording of the desired skill as it is demonstrated by other people. Jung and Sainato (2015) incorporated participants' toy preference into a video-modeling procedure to increase peer-play in three children with ASD. Jung and Sainato used least-to-most prompt along with video-modeling to increase participants' engagement in play activities with a peer of typical development. Video-modeling has also been used to teach conversation skills. Charlop et al. (2010) used video-modeling to increase appropriate verbal (comments and intonation) and non-verbal (gestures and facial expression) communication skills in three children with ASD. Children in the study watched two adults engage in appropriate conversation interexchanges, and then practiced the skills with the therapist. Generalization probes, including conversations with peers, were conducted after mastery of the skill in the intervention setting.

Behavioral skills training (BST) is another strategy that has been used for social skills training for individuals with ASD (Leaf et al., 2015). BST is an evidence-based intervention package used to teach and train individuals on specific behaviors or skills (Parsons et al., 2012). BST involves the following components:

(a) Vocal instructions with or without written instructions of how to perform the skill; (b) demonstration of the skill by the trainer; (c) practice of the skill by the trainee; and (d) praise and corrective feedback during practice. An important feature of BST is that it involves direct observation of the trainee's performance and it is only concluded once the trainee reaches an acceptable level of competency demonstrated by data of directly-observed behaviors (Miltenberger, 2004). Ryan et al. (2019) used BST to teach and increase appropriate conversation skills to six adults with intellectual disability and ASD. In another application of BST, Roberts et al. (2020) implemented BST to improve the interview skills to three young adults of 19 and 20 years old with ASD. Participants practiced and learned how to properly respond to possible questions during interviews, appropriate questions to ask to a potential employer, and appropriate body language expected during an interview. Two of the participants had an interview (with accommodation for the candidate's disability) for a real position and at least one of the participants was offered a position.

Several authors have discussed the importance of diversity and inclusion in not only services delivered but also in research (Fong et al., 2017). Davenport et al. (2018) conducted a literature review of studies evaluating social skills interventions in individuals with ASD. The purpose of the review was to examine cultural considerations and adaptation during social skills training. Out of the 329 articles included for analysis, 124 or 38% did not include information on participants race, ethnicity, or nationality. The remaining articles (n = 205) were further analyzed for the presence of cultural adaptation in their intervention. Only five articles meet this criterion and were included in the review. The authors discussed the importance of reporting race, ethnicity, and nationality of participants and the need for additional research evaluating the implementation of evidence-based social skills training with adaptation to meet the needs of diverse populations with ASD.

Focus Interventions for Challenging Behaviors

The presence of challenging behavior can affect individuals with ASD at any age and interfere with learning and quality social interactions (Issarraras & Matson, 2018). Research has shown that children with ASD demonstrate greater levels of challenging behavior as compared to typically-developing children and children with other developmental disabilities (Matson et al., 2009). The most common challenging behaviors observed in individuals with ASD are self-injurious behavior, aggression, and stereotypy (Fodstad et al., 2012). Furthermore, the levels and intensity of these challenging behaviors seem to be highly correlated with the severity of ASD symptoms (Matson et al., 2009).

The literature for the intervention of challenging behavior has been robust and made great progress in the last 30 years. Evidence-based interventions for challenging behavior involve first a functional assessment and selection of function-based interventions (Beavers et al., 2013). The functional analysis is today considered the gold standard for the assessment of challenging behavior (Hanley, 2012). The assessment involves manipulating antecedents and consequences that could potentially evoke and maintain the challenging behavior and evaluating the effects these changes have on the levels of challenging behavior. The idea behind functional analysis is that every behavior, including challenging behavior, serves a function for the individual. The functions of challenging behavior can be attention or tangible (social-positive reinforcement), escape (social-positive reinforcement), and automatic (positive and negative reinforcement). By manipulating the variables in the environment (antecedents and consequences), one can identify what variables are controlling the behavior and therefore arrive at the function of the challenging behavior (Beavers et al., 2013). Once the function is identified, the practitioner can select an intervention that has shown to be effective for challenging behavior maintained by the identified function. There has been strong evidence that function-based interventions for challenging behavior are more likely to be effective and have long-lasting effects (Horner et al., 2002).

Self-Injurious Behavior

Self-injurious behavior (SIB) is a type of challenging behavior commonly observed in individuals with ASD (Barrera et al., 2007). According to Dominick et al. (2007), about one-third of children with ASD present with some form of SIB. The topography of the challenging behavior varies across individuals and can take the form of body and head hitting, head banging, self-biting, skin picking among others (Chezan et al., 2017; Dominick et al., 2007). The severity of these behaviors can also range from mild with the appearance of rashes or bruises, to severe with the occurrence of concussions or open-skin wounds requiring medical care (Rojahn et al., 2007). Depending on the severity of the SIB, protective equipment (e.g., helmet) might be required until an effective intervention is implemented to preserve the physical integrity of the individual (Moore et al., 2013).

Chezan et al. (2017) conducted a literature review of studies focusing on the intervention of SIB for children with ASD. The review included 24 single-subject-design studies published from 2000 to 2016 with a total combined of 38 participants. Functional communication training (FCT) was the intervention implemented with the majority of participants in the review (24 out of 30). FCT is an evidence-based intervention that involves teaching as a replacement behavior to a challenging behavior, a communicative response that will serve the same function as the challenging behavior (Carr & Durand, 1985; Ghaemmaghami et al., 2020). By engaging in the new, appropriate replacement behavior, the individual will still get access to the same consequence obtained with the challenging behavior. Typically, FCT is implemented along with extinction for the challenging behavior (i.e., SIB no longer produces the consequence that maintains it; Hagopian et al., 1998). As a result, the levels of challenging behavior tend to decrease as the levels of the communicative response increase. For children whose SIB is maintained by escape from demands, the communicative response would be requesting a break from tasks (Lalli et al., 1995). For children whose SIB is maintained by access to attention from adults or tangible items, the communicative response would involve requesting for attention or for a specific tangible item (Hagopian et al., 2001). The effectiveness of FCT relies on the fact that the individual's SIB is maintained by social reinforcement (i.e., attention, tangible, and escape). When the function of the SIB is automatic, other interventions might be required.

Chezan et al. (2017) reported that 27% of studies implemented antecedent interventions. Antecedent interventions involve the manipulation of antecedent variables in an attempt to prevent or decrease the motivation of the individual to engage in the challenging behavior (Smith, 2011). Antecedent interventions can be implemented in a form of environmental arrangements. DeLeon et al. (2004) implemented an antecedent modification to decrease the levels of SIB in a 4-year-old boy with ASD. The experimenters identified through direct observation, that the levels of the boy's SIB were higher during his first waking hours than at any other time. The intervention involved a faded bedtime strategy to adjust the boy's sleeping schedule. This intervention changed the boy's sleep patterns resulting in less night-wakings and lower levels of SIB at his waking-time. Noncontingent reinforcement (NCR) is another antecedent strategy used as an intervention for SIB. During NCR, reinforcement (preferably the one maintaining the challenging behavior) is delivered on a time-based schedule regardless of the levels of challenging behavior (Phillips et al., 2017). Falcomata and Gainey (2014) compared the effects of different forms of NCR on the levels of multiply-controlled SIB in a 4-year-old girl with ASD. The experimenters compared the delivery of NCR with attention versus NCR with attention plus preferred activities both in the presence and absence of work. NCR with attention plus preferred activities was more effective in decreasing the levels of challenging behavior regardless of the presence or absence of work. When the reinforcer delivered during NCR is not the one maintaining the SIB (e.g., reinforcer is attention but SIB is maintained by automatic reinforcement), it is important to select the reinforcer via a competing stimulus assessment to increase the likelihood that the intervention would be successful (Rooker et al., 2018). Other antecedent interventions that have been implemented to address escape-maintained SIB are choice, task modification, and visual schedule (Chezan et al., 2017).

Results from previous research have suggested that about 27% of SIB are maintained by automatic reinforcement (Chezan et al., 2017; Iwata et al., 1994). One of the difficulties of identifying the exact source of reinforcement of automatically-maintained SIBs is that the consequence of SIB is only perceived by the individual himself. Rooker et al. (2018) suggested that with automatic-positive reinforcement, the SIB produces sensory stimulation reinforcing for the individual; whereas with automatic-negative reinforcement, the SIB produces the elimination or reduction in aversive stimulation (e.g., pain) which removal is reinforcing for the individual. Iwata et al. (1994) demonstrated that reinforcement-based interventions were effective to decrease the levels of SIB of 90% of individuals whose SIB was maintained by social reinforcement in contrast with only 65% of individuals whose SIB was maintained by automatic reinforcement. Rooker et al. argued that these data suggested that automatically-maintained SIB seems to be, in general, more resistant to interventions. According to Rooker et al., (2018), the most common intervention used for SIB maintained by automatic reinforcement was reinforcement-based procedures alone. Toussaint and Tiger (2013) implemented a differential reinforcement of other behavior (DRO) procedure to decrease the levels of covert SIB (skin picking when none was looking) in a 12-year-old boy with ASD. During the intervention, the boy was left by himself in a room without access to leisure items. If the boy was not picking at his skin the moment the therapist entered the room, he would receive a token that could later be exchanged for his preferred items or activities.

There has been a relatively small number of studies that examined interventions involving punishment procedures (Rooker et al., 2018). Manente and LaRue (2017) evaluated the effects of differential punishment of high rates of behavior on the levels of severe SIB in the form of head hitting and head banging in a 28-year-old man with ASD. During the intervention, the therapist delivered a vocal reprimand if the man engaged in rates of SIB that was above an established criterion within a specified time interval. The intervention resulted in a decrease of levels of SIB and long-term maintenance of these outcomes. Punishment-based interventions or procedures using any type of physical restraint should be implemented when other less intrusive and reinforcement-based procedures have been tried without success. It is important as well to analyze if the benefits of the reduction in a specific behavior surpass the possible side effects of punishment procedures (Horner et al., 1990; Lerman & Vorndran, 2002). Moreover, punishment-based interventions should always be accompanied by reinforcement procedures contingent on appropriate behaviors.

Aggression

Kanne and Mazurek (2011) indicated that 56% of individuals with ASD engage in some type of aggression, either physical (e.g., hitting, biting, hair pulling) or verbal (e.g., cursing, insulting) against others (Issarraras & Matson, 2018). According to Matson and Jang (2014), adults who engage in aggression are likely to do so in a higher intensity and severity when compared to children due to their superior strength and longer history of reinforcement for these behaviors. The presence of aggression might put the individual at risk of social isolation and being placed in a restrictive environment under intrusive procedures (Brosnan & Healy, 2011). This alone makes the need for the design and planning of early and effective interventions even more urgent so to guarantee the quality of life of these individuals and the physical integrity of caregivers and other individuals around them. As such, the first step towards the intervention is to conduct a functional behavior assessment (Hanley, 2012) of the aggressive behavior.

As discussed earlier, functional analysis is the gold-standard procedure for the assessment of challenging behavior. Because the functional analysis involves the intentional manipulation of the antecedents that can potentially evoke the behavior and the consequences that might maintain it, it is possible that aggression will be emitted at high levels during the assessment. For the past 30 years, several variations in functional analysis have been developed to prevent situations where therapists and direct care staff might be placed at serious risk of injury because of the behavior-evocative nature of this assessment (Hanley, 2012). These technologies of assessment have provided practitioners with different options to complete a functional analysis. Horner et al. (2002) showed that function-based behavioral interventions can decrease by 80–90% the levels of challenging behaviors in individuals with ASD and other developmental disabilities.

According to Brosnan and Healy (2011), if not addressed, aggression will most likely persist and aggravate throughout the individual's lifespan limiting his access to social and community activities. Research on the assessment and intervention of severe challenging behavior has repeatedly demonstrated that the lack of communication skills leads to the occurrence of challenging behavior that, many times, have a communicative function. Beavers et al. (2013) conducted a literature review of 435 studies in functional analysis of problem behavior with a sample of 981 functional analysis. Aggression was the most reported target behavior representing 47.5% of reported challenging behaviors. Furthermore, results showed that aggression was mostly maintained by social reinforcement, although there have been a few examples in the literature that showed that aggression was maintained by automatic reinforcement (Beavers et al., 2013).

FCT is one of the most recommended and implemented interventions for socially-controlled challenging behavior, including aggression (Brosnan & Healy, 2011). Wacker et al. (2013) demonstrated the effectiveness of FCT to decrease aggression along with other topographies of challenging behavior in 17 young children with ASD. The intervention was implemented by parents who were coached via tele-health in how to teach the appropriate communicative response to their child, provide reinforcement for appropriate requests, and block and ignore challenging behavior. During FCT for aggression maintained by tangible and attention (social positive reinforcement), the child was taught to wait for a brief moment (1–2 min) and request for a preferred item or the parent's attention. Contingent on appropriate waiting and requesting, the parent delivered the item to the child or provided 1–2 min of positive attention. During FCT for escape (social negative reinforcement), the child was taught to request for a break after complimenting simple tasks. The parent showed the child a picture indicating that it was time to work; contingent on compliance with work, the parent praised the child and switched to a card signaling that it was time to play. At this moment, the child was allowed to request and receive a break from task and access to play activities. Most children (15 out 17) demonstrated over 80% reduction in problem behavior relative to baseline.

Other reinforcement-based procedures have also been used to decrease aggression in individuals with ASD and other developmental disabilities (Brosnan & Healy, 2011). Typically, differential reinforcement procedures (e.g., DRA, DRO, and FCT) have an extinction component embedded to them as the replacement target response is followed by reinforcement while the challenging target behavior receives no programmed consequence (Brosnan & Healy, 2011). Although extinction can be effective in decreasing the rate of challenging behavior, there might be situations when extinction cannot be implemented, compromising the integrity of the intervention. Furthermore, the side effects associated with extinction (e.g., extinction burst, emotional reactions) can be challenging in particular when it will be carried over by parents or other caregivers (Athens & Vollmer, 2010). There have been several studies that evaluated the effect of differential reinforcement procedures without extinction on the level of challenging behavior in individuals with developmental disabilities. Athens and Vollmer (2010) implemented a differential reinforcement of alternative behavior (DRA) without extinction to decrease the levels of aggression of seven children from 4 to 12 years old with a diagnosis of ASD. All children showed a decrease in the levels of aggression and increase in the levels of compliance after manipulation of different parameters of reinforcement for appropriate behavior such as the duration, the quality, and the immediacy of delivery of reinforcement.

When designing interventions for challenging behavior, it is important that the practitioner evaluates not only the effectiveness of the intervention but also its feasibility (Fisher & Bouxsein, 2011). Interventions that have many components (e.g., environmental manipulation, prompts, different types of reinforcement) or require constant monitoring of the individual will very likely not be practical for parents and caregivers or possible to be carried over. Fisher and Bouxsein (2011) described several procedures that have been developed and empirically tested to make intervention more practical for parents, caregivers, teachers, and staff. Some of these procedures that can be implemented alongside FCT are (a) *Schedule thinning* can be implemented to lean the rate of reinforcement delivery thus decreasing the need to provide excessive edibles or time away from tasks; (b) *response restriction* is a strategy used to decreased the rates of requests (only for responses that involve the exchange of a picture-card) by making the request response unavailable; (c) when the communicative response is vocal, compound schedules of reinforcement (multiple or chained) haves been implemented to signal when requests will and will not be honored. For NCR, the authors suggested gradually changing the schedule of reinforcement from lean to dense; also, it would be helpful to identify alternative reinforcers when it's impractical or impossible to deliver the item that previously served as reinforcement for challenging behavior. Finally, one strategy for challenging behavior maintained by escape from demands is *demand fading* which involves gradually incorporating tasks before break from demands is available as a reinforcer (Fisher & Bouxsein, 2011).

Stereotypy

Restricted interest and repetitive behaviors (e.g., focused interest in specific toys, objects, or topic; repetitive body movements and vocalizations) are core characteristics of ASD (Lanovaz et al., 2013a) and are in fact what differentiates a diagnosis of ASD from other developmental disabilities. According to Lanovaz et al. (2013a), most children present with some type of repetitive behavior; however, these behaviors decrease around the age of 2 years old for typically-developing children, while it will persist past that age for children with ASD. Repetitive behaviors are persistent and might interfere with the individual's effective functioning and social interactions (Matson et al., 2006). Another issue related to the presence of stereotypy is that the individual might spend most of her time engaging in these behaviors and might miss the opportunity to engage in appropriate social interactions, functional leisure activities, learning opportunities, and academic tasks (Lanovaz et al., 2013a). In these cases and when the repetitive behavior might cause physical harm (e.g., hand-mouthing), they are considered a challenging behavior and should be a target for intervention. Differently from other types of challenging behavior such as SIB and aggression, stereotypies are most often maintained by automatic reinforcement (Akers et al., 2020). As such, interventions, which rely on communicative responses such as FCT, might not be effective due to the fact that reinforcement for the repetitive behavior might not be mediated by the behavior of others.

In a systematic review, Akers et al. (2020) analyzed 109 research articles investigating interventions for motor stereotypy in individuals with ASD. Results showed that 59% of participants received some sort of antecedent intervention for motor stereotypy. The most common antecedent intervention employed was environmental enrichment which involves making highly-preferred reinforcers, identified via a preference assessment, non-contingently available to the individual (Rapp, 2004). Hansen and Wadsworth

(2015) used environment enrichment to decrease the levels of motor stereotypies in a 10-year-old boy with ASD. The authors compared the effects of environmental enrichment with access to a therapist-selected matching-simulation toy and environmental enrichment with a choice of matching toys selected by the participant. Both conditions were effective in decreasing levels of stereotypies, but the environmental enrichment with the choice condition resulted in zero levels of stereotyped behaviors. A review of literature conducted by Gover et al. (2019) showed that environmental enrichment as a sole intervention for automatically-controlled challenging behavior was effective in only 41% of studies. As a result, supplemental procedures might be necessary to increase the effectiveness of environmental enrichment (Gover et al., 2019).

Consequence-based interventions, such as DRA, have focused on increasing the rates of appropriate behaviors competing with the stereotypy (Akers et al., 2020). Hedquist and Roscoe (2020) compared the effects of DRA and DRO without response blocking or interruption on the levels of motor stereotypy and task engagement and completion in three adolescents with ASD. During the DRA condition, the experimenter delivered a preferred item contingent on task completion and provided no consequences for motor stereotypy. During the DRO condition, the experimenter delivered a preferred item after a specific time interval if motor stereotpy had not happened during the entire interval, and provided no consequence for task engagement or completion. The results demonstrated that DRA was more effective than DRO in decreasing the levels of stereotypy and increasing levels of task engagement and completion for all participants.

Two interventions that have been successfully used for vocal stereotypy in individuals with ASD are DRO and response interruption and redirection (RIRD; Lanovaz et al., 2013b). DRO DRO consists of having a preferred item (preferably one that matches the same stimulation input produced by the stereotypy) delivered after a specific interval of time if the target stereotypy has not occurred within the interval (Lanovaz et al., 2013b). Lanovaz et al. (2014) used a DRO procedure with two children with ASD after noncontingent music and DRA failed to decrease levels of vocal stereotypy. The results for both participants showed that levels of vocal stereotypy decreased below baseline levels during the DRO procedure. Although DRO can be effective in decreasing the levels of stereotypy, one of the limitations is the fact that the procedure alone does not teach the individual any functional skills (Lanovaz et al., 2013b). RIRB is a consequence-based procedure consisting of interrupting the stereotypy and redirecting the individual to a functional vocal response. Contingent on the emission of a vocal stereotypy, the therapist interrupts the vocalization by asking for an attending behavior (e.g., "Look at me!") or by saying the individual's name. Next, the therapist presents a series of tasks known to the individual requiring a vocal response (Ahearn et al., 2007). In addition to being effective in decreasing the levels of vocal stereotypy, there have been a few cases in which RIRD has resulted in the increase in appropriate vocalizations (Miguel et al., 2009).

When the stereotypy does not cause physical harm to the individual or property damage to the environment, one potential solution is to bring the behavior under the control of an environmental stimulus that signals when is appropriate and when is not appropriate to engage in the behavior (Akers et al., 2020). Slaton and Hanley (2016) compared the effects of two different compound schedules of reinforcement with a discriminative stimulus (multiple and chained) to bring motor stereotypy under the control of a colored card signaling when motor stereotypy was and was not allowed to happen. During the multiple-schedule condition, the availability and non-availability for engaging in motor stereotypy alternated based on the passage of time regardless of participants engagement in tasks as directed by the experimenter. During the chained-schedule condition, engaging in motor stereotypy was made available contingent on engaging in a specific number of leisure or vocational tasks after being directed by the experimenter. The experimenter blocked motor stereotypy during both conditions. The chained schedule was more effective than the multiple-schedule in decreasing the levels of motor stereotypy and increasing the levels of task engagement. Furthermore, the results of a concurrent-chain assessment demonstrated that participants preferred being exposed to the chained-schedule condition over the multiple-schedule condition.

Final Considerations

The prevalence of children diagnosed with ASD has greatly increased in the last 10 years (Zablotsky et al., 2019) so have the options for interventions including behavioral, nutritional, and medical. As such, it became imperative that potential interventions have the level of evidence to be considered as effective practices. Interventions recognized as evidence-based (APA, 2008) are the most effective options and the ones that provide the best potential for positive outcomes. Hundreds of researches have demonstrated that interventions based on applied behavior analysis are effective for addressing the core symptoms of individuals with ASD (NAC, 2015; Steinbrenner et al., 2020). Furthermore, ABA has been shown to also have a positive impact on the life of families and in society as a whole (Dillenburger et al., 2014).

Young children who present with developmental delays and who are at risk of receiving a diagnosis of ASD should start intervention as early as possible; the earlier the child starts intensive intervention, the bigger are her chances to acquire functional skills (Ramey & Ramey, 1998). The general recommendation is that early intensive comprehensive interventions should be delivered for 10–20 h per week for young children between the ages of 0–36 months and 30–40 for older children with a diagnosis of ASD (ONTABA, 2017). To accomplish these hours, intervention should be implemented in different aspects of the child's life including the school setting and other typical daily routines (e.g., meals, play time).

According to CDC (2020), the average age for receiving a diagnosis of ASD is 4 years and 4 months. Some children have received a diagnosis as young as 18 months while others might not receive one until the age of 8 years old. For the later, comprehensive intervention models might no longer be a viable or recommended option. At this point, focused interventions targeting areas of priority might be the most appropriate model of service. Targeted and effective interventions for older children and adolescents with ASD can promote autonomy once they reach adulthood increasing their chances of becoming active members of their communities.

The NAC (2015) pointed to two major limitations of the behavior literature for individuals with ASD. One limitation relates to the level of evidence of ABA interventions for individuals with ASD across their lifespan. There is a big gap in the empirical demonstration of intervention effectiveness for adults with ASD. Specifically, research targeting training programs for vocational skills, social skills, and sexuality education for adults with ASD is much needed (NAC, 2015) and critical for increasing their likelihood of entering the workplace, developing meaningful relationships, and participating in their peer groups.

Another limitation refers to the lack of demographic information including race or ethnicity, cultural background, and socioeconomic status in ABA research (NAC, 2015). A recent review conducted by Jones et al. (2020) examined the demographic variables reported in studies published in the *Journal of Applied Behavior Analysis* from 2013 to 2019. Jones et al. showed that only 7% of studies reported on race or ethnicity of participants, 4% of studies reported on their language, and 2% reported on participant's socioeconomic status. Of the studies which reported the race or ethnicity of participants, 69% were Caucasian, followed by 20% African American. Less than 5% of participants were of any other race. These results exposed not only the disparity in the availability of intervention across groups of people but also the importance of ensuring that practices yielded from the empirical literature are adapted and acceptable for a particular group of individuals, in particular minorities who are poorly represented in research (Jones et al., 2020).

ABA interventions focus on using the knowledge gained from the science of behavior analysis to address socially-significant behaviors (Baer et al., 1968) including the behavior concerns typically observed in children, adolescents, and adults with ASD. Even though ABA interventions have already been consolidated as evidence-based, there is a general sense in the field of constant reevaluation of well-known procedures and development of new ones to ensure practices that are as effective and as efficient as possible in order to guarantee a better quality of life for individuals with ASD and their families.

Conflict of Interest We have no known conflict of interest to disclose.

65 Substance Abuse

Kenneth Silverman, August F. Holtyn, Forrest Toegel, and Matthew D. Novak

Introduction

Addiction to drugs, alcohol, and cigarettes costs the United States about $740 billion annually in crime, lost work productivity, and health care (National Institute on Drug Abuse, 2020). Although some pharmacological treatments produce beneficial effects, their effects are drug specific, they do not completely eliminate the targeted drug use in all participants, and their effects do not persist after the pharmacological treatment ends (Mattick et al., 2014; Sees et al., 2000). Furthermore, pharmacological interventions are not available for some drugs, like cocaine (Chan et al., 2019). Psychosocial treatments may have limited or no effect (Amato et al., 2011; De Crescenzo et al., 2018). We clearly need treatments that are more effective.

Operant conditioning treatments for drug addiction, frequently called contingency management interventions, hold great promise. Extensive research in the laboratory and the clinic shows that contingency management interventions have a strong empirical foundation and may be one of the most effective types of treatments for drug addiction (Dutra et al., 2008). This chapter will review the scientific foundation of contingency management interventions, provide an overview of both the strengths and limitations of contingency management interventions, and suggest broad areas for future directions. Because this chapter will address a large body of research, we will primarily reference reviews where readers can learn more about specific areas. We will use examples from our own research in adults with opioid use disorder to illustrate the main points of the chapter. Although these examples focus on a specific population (i.e., adults with opioid use disorder) and particular drugs (i.e., opiates and cocaine), the methods and outcomes apply to other populations and drugs of abuse.

A Laboratory Model of Drug Addiction

Contingency management interventions are rooted in a robust laboratory model of drug addiction as operant behavior (Bigelow et al., 1981; Deneau et al., 1969; Schuster & Thompson, 1969). Central to that model, laboratory research has shown that most commonly abused drugs can serve as reinforcers to maintain their self-administration. Virtually all drugs abused by humans can serve as reinforcers in the laboratory (Griffiths et al., 1980); most notably, cocaine (Johanson & Fischman, 1989), opiates (Schuster & Johanson, 1981), barbiturates (Ator &

Griffiths, 1987), benzodiazepines (Ator & Griffiths, 1987), marijuana (Justinova et al., 2005), and nicotine (Le Foll & Goldberg, 2005). The findings that drugs can serve as reinforcers generalize across a wide range of species, including humans (Griffiths et al., 1980). Importantly, this research showed that drugs could serve as reinforcers in naïve nonhuman organisms who were not exposed to special environmental circumstances or particular behavioral histories. In addition to suggesting that drug addiction can be operant behavior, this research suggests that drug reinforcement is biologically normal (Bigelow et al., 1981). That is, the reinforcing efficacy of drugs is not limited to certain individuals or specific environmental factors. Like clinical observations, drug reinforcement in the laboratory can maintain drug self-administration despite severe adverse consequences. For example—and most remarkably—animals given unlimited access to cocaine will self-administer the drug at levels that ultimately lead to death (Aigner & Balster, 1978; Deneau et al., 1969). Although drug addiction has frequently been described as a disease (Barnett et al., 2018; Leshner, 1997; Volkow et al., 2016), we can view drug addiction as operant behavior under the control of powerful and biologically normal drug reinforcement (Bigelow et al., 1981).

Environmental Modulation of Drug Reinforcement

Despite the powerful effects of drug reinforcement, laboratory researchers have shown that the same range of environmental variables that affect other operant behaviors can modulate behaviors maintained by drug reinforcement (Griffiths et al., 1980; Johanson & Fischman, 1989; Schuster & Johanson, 1981; Schuster & Thompson, 1969; Woolverton, 1992). Most relevant to the operant treatment of drug addiction, we can decrease drug-reinforced responding and drug consumption by arranging reinforcement with non-drug reinforcers for an alternative response. The effect on drug-reinforced responding and drug consumption is most substantial when laboratory subjects are required to make mutually exclusive choices between drug and non-drug reinforcers. The reduction in drug-reinforced responding and drug consumption is positively related to the magnitude of the non-drug reinforcer and the response requirement for drug reinforcements. Likewise, the reduction in drug-reinforced responding and drug consumption is negatively related to the dose of the drug and the delay to the non-drug reinforcer. Finally, we can decrease drug-reinforced responding and drug consumption by punishing drug-reinforced responding.

Nowhere is the potential of the environment to modulate drug use more evident than in a series of residential laboratory studies with so-called "skid-row alcoholics" (Bigelow et al., 1975). In these studies, participants living in a residential unit accessed alcohol drinks while under different contingencies. The studies showed that environmental consequences of alcohol use could reduce alcohol consumption. For example, access to enriched environments contingent on limited drinking (Cohen et al., 1971) or brief time outs for alcohol use (Bigelow et al., 1974) reduced alcohol use. Whereas many thought that the drinking of these skid-row alcoholics was "out of control," these studies showed that alcohol drinking in these individuals could be modulated by the consequences of drinking (Cohen et al., 1971).

Models of Relapse

Researchers and clinicians frequently describe drug addiction as a chronic relapsing disorder (McLellan et al., 2000). This conception comes from observations that many people alternate between periods of drug use and abstinence, but frequently continue drug use for many years and sometimes throughout life (Hser et al., 2001; McLellan et al., 2000; Vaillant, 1973). From an operant perspective, relapse is an orderly and predictable event. Laboratory models of relapse show that organisms whose responses (e.g., lever pressing) are acquired and maintained by drug reinforcement will stop responding when the reinforced response no longer produces drug administrations, but that those organisms will resume responding when a discriminative stimulus that previously set the occasion for drug reinforced responding is re-introduced. Laboratory researchers have demonstrated this so-called reinstatement model of relapse across a wide range of organisms and conditions (Katz & Higgins, 2003).

Physical Dependence

Some drugs when taken regularly produce physical dependence, and their discontinuation can produce an uncomfortable and potentially dangerous withdrawal syndrome. Although physical dependence and withdrawal are not necessary for drug reinforcement, they can increase drug reinforcement (Schuster & Johanson, 1981). For example, an individual who becomes physically dependent on opioids may take them in part because opioid self-administration avoids or alleviates opioid withdrawal symptoms. To the extent possible, any treatment for drug addiction, including operant treatments, should manage and diminish drug physical dependence and withdrawal.

Addiction Treatment Medications

Medications are available to treat addiction to some drugs and can provide great benefit in treatment (Volkow, 2020). Laboratory research shows that effective medications for the treatment of drug addiction diminish the withdrawal syndrome associated with abrupt termination of drug use and/or reduce the reinforcing effects of the abused drugs (Mello & Negus, 1996). When available, treatment medications can be enormously helpful in the operant treatment of drug addiction.

Application of Operant Conditioning to Treat Drug Addiction

Researchers have applied contingency management interventions to treat drug addiction in two ways: through the direct reinforcement of drug abstinence and through the reinforcement of behaviors that might increase drug abstinence.

Abstinence Reinforcement

Drug use is operant behavior that we can reduce by arranging reinforcement for drug abstinence. However, arranging abstinence reinforcement poses special challenges. People addicted to drugs use drugs at home or in other areas in the community, under a wide range of conditions, and at all hours of the day and night. Therapists cannot be present to continuously observe behavior and provide programmed consequences to reinforce abstinence or alternative behaviors. To circumvent this practical limitation, therapists can provide reinforcement when biological samples (i.e., permanent products) show that a patient has been abstinent from drugs. Researchers have used biologically based abstinence reinforcement interventions to promote abstinence from most commonly abused drugs across diverse populations (Bigelow et al., 1981; Silverman et al., 2011).

Biological Measures of Drug Use

People take drugs into the body through various routes (e.g., oral, intravenous, intranasal) and eliminate those drugs from the body—as the original drug or as converted or metabolized versions of the drug—through biological products. We can determine whether an individual used a particular drug by analyzing those biological products. We can reinforce abstinence from a drug by providing reinforcement when those biological products confirm abstinence from that drug. Abstinence reinforcement interventions are best when analyses of collected biological products identify relatively recent instances of drug use and when we can detect all or most instances of drug use in those products for a given period.

The value of tests of biological products The value of tests of biological products for abstinence reinforcement interventions can vary considerably. Tests of biological products that only reveal recent drug use (e.g., drug use that occurred in the past few hours) can be useful because they allow relatively immediate reinforcement of abstinence; however, they pose special challenges for abstinence reinforcement interventions because we must conduct those tests frequently or on a random schedule to avoid missing some instances of drug use. Tests of biological products that reveal less recent drug use (e.g., drug use that has occurred in the past few days) can be useful because they reduce the chance of missing any instances of drug use; however, those tests limit the potential to reinforce recent abstinence. For example, interventions designed to reinforce abstinence from heroin and cocaine typically rely on qualitative analyses of drug metabolites (morphine and benzoylecgonine, respectively) in urine samples (Phan et al., 2012; Tenore, 2010). Abstinence reinforcement interventions to promote smoking cessation can use breath Carbon Monoxide samples, which can confirm very recent smoking cessation, or urine cotinine (a metabolite of nicotine), which can confirm smoking cessation over several days (SRNT Subcommittee on Biochemical Verification, 2002).

Valid sample collection In conducting an abstinence reinforcement intervention, we must confirm that the sample is valid so that we can be sure that we are reinforcing the behavior that our intervention targets. Specifically, we must confirm that the participant provided the biological sample and that the sample is not adulterated. We can do this in different ways, depending on the type of sample provided and the location of the collection. For example, treatment providers typically collect urine samples under direct observation by a same-sex staff person and breath samples under direct observation or through remote video recordings. We require that a urine sample be close to body temperature to confirm that the sample came directly from the participant's body. We can test the urine for creatinine to confirm that the participant did not dilute the sample and test for other adulterants to confirm that the participant did not add other chemicals to the urine sample that could obscure the test results (Phan et al., 2012).

Effectiveness of Abstinence Reinforcement

Abstinence reinforcement interventions are among the most effective psychosocial treatments for drug addiction. One meta-analytic review showed that abstinence reinforcement interventions were the most effective of all psychosocial interventions examined in controlled studies (Dutra et al., 2008). Similarly, the National Institute for Health and Care Excellence in the United Kingdom reviewed psychosocial treatments for drug addiction and concluded that abstinence reinforcement interventions are among the most effective of available treatments (Pilling et al., 2007). Cochrane reviews have shown that abstinence reinforcement interventions are effective in the treatment of cocaine addiction (Knapp et al., 2007) and cigarette smoking (Notley et al., 2019).

Early studies Researchers like Maxine L Stitzer, George E. Bigelow, Peter M. Miller, and Thomas J. Crowley started investigating the effectiveness of abstinence reinforcement interventions over 40 years ago. Early studies (Silverman et al., 2011; Stitzer & Kirby, 1991) showed that abstinence reinforcement interventions could promote abstinence from alcohol, they could promote abstinence from opiates and benzodiazepines in adults enrolled in methadone treatment, they appeared useful to promoting drug abstinence in "impaired" health professionals, and they proved effective in promoting smoking cessation in diverse populations of cigarette smokers.

Voucher-based reinforcement In the early 1990s, Stephen T. Higgins and his colleagues at the University of Vermont developed what proved to be one of the most effective and versatile abstinence reinforcement interventions (Higgins et al., 1991). Under that intervention, participants received monetary vouchers exchangeable for goods and services for providing thrice-weekly urine samples that were negative for cocaine. The intervention was in effect for 12 weeks, and the value of the vouchers increased as the number of consecutive cocaine-negative urine samples increased. In addition, participants received bonus vouchers for every three consecutive cocaine-negative urine samples. Since its original development, this voucher intervention has proved effective in promoting abstinence from most commonly abused drugs and in diverse populations (Davis et al., 2016; Lussier et al., 2006).

Prize reinforcement In 2000, Nancy M. Petry developed a variation in the voucher intervention that proved effective and attractive to clinicians and others (Petry et al., 2000). Under that intervention, participants earned the opportunity to draw "prizes" from a bowl contingent on providing alcohol-negative breath samples. The bowl contained a number of slips of paper with a message. Seventy-five percent of the slips indicated that the participant won a small, medium, or large prize; the remaining slips did not produce a prize and said, "Sorry, try again." The prizes were onsite in a locked file cabinet. Similar to the schedule of escalating reinforcement for sustained abstinence that Higgins and colleagues had developed, participants earned progressively more draws as the number of their consecutive alcohol-negative breath samples increased. They also earned bonus draws when they maintained abstinence from alcohol for a full week. Many investigators have used this prize reinforcement intervention to promote abstinence from a range of drugs and in diverse populations, including studies conducted by NIDA's Clinical Trials Network, a national network of drug-abuse treatment programs in the United States (Benishek et al., 2014).

An illustrative example One study of injection drug users who used cocaine during methadone treatment provides a good example of the benefits and limitations of abstinence reinforcement interventions (Silverman et al., 1996). In that study, after a five-week baseline period, participants were randomly assigned to a voucher-based abstinence reinforcement condition or a yoked control condition. The voucher-based abstinence reinforcement condition was similar to the intervention developed by Higgins and colleagues (Higgins et al., 1991). Participants in the yoked control condition received the same vouchers independent of their cocaine abstinence. Over the 12-week intervention period, participants in the voucher-based abstinence reinforcement condition achieved significantly more cocaine abstinence than participants in the yoked control condition. This study illustrates both the benefits and limitations of abstinence reinforcement interventions. First, the abstinence reinforcement intervention was highly effective in promoting cocaine abstinence in this population. Second, although effective, not all participants achieved sustained cocaine abstinence when exposed to this intervention. Finally, many participants relapsed to cocaine use when the voucher-based abstinence reinforcement intervention ended.

Critical Parameters of Abstinence Reinforcement Interventions

Although abstinence reinforcement interventions have been highly effective, as described above, not all participants have responded to these interventions. In virtually all applications of abstinence reinforcement interventions, some proportion of participants do not respond to the intervention (Silverman et al., 2011). In many applications, half or more of participants appear unresponsive. A range of key parameters probably influences the effectiveness of abstinence reinforcement interventions. Researchers have not studied most parameters directly, but employing optimal parameters known to affect other instances of operant conditioning is probably appropriate.

Reinforcement magnitude Researchers have studied the effects of reinforcement magnitude in abstinence reinforcement interventions more than other parameters. Early research showed that increasing reinforcement magnitude in an abstinence reinforcement intervention could increase smoking cessation (Stitzer & Bigelow, 1984). Two studies showed that increasing abstinence reinforcement magnitude could promote abstinence in refractory participants who did not initiate abstinence at lower reinforcement magnitudes (Dallery et al., 2001; Silverman et al., 1999). In one of those studies (Silverman et al., 1999), researchers offered adults who had evidence of injection drug use and continued to use cocaine during methadone treatment $1155 over 13 weeks for providing cocaine-negative urine samples three times per week. Participants who did not initiate cocaine abstinence in that "treatment failure screening" condition, were then exposed to a zero, low-magnitude, and high-magnitude condition in counterbalanced order in which they could earn $0, $380, or $3400, respectively, for providing cocaine-negative urine samples three times per week for nine weeks. Figure 65.1 shows the longest duration of sustained cocaine abstinence that participants achieved in the three nine-week conditions. Participants achieved significantly longer periods of sustained cocaine abstinence in the high-magnitude condition than in the other two conditions (i.e., zero and low-magnitude conditions). Although the percentage of participants who provided cocaine-negative urine samples never exceeded 25% during the 13-week treatment failure condition or during the nine-week zero or low-magnitude conditions, the percentage of participants who provided cocaine-negative urine samples exceeded 50% during five of the weeks of the nine-week high-magnitude condition.

Other studies showed that abstinence reinforcement magnitude affects abstinence outcomes (Higgins et al., 2007; Petry et al., 2004). For example, Petry and colleagues (Petry et al., 2004) randomly assigned cocaine users to one of three conditions: a standard treatment, standard-magnitude abstinence reinforcement, and low-magnitude abstinence reinforcement. In the standard-magnitude condition, partici-

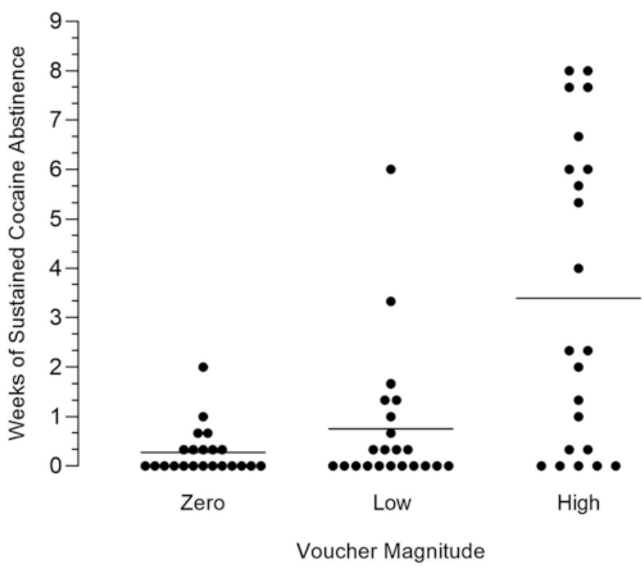

Fig. 65.1 Longest duration of sustained cocaine abstinence achieved during the zero (*left column*), low (*middle column*), and high (*right column*) magnitude voucher conditions. Each *point* represents data for an individual participant ($n = 22$) and the *lines* represent condition means. Each participant was exposed to each of the three voucher conditions in counterbalanced order. The maximum possible duration of sustained abstinence was nine weeks for each condition. (Adapted from Silverman et al. (1999), Fig. 2, with permission)

pants received a reinforcer that was a similar magnitude as those found effective in prior studies; whereas, in the low-magnitude condition, participants received a reinforcer one third the size of that in the standard-magnitude condition. The study found that, although the standard-magnitude condition was effective in increasing cocaine abstinence, the low-magnitude condition had no effect on cocaine abstinence.

Unpredictable reinforcement (lottery-like reinforcement) Some researchers have suggested that offering unpredictable and varying reinforcement magnitudes, like a lottery, can increase effectiveness over a predictable reinforcement magnitude, like the voucher-based abstinence reinforcement intervention developed by Higgins and colleagues. Prize reinforcement is a common intervention that uses this unpredictable-magnitude approach. Prize reinforcement researchers have proposed that one could use variable or unpredictable reinforcement to reduce the magnitude of reinforcement (and cost) without sacrificing effectiveness. One study that directly compared prize reinforcement to standard voucher-based abstinence reinforcement (i.e., predictable magnitude) showed that the two approaches produced similar results when overall reinforcement magnitude was similar (Petry et al., 2005).

Other reinforcement parameters Other parameters of abstinence reinforcement (e.g., immediacy) appear to alter the effectiveness of abstinence reinforcement interventions, but the evidence comes mostly from basic laboratory research or by comparison across clinical studies. For example, one meta-analysis used data from different studies that arranged various delays to reinforcement and found that effectiveness decreased as the delay to reinforcement increased (Lussier et al., 2006).

Relapse Prevention

Researchers and clinicians have called drug addiction a chronic relapsing condition (McLellan et al., 2000). Although occasionally interrupted, drug addiction frequently lasts for many years and often throughout a person's lifetime (Hser et al., 2001; Vaillant, 1973). Despite their success in the short-term, addiction treatments have generally failed to produce long-term drug abstinence. For example, Methadone maintenance treatment is one of the most effective treatments for opioid addiction; however, when the methadone dose decreases, participants return to opioid use (Sees et al., 2000). Similarly, from the earliest applications, abstinence reinforcement interventions have failed to promote abstinence that reliably lasts after the abstinence reinforcement ends (Silverman et al., 2011). Some studies show that the effects of abstinence reinforcement interventions are detectable after the abstinence reinforcement ends, but even those studies show that progressively more participants relapse to drug use as the time after discontinuation of the abstinence reinforcement intervention increases.

Combining abstinence reinforcement with relapse-prevention counseling Some observers and researchers have suggested that abstinence reinforcement interventions might produce lasting effects when combined with cognitive-behavior relapse prevention counseling. However, several studies that evaluated this possibility failed to show any benefit of this combination, during or after the interventions were applied (Silverman et al., 2011).

Abstinence reinforcement as a maintenance intervention Abstinence interventions may need to be continued on a long-term basis to maintain their effectiveness over time—similar to various medical interventions that need to be continued over time (e.g., antiretroviral medications for HIV, methadone for opioid use disorder). Silverman and colleagues have proposed using abstinence reinforcement as a maintenance intervention to prevent relapse (Silverman et al., 2002, 2004). Two studies showed that long-term exposure to abstinence reinforcement could maintain cocaine abstinence (Silverman et al., 2004) and cocaine and opiate abstinence (Silverman et al., 2002) for one and three years, respectively. One study randomly assigned participants to a short-term or longer-term reinforcement of cocaine abstinence and showed that longer-term exposure to voucher-based abstinence reinforcement maintained higher rates of cocaine abstinence, at least as long as the abstinence reinforcement was maintained (Kirby et al., 2013).

Another study in methadone patients who continued to use cocaine during methadone treatment demonstrated the effectiveness and limitation of using abstinence reinforcement as a maintenance intervention (DeFulio et al., 2009; DeFulio & Silverman, 2011). In that study, all participants attended a model "therapeutic" workplace for 18 months, where they could work every weekday and earn about $10 per hour. During a six-month training phase, the therapeutic workplace staff trained participants to become data entry operators and exposed them to employment-based abstinence reinforcement in which they could maintain maximum pay as long as they continued to provide urine samples negative for drugs (opiates and cocaine). If a participant ever failed to provide a urine sample or provided a drug-positive sample, the staff temporarily reduced the participant's hourly pay for working in the workplace. After the first six months, participants who continued attending the therapeutic workplace and initiated drug abstinence were hired as data entry operators in a simulated therapeutic workplace business for one year and randomly assigned to an Employment Only group or to an Abstinence-Contingent Employment group. Employment Only participants could work and earn pay independent of their urinalysis results. Participants in the Abstinence-Contingent Employment group had to provide drug-negative urine samples to access the workplace and to maintain maximum pay.

Figure 65.2 (DeFulio & Silverman, 2011) shows the percentage of participants that provided cocaine-negative urine samples every six months before, during and after exposure to the Employment Only and Abstinence-Contingent Employment conditions in the therapeutic workplace business. As designed, almost no participants from both groups provided cocaine-negative urine samples at Intake to the study, but almost all participants provided cocaine-negative urines samples at the end of the six-month training phase when all participants experienced employment-based abstinence reinforcement. During the year of employment after random assignment, Abstinence-Contingent Employment participants maintained significantly higher rates of cocaine abstinence than Employment Only participants, demonstrating that employment-based abstinence

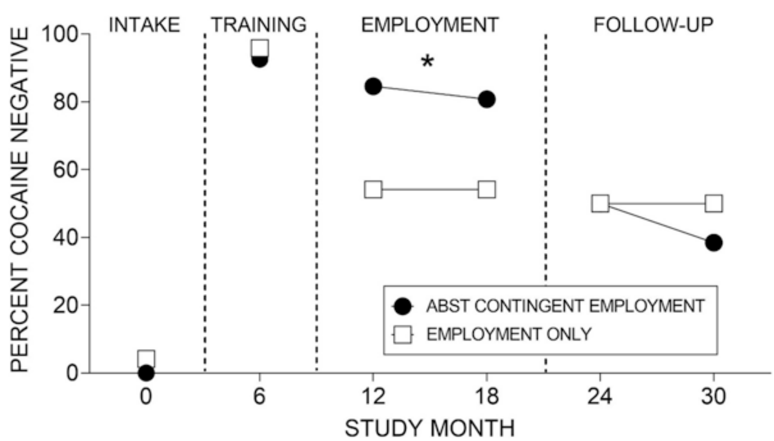

Fig. 65.2 Percentage of cocaine-negative samples collected at intake (study month 0), the end of the abstinence initiation and training phase (study month 6), during employment (study months 12 and 18), and at post-treatment follow-up (study months 24 and 30). Missing samples were counted as positive. The asterisk indicates that the groups are significantly different ($P < 0.05$) based on generalized estimating equation (GEE) analysis. (Adapted from DeFulio and Silverman et al. (2011), *Addiction*, Fig. 1, with permission)

reinforcement can serve as an effective maintenance intervention. Despite experiencing 18 months of employment-based reinforcement, many Abstinence-Contingent Employment participants relapsed to cocaine use in the follow-up year and provided similar rates of cocaine-negative urine samples as the Employment Only participants. This study showed that abstinence reinforcement could serve as an effective maintenance intervention and could maintain abstinence over extended periods. However, as many other studies have shown, many people relapse to drug use after the abstinence reinforcement contingencies end

Reinforcement of Behaviors that Might Reduce Drug Use

Researchers have also used operant conditioning or contingency management to increase other behaviors that might increase drug abstinence. These applications have sought to increase attendance in counseling, to increase alternative behaviors that might be incompatible with drug use, to increase the use of addiction medications, and to reduce risk factors that might increase vulnerability to drug addiction.

Attendance in Counseling or Alternative Behaviors

Some investigators have used operant conditioning to promote attendance in substance abuse treatment (Kidorf et al., 1994; Schacht et al., 2017) or alternative behaviors that are incompatible with drug use (Petry et al., 2006). These types of interventions can increase the target behaviors, but they do not appear to increase drug abstinence.

Medication Adherence

Some addiction treatment medications, like methadone or buprenorphine, can serve as reinforcers and can help retain participants in treatment and promote adherence to the medication regimen. However, some treatment medications are not reinforcers and treatment retention and adherence are serious problems. In those cases, reinforcement can promote adherence to medication regimens (DeFulio & Silverman, 2012; Petry et al., 2012). Naltrexone is a good example. Naltrexone has no effects on its own, but blocks the effects of opioids. Although it has features that could make it a good medication for the treatment of opioid addiction, many patients refuse to take it. Several randomized controlled trials have shown that financial incentives can reinforce naltrexone adherence, but failed to show that reinforcement of naltrexone adherence increases opioid abstinence. One secondary analysis that combined data from three studies did provide some evidence that reinforcement of naltrexone adherence can increase opiate abstinence (Jarvis et al., 2017).

Risk Factors

Researchers have also used operant conditioning or contingency management to modify risk factors that might affect drug use (Silverman et al., 2019), although relatively little research has addressed risk factors. As discussed above, drug reinforcement is biologically normal, as evidenced by the fact that it is common in laboratory animals independent of any special history. Yet drug addiction is more common in some populations than in others. Some vulnerabilities appear rooted in environmental circumstances that operant conditioning could modify. For example, people with limited education, who are unemployed, and who live in poverty appear particularly vulnerable to drug addiction.

The Institute of Medicine identified poverty and high-school graduation as two of the "most powerful determinants of health for which meaningful action can be taken (p. 3) (National Center for Health Statistics, 2012)." A large-scale and rigorous analysis showed that "poverty, smoking, and high-school dropouts impose the greatest burden of disease in the United States" of major known risk factors (Muennig et al., 2010). A number of studies have shown that poverty is associated with reduced lifespan and a variety of health problems, including drug addiction (Armstrong, 2007; Chetty et al., 2016; Muennig et al., 2010; Silverman et al., 2019; Williams & Latkin, 2007).

Education Importantly, scientific evidence suggests that "schooling is causally related to improvements in health outcomes" as is "raising the incomes of the poor (Kawachi et al., 2010)." Improving education could be an ideal means to improve the lives of poorly educated and low-income populations because increasing education appears to increase income. Data from the U.S. Census Bureau shows that lifetime income increases progressively as adults achieve higher levels of education (Bauman & Ryan, 2001; Day & Newburger, 2002). Health policy experts writing for the New York Academy of Sciences concluded that "if socioeconomic disparities in U.S. population health are to be substantially improved by the next generation, investing in all manner of education is broadly speaking one of the most promising approaches (Dow et al., 2010)."

Despite the need and potential benefits of education, very few adults who do not have a high-school diploma or equivalent participate in adult education. The Institutes of Education Sciences, National Center for Education Statistics estimated that among adults over the age of 16 who did not have a high-school diploma or equivalent, only 1.0% participated in degree or diploma programs, and only 4.2% participated in work-related courses (Planty et al., 2007).

In their efforts to combat poverty, governments and private foundations have attempted to promote the education of low-income adults, but these efforts have generally failed because of low rates of participation in the available educational opportunities (Courtin et al., 2020; Holtyn et al., 2017). A large-scale randomized controlled study evaluated "education-focused" programs for adult welfare-recipients, but failed to show definitive benefit of the education-focused approach because most participants did not attend the education and training programs long enough to reap their potential benefits (Bos et al., 2002). Importantly, secondary analyses showed that increased retention and participation in educational programs were associated with improvements in basic literacy and math skills, increased attainment of GEDs, and increased employment earnings. In reviewing these results, Bos and colleagues (Bos et al., 2002) concluded that "All this suggests that [education-focused] programs could have more substantial effects on economic outcomes of welfare recipients if these programs managed to improve their effects on mediating education outcomes. Our analyses suggest that increased retention might be one way to achieve this (p. 14)." Similar results were obtained in adult literacy programs (Porter et al., 2005).

A series of studies conducted in the therapeutic workplace showed that reinforcement could increase attendance in education and progress through training programs (Silverman et al., 2018). One study by Koffarnus and colleagues illustrates the need for and potential of reinforcement to promote education in low-income drug users (Koffarnus et al., 2013). In that study, unemployed injection drug users could work on typing and keypad training programs. In both of the programs, participants practiced the skills in 1-minute timings. The investigators randomly assigned participants to two groups: Group A and Group B. Group A participants earned base and productivity pay while working on the typing program and base pay only while working on the keypad program. Group B participants earned base and productivity pay while working on the keypad program and base pay only while working on the typing program. Participants always earned about $10 per hour. Participants completed significantly more training program steps (Fig. 65.3, top panel) and significantly more timings per hour (Fig. 65.3, bottom panel) when they earned productivity and base pay (filled circles) than when they only earned base pay (open circles). That study showed that the unemployed injection drug users who participated in this study will work on training programs significantly more when offered pay for performance on training programs than when they do not earn incentives for performance on training programs (Koffarnus et al., 2013). Similar reinforcement contingencies could promote academic and job skills that might promote employment and reduce poverty.

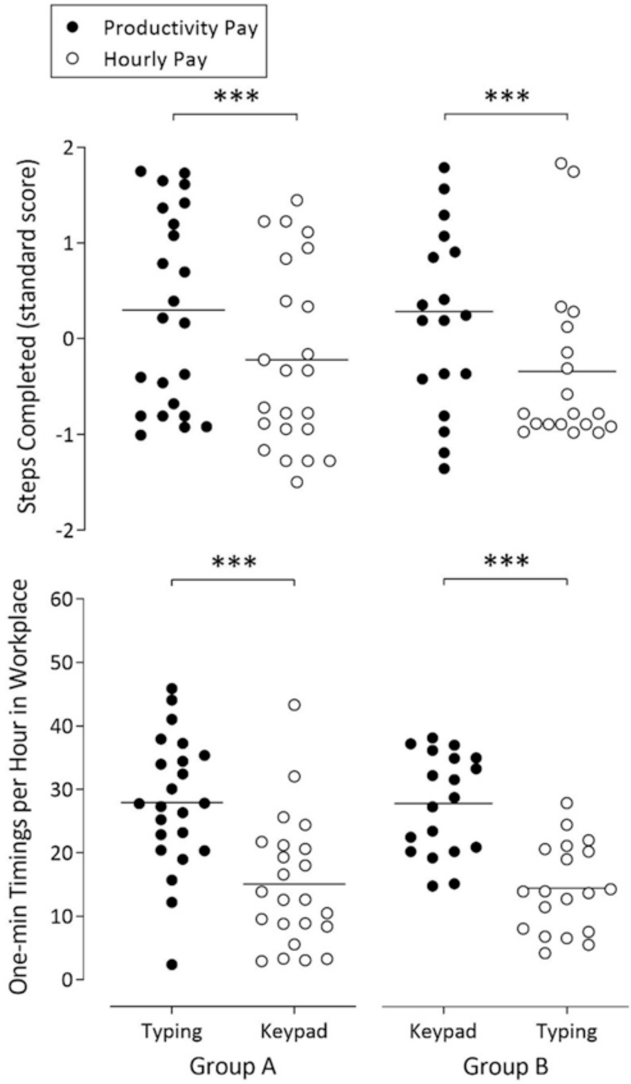

Fig. 65.3 Steps completed (top) represented as a standard score and timings initiated per hour (bottom) as a function of group and payment condition. Each point represents an individual participant, and the horizontal lines represent the group means. Asterisks indicate a significant effect of planned comparisons between payment conditions for each group (***$p < 0.001$). (Adapted from Koffarnus et al. (2013), Fig. 1 with permission)

Unemployment and poverty Governments in Minnesota, Connecticut, Milwaukee, New York, and Canada have used wage supplements to increase employment in welfare recipients (Holtyn et al., 2017). One study showed that reinforcement contingencies, specifically abstinence-contingent wage supplements, could directly increase employment and reduce poverty in a group of unemployed drug users (Holtyn et al., 2020). Under wage supplement programs, participants earned wage supplements for working in community jobs. Abstinence-contingent wage supplements use wage supplements (e.g., supplemental hourly pay) to promote employment, while simultaneously harnessing the power of the wage supplements to reinforce drug abstinence. In this study, after a three-month abstinence initiation and training period, unemployed adults in medication-assisted treatment (methadone or buprenorphine) for opioid use disorder ($N = 91$) were randomly assigned to a Usual Care Control group or to an Abstinence-Contingent Wage Supplement group. All participants could work with an employment specialist to seek employment in a community job for 12 months. Abstinence-Contingent Wage

Supplement participants could earn employment-based incentives in the form of stipends for working with the employment specialist and wage supplements for working in a community job, but had to provide opiate- and cocaine-negative urine samples to maximize pay. Abstinence-Contingent Wage Supplement participants provided significantly more opiate- and cocaine-negative urine samples than Usual Care Control participants during the 12-month intervention. In addition, Abstinence-Contingent Wage Supplement participants were significantly more likely to obtain employment (59% versus 28%; Fig. 65.4, top panel) and live out of poverty (61% versus 30%; Fig. 65.4, bottom panel) by the end of the 12-month intervention than Usual Care Control participants. That study showed that abstinence-contingent wage supplements can promote drug abstinence, increase employment, and reduce poverty (Holtyn et al., 2020).

Applications for Widespread Use

Despite the strong empirical evidence of effectiveness, our society has not applied contingency management interventions widely. Several researchers have made efforts to develop applications that we could use widely in society. This section provides important examples of these interventions.

Remote Technology

One barrier to adoption of contingency management interventions is transportation to and from the clinic. Transportation is particularly problematic when frequent participant visits are required. To address this logistical problem, several researchers have developed contingency management interventions that utilize remote internet and computer technology (Dallery et al., 2019; Getty et al., 2019). Under these interventions, participants can video record themselves emitting

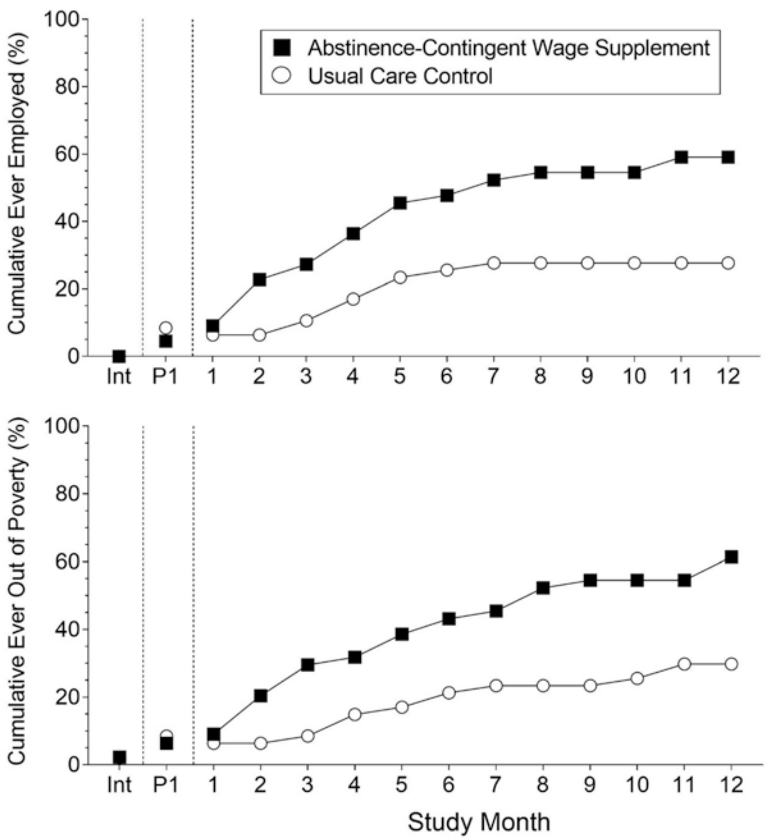

Fig. 65.4 Percentage of participants who were ever employed (top) and ever lived out of poverty (bottom) in the usual care control group (circles) and the abstinence-contingent wage supplement group (squares) at intake (Int), during phase 1 (P1), and across consecutive months during the intervention (phase 2). The difference between groups at the end of phase 2 was statistically significant for "ever employed" (OR = 3.88, 95% CI 1.60 to 9.41, $p = 0.004$) and "ever lived out of poverty" (OR = 3.77, 95% CI 1.57 to 9.04, $p = 0.004$). (Adapted from Holtyn et al. (2020), Figs. 3 and 4, with permission)

the required behaviors and transmit the videos through the internet. In addition, some devices allow for direct transmission of the results of biological testing. Using these technologies, treatment providers can evaluate participant behavior and arrange reinforcement remotely. Researchers have used these remote technology interventions to promote smoking cessation, medication adherence, and abstinence from alcohol and marijuana. These remote internet technologies can extend the reach and reduce the cost of contingency management interventions.

Dallery and colleagues pioneered this type of intervention to promote smoking cessation. Under their intervention, participants recorded videos of themselves providing Carbon Monoxide (CO) breath samples, which provided evidence of recent smoking or smoking cessation, and sent the time-stamped videos to researchers through the internet. Researchers reviewed the videos and provided incentives through the internet if the video was valid and if the CO level met the criterion for reinforcement. Results across multiple studies have demonstrated the effectiveness of this intervention in reducing smoking. In one study, Dallery and colleagues demonstrated the remarkable reach of this intervention (Dallery et al., 2017). They randomly assigned 94 smokers from 26 states across the United States to an Abstinence-Contingent group or to a Submission Contingent group. Both groups provided a $50 deposit. Abstinence-Contingent participants received the internet-based contingency management smoking cessation intervention. Abstinence-Contingent participants provided significantly more negative CO samples during the intervention.

Short-Term Benefits

As discussed previously, one of the greatest limitations of contingency management interventions is that their effects do not reliably persist after the intervention ends. However, a contingency management intervention can be extremely beneficial in situations in which only a short-term effect is required.

Abstinence reinforcement interventions have promoted smoking cessation in pregnant cigarette smokers, and short-term exposure to these interventions has produced important beneficial effects on the fetus and newborn child (Higgins et al., 2010). For example, an analysis of three randomized controlled trials in pregnant cigarette smokers showed that voucher-based reinforcement for smoking cessation promoted smoking cessation in the women, increased birth weight of the babies, and reduced the percentage of low-birth-weight babies (Higgins et al., 2010). The effects of the voucher-based abstinence reinforcement intervention on smoking cessation in the women was still evident and statistically significant after the intervention ended, although the rates of smoking cessation decreased progressively over the weeks after delivery and after the abstinence reinforcement ended. The voucher-based abstinence reinforcement produced short-term beneficial effects on the newborn babies, despite the fact than many of the mothers relapsed to cigarette smoking after the abstinence reinforcement ended.

Businesses and Government Organizations

Contingency management interventions might be applied by organizations that see benefit in promoting therapeutic behavior change in its members. Businesses might be one such organization. Halpern and colleagues conducted studies of smoking cessation interventions of employees in large businesses (Halpern et al., 2015, 2018). One study included 2538 employees (and their relatives and friends) of CVS Caremark and the other included 6006 employees of 54 different companies. Both studies showed that reinforcement of smoking cessation could significantly increase the percentage of people who stopped smoking—although both studies used very small magnitude incentives and affected the behavior of relatively small percentages of participants. In addition, the U.S. Department of Veterans Affairs implemented prize-based abstinence reinforcement in over 70 substance abuse treatment clinics in the United States (Petry et al., 2014).

Harnessing Existing Reinforcement

Some researchers have harnessed the power of high-magnitude reinforcers dispensed for non-therapeutic reasons and arranged abstinence reinforcement contingencies using those reinforcers (Silverman et al., 2011). Social businesses, which exist to address the problems of poverty (Yunus & Weber, 2010), could address the problems of drug addiction in the poor and unemployed by using the social business to arrange employment-based abstinence reinforcement (Silverman et al., 2016). A therapeutic-workplace social business (Hopkins Data Services) employed and paid drug users to serve as data entry operators (Aklin et al., 2014). To promote abstinence, the data entry operators were required to provide routine drug-negative urine samples to maintain access to the workplace and to maintain maximum pay. Participants randomly assigned to a therapeutic workplace group that received the employment-based abstinence reinforcement described above achieved significantly higher rates of drug (opiates and cocaine) abstinence than participants randomly assigned to a usual care control group (see Fig. 65.5). This study suggests that we could use social businesses to address the problems of drug addiction in the poor and unemployed by using the social business to arrange employment-based abstinence reinforcement.

Conclusions

Contingency management interventions are rooted in a robust laboratory model of drug addiction, and many controlled studies show that these interventions can be highly effective in the treatment of drug addiction. Indeed, contingency management interventions may be some of the most effective and versatile interventions available for the treatment of drug addiction. Abstinence reinforcement interventions are arguably the most useful of these interventions. However, contingency management interventions in general and abstinence reinforcement interventions in particular have at least three limitations that we should recognize and address. (1) Contingency management interventions are not effective in all participants. (2) Their effects do not reliably last after the interventions end. (3) Despite the strong empirical evidence of effectiveness, our society has not applied these interventions widely.

Promoting widespread use of these interventions is a great challenge. We do not know why people have not used these interventions widely, although we have some suspicions. As those suspicions have limited factual foundation, we have not offered them. Some researchers have sought to identify barriers to widespread dissemination of contingency management interventions and we refer the interested reader to those resources (Oluwoye et al., 2020). We might see reason for optimism in the fact that various clinicians, governments, and other organizations have used abstinence reinforcement in the treatment of drug addiction, although without experimental evaluation and without clear reference to the empirical support reviewed in this chapter. For example, governments have applied taxes for cigarettes to decrease cigarette smoking (Chaloupka et al., 2012). Physicians addicted to drugs have undergone random urine testing for extended periods that can last as long as five years with severe consequences (loss of ability to continue to work, including loss of license) for detected drug use (DuPont et al., 2009; McLellan et al., 2008). Similarly, drug addicted workers, particularly those in safety sensitive jobs, may be required to undergo a long-term regimen of random urine testing and risk losing employment for detected drug use (Cashman et al., 2009).

Contingency management interventions are unique in that they have a strong empirical foundation, both in the laboratory research that underlies them and in the large number of controlled trials that demonstrate their effectiveness. Widespread application of contingency management interventions could improve treatment outcomes for many drug-addicted individuals. One of our greatest challenges is to ensure that clinicians, governments, and other organizations embrace and adopt effective contingency management interventions for the treatment of drug addiction. This goal will be particularly difficult to achieve if the contingency management

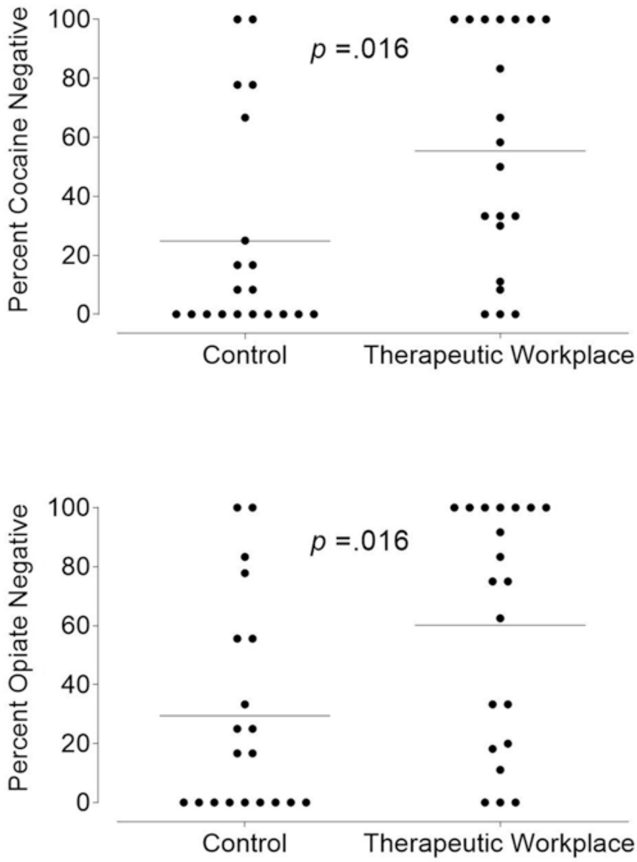

Fig. 65.5 Percentage of negative urine samples for cocaine (top panel) and opiates (bottom panel) during the period while the data entry business, Hopkins Data Services, was opened. Dots represent data for individual participants and horizontal represent group means. Missing samples were considered positive. (Adapted from Aklin et al. (2014), Fig. 2, with permission)

interventions employ high-magnitude reinforcement to promote behavior change in the largest proportion of participants possible and if the contingency management interventions maintain reinforcement over time to sustain the desired behavior change. Promoting adoption of important innovations is not simple (Rogers, 2003), but the extensive body of research conducted to date should serve as a strong foundation for the adoption and diffusion of this important innovation.

People with Intellectual and Developmental Disabilities

66

Rebecca A. Sharp, Katrina J. Phillips, and Sarah A. Taylor

The history of people with intellectual and developmental disabilities (IDD; note some people prefer identity-first language and to be referred to as intellectually-disabled people) is generally one of shunning and mistreatment (Trent, 2016). In the 1950s and 1960s when other areas of psychology were calling people with IDD unteachable, behavior analysts were evaluating how the principles of behavior could be used to teach new skills and remediate behavioral excesses. This interplay between intellectual disabilities and behavior analysis is still present today both in research and in practice. According the Behavior Analyst Certification Board (BACB) statistics, the number of Board Certified Behavior Analysts (BCBAs) who work with people with IDD is third only to the number who work with people with autism spectrum disorder (ASD) and in education (Behavior Analyst Certification Board, 2020). It is likely that these two most common practice areas include people with IDD. Similarly, Jones et al. (2020) found that the largest population to participate in research in the *Journal of Applied Behavior Analysis* was those with IDD (36%). In this chapter, we will discuss the influence people with IDD have had on behavior analysis in the early years. It will also provide a review of the role that applied behavior analysis (ABA), both as a science and as a profession, has had in upholding the rights of people with IDD and discuss areas in which we need to provide further support.

What Is IDD?

People with IDD make up approximately 1.04% of the world's population (Maulik et al., 2011). including genetic syndromes (e.g., Down syndrome), perinatal causes (including birth injury and birth asphyxia), and postnatal causes (e.g., infections). Intellectual disability is defined in the Diagnostic and Statistical Manual of Mental Disorders (American Psychiatric Association, 2022) as deficits in both intellectual and adaptive functioning. This deficit is confirmed by both clinical assessment and standardized intelligence testing (i.e., IQ testing). The onset of the IDD must occur during the developmental period, and limit the individual's functioning in cognitive, conceptual, academic, social, communication, and practical domains (American Psychiatric Association, 2013; Jacobson et al., 2007).

Behavior Analysis and Early Applications with People with IDD

Throughout the 1930s and 1940s, Skinner began collecting and publishing data on operant conditioning, and this research evolved into the science of behavior analysis (Morris et al., 2013). The aim of this science was to use methods that allowed for prediction and control to understand behavior, something that Skinner believed was not present in the applied psychology fields at the time (Morris, 1992). Although the original studies were animal studies, Skinner believed that people should not be "expected to be interested in the behavior of the rat for its own sake. The importance of a science of behavior derives largely from the possibility of an eventual extension to human affairs" (Skinner, 1938, p. 441).

The first published instance of the use of operant conditioning with humans was recorded by Fuller (1949). Fuller showed that an 18-year-old male with profound intellectual disabilities increased the number of times he raised his arm when this behavior was reinforced by access to sweet milk. By no means is Fuller's demonstration an example of ABA because arm-raising did not improve the man's quality of life (QoL). Similarly, many current behavior analysts would be shocked at Fuller's description of the man involved in the research as "a vegetative idiot" (p. 588) from a "feeble minded institution" (p. 588) who was only a step above "infra-human subjects" (p. 590) such as rats. The terminology used by Fuller and other researchers during this era, although accurate for a time period in which clinical notes referred to people with IDD as idiots, morons, feeble minded, simpletons, retards, and imbeciles, leaves a lot to be desired as a description by the standards of today. Despite this, Fuller demonstrated that people with IDD who had been labelled as "unable to learn" by medical and psychology professionals could develop new behaviors if the environment supported learning. Through the 1950s and 1960s, the knowledge regarding operant conditioning continued to expand, especially with regard to changing human behavior (Morris et al., 1990).

Although there was a diagnostic criterion for mental retardation (now referred to as IDD), during the early to mid-twentieth century, people with IDD were also often given mental health diagnoses (e.g., psychosis and schizophrenia) and ASD diagnoses (Atkinson & Walmsley, 2010). This lack of specificity makes it difficult to always determine if those involved in early behavior-analytic research did have an IDD. However, subsequent to Fuller's paper there were a number of demonstrations of the application of operant learning to change behavior of people with IDD, or related diagnoses. For example, Barrett and Lindsley (1962) looked at the ability of children with IDD to discriminate between stimuli, and Bijou and Orlando (1961) used multiple schedules with children with IDD. Ayllon and Michael (1959) demonstrated that operant conditioning was not only able to change specific operant behaviors, but that they could teach nursing staff to implement the principles to change problematic behavior on the ward. Their work is often cited as the first example of the application of behavior analysis to changing socially significant behaviors (i.e., behaviors that are important to the person or those around them; Baer et al., 1968). It is also likely the first example of behavior analysis with people with IDD to improve quality of life.

Ayllon went on to publish extensively through the 1960s on the clinical impact that behavior analysis could have with the behaviors of people with IDD (e.g., increased eating behavior; Ayllon, 1965; decreased food stealing and towel hoarding; Ayllon, 1963). In 1968, Ayllon and Azrin published on the use of conditioned reinforcers in the form of a token system, an intervention that is still widely used today. At the same time, Wolf and colleagues were demonstrating the effectiveness of analysis to change behaviors that were important for the person and those around them. They worked with an autistic and developmentally delayed client called Dicky, teaching him to wear his glasses, decreasing aggressive behavior, and increasing toileting (Wolf et al., 1963, 1967).

The work of the early pioneers in the application of behavior analysis and findings that had occurred in the application of stimulus-response

(SR) behaviorism (e.g., Mowrer & Mowrer's, 1938 application of the bell-and-pad method for treating enuresis) led to technologies that could be applied to change behavior. Confusingly, this application of technology is sometimes called ABA and until the early 2000s was often referred to as "behavior modification." There is no doubt that the application of ABA and behavior modification had the ability to present a better solution for behavior change (for those with and without IDD) than had been presented previously (Kanfer & Phillips, 1970). Following the seminal article by Baer et al. (1968) that outlined the characteristics of good applied behavior-analytic research, the examples of applications of the science and practice continued to grow (Cautela, 1986).

The application of ABA (like many technologies) is only as good as the person implementing the technology. Unfortunately, many who took up the use of behavior modification as a tool for working with vulnerable populations, such as people with IDD, were not behavior analysts and this was, in some cases, detrimental to the science and those who received intervention (Abidin, 1971). They did not know about the principles that underpinned the interventions they were using, meaning they were unable to adapt the technology effectively. Nor were they potentially aware of the conversations about the need for ethical practice that were taking place in the field. For example, Skinner took a clear position that although punishment by definition decreased a behavior, it should not be the first intervention of choice. Similarly, he spoke out against corporal punishment (Skinner, 1973). Baer et al. (1968) clearly identified that ABA should be used for socially significant behaviors and Wolf (1978) discussed the concept of social validity (i.e., the acceptability of the intervention and the outcome). Indeed, by the end of the 1970s, some behavior modification was an eclectic collection of applications. Some of the applications had little or no link to behavior analysis and involved a number of aversive interventions (e.g., water misting, electric shocks, slapping, and seclusionary time-out) that raised concerns with advocates and authorities (Johnston et al., 2017). Indeed, Turkat and Feuerstein (1978) reviewed 5 years of articles from the New York Times and found that of 27 articles, over half erroneously claimed to be ABA. As a result of this history, many people still associate ABA and behavior modification with changing behavior through aversive control, restraint, and seclusion. Concerns of poor practice resulted in the creation of credentialing programs that would lay the groundwork for the current BACB (Rutherford, 2006; Johnston et al., 2017).

Although ABA's reputation had been tarnished by association with misuse of behavior modification, this is not to say that ABA was not without its controversy. The vast majority of research from the 1960s to the1980s continued to focus on reinforcement (Todd & Morris, 1992). However, there was research on the use of punishment-based techniques for changing behavior. Punishment is conceptualized behaviorally as the presentation (positive) or removal (negative) of a stimulus that decreases the future likelihood of a behavior. In other words, it is a function-based definition rather than a topographical definition; punishment and aversives are not the same thing. Research was conducted on both positive (e.g., O'Leary et al., 1970) and negative (e.g., Kaufman & Baron, 1968) punishment, and punishment in conjunction with reinforcement-based techniques (e.g., toilet training adult with IDD who had previously been left to be incontinent due to an assumption of an inability to learn; Azrin et al., 1974). Although some of these treatments continue to have high social validity (e.g., timeout; Dupuis et al., 2015), many are now seen as unacceptable (e.g., Lovaas, 1987 use of physical punishment). It should be noted that the field has discussed the concerns of the use of punishment-based interventions and the need to weigh up the consequences for the person of not intervening (e.g., Van Houten et al., 1988). The need to weigh up the rights and choices of the client against the potential outcome of intervention or not having intervention is still legitimate today, but there is a more robust ethical process to resolve concerns. A good example of the potential complexities of the use of punishment was reported by Mudford (1995) who described a case of a man with life-threatening operant rumination for whom a legal court denied the use of a mild electric shock. Although this might be argued to have been protective, the unfortunate outcome was that the man did not receive any successful reinforcement-based interventions (none were identified) resulting in both an intrusive medical procedure and being placed in a restrictive environment.

Deinstitutionalization, Change in the Quality of Life, and the Rights of People with ID

ABA has its roots in the application of behavioral science with people with IDD living in large institutions in the 1950s and 1960s. However, early practitioners trying to apply the principles quickly identified that there were a number of barriers to effective treatment in the institutions (Holburn, 1997). In general, institutions did not provide naturally occurring environmental contingencies to support pro-social behavior. For example, the focus was on the severity of a person's disability with a lack of recognition that all can learn, there were few staff to support the people with IDD, there was no personalization of services, and the environments tended to be barren. Although there were a number of antecedents to deinstitutionalization, one was the societal recognition that institutionalization of people with IDD in custodial care environments was not helpful (and potentially detrimental) to them or the wider community (Beadle-Brown et al., 2007).

Deinstitutionalization moved people with IDD from institutionalizations to smaller community-based residential services, with the aim to increase engagement in activities, contact from care staff, use of community facilitates, opportunities for choice, contact with family and friends, and level of material standard of living. The success of deinstitutionalization in general resulted in improvement in people's lives, although minimally for some facets of life, or with mixed results across people (Beadle-Brown et al., 2007; Larson & Lakin, 1989). It should be noted that the change in challenging behavior as a result of changing settings alone was minimal, especially for self-injurious. Indeed, the ultimate success of the deinstitutionalization for each individual appeared to depend on the match of the environment with the needs of the person (Fox & Karan, 1976). Research reviewing the barriers to improvements in their quality of life unsurprisingly included the location of their home (e.g., access to transport) and the attitudes of the community (Abbott & McConkey, 2006). From an ABA perspective, it was also interesting to note that people with IDD their own skills (or lack of skills) and the staff's ability to provide appropriate support were also essential.

As a result of deinstitutionalization, the focus of support for people with IDD shifted from custodial care to supporting people with IDD to live their life their way. As part of this shift in ideologies, we have seen people seeking a greater understanding of what quality of life (QoL) and dignity means, and a desire to uphold the rights of people with IDD. There is widespread agreement that improving and ensuring QoL should fundamentally underpin service provision. However, QoL is a complex concept defined and measured in numerous ways dependent on theoretical philosophy and current contextual factors (Felce & Perry, 1995). Recently, Townsend-White et al. (2012) reviewed the QoL literature and distillated eight core domains of QoL: "emotional wellbeing, interpersonal relationships, material wellbeing, personal development, physical wellbeing, self-determination, social inclusion, and rights" (pp. 272). The broad scope of behaviors that can be addressed using behavior-analytic research means can contribute to the full range of aspects of QoL. Stark and Goldsbury (1990) suggested that there are two broad aspects of QoL: quantitative measures and subjective experiences. Behavior analysis is well-placed to measure not just the observed changes in behaviors associated with QoL but also the qualitative subjective experience (if subjective experiences are captured in measures of social validity). Wolf (1978) identified three dimensions of social validity; how much people like the (a) selected goals, (b) methods used, and (c) outcomes attained.

As more people with IDD started to live in the community, it quickly became apparent that despite a desire to ensure they had high QoL, many of their basic human rights were not being upheld. In 2006, the *UN Convention on the Rights of Persons with Disabilities* (UNCRPD, 2006) came into force. This convention was designed to move the view of people with disabilities from objects of charity (e.g., who were sick or feeble and in need of protection and fixing) to a view of people with IDD as full and equal members of society, with the same human rights as people without IDD. It should be noted that "disabilities" is a "catch all" term and includes physical, mental health, and intellectual disabilities.

Having one's human rights upheld and the changes in the living environment as a result of deinstitutionalization should improve QoL for a person with IDD. However, there is evidence to show that this is not the case (e.g., Simões & Santos, 2016). People with IDD have been shown to have smaller social networks including fewer people without IDD (Lippold & Burns, 2009), use medical care such as cancer screening less than people without IDD (Havercamp et al., 2004), and participate less often in recreation activities than people without IDD (Sands & Kozleski, 1994). Additionally, people with IDD remain hugely underrepresented in employment figures. Bush and Tassé (2017) found that 16% of individuals with Down syndrome and 14% of individuals with IDD were in employment, and that people with less severe intellectual disabilities were more likely to be in employment than people with more severe intellectual disabilities. These data highlight some key areas in which behavior-analytic methods can be focused to enable people with IDD to access a full range of life experiences if they are to truly improve their QoL.

Use of ABA to Support Dignity, Quality of Life, and Rights of People with IDD

To facilitate an understanding of how QoL, UNCRPD, and ABA research overlap, we direct you to Table 66.1. On this table, we have attempted to map some of the articles from the UNCRPD with Townsend-White et al.'s (2012) areas for QoL, and provide examples of ABA researchers have supported and facilitated QoL and the rights of people with IDD. Readers should note that this is not an exhaustive list of research, rather a sample demonstrating that just like Wolf in 1978, the behavior analytic community remains committed to providing socially valid interventions for socially important behaviors.

Right to Effective Treatment and a Therapeutic Environment

An overarching theme for all behavior-analytic work is to implement behavioral programs that facilitate a good quality of life for people with IDD. Early work by behavior analysts stressed the need for a therapeutic environment and the right to effective treatment (Favell & McGimsey, 1993; Van Houten et al., 1988), which is still true today and aligns with the current code of ethics for behavior analysts (Behavior Analyst Certification Board, 2020; Lee et al., 2018). This right to the therapeutic environment seems to be central to Article 26 of the UNCRPD which outlines a person with disabilities right to environments and programs that support habilitation and the appropriately trained staff to support this habilitation.

Favell and McGimsey defined the features of a therapeutic environment. They suggested that an environment should be least restrictive (e.g., safe access to preferred items, activities, or areas), stable, and safe in order to provide effective and efficient treatments or interventions. They defined a humane environment as one with available preferred activities and interactions that promote the individual's active participation. The environment

Table 66.1 Key articles from the United Nations Convention on the Rights of Persons with Disabilities mapped onto dimensions of quality of life

Article from the *UN Convention on the Rights of Persons with Disabilities* (2006)	Key concepts from the UN article	Relevant quality of life domains (Townsend-White et al., 2012)	Examples of areas to which behavior analysis has contributed
Article 12. Equal recognition before the law	Enjoy legal capacity on an equal basis with others	Material well-being Self-determination	Improving money management
Article 15. Freedom from torture or cruel, inhuman or degrading treatment or punishment	Free from scientific experimentation without consent Protection from harm	Emotional well-being Physical well-being Social inclusion	Challenging behavior, restraint and functional assessment Understanding choice making and preference
Article 16. Freedom from exploitation, violence, and abuse	Taking appropriate education measures to protect people with disabilities	Interpersonal relationships Emotional well-being	Prevention of harm
Article 19. Living independently and being included in the community	Choice of where and with whom live Full inclusion and participation in the community	Interpersonal relationships Self-determination Social inclusion	Increasing independent living skills and self-care
Article 20. Personal mobility	Mobility at time of choice and at affordable cost Training in mobility skills	Personal development Self-determination Social inclusion	Improving mobility
Article 21. Freedom of expression and opinion	Right to express opinion Facilitating augmentative and alternative communication	Self-determination	Facilitating language and communication Understanding choice making and preference
Article 23. Respect for home and the family	Right to marry and found a family	Interpersonal relationships self-determination	Supports for people with IDD as parents
Article 24. Education	Support for effective education Individualized support measures Life and social development skills	Personal development Interpersonal relationships	Education
Article 25. Health	Right to highest attainable standard of health	Physical well-being	Improving health outcomes
Article 26. Habilitation and rehabilitation	Attain maximum independence Full inclusion and participation in community and society	Self-determination Personal development Material well-being Social inclusion Emotional well-being	Right to effective treatment and a therapeutic environment
Article 27. Work and employment	Assistance in finding, obtaining, and maintaining employment Access to vocational training	Material well-being Personal development	Vocation and job training.
Article 30. Participation in cultural life, recreation, leisure, and sport	Access to activities Encourage and promote participation	Social inclusion Emotional well-being	Teaching of recreational and leisure skills

Areas in which behavior analysis has been used to contribute to quality of life are identified for each article should include family members, teachers, or staff who are caring and responsive, and who provide frequent positive interactions (i.e., is engaging). Studies have shown that staff can be trained to focus on engagement, resulting in active client participation and increases in adaptive behaviors (Mansell et al., 2002) and the behavior-analytic literature is full of examples of effective training of support staff through behavior skills training (BST; Parson et al. 2012b). BST is a systematic way of teaching skills that involves four steps: (1) information about what needs to be learned (either in writing or verbally), (2) a demonstration of the skill (either in person or on a video), (3) the opportunity to practice (e.g., role plays or in-vivo opportunities) (4) feedback on skills demonstrated. Each of these steps is repeated until a person shows competency.

Materials in the setting should be selected on the basis of preference and age-appropriateness. In certain situations, client preference will outweigh age-appropriateness (Phillips & Mudford, 2011). While preference for items or activities may be challenging to assess, preference can be indicated by physical contact with an item, motion towards, eye gaze, or idiosyncratic facial expressions such as smiling or positive vocalizations (e.g., Parson et al. 2012a, b; Sigafoos & Dempsey, 1992). The teaching of functional skills (described in subsequent sections) should be emphasized, and this should be embedded in preferred activities, for example, cooking or gardening. Favell and McGimsey also suggested that access to activities in the home or community should be accompanied by measures of active participation.

Treatments should prioritize immediate and long-term welfare and be selected with input from the person with IDD (including input on the goals for intervention). The type of input may be determined by the person's ability to communicate, and family members can be involved in the process (methods for which are discussed in subsequent sections). Goals should facilitate an individual's ability to participate in their home and community. Initially targeted skills may include those that allow access to preferred materials, such as requesting, social initiation, moving to areas of the home, or accessing public transport. The individual may also learn communication to cease events they do not prefer or to take a break. Behaviors that are unsafe or those that prevent inclusion may also be targeted. The increase in skill and/or reduction in challenging behavior should extend to greater freedom, increased development, and enhanced QoL (Favell & McGimsey, 1993).

Positive behavior support (PBS), which many believe has its groundings in ABA, was initially suggested as an approach to avoid the use of aversive techniques for people who engaged in problematic behavior (Horner et al., 1990). PBS at its core focuses on this need for an effective therapeutic environment in order to change behavior. Since its introduction, however, there has been debate over the relation between PBS and ABA, the use of PBS by non-behavioral practitioners, and what constitutes PBS. It is beyond the scope of this chapter to provide an in-depth discussion on this debate; however, for those who are interested, the authors direct readers to Dunlap et al. (2008), Johnston et al. (2006), and Tincani (2007).

Challenging Behavior, Restraint, and Functional Assessment

Article 15 of the UNCRPD states that people with disability should be free from torture or cruel, inhumane, or degrading treatment or punishment. People with IDD are more likely to engage in challenging behavior than the average population, and it is often in "treating" these behaviors that historical interventions would be considered torture, cruel, inhuman, degrading, or punitive.

Challenging behavior may be addressed for a range of reasons. It is known that problematic behaviors are associated with parental stress that affects parents' ability to manage (e.g., Herring et al., 2006) and can be aversive for staff (Tierney et al., 2007) which affects the quality of interactions they have with the person with IDD. However, most importantly engaging in problematic behaviors impacts on the life of the person with IDD. Challenging behavior may preclude a person from engaging in other behaviors or being excluding from settings (e.g., school), these behaviors may put the person at risk of abuse (Emerson et al., 1994), and in some circumstance may put the person themselves at risk of harm or death.

As discussed earlier, behaviorally defined punishment is different than everyday use of the term punishment. The BACB provides clear guidelines for the use of behaviorally-defined punishment to ensure the protection of clients (BACB, 2010). However, since the publications by Carr (1977) and Iwata et al. (1982) the use of even behaviorally-defined punishment-based techniques has reduced both clinically and in research. Carr and Iwata et al.'s work showed that behavior was purposeful and occurred as a result of maintaining environmental contingencies. Since these seminal articles a rich body of ABA research showing effective interventions to address problematic behaviors in people with IDD has emerged. The literature centers around third main themes: first, assessment of function of problematic behaviors (e.g., functional analysis; Iwata & Dozier, 2008; antecedent assessment; Anderson & Long, 2002); second, reduction of problematic and teaching functionally equivalent behaviors; common intervention methods include functional communication training (FCT; Tiger et al., 2008), antecedent interventions such as reducing task difficulty (Dunlap et al., 1991), differential reinforcement (e.g., Chowdhury & Benson, 2011), and noncontingent reinforcement (Carr et al., 2009); third, evaluation of staff training to implement both assessments (e.g., Phillips & Mudford, 2008) and methods to address problematic behavior (e.g., Metoyer et al., 2020). A secondary goal of many modern studies is to find alternatives to aversive or unethical methods such as restraint and seclusion (see Vollmer et al., 2011 for a discussion and ABAI (2010) for a position statement on restraint and seclusion).

Despite good research evidence for effective assessment and interventions for reducing challenging behavior, behavior analysis still has more to do. With regard to assessment and intervention, Lloyd and Kennedy (2014) suggested that more longitudinal research was needed to assess the long-term impact of interventions that further focus on generalization and maintenance is needed, and that methods to incorporate functional assessments into wider service delivery should be explored. There is also a need for greater dissemination of the knowledge of how to ethically intervene in the reduction of challenging behavior to avoid the over prescription of psychotropic drugs that have severe and, in some cases, lasting side effects. For example, Sheehan et al. (2015) found that people who engaged in challenging behavior were more likely to be prescribed antipsychotic drugs in the absence of diagnosed mental illness, and compared to less than 1% of people without IDD, 21% of the people with IDD in their study were prescribed antipsychotics. Finally, if behavior analysts are truly aiming to support Article 15 and improve the QoL for people with disabilities, we must support them giving "free consent" and truly participate in the selection of goals and treatments (Favell & McGimsey, 1993).

Understanding Choice Making and Preference

Choice may be correlated with the ability to make an uncoerced (i.e., free) selection between events, consequences, or responses. Choices may be made via idiosyncratic gestures including looking at an item, physically reaching, or facial expression (Cannella-Malone et al., 2015; Sigafoos & Dempsey, 1992).

The behavior analytic focus on what one does rather than what one says means people with IDD do not need to be able to engage in vocal-verbal behavior to make decisions about their life. For example, which intervention they prefer (e.g., Hanley et al., 1997), working with preferred versus non-preferred staff (e.g., Jerome & Sturmey, 2008), and preference for work requirements (Cuvo et al., 1998). Therefore, this is an area in which behavior analysis can promote self-determination and autonomy among people with IDD. Research such as that by Hanley et al. (2005) has been able to demonstrate that for some people with IDD they preferred to have a functional communication program that replaced their challenging behavior that included a behaviorally defined punishment component over an extinction component. Thus, behavior analytic research that facilitates choice helps to uphold Article 15 of the UNCRPD.

Promoting choice-making in people IDD also improves their QoL through facilitating self-determinism and supports Article 21 of UNCRPD. Article 21 focuses on the freedom of expression and opinion. The behavior analytic research is full of examples of program that facilitate choice making for people with IDD. In some cases, the research has aimed to teach the people with IDD to make choices themselves. For example, Tam et al. (2011) taught people with profound IDD and physical disabilities to make choices between stimuli by activating microswitches. In other cases, behavioral interventions have been designed to teach staff members supporting people with IDD, to provide choice-making opportunities to people with disabilities (Reid et al., 2003). For example, Reid et al. trained job coaches to provide choice-making opportunities to employees with severe intellectual and physical disabilities. Using BST, job coaches were trained to provide choices, such as “Would you like to work with Sam or Jane?” or presenting a choice of two items (e.g., labels and tabs).

It is clear that ABA research is able to teach people with IDD to make choices. However, if we are aiming to support people with IDD to have true self determinism, then we must continue to investigate how to facilitate supported decision making by people with varying levels of IDD about all aspects of their life. This is especially important for those with profound and severe IDD, or those who use alternative augmentative communication (AAC), who may not communicate via traditional verbal-vocal means.

Facilitating Language and Communication

The ability to express one’s self and one’s opinions is upheld in Article 21. Many people with IDD do not acquire formal language (Kent-Walsh et al., 2008); this may be due to speech unintelligibility due to weakened muscles or apraxia (Coppens-Hofman et al., 2016) or behavioral phenotypes (e.g., Fragile X syndrome and Down syndrome; Price et al., 2007). Behavior analysts focus on the contingencies in which language occurs (i.e., a functional approach to language; Skinner, 1957) rather than the topography. As such, we are often able to teach communication skills to people with IDD that are useful for them to express themselves vocally, or through sign language or augmentative communication systems (e.g., PECS).

A commonly targeted verbal operant is a mand; a request for which the reinforcer is functionally related to the response (e.g., a drink is provided contingent on a person asking for a drink; Skinner, 1957). A mand is often targeted as it is a way to improve a person’s QoL by providing them the ability to communicate what they want or need. Mands and what is manded for is highly varied in the literature (e.g., signing for preferred food, Sigafoos, 1995; or using speech generating devices to access preferred food or items, Suberman & Cividini-Motta, 2020) with each strategy dependent on the individual learner’s needs. Pennington et al. (2016) reviewed the literature on teaching mands to people with IDD, reporting that very few studies have been conducted with adults over 18 years of age, and that the majority of mand teaching research has been conducted in educational settings with children.

Like with mands, for other aspects of verbal behavior there is a noted lack of research with adult learners, and it is difficult to distinguish studies conducted with children with ASD from those conducted with children with IDD (including children with ASD and IDD). However, research on teaching intraverbals (e.g., Hicks et al., 2011; Kisamore et al., 2016) and tacts (e.g., McCormack et al., 2020) show the promise for teaching complex social interactions such as conversations. Hood et al. (2020) taught three young people with IDD to pay compliments to a conversation partner. The ability to engage in these more complex conversations may enable access to more interactions and foster friendships, which then enhances QoL.

Similarly, the ability for a person with IDD to engage in receptive language or listener responding (i.e., the ability to respond appropriately to spoken or written language; Leaf & McEachin, 1999) is essential for everyday life activities such as following written or spoken instructions. Both Grow and LeBlanc (2013) and LaMarca and LaMarca (2018) reviewed and provided comprehensive lists and rationales for teaching strategies for receptive language skills including minimizing inadvertent prompts and stimulus-specific reinforcement. Like with other areas of language, there appear to be few studies addressing receptive language skills in adults with IDD, and much receptive language teaching is embedded in Early Intensive Behavioral Intervention (EIBI).

Independent Living Skills and Self-Care

The ability to care for one's own personal hygiene not only improves ones QoL but also promotes dignity for people with IDD. Early studies evaluating behavioral toilet training methods (e.g., Azrin & Foxx, 1971) formed the basis for further studies that have demonstrated these methods to be effective without the need for increased fluid intake and in a home-environment (Post & Kirkpatrick, 2004) and without the use of a potty and alarms (Didden et al., 2001). In addition to urinary hygiene, bowel hygiene (i.e., wiping after a bowel motion) has been effectively taught using correspondence training (in which participants are taught to say what they are going to do, do it, and report that they have done it) (Stokes et al., 2004). Menstrual hygiene has also been taught effectively using chaining procedures (Veazey et al., 2016). However, considerably less attention has been given to hygiene other than toilet training, and more research is needed.

Related to the ability to independently complete self-cares, Article 19 explicitly identifies the right of people with IDD to reside in the community and live independently. However, people with IDD still experience a lack of choice, control, and may not actively participate in decisions about their lives (e.g., Gjermestad et al., 2017). Reed et al. (2014) asked professional and family carers of people with IDD to identify barriers to independent living. They found that the most commonly identified barriers represented skill deficits; safety, household, medication, and daily living skills. Behavior analysts are very well placed to help people with IDD overcome these barriers because of the well-established skill acquisition literature.

With regard to household and daily living skills, a number of studies have shown behavioral methods to be effective in teaching people with IDD a range of skills. For example, video modeling, in which participants viewed videos of models performing the task, has been shown to be effective for teaching skills such as setting the table and cleaning a counter (Aldi et al., 2016). Furthermore, video prompting (in which the task is broken into steps and a video watched prior to each step being completed) has been shown to be even more effective than traditional video modeling, although it is more laborious (Mechling et al., 2014).

Many component interventions such as video modeling include common components such as modeling, feedback, and reinforcement (for example BST). Such interventions have been used to teach vital skills such as making a quesadilla (with the training delivered through videoconferencing; Pellegrino & DiGennaro Reed, 2020), BST to teach fire safety skills (Houvouras IV & Harvey, 2014), simulation training for firearm safety (Maxfield et al., 2019), backwards chaining to teach first aid skills (Gast et al., 1992), and matrix training (in which some combinations of stimuli are taught and some arise through generative learning) to teach time-telling (Curiel et al., 2020). These are all examples of skills that facilitate independent living.

Despite a number of studies using contingency-based interventions (e.g., shaping, chaining, prompting), there are relatively fewer using interventions based on rule-governance. Self-rules, overt or covert verbal behavior in which a contingency is stated, are generated and followed by an individual (Zettle, 1990). Taylor and O'Reilly

(1997) taught self-instruction to people with IDD by teaching participants to articulate four statements (a statement of the problem, a statement of the correct response, a report of the response, and self-acknowledgement). Their participants were able to use self-instruction to effectively complete a shopping list, and they were able to demonstrate that the behavior was under the control of the self-instruction when performance decreased and when participants were unable to state the self-instruction. Faloon and Rehfeldt (2008) furthered this work by showing that self-rule training could be used to teach people with IDD to perform daily tasks such as ironing. They also found generalization to novel settings and stimuli and demonstrated control by the self-rules. The implications of these studies are that people with IDD can be taught generalizable self-instructional skills that can promote independence and reduce reliance on assistance from others.

One way to promote independence is to augment the environment with prompts to help people with IDD complete tasks. A number of studies have evaluated the use of various prompting methods. For example, Gil et al. (2019) used in-situ least-to-most prompting to teach people with IDD to read grocery items from a list on an iPad, identify the item, and place it in the cart. They found that all three participants made gains and successfully conducted the training in the grocery store. However, their results were limited by a lack of generalization to novel items (for two out of three participants) and that no participant ever completed 100% of the steps of the task analysis correctly. By contrast, Lancioni et al. (1998) compared computer-based and pictorial prompts to help people with IDD to complete cleaning or food preparation tasks. They found that the computer prompts were more effective and were able to demonstrate skill acquisition in people with relatively severe IDD.

Parsons et al. (2008) identified a number of barriers to teaching programs for independence for people with IDD, including rejection of complex or labor-intensive approaches by services, and a dearth of current research on intensive teaching programs after the initial cluster of articles in early behavior analysis. One solution might be to target staff behavior rather than that of people with IDD. For example, Towery et al. (2014) used a component intervention of feedback, instruction, and sharing baseline data to increase the number of opportunities to teach people with IDD and decrease the opportunities in which staff completed tasks on behalf of someone.

Prevention of Harm

One of the barriers that is often in place for people with IDD to realize independence is the paternalistic concern that people with ID need to be protected from harm. There is no doubt that there is a need to balance the QoL that comes with self-determination with the concerns about the impact choices may have on QoL with regard to physical and emotional well-being. For example, Article 16 states that people with disability shall be free from exploitation, violence, and abuse; this is not to say that we should not allow them to experience risk. Rather this article ensures there are appropriate laws and processes in place to reasonably protect a person with disabilities from first and foremost being harmed, and if harm occurs, that they are supported through the process of rehabilitation.

Given that most abuse of people with IDD occurs from those who they know (e.g., Mitra et al., 2016), programs are designed to facilitate their ability to not only protect themselves but also to improve their physical and emotional well-being and their ability to have healthy interpersonal relationships. Bollman et al. (2009) used videoed scenarios to teach two women with IDD to identify and respond to inappropriate staff interactions such as yelling, hitting, and inappropriate sexual-verbal behavior. They found that both participants could discriminate between appropriate and inappropriate interactions and report them accurately.

Bullying is a major issue for people with IDD; 66–90% of people report experiencing bullying (Reiter & Lapidot-Lefler, 2007; McGrath et al., 2010). Bullying is stressful for the person with

IDD and impacts upon their quality of life because it decreases their physical and emotional well-being and increases the chance of social isolation (Fried & Fried, 1996). Stannis et al. (2019) used BST with in-situ training to teach four men with IDD to learn to deal with bullying using these four strategies: (a) refraining from retaliating against the bully by avoiding physical contact or vocal statements other than those taught during training, (b) stating a short comment of disapproval, such as “I don’t like that,” (c) walking away from the bully, and (d) telling a staff member about the interaction.

There is not an extensive amount of research on behavioral interventions to reduce harm of people with IDD. However, studies have taught people with IDD to use cell phones when lost (Hoch et al., 2009) and to address potentially harmful situations such as broken glassware (Winterling et al., 1992). One of the behaviors that behavior analysts are often called upon to address is non-compliance. Although non-compliance in the extreme (e.g., aggression and property destruction) is disruptive to learning, behavior analysts must be careful not to teach a person with IDD to comply for the sake of compliance. The reason for this caution is that teaching people with IDD to “always do what someone in authority says” may leave them at risk of being harmed if the person seeking the compliance does not have the person’s interests at heart. Therefore, the authors encourage behavior analysts to consider allowing for a tolerance of non-compliance, and teaching people to say “no” as part of this process.

Improving Money Management

Article 12 of the UNCRPD states that people with disabilities have the right of “equal recognition before the law.” Although there are many areas of life underpinned by legal rights, ABA has had the greatest impact in helping people with DD to control their own finances, which can facilitate independence and material well-being. Browder and Grasso (1999) identified that for someone to be able to manage their money they must be able to (1) demonstrate computational and record-keeping skills, (2) complete banking requirements, (3) budget their money, (4) compare prices, (5) make purchases, and (6) save money. Behavioral approaches have most commonly been used to teach people to make purchases.

The main behavioral methods that have been used to teach people with IDD to make purchases are to teach the person to pay using an amount of money that covers all costs (e.g., handing over $20 for all purchases when the total purchase value is under this amount), the next dollar strategy (e.g., to count out one more dollar than the total dollar value of the purchase to cover the cents; Colyer & Collins, 1996)), to use a calculator (Wheeler et al., 1980), to recognize money (Nietupski et al., 1984), and more recently, to use a debit cards (e.g., Mechling et al., 2003). Other studies have used video modeling to teach people with IDD to use an ATM machine (Scott et al., 2013), and compared time delay prompts or most-to-least prompting to teach making cash withdrawals (McDonnell & Ferguson, 1989). Most studies teaching purchasing skills have used component interventions including prompting, feedback, reinforcement, or either person or computer-delivered instruction (e.g., Cooper & Browder, 2001; Ayres & Langone, 2002). However, because much of the research has focused on purchasing skills, there remains a dearth of research on specific skills such as saving, budgeting, and comparing prices.

Improving Mobility

Facilitating independent mobility will allow people with IDD to contact a broad range of reinforcers (including social and vocational). For people with multiple disabilities that include physical disabilities, there are a number of behavioral studies showing how ambulation can be promoted. Selecting ambulation or posture as a behavioral goal can prevent a person becoming physically more limited and can safeguard against isolation for people who spend a lot of time sitting down (Stasolla et al., 2017). Lancioni et al. (2010), Lancioni et al. (2014), and Stasolla et al. (2017) showed that microswitches providing stimulation contingent on ambulation increased responding. Additionally, Stasolla et al. (2017) found an increase in indices of happiness and ambulation (number of steps) in two children with congenital encephalopathy and perinatal hypoxia when their walkers were fitted with microswitches that provided access to preferred sensory stimuli contingent on taking a step. However, there is currently a paucity of research on other behavioral methods to improve ambulation in people with multiple disabilities.

For people with IDD who do not have physical disabilities, there has been some work conducted in teaching skills required to promote mobility. The ability to move within an environment with minimal restrictions is a right. Early studies include Gruber et al. (1979), who taught four young men with IDD to walk independently to school. After mapping the route from their home to school, and painting lines on the path every 25 feet to assist with data collection (distance travelled), they conducted a component intervention consisting of instructions, prompts, reinforcement, and corrective feedback. Their intervention was effective in teaching all four participants to walk to school without staff assistance, and they attained generalization (participants walked the route in reverse without training) and maintenance after 8 weeks. Similarly, Matson (1980) demonstrated that component behaviors of travelling between two locations such as crossing the street and stopping at an intersection were successfully taught using a mock intersection.

More recently, Batu et al. (2004) found most-to-least prompting to be the most effective prompting strategy for teaching pedestrian skills to people with IDD in a component intervention. Additionally, Price et al. (2018) used total task chaining to teach four young adults with IDD to use Google Maps to travel on public transport. The approach taken by many of the studies on this topic is to identify and define specific ambulation skills, deliver a training package consisting of prompts, instruction, and reinforcement, and train either in mock situations or in-situ. The research shows that this approach is effective and can promote independent mobility. Assistance can be gradually faded, and once acquired, these skills can be generalized to other settings or routes, further broadening access to reinforcement. Despite research on teaching people with IDD to be pedestrians or use public transport, there is a paucity of research teaching driving skills. Bell et al. (1991) successfully used peer tutoring to teach two people with IDD written responses for driving maneuvers. However, despite one of the two participants reportedly having gained their driver's license, practical driving skills were not taught or evaluated in the study. The lack of research could be due to acceptability of driving behavior as a goal for people with IDD; however, we must be cautious to avoid assuming that all people with IDD cannot or should not drive. This is a complex idea that requires further consideration. Driving would not be a suitable behavioral goal for everyone, but we must consider driving as a complex behavior chain able to be taught, and how it might be related to right to mobility.

Supports for People with IDD as Parents

Parents with IDD are capable of parenting effectively and share the right to be parents with their peers without disabilities. However, people with IDD who are parents experience high levels of stress (Feldman et al., 2002), and are disproportionately represented in welfare systems (Zeitlin et al., 2020) in which decisions about supports may be made based on evaluations of parental skills and abilities (Aunos & Pacheco, 2020). From a behavioral perspective, parental skills can be taught like any other skills, and there is a small body of research showing the behavioral methods that can be used. For example, Feldman et al. (1992) used a component intervention of instructions, modeling, feedback, and reinforcement to target specific baby-care skills (e.g., bathing and cleaning bottles) in women with IDD.

In addition to tangible care skills such as bathing and feeding, parents with IDD can be taught communication, play, and interactive skills that will contribute to their child's development. Children with parents with IDD are at increased risk of developmental delay, and at particular risk of language delay (Feldman et al., 1985). Feldman et al. (1986) used instruction, modeling, feedback, and reinforcement to increase social play behaviors in mothers with IDD. They found that vocalizations increased in some but not all children, however, that the training was effective to change the mothers' behavior, that the training did not require adapting for the mothers with IDD, and that gains were maintained after 10 months. Similarly, Feldman et al. (1993) found an in-home training program on interactions for mothers with IDD successfully increased the rate of child vocalizations and Feldman et al. (1989) increased the verbal behavior of children whose parents were taught to vocally imitate them. Common components of such training programs include prompting, instruction, feedback, and modeling.

Because parenting is underpinned by a number of complex behaviors, it can be difficult to determine what sort of support a person may need. However, Zeitlin et al. (2020) validated the Skills Assessment for Parents with Intellectual Disability (SAPID), a tool based on direct measurement of competencies. Tools such as this have obvious advantages of other assessments based on self-report or professional opinion. The SAPID gives a method by which professionals can objectively assess a person's skills, which may help to reduce stigma for parents with IDD. Despite the successful programs that can be implemented to give people with IDD parenting skills, it is important to note that there are a number of prohibitive systemic factors (e.g., poverty, stigma; Feldman et al., 1992) that have not yet been addressed in the behavior-analytic literature. Additionally, there is little research evaluating child outcomes (Feldman, 1994), little behavioral literature from the twenty-first century, and very little conducted with fathers as participants.

Education

People with IDD have the right to fully access and benefit from education (Article 24) and behavior-analytic methods can be used to provide individualized supports to enable this. The behavioral literature on providing support for education falls broadly into two categories; reducing barriers to learning in education settings (i.e., reducing problem behavior) and teaching academic skills.

Engaging in challenging behavior can preclude academic learning by reducing the amount of time the person spends engaged in their work and by reducing the quality of interactions with teachers and peers. Problem behaviors exhibited by students with IDD in academic settings can be associated with non-preferred activities (Foster-Johnson et al., 1994), transitions to activities that provide a leaner schedule of reinforcement to the activity prior (Castillo et al., 2018), and might be emitted to avoid academic demands (Dolezal & Kurtz, 2010). Each of the above studies demonstrated the use of functional assessment (including antecedent assessment) methods to determine controlling variables, and the use of a successful intervention in an educational setting.

Studies that have used behavioral methods to teach academic skills have shown that there is a range of available interventions. For example, computer-based matching-to-sample has been used to teach students with IDD to read Japanese Hiragana characters (Sugasawara & Yamamoto, 2007) and write Japanese Kanji characters (Sugasawara & Yamamoto, 2009). Matching-to-sample training is a method often used to teach relations between stimuli (i.e., equivalence training) and teaching attempting to produce derived relational responding can be useful in academic settings. Rehfeldt (2011) reviewed studies in the Journal of Applied Behavior Analysis that involved derived relational responding, finding that 46% of those studies involved people with IDD, but that reading was the skill most commonly targeted (and suggested others should be addressed) and that the technology has yet to be adapted from individualized to small group instruction.

There are a number of dimensions of behavior that can be targeted in academic interventions, including accuracy, fluency, and duration. Fluency, which describes the ability to produce a response with accuracy and speed (Binder, 1996), is often a target for academic interventions. To achieve fluent academic responding in students with IDD, Clark et al. (2016) used percentile schedules (in which the criterion for reinforcement is linked to previous responses and specified parameters). However, percentile schedules can be complicated for use in applied settings. With regard to accuracy, Cuvo et al. (1995) showed that a simple intervention of prompting and reinforcement increased spelling and sight vocabulary responses in students with IDD. However, although there are a number of articles showing behavioral methods to teach academic responses, the literature does not yet offer a comprehensive method for teaching a range of skills; many studies focus either on a single topography or single technology.

Improving Health Outcomes

Maintaining and improving health is underpinned by a range of behaviors. For example, to improve health outcomes, a person must access health care, engage in physical exercise, eat well, adhere to medication regimes, and avoid behaviors related to ill-health such as smoking. People with IDD experience inequalities in health outcomes (Beange & Durvasula, 2001), and although there are likely other factors that might contribute to ill-health in people with IDD such as socioeconomic disadvantage (Emerson & Hatton, 2014), behavior analysis can be used to promote health by addressing health-related behaviors.

There is a small body of research exploring methods to promote physical activity in people with IDD. For example, Normand (2008) used a self-management package including goal setting, self-monitoring and feedback to increase the number of steps taken by people with IDD. Similarly, Krentz et al. (2016) used a token economy to increase the number of 50-m laps each participant walked, and Li et al. (2019) used goal setting and a lottery system for reinforcers to increase the number of steps each person walked. Many interventions are comprised of multiple components and show good success in increasing physical exercise. It is much more difficult to demonstrate the effect on long-term health outcomes, however.

In addition to long-term health outcomes, behavior analysts should also be concerned with health in people with IDD because there is evidence that health and challenging behavior can be linked. May and Kennedy (2010) reviewed the evidence for relations between health and challenging behavior and suggested that there are two ways in with health problems can affect operant contingencies. First, health problems can increase the value of a reinforcer for a problem behavior (e.g., dysmenorrhea, pain associated with menstruation, can make demands more aversive and therefore escape more reinforcing). And second, problem behaviors directly related to the health problem might be evoked (e.g., head hitting to alleviate a headache). May and Kennedy suggested that practitioners should account for possible health issues in functional assessments, take data on the temporal presence of health issues, and work alongside health professionals to alleviate problems.

Another way in which behavior analysts can contribute to good health outcomes is to teach people with IDD to tolerate or engage with medical procedures or devices. Studies that have taught tolerance to aversive medical procedures have used methods such as stimulus fading to decrease problem behavior during having blood drawn (Stuesser & Roscoe, 2020), differential reinforcement to increase heart monitor wearing (Dufour & Lanovaz, 2020), and shaping to increase lying still in an MRI machine (Cox et al., 2017). Part of promoting health is to help people with IDD be involved in their own health. Ferguson and Murphy (2014) used visual aids to train 28 adults with mild to moderate IDD on the function, risks, benefits, and potential side effects of the medication they were prescribed. They also discussed potential alternatives to the medication, such as avoiding alcohol, the right to ask professionals for further information, and the right to refuse the medication. They showed overall increases in capacity to consent, measured by a specifically tailored measure with relevant vignettes. These studies show how behavior-analytic methods can be used to help people with IDD attain good health outcomes.

Vocational Training and Employment

Early employment opportunities for people with IDD were available in the mid-twentieth century in the form of sheltered workshops; day services in which people learned skills such as assembling (Blick et al., 2016). There is an argument that sheltered workshops were able to provide people with IDD prerequisite skills need to gain community-integrated employment (i.e., alongside peers without disabilities). However, research has shown that sheltered workshops do not necessarily increase employment outcomes (Cimera, 2011), and that many people with IDD would like opportunities for employment outside sheltered workshops (Migliore et al., 2007). The 1980s saw further community-integrated opportunities for employment (Dague, 2012). However, in order to gain and successfully retain employment, people with IDD might benefit from behavioral programs to teach vocational or social skills.

There are a number of skills required to gain employment, and behavioral programs have been used to teach skills to people with IDD to help them compete for jobs in an integrated job market. For example, gaining a job requires skills such as searching for a post aligned with your skills and interests, application skills, and interview skills. Pennington et al. (2014) taught three young men with IDD to write cover letters through a component intervention comprised of modeling, response prompts, self-monitoring, and graphing. They found that all three participants improved the quality of their cover letters.

When someone is employed and in need of support, a first step is to determine what support is required for which skills. One approach is to use the Performance Diagnostic Checklist-Human Services (PDC-HS; Carr et al., 2013). The PDC-HS includes both interview questions and direct observation to determine the specific variables involved in performance deficits in work tasks. Smith and Wilder (2018) used the PDC-HS to assess and improve the performance of people with IDD working in a thrift store. Each participant was paired with a supervisor, who was also a person with IDD. Supervisors used the PDC-HS, observed their supervisee's performance, and provided training using a tailored training package (including instruction and modeling) designed to address the specific task error conducted by their supervisee. They found that not only was the use of the PDC-HS and the subsequent training successful, that the supervisors with IDD reported increased confidence in supervising. An advantage of the PDC-HS is that it provides an objective measure of the work task skill issue, and therefore leads to the selection of a data-based intervention. Other methods to support people with IDD in employment include covert audio coaching (Bennett et al., 2010) and activity schedules (Lora et al., 2020).

Other studies have evaluated the use of specific behavioral methods to teach vocational skills (e.g., problem solving skills; Villante et al., 2020). For example, Kobylarz et al. (2020) compared three backwards chaining methods in teaching people with IDD cleaning tasks. They found that the participant-completion variation (in which participants were assisted to complete untrained steps of the chain using least-to-most prompting) was more efficient than teacher-completion (the instructor completed the untrained steps in sight) and no-completion (the instructor completed the untrained steps out of sight) variations. Lerman et al. (2013) evaluated the use of BST to teach adults with mild IDD to implement discrete-trial teaching (DTT) for young children with autism. Despite some success, they noted a potential relation between the level of participant intellectual disability and the success of the training (i.e., training was less successful for participants with lower IQ scores). Additionally, despite the participants' ability to accurately implement DTT, other elements of their performance such as tone of voice and enthusiasm were rated lower by observers than therapists without IDD. This suggests that people with IDD might need vocational support beyond simply the work tasks to which they are assigned.

Success and productivity in the workplace are likely to be influenced by social factors such as "fitting in" and being able to resist distraction. Otalvaro et al. (2020) used differential reinforcement of low-rate behavior (DRL) to reduce excessive questioning by people with IDD working in an adult training center. The two participants were provided with notecards that indicated the number of questions they could ask in each session. They found that excessive questions decreased, and productivity remained high. Other studies have taught workplace social skills such as responding appropriately to feedback (Grob et al., 2019) and social niceties (Yamamoto & Isawa, 2020). Behavioral programs such as this may help people with IDD learn workplace social skills that enable productive and fulfilling employment.

Recreation and Leisure Skills

There are a number of reasons why leisure skills are a useful target for behavior change programs. First, access to and engagement with preferred activities help people with IDD be included in community groups and clubs (Article 19) and facilitate social interaction. Second, it enables the right to participation in recreational activities (Article 30). And third, access to pleasurable activities might help to reduce the incidence of problematic behavior.

Behavior analysis offers a suite of methods to help people with IDD communicate their preferences for activities and social interactions. For example, Morris and Vollmer (2020) found that pictorially or verbally-presented choices between types of interaction (e.g., praise or high-5) could yield preference hierarchies in some participants (but not all). Similarly, Curiel et al. (2018) found that preferences for video clips could be assessed using an iPad to display and record choices. Offering choice to people with IDD is preferable to simply providing access to preferred items and activities for a number of reasons. Staff predictions of preferred activities are not always accurate (e.g., Newton et al., 1993) and it has been demonstrated that being given a choice can be more valued than being provided with a highly preferred item, even if that choice is between less preferred items (Ackerlund Brandt et al., 2015).

Offering a choice between preferred activities can also be used in behavior reduction programs, especially when the function of the behavior is stimulatory. For example, Leif et al. (2020) found that item engagement increased and automatically maintained problem behavior decreased when preferred items identified through a preference assessment were provided. They found that further treatment effects were produced when participants were prompted to engage with the item, and when differential reinforcement for interacting with the items (DRA) was added. Similarly, Sigafoos and Kerr (1994) demonstrated that providing access to leisure activities reduced problem behavior for people with IDD who were observed to engage in problem behavior when unengaged. Other uses of preference assessments for leisure items that contribute to broader behavior programs include assessing preference for level of physical activity to design interventions to promote physical activity. Pincus et al. (2019) found that two of three participants preferred physical activity to being sedentary and suggested that identifying preferred exercise can individualize interventions.

In addition to assessing preferences and using preferences in behavior programs, behavior-analytic methods can be used to teach people with IDD skills to be able to successfully engage in leisure activities. These skills can be directly related to the leisure activity. For example, chaining and discrete-trial teaching have been used to teach a person to play basketball (Lambert et al., 2016) and lag schedules have been used to teach children to engage in more varied toy play (Baruni et al., 2014).

Alternatively, people with IDD can be taught social skills that facilitate involvement in leisure activities. For example, Foxx et al. (1983) increased social skills in people with IDD through a card game (Stacking the Deck) that taught responses to common social situations such as criticism and social confrontation. Some people with IDD might engage in behaviors that preclude their involvement in leisure activities. Therefore, a goal of behavioral programs might be to replace these behaviors with socially appropriate alternatives. For example, Guertin et al. (2019) gradually disrupted the routines of a young boy with mild IDD to reduce obsessive-compulsive behaviors and concomitantly increase play behaviors. Similarly, Dowdy and Tincani (2020) used differential reinforcement without extinction to reduce problem behavior related to transitioning into a swimming pool. Successfully reducing the problem behavior increased participation in swimming and reduced safety concerns. Interventions such as this enable access to activities for people with IDD.

In addition to the behavior programs targeting the behavior of people with IDD, a number of studies have looked at training needs to increase staff facilitating access to recreation and leisure. Davis et al. (2019) used BST to give volunteers the skills to teach people with IDD motor skills for use in physical education sessions. Parsons and Reid (1993) took a more systemic approach, implementing group active treatment which was comprised of formally scheduling activities, assigning staff specific duties, having a coordinator rotate around the room to prompt and reinforce engagement, and staff training. They found that the intervention was efficient and effective; however, a replication by Sturmey (1995) found staff implementation to be variable. It is likely that implementation fidelity is affected by factors such as competing contingencies for staff. However, it is important to ensure that staff have both the time and skills to promote participation in recreation and leisure activities.

Areas to Improve

Although behavior analysis has much to offer in improving QoL for people with IDD, there are a number of areas for improvement. We have highlighted some specific areas for future development throughout the chapter; however, this chapter suggests some broader areas here. First, many studies have been conducted with children rather than adults with IDD. Adults with IDD are likely to have different goals for intervention and may benefit from programs to teach skills not appropriate for children (e.g., teaching voting skills or safe sex behaviors). We need to broaden the range of behaviors investigated for adults.

Second, there have been calls for the inclusion of more objective social validity measures, particularly from the recipients of behavioral programs. We should seek objective social validity for the targets selected for behavior change, the methods we use to change them, and the outcomes of our programs. There is a small number of studies evaluating social validity from staff or family members (e.g., showing less restrictive interventions are more acceptable than more restrictive interventions; Miltenberger & Lumley, 1997). However, there is little work evaluating how to take objective social validity measures from people with IDD.

Hanley (2010) advocated for the use of concurrent-chain arrangements to involve people in choosing interventions, a method we have discussed in the context of facilitating choice. However, this method can be complex and may not always be feasible in clinical settings. Additionally, this method is largely used to offer a choice between interventions and does not provide a method by which to choose intervention goals with clients. Another method is to measure indices of happiness (e.g., Green & Reid, 1996), under the assumption that more preferred environmental conditions will evoke more indices of happiness than less preferred conditions. This can be especially useful for people with profound and multiple disabilities for whom traditional communication is difficult, and because indices of happiness allow for idiosyncrasies to be captured. We call for more inclusion of indices of happiness as a measure of social validity in both research and practice. We do, however, acknowledge the limitations identified by Dillon and Carr (2007) that there is currently no way to establish a clear relation between indices of happiness and unhappiness and private events, and there is no clear solution when indices of happiness change in a direction not predicted. Happiness is a QoL indicator, and as such should be evaluated systematically and included in service provision (Parson et al. 2012a, b). However, there is again little work on using indices of happiness to choose targets for behavior change programs and therefore more research is needed.

In the last 10 years, there has been an approximate 500% increase in clinicians with the BCBA credential (Behavior Analyst Certification Board, 2020). Given this increase, it is important the field listens to calls and suggested solutions to address misconceptions that continue to be associated with ABA today (e.g., Critchfield, 2014).

Conclusion

Behavior analysis has a lot to offer and certainly has its roots working with people with IDD. Despite a robust body of research to inform clinical practice, there are a number of areas to be explored and improved. Like authors before us, we urge practitioners to keep abreast of the new research (Gillis & Carr, 2014), and to continue to work with people with IDD and their families and caregivers to improve behavior-analytic services. It is important to acknowledge that the impact of our work improves the lives of both the person with IDD and their families (Feldman & Werner, 2002), and our approach is useful to address the broad range of aspects of QoL.

67 Behavioral Gerontology

Rebecca A. Sharp, Katrina J. Phillips,
and Denys Brand

Behavior analysis is the scientific study of the relationship between behavior and its interaction with the environment (Skinner, 1938). That is, behavior followed by reinforcement is more likely to occur under similar stimulus conditions, and behavior that is punished (or placed on extinction) is less likely to occur. In addition, other features of the environment, such as antecedents, discriminative stimuli, setting events, and motivating operations are also considered when attempting to identify the underlying cause of behavior. Applied behavior analysis (ABA) is the application of basic behavioral principles in clinical settings to address socially significant behavior (Baer et al., 1968) and has been successfully implemented across a variety of populations and settings. These include children with autism spectrum disorder (ASD, e.g., Lovaas, 1987), adults with disabilities (e.g., Lattimore et al., 2008), organizational settings (e.g., Ditzian et al., 2015), adolescents with drug and alcohol issues (e.g., Taylor et al., 2011), and increasing levels of activity engagement (e.g., Van Wormer, 2004), just to name a few. Given that a behavioral approach has been successful in changing socially significant behavior across a number of domains, it appears likely that it should also be successful when applied to elderly individuals.

Using behavioral principles to improve the lives of older adults is not a recent application of our science. In 1982, B. F. Skinner gave a talk at the 90th convention of the American Psychological Association entitled "*Intellectual Self-Management in Old Age*." Based on his own reflections and experience, he discussed how ageing can result in a loss of reinforcement in the physical and social environment that affects both a person's behavioral repertoire and private events. His talk gained media attention, including an article published in The Washington Post (Meyer, 1982), showing a mainstream interest in psychological approaches to improving the ageing experience that is still present today. Subsequently, Skinner co-authored a book with Margaret Vaughan entitled "*Enjoy Old Age: A Practical Guide*." Written in lay terms with an appendix in which colloquialisms are translated into behavioral principles, the book describes a range of ageing experiences (and how to self-manage those experiences) such as retiring, fearing death, and physical changes.

If we define ageing behaviorally, as Skinner did, as a person's response to changes in stimulus conditions associated with chronological age, then we are all ageing regardless of which stage of life we are experiencing. Indeed, Skinner's

talk and book were focused on the typical ageing process experienced by the majority of the population. Early studies focused on older adults generally and demonstrated the principle of "behavioral plasticity"; that learning and behavior change can occur at any age (Baltes & Barton, 1977). Examples from the early literature include demonstrations that simple environmental changes could produce concomitant changes in behavior (e.g., access to free coffee and cookies could increase interactions between residents of a nursing home; Quattrochi-Tubin & Jason, 1980). Additionally, studies showed that the application of behavioral principles such the Premack principle, stimulus control, and reinforcement could be used to promote independence in older adults (e.g., self-feeding; Baltes & Zerbe, 1976). However, the more recent research on the utility of behavioral methods for supporting behavior change during the aging process has focused largely on addressing issues faced by people experiencing abnormal ageing (i.e., major neurocognitive disorder).

Behavioral gerontology is the term used to describe the application of behavioral principles to address the behavioral changes that occur with ageing (Burgio & Burgio, 1986), and there has been particular recent emphasis on addressing the excesses and deficits that accompany major neurocognitive disorder (formerly known as dementia) in older adults. The literature includes examples of where this approach has been successful in both increasing desirable behavior (e.g., levels of activity engagement; Engstrom et al., 2015) and decreasing undesirable behavior (e.g., aggression; Cohen-Mansfield et al., 1992).

Major Neurocognitive Disorder

The World Health Organization (WHO) published a report in 2017 showing that the number of individuals worldwide over the age of 60 will increase from approximately 900 million in 2015 to roughly 2 billion in 2050 (WHO, 2017). The WHO (2017) also reported that approximately 5% of the world's elderly population has a major neurocognitive disorder such as Alzheimer' disease (American Psychological Association, 2013). Major neurocognitive disorder is characterized by decreases in cognitive, social, and/or occupational functioning, which can lead to significant detrimental outcomes for these individuals, their families, and communities (WHO, 2017).

Although it is inevitable that these deficits will occur for a person with major neurocognitive disorder, no two people with the same diagnosis will experience major neurocognitive disorder in the same way. A number of factors have been shown to affect the rate of progression (i.e., skill loss), including the age of onset and the extent of cerebrovascular disease (Mungas et al., 2001). Additionally, progression varies across diagnoses. For example, some people with vascular dementia generally experience stepwise changes in which a number of skills will be abruptly affected after an infarct, but this is not the case for all because it depends on the location and number of vascular lesions (Rockwood, 2002). By contrast, people with Alzheimer's disease might experience a more gradual progression (Lee et al., 2019). Additionally, Poos et al. (2020) showed that participants with different subtypes of frontotemporal dementia showed deficits in different cognitive skill domains and experienced loss of different skills at different rates.

The progression of the disease also influences the cost of treatment, with the costs of care increasing with severity (Jönsson & Wimo, 2009). It has been estimated that the annual overall cost of major neurocognitive disorder worldwide is US$604 billion dollars (Wimo et al., 2013). This cost includes all resources required to support a person with major neurocognitive disorder; medical expenditure, economic loss, and both formal and informal care. As the population ages and the rate of major neurocognitive disorder increases, so too will the associated financial costs.

Increasing awareness of the growing number of older adults experiencing major neurocognitive disorder and the disorders impact both financially and socially, along with an increase in political commitments to understanding and addressing the problem (e.g., the United

Kingdom's Prime Minister's Challenge on Dementia; Department of Health and Social Care, 2015) have resulted in an increase in funding for research. For example, the United States Congress voted to increase funding into Alzheimer's disease yearly from 2016 to 2019 (Sauer, 2018). Although much research is focused on underlying medical causes of major neurocognitive disorder, there is a clear opportunity for behavior-analytic researchers to seek funding (and therefore increased visibility) for their work into addressing behavioral and cognitive needs.

Medical and Behavioral Interventions

The deterioration of cognitive functioning that typically accompanies major neurocognitive disorder often coincide with decreased levels of desirable behaviors (e.g., activity engagement; Altus et al., 2002) and increased amounts of challenging behaviors (e.g., agitation; Stadlober et al., 2016). Trahan et al. (2011) reported that the medical model (i.e., pharmacological interventions) largely guided treatment decisions when addressing the behavioral excesses and deficits that accompany major neurocognitive disorder. Unfortunately, pharmacological interventions can lead to potentially dangerous side effects (e.g., delirium, confusion, problems sleeping, loss of appetite, unsteady gait) and does not represent a viable long-term treatment for addressing age-related behavioral concerns (Mueller et al., 2020). Thus, a different approach is needed.

There is an increasing interest in non-pharmacological approaches, including a number of proposed models that allude to environmental factors as contributing to behaviors of concern for people with major neurocognitive disorder. For example, under the Newcastle model (James, 2011) behaviors of concern are conceptualized as resulting from unmet needs occurring in "trigger situations"; a functional approach not dissimilar from a behavioral conceptualization using the three-term contingency. Although a conceptually systematic behavior analyst can see the underlying behavioral principles at work in these models, rarely do the model creators make explicit reference to the field of behavior analysis, and such models are sometimes discussed as being "new," "modern," or "innovative." In some cases, the authors appear to consider their model new, modern, and innovative due to a lack of understanding of behavior analysis beyond an oversimplified conceptualization of the three-term contingency. For example, Cohen-Mansfield's (2000) description of the *unmet needs model* tries to set itself apart from a behavioral model (described as a simple three-term contingency) by including (a) consideration of factors such as behavior as an outcome of frustration, communication, or fulfilling needs (i.e., behaviorally we would consider these factors in the function of behavior and the person's current skill repertoire), (b) influenced by factors such as lifelong habits (i.e., behaviorally we would consider these in relation to the person's learning history), and (c) current physical condition (i.e., behaviorally we would consider these by taking into account underlying medical needs as part of an assessment of setting events). Although behavior analysts can lament about the misunderstanding or misappropriation of behavioral concepts, we would be better served as a science to see it as an opportunity for behavior analysts to contribute their understanding and expertise from behavioral gerontology, in an acceptable and understandable way, to a field in which there is a clear appetite for behaviorally oriented approaches.

Unfortunately, behavioral gerontology has not experienced the same level of exponential growth that has been observed in other areas of ABA, such as ASD. However, much has been written over the past few decades about the importance of behavioral gerontology and the need to grow this area of application (e.g., Aggio et al., 2018; Burgio, 1996; Burgio & Burgio, 1986; Carstensen, 1988; Gallagher & Keenan, 2006). The need to grow behavioral gerontology research and practice to allow the science to develop and refine procedures and methods of providing effective intervention is important for a number of reasons. First, the projected increases in the number of elderly individuals with major neurocognitive disorder in the coming decades represent a huge clinical need. The clinical need will be best met if there is research evidence to support clinicians to engage in evidence-based practice. Second, a large area of existing clinical practice in ABA is with adults with intellectual and developmental disabilities (IDD). There is evidence that adults with IDD are more likely to develop major neurocognitive disorder than their typically developing peers, and at a younger age (Janicki & Dalton, 2000). Therefore, it is likely that behavior analysts working in adult settings will encounter people with confirmed or suspected major neurocognitive disorder. Currently, the research supporting adults with dual diagnoses is scant (Lucock et al., 2019), and more is needed to inform clinical practice. Third, the increased public and government interest in living with major neurocognitive disorder has increased funding opportunities and the social validity of non-pharmacological approaches, allowing for greater participation in behavioral gerontology research. Moreover, the founding minds of behavior analysis envisaged that the science could be used to improve the quality of life of a range of people in a range of settings. In his early work, Skinner stated that the number of applications to human problems was only limited by the number of which people could think (Skinner, 1938). It is congruent with the early philosophy of our field to ensure the widespread application of our science.

Behavioral Gerontology and Underlying Behavioral Mechanisms

The inductive approach adopted in behavior analysis involves asking questions such as "what happens when we…" and places the emphasis on data over developing theories and testing hypotheses (Skinner, 1950). An inductive approach is well suited to exploring the underlying mechanisms responsible for behavioral changes in people with major neurocognitive disorder. Two areas of particular interest for adults with major neurocognitive disorder are changes to their cognition and memory. Memory, behaviorally defined, is engaging in remembering behavior (i.e., the ability to recall events or information from the past, even if the specific stimulus context in which the information was obtained has changed). Cognition might be conceptualized behaviorally as including equivalence learning, concept formation, verbal behavior, rule-governed behavior, and choice responding (Dougher & Hackbert, 2000). There is a paucity of translational research (i.e., that which links research on basic principles to practice; Lerman, 2003) on the ageing process from a behavioral perspective.

There is often a perception that due to the decline in memory that people with major neurocognitive disorder cannot learn from reinforcement. However, Steingrimsdottir and Arntzen (2014) found response latency decreased across trials for the people with major neurocognitive disorder, showing at least for some people the ability to learn from consequences remains intact. Similarly, there are a number of other studies that have shown the sensitivity of older adults to reinforcement. For example, Spira and Edelstein (2007) found that the responding of people with major neurocognitive disorder was sensitive to changes in schedules of reinforcement, but that responding in one participant out of three was less sensitive when the schedule changes were subtle. Burgess et al. (1992) found that people with major neurocognitive disorder were able to learn to respond under fixed interval schedules (i.e., demonstrating temporal control of responding). They also recorded participants' verbalizations during the computer-based task, reporting that although participants showed an understanding of a functional relation between their behavior and the response-contingent stimulus (e.g., "You need to hit it hard," p. 234), they did not show an understanding of the temporal relation (e.g., "The music's a bit faulty" when the response was not followed by a response-contingent stimulus, p. 234). This verbal behavior might indicate deficits in the ability to discriminate all functional properties of stimuli.

Stimulus control underlies many of the suggested mechanisms outlined as influencing cognition and memory, and was defined by

Steingrimsdottir and Arntzen as "the unit of analysis is the functional relationship between the behavior and its environment" (2011a, p. 247). Problems for people with major neurocognitive disorder related to deficits in stimulus control are commonly reported in applied settings. For example, asking a person with a major neurocognitive disorder whether they mind if we talk with them might be met with a topographically irrelevant response such as "I told him that the birds are blue" that is under stimulus control of unseen or past events. Gallagher and Keenan (2006) described examples of behavior that are not problematic due to topography, but because of the inappropriate context in which they occur (e.g., urinating in plant pots that bear similar characteristics to a toilet).

A number of translational research studies have investigated stimulus control deficits in older adults, many of which used a stimulus equivalence paradigm and matching to sample tasks (MTS). Of the studies investigating the effect of procedural variations on correct matching responses in older adults, it has been shown that more comparison stimuli result in more incorrect responses (Steingrimsdottir & Arntzen, 2011a) and longer delays between antecedents and response produce more incorrect responses (Steingrimsdottir & Arntzen, 2011b). Although these examples suggest that the antecedent context influences responding, the applied relevance for intervention of these findings has not yet been explored, demonstrating a need for more applications of translational research.

Despite the lack of obvious clinical relevance from some translational research on stimulus control, some have a more obvious application for clinical assessments. For example, Gallagher and Keenan (2009) compared matching-to-sample (MTS) responding to participant scores on the Mini Mental State Examination (MMSE; Folstein et al., 1975). They found that for some participants, MTS tasks were more sensitive to detecting cognitive deficits than the MMSE, and therefore suggested that assessments of cognitive deficits might include equivalence responding. Additionally, MTS tasks have been suggested as a valuable method by which to track progressive cognitive decline (e.g., Brogård-Antonsen & Arntzen, 2019) and to determine which relations are in-tact and which might need re-teaching (e.g., for facial recognition or object identification).

Although it is important to understand the behavioral mechanisms responsible for cognitive changes in people with major neurocognitive disorder, it is also important to recognize that these deficits in stimulus control are not immutable. Gallagher and Keenan (2006) suggested that remembering behaviors are often placed on extinction in residential settings and that interventions could be focused on replacing now-ineffective stimuli with discriminative stimuli that occasion appropriate responding. However, there is little research on whether prompts can be faded for people with major neurocognitive disorder, or whether they are required for ongoing stimulus control (and therefore act as additional discriminative stimuli rather than temporary prompts). Attempts to improve remembering behavior with stimulus control-based interventions have been successful, including increasing recall using an echoic prompt for participants to vocalize the names of objects (Dixon et al., 2011). Similarly, Bourgeois (1993) and Bourgeois and Mason (1996) successfully used textual and picture prompts to promote conversation in participants with major neurocognitive disorder.

While these studies provide evidence that the behavior of people with major neurocognitive disorder is under operant contingencies despite neurocognitive changes, the research is sporadic and somewhat splintered in its focus. For behavior gerontology to truly provide support for clinicians, and those with whom they work, there is a desperate need for researchers and clinicians to champion an expansion of the science to gain further insight into these underlying mechanisms. Specifically, there is a need for research that bridges these laboratory findings to clinical practice. For example, there is little research on the degree to which discrimination might affect sensitivity to reinforcement schedules or whether straightforward changes to the density of reinforcement schedules in applied settings might promote skill maintenance. The applied literature is currently dominated by evaluations of interventions designed to target specific topographies of behavior. More basic and translational research is needed.

Behavioral Gerontology and Major Neurocognitive Disorder: Application and Intervention

Behavioral gerontology research and clinical application for people with major neurocognitive disorder, especially when conducted over a lengthier period of time, might be affected by changes in a person's behavior. Therefore, irrespective of intervention or target behavior it is important to understand a person's suspected type of major neurocognitive disorder because it might help to explain sudden or gradual changes in the person's skills that occur even when environmental contingencies remain constant.

Behavioral gerontology research and clinical application with people with major neurocognitive disorder falls broadly into four categories: (1) Systemic changes including environmental supports and staff and family training; (2) Decreasing behaviors that are challenging for the person or those around them; (3) Increasing desirable behaviors (novel or reinstated); and (4) Promoting the maintenance of current behavioral repertoires. The first three are ubiquitous in applied behavior analysis with other populations. However, aiming to maintain behaviors that a person already has in their repertoire as they experience biological and neurocognitive changes is unique to working with people with major neurocognitive disorder.

Maintenance of Skills, Re-teaching Skills, and Teaching New Skills

Due to major neurocognitive disorder being progressive, the maintenance of skills and promotion of independence are likely socially valid aims of behavioral interventions, particularly for people with early-onset dementia (i.e., diagnosed under the age of 65). Maintaining behaviors might be the first step in a hierarchical approach to supporting someone's repertoire, with more intrusive and intensive interventions included as needed. For example, an early goal might be to schedule structured social activities to promote and maintain conversation skills. If unsuccessful or as the person's skills deteriorate, the goal might change to re-teaching the skill (e.g., using prompting and reinforcement to increase conversation). Further skill loss might necessitate teaching a new skill that ameliorates the effects of the skill lost (i.e., represents a functional alternative). For example, when the person can no longer communicate using speech, a new method of communication could be taught. Therefore, teaching new skills, re-teaching skills, and promoting the maintenance of current skills are linked areas of practice. There are a number of areas on which one could focus to improve the quality of life for people with major neurocognitive disorder; however, for the purpose of consciousness we will focus on social skills and engagement, physical activity, activities for daily living, and communication and verbal behavior.

Social Skills and Engagement

There is a small body of literature on interventions to promote the maintenance of social skills. Often, the interventions involve enhancing stimulus control or augmenting the environment. For example, Sharp et al. (2019) rearranged the lounge furniture in a residential setting to promote engagement with activities, communication between people with major neurocognitive disorder, and indices of happiness. They found that simply facing seating toward other seating increased social behaviors, which occurred much less when the lounge was arranged with the seating against the walls facing the middle of the room (a typical lounge arrangement in care settings). Their study showed that simple environmental changes could promote the maintenance of social skills, without the need for more intrusive intervention.

In addition to ensuring that the physical environment promotes interactions, a number of studies have evaluated the effect of programmed activities on observable behaviors in residential settings. Both Hensman et al. (2015) and Moore et al. (2007) found that indices of positive affect increased during sensory-based and leisure activities such as a petting zoo and ice cream parlor (respectively); however, these changes did not persist for long after the activity finished. Moore et al. found no increases in persistent positive affect with increasing durations of the activity (5, 10, and 20 min), although found very small increases in positive affect 10-min post activity compared to baseline. These data show that although programmed activities are useful for increasing engagement and positive affect, they should be used in conjunction with other interventions to ensure more than transient increases in these behaviors.

For some people, participation during activities may be low and simply providing access to activities may not be sufficient to promote social skill maintenance. For example, Westberg et al. (2017) found that nursing home residents were engaged for only approximately 50% of an activity. There have been a number of behavior-analytic studies that have used reinforcement and prompting to increase engagement and social behaviors. The check-in procedure (Engelman et al., 1999; Engstrom et al., 2015) involves periodic contact from staff (usually every 15 min) to provide a choice of activities and where necessary a prompt to engage in an activity and praise for engagement. Both studies reported increases in engagement. Prompts were also used by Brenske et al. (2008), who showed that descriptive prompts describing available activities were effective in increasing both engagement and physical presence in the room in which the activities were available.

To maximize the effectiveness of engagement strategies, it is useful to assess a person's preferences for the activities available. There have been a number of studies evaluating the use of stimulus preference assessment procedures for people with major neurocognitive disorder, including a recent review (Wagner et al., 2020). The general findings are that: (1) stimulus preference assessments can be used for people with major neurocognitive disorder, but the modality of the stimuli (e.g., vocal, tangible, textual, or pictorial) that best promotes choice responding differs across people (LeBlanc et al., 2006); (2) preferences for leisure items displace preferences for food items when mixed arrays are used (Lucock et al., 2020); (3) preferences are largely stable 3–5 months after an assessment (Raetz et al., 2013); (4) staff or family reports of preferences are relatively inaccurate when compared to stimulus preference assessment data (Mesman et al., 2011); and (5) stimuli identified in preference assessments can be used as reinforcers (Virués-Ortega et al., 2012). The existing literature provides a foundation for understanding the assessment of preference of people with major neurocognitive disorder, but there is little by way of how this information can be used in everyday care. For example, we need to explore how often activities in care homes should be rotated, how best to support people when they demonstrate preferences for activities that they can no longer complete independently, and how to train caregivers to continue to provide choice opportunities and evaluate preferences. Garcia et al. (2018) also suggested that the social validity and practicality of preference assessments should be explored.

Physical Activity

It has been demonstrated that people living in residential settings spend most of their time physically inactive; either sitting or lying down. For example, den Ouden et al. (2015) found that people were sitting or lying down in between 89% and 92% of their observations. Physical inactivity leads to muscle atrophy and a loss of physical strength. Additionally, physical inactivity has been linked to more rapid brain atrophy (Boyle et al., 2015), which suggests that interventions to increase physical activity might help to attenuate the effects of other skill losses.

Physical inactivity might be encouraged by a lack of positive reinforcement for movement, both for the person and for those caring for them. For example, staff may encourage people to remain seated to minimize fall risks, there might be a lack of programmed physical activities in a care home, staff may provide unneeded or excessive assistance for ambulation, and with aging comes increased rates of arthritis resulting in pain from movement. Behavioral approaches are useful to introduce contingencies that promote physical activity. In a residential setting, Burgio et al. (1986) provided a descriptive prompt for residents (some of whom were diagnosed with dementia) to walk to the table for mealtimes, followed by praise for independent mobility. They found that participants who rarely walked during baseline increased the number of feet they walked and attained generalization across mealtimes for some participants. The participants also ambulated more independently (e.g., required less staff or equipment assistance). Lancioni et al. (2017) used a computer and microswitch to increase leg lifting as a form of exercise. The computer prompted leg lifting every 15 s in the absence of responding, and leg lifting activated a microswitch which produced preferred music or videos. They found that leg lifting increased for all participants, and that some participants (but not all) required fewer prompts across sessions. It is important to note that in both of these studies, the amount of physical activity was insufficient to slow brain atrophy and they both used reinforcers other than praise. Burgio et al. capitalized on the natural reinforcer of reaching the dining table, and Lancioni et al. ensured that the leg lifting resulted in access to preferred stimuli. Introducing contingencies under which physical activity is reinforced in daily activities may help to promote maintenance of such programs by both reducing effort for staff and allowing people with major neurocognitive disorder to contact naturally occurring reinforcers.

Activities of Daily Living

Currently, there does not appear to be any behavior gerontology research evaluating interventions to promote engagement in complex activities of daily living such as using a computer, managing finances, upkeeping a home, managing medication, shopping, or accessing public transport. There is limited research on assisting people with major neurocognitive disorder to engage in activities with fewer components such as preparing a tea or coffee, using a telephone, or getting dressed. The few examples demonstrate the use of technological interventions to help people complete simple behavior chains such as making a snack or shaving (e.g., Lancioni et al., 2009). There is a need for more research in these areas as it has been demonstrated that people with more severe dementia are less able to complete more complex activities such as preparing a meal than people with mild dementia (e.g., Giebel et al., 2017). However, these often studies involve the use of questionnaires or family report rather than direct observation which would provide us more detailed information on how to support people clinically.

Direct observation would allow for individual evaluations of whether skill deficits are restricted to one or a few components of a behavior chain, are due to issues with initiation (i.e., stimulus control), or due to a combination of deficits or unsystematic errors. Additionally, deficits in activities are likely to vary across individuals and diagnoses, and therefore warrant individual assessment. For example, it has been shown that people with Lewy body dementia experience attention, concentration, and visuospatial difficulties that might adversely affect their ability to engage in activities of daily living (Leggett et al., 2011).

One possible reason for the paucity of behavior gerontology research on activities of daily living is that the majority of the research has been conducted in residential settings. Gaugler et al. (2009) conducted a systematic review of articles evaluating factors that affected care home admission. They found that after a diagnosis of dementia and severity of impairment, deficits in activities of daily living were the third most commonly reported predictor of admission (reported in 60% of their reviewed articles). Despite a clear need for preventing further skill loss, opportunities for practicing complex activities of daily living are likely to be reduced, either due to spatial lay-outs in care homes that do not allow for easy identification of room function (Marquardt et al., 2011) or because caregivers do not perceive engagement in such activities to contribute to quality of life (Giebel et al., 2015). Therefore, the current literature might reflect other targets (e.g., reducing behavior that challenges or increasing activity engagement) for behavioral studies that might have been more socially valid for people for whom activities of daily living were likely already in deficit.

Using the toilet is a basic activity of daily living that has been successfully addressed in the behavioral gerontology literature. Burgio et al. (1990) taught staff to prompt people to use the toilet every 2 or 3 h and were able to fade the prompts to every 3 or 4 h. Their intervention resulted in more dry incontinence pad checks, however, did not increase self-initiated trips to the toilet. Despite this promising research, continence issues are currently under-explored in the behavior gerontology literature. There is a need for more research on fecal incontinence, the practicality and social validity of programs to address continence for caregivers, and the interaction between stimulus control, mobility, and physical issues for continence in people with major neurocognitive disorder.

Communication and Verbal Behavior

People with major neurocognitive disorder experience a range of communicative and verbal behavior problems. These can range from word-finding problems in the early stages, to difficulty following instructions, verbal reports of delusions, repetitive questioning, incoherent utterances, and mutism in later stages (Bourgeois, 2002). Although some of these communication problems stem from stimulus control issues, there are few behavioral gerontology studies that have addressed maintenance or re-teaching of specific verbal topographies and functions.

Gross et al. (2013) used Skinner's verbal operants (1957) to develop a function-based assessment for language deficits in older adults. They found that older adults performed more poorly on some tacts than vocal mands and intraverbals. Additionally, participants with a diagnosis of dementia performed more poorly than participants without a diagnosis of dementia. Their findings provide evidence for functional independence of the verbal operants; that a person may not lose a word from their repertoire entirely, but may lose the ability to produce that word under different stimulus conditions (i.e., for different functions). There have not yet been any longitudinal, empirical demonstrations of the likely order in which people with major neurocognitive disorder might lose verbal operants from their repertoire. However, Gross et al.'s findings provide a method by which to assess verbal repertoires in people with major neurocognitive disorder. They also provided some preliminary evidence for the accuracy of Skinner's (1957) prediction that echoics and textuals might be preserved longer, but that his prediction that verbal operants followed by generalized reinforcement might become impaired first (e.g., tacts) might not be accurate.

The few behavioral gerontology studies that have sought to re-teach verbal operants have focused predominantly on mands (e.g., Henry & Horne, 2000). Trahan et al. (2014a) taught three women with dementia to mand for preferred activities by exchanging a picture as an alternative to a vocal verbal response. They suggested that a physical response might represent an easier, functionally equivalent response for people whose vocal–verbal repertoire is in deficit, and that it could be easier to teach than re-teaching vocal responding. Oleson and Baker (2014) used textual prompts (written cards) to teach two women with dementia to mand for preferred activities. They found their method to be successful for one participant but did not increase mands for the second.

The importance of stimulus control in language has been discussed by both Oleson and Baker (2014) and Trahan et al. (2014a). Trahan et al. acknowledged that having the items in sight during trials may have resulted in mands being emitted under the control of the items as discriminative stimuli rather than the establishing operation (i.e., as for a pure mand). Similarly, Oleson and Baker found that the addition of a contingency-specifying stimulus (CSS; Schlinger & Blakely, 1987) regarding the required response was needed for one participant. They suggested that the addition of the CSS may have resulted in stimulus control where the CSS was a discriminative stimulus for the mand, rather than the establishing operation.

In interpreting the application of the findings of these two studies to clinical practice, they show the importance of assessing mands with regard to both motivating operations and discriminative stimuli. It might be that although establishing operations are in place for attention or activities, discriminative stimuli are not. For example, staff look too busy for people to chat with them or to ask them for a cup of tea, or activities may be kept out of sight in cupboards and therefore there is no discriminative stimulus to occasion the mand, despite a potential motivating operation being in place.

Stimulus control is not the only mechanism to consider when trying to understand the reason for manding deficits among people with major neurocognitive disorder. The competing contingencies in care homes for staff to complete other tasks might mean that communicative behaviors are placed on extinction or inadvertently punished. For example, Qian et al. (2012) found that care staff spent about 31% of their time engaged in direct care such as assisting people to eat or transfer. They also found that care staff engaged in communication between 47% and 64% of the time. However, communication included exchanges between staff as well as between staff and people with major neurocognitive disorder. And while representing a large percentage of overall time, individual occurrences were of short duration (two thirds were less than 1 min). Staff under pressure to complete required personal care tasks may not have the time to engage with people in activities or social chatter. Under such circumstances, a person's communicative repertoire might diminish, or alternative, less appropriate, behaviors that access attention and activities may be reinforced.

Decreasing Challenging Behaviors

There are a number of topographies of behavior which are associated with major neurocognitive disorder that are challenging. However, a lack of agreement on definitions for topographies, severity, and inconsistencies in measurement make it difficult to be conclusive about prevalence (Gerritsen et al., 2019). Two of the most commonly reported topographies, disruptive vocalizations and physical aggression, have been estimated to occur in 2% and 12% (respectively) of people in specialist dementia care facilities (Veldwijk-Rouwenhorst et al., 2020). Along with aggression (Baker et al., 2006) and disruptive vocalizations (Buchanan & Fisher, 2002), other topographies that cause problems for the person with major neurocognitive disorder or those around have been addressed in the behavioral gerontology literature including sundowning (Stadlober et al., 2016), wandering (Heard & Watson, 1999), and hoarding (Donaldson et al., 2014).

It is interesting to note that none of these topographies are exclusively associated with people with major neurocognitive disorder, except perhaps for sundowning. Sundowning is widely described as an increase in disruptive behaviors later in the day (i.e., as the sun goes down); however, there is no agreed-upon definition or description of sundowning (Canevelli et al., 2016). A lack of agreement on the topography of the behavior has resulted in hugely variable estimates of prevalence (e.g., 2–82%; Boronat et al., 2019), and underlying causes (e.g., circadian, hormonal, physiological, epidemiological, environmental, medical, and pharmacological correlates have all been suggested; Gnanasekaran, 2016). Stadlober et al. (2016) conceptualized and evaluated sundowning from a behavioral perspective. Working with two people in a care home identified by staff as "sundowners," they found that the topography and function of sundowning varied and that only one of the two participants engaged in the behavior in temporal patterns congruent with typical sundowning. They concluded that sundowning was unlikely to be a topography of behavior unique to people with major neurocognitive disorder, but a description of the distribution of behavior across a day. Stadlober et al. also suggested that an explanation for the occurrence of sundowning might be found in environmental variables likely occurring at that time of day (e.g., shift changeovers, busy mealtimes in which attention is less available and there is more noise). Their study is an example of a conceptually systematic approach to problems associated with people with major neurocognitive disorder.

Assessment

Congruent with behavior-analytic approaches to assessing and reducing challenging behavior in other populations (e.g., children with ASD), a number of studies have used functional assessments (including experimental functional analyses; Iwata et al., 1982) to guide the selection of function-based interventions (e.g., Baker et al., 2006). For example, Buchanan and Fisher (2002) conducted pairwise functional analyses to identify the reinforcers for disruptive vocalizations in three people with dementia and subsequently used non-contingent reinforcement as an intervention. However, because it has been postulated that people with major neurocognitive disorder experience stimulus control deficits (Gallagher & Keenan, 2006; Skinner, 1983) antecedent assessments might be as important, if not more important, than the focus on consequences in traditional functional analyses.

Trahan et al. (2014b) found that an antecedent analysis yielded clearer differentiation between conditions than a traditional and modified functional analysis in which consequences for bizarre speech were manipulated. Additionally, Williams et al. (2020) developed a demand assessment to determine the specific antecedents under which "rude" vocal responses were emitted in a woman with dementia. Analyses like those conducted in these two studies are useful for informing interventions for the specific participants for whom they are implemented, but also may help to inform how caregivers are trained to interact with people with major neurocognitive disorder, e.g., avoiding open-ended questions (Trahan et al., 2014b) or considering social niceties (Williams et al., 2020). It is interesting that these two studies which found antecedent analyses to be useful focused on vocal responses. Because verbal behavior in adults with long and typical learning histories is often multiply controlled and complex (Trahan et al., 2014b), our current suite of assessments that were developed through working with other populations may not be sufficient or may require adaptation for people with major neurocognitive disorder.

Intervention

The majority of studies aiming to reduce problematic behavior in people with major neurocognitive disorder have used antecedent interventions (e.g., offering choices; Williams et al., 2020). A particularly effective antecedent strategy is to identify the maintaining reinforcer for a behavior and provide noncontingent access to that reinforcer. A number of studies have demonstrated the usefulness of noncontingent reinforcement. Baker et al. (2006) provided 10 s noncontingent breaks every 20 s during bathroom routines for a person with dementia whose aggressive behavior was maintained by escape. Buchanan and Fisher (2002) provided noncontingent attention to successfully reduce disruptive vocalizations maintained by attention. Noncontingent reinforcement interventions are a relatively simple intervention to address problematic behavior, and do not require alternative behaviors to be taught when used as a single component intervention. However, in order to be effective, a functional analysis needs to be conducted to identify the relevant reinforcer, and there is some evidence that very dense fixed-time schedules might be needed for some behaviors (e.g., Baker et al., 2006). Buchanan and Fisher (2002) found music to be successful in reducing stimulatory disruptive vocalizations, but only when the density of the schedule was increased from FT 80 s to FT 40 s. It is unlikely that staff in a care home have the capacity to provide reinforcers on such dense schedules.

Another way to provide noncontingent reinforcement is to provide continuous (rather than FT) access. Locke and Mudford (2010) compared the effectiveness of ambient music, silent headphones, and music on headphones to decrease disruptive vocalizations in a man with dementia. They found that music played through headphones was the most successful intervention and suggested that the matched stimulation (i.e., music was an alternative to the sound produced by vocalizing) was the underlying behavioral mechanism for the effectiveness of the intervention. However, they did acknowledge that the music may have also acted as a punisher or abolishing operation; reducing the quality of the stimulation gained from vocalizing.

Because stimulus control appears to be a deficit for people with major neurocognitive disorder, it is logical to explore interventions based on stimulus control. Feliciano et al. (2004) used an eye-level cloth barrier as a visual stimulus to signal that entry was not permitted and reinforcement was not available in a restricted area. Redirection involved minimal social interaction and social interaction was available outside the restricted area. They found that they were able to gradually fade the barrier to a minimal size while maintaining a decrease in entry attempts. There is a need for more research on interventions attempting to place behaviors under appropriate stimulus control for people with major neurocognitive disorder, especially given they often lose previously learned stimulus control.

Few studies have evaluated differential reinforcement (DR) interventions for people with major neurocognitive disorder. Dwyer-Moore and Dixon (2007) used differential reinforcement of alternative behavior (DRA) and extinction to increase appropriate and reduce disruptive vocalizations. However, the participant was not taught any new alternative behaviors; appropriate vocalizations already in their repertoire were reinforced. Heard and Watson (1999) implemented DR to reduce wandering but acknowledged that the schedule of reinforcement was dense and impractical (15–30 s). It might be that DR interventions using a leaner schedule of reinforcement, that require a novel response to be taught, or for use with people with vocal verbal behavior deficits might be more difficult to implement.

Although there is promising evidence for the use of behavioral interventions to decrease problematic behaviors in people with major neurocognitive disorder, we suggest that a fruitful way forward would be to gain a better understanding of the relevant behavioral mechanisms (e.g., stimulus control), rather than research focusing on specific topographies of behavior. Additionally, more research on how our assessments and interventions should be adapted to be more effective and socially valid for people with major neurocognitive disorder is needed.

Working Within Systems

Although the majority of behavioral gerontology research has been conducted in residential homes, there are a number of settings in which people with major neurocognitive disorder live, work, and engage where behavior analysis can be used (e.g., hospitals, family homes, nursing homes). In addition to targeting the behaviors of people with major neurocognitive disorder, a contextual approach allows a behavior-analytic practitioner to consider the physical environment and the behavior of caregivers as a way of improving the quality of life for people with major neurocognitive disorder.

Physical Environment

There are a number of recommendations for and trends in environmental design, for example the inclusion of therapeutic kitchens (Marsden et al., 2001), unique room door designs (Varshawsky & Traynor, 2019), and dementia villages (Peoples et al., 2018). However, recommendations are often based on expert opinion and infrequently derived from direct measures of behavior. Day et al. (2000) conducted a review of the empirical research on therapeutic design for care homes, concluding that a lack of consistent theoretical underpinnings, and lack of measures of behaviors, other than problematic ones, limited the research.

Given that behavior analysis recognizes the influence that the environment has on behavior and its use of direct observation measures, the impact of the environment on the quality of life of people with major neurocognitive disorder seem like this should be an area in which behavior analysis would excel. However, there have only been a few studies that have used a behavior-analytic approach to evaluating the effects of environmental design. Cash et al. (1995) evaluated "room management" in which chairs were arranged in a horseshoe shape, activities were made available, and a helper assisted people with major neurocognitive disorder to engage. They found that engagement increased. However, it was unclear in the Cash et al. study whether the increase in engagement was due to the environmental change or the increased helper assistance. Sharp et al. (2019) evaluated the effect of just the placement of furniture in the lounge on engagement and Ilem and Feliciano (2018) evaluated the impact of shadowboxes (containing personal, photographic, or textual stimuli) outside people's rooms on wayfinding. Both Sharp et al. and Ilem and Feliciano found that these simple environmental changes improved engagement and way finding respectively for the participants with major neurocognitive disorder without the need for additional staffing support. It should however be noted that Ilem and Feliciano found that for some participants personalized boxes were needed to improve wayfinding.

Although Ilem and Feliciano (2018), Cash et al. (1995), and Sharp et al. (2019) showed promising results using a behavioral framework to assess the impact of environmental design on the observable behavior of staff and people with major neurocognitive disorder, further research is most definitely needed. Elements of care home design such as personalized wayfinding aids and outdoor space have been shown to be valued by people with major neurocognitive disorder and their caregivers (Innes et al., 2011), and therefore the social validity of physical environments should be evaluated in future research.

Addressing the Needs of Caregivers

A person with major neurocognitive disorder has a range of supports in their lives ranging from naturalistic supports in the form of family and friends to formalized supports in the form of professional staff. As a person's major neurocognitive disorder progresses, the stressors and stains on these supports also change. Just as behavior analysis acknowledges the impact of the physical environment of the quality of life of people with increased support needs, it too acknowledges the impact that those supporting them also has.

Family Caregivers It is estimated that there are approximately 16 million unpaid caregivers in the United States (Alzheimer's Association, 2020), therefore this group needs support and evidence-based interventions. Family caregivers of people with major neurocognitive disorder might find their caring role gradually change as the person's major neurocognitive disorder progresses, including adopting proxy decision-making, healthcare advocate, and behavior management roles (Black et al., 2013).

Relative to the intellectual disability sector, less is known about how behavior analysis might benefit the family caregivers (e.g., spouses, children) of people with major neurocognitive disorder residing in the community. However, the small amount of research suggests that behavior analysis could be useful to teach caregivers strategies to more effectively manage behavior that challenges, maintain independent behaviors, and self-care skills. There are a few examples of training caregivers to maintain skills in people with major neurocognitive disorder in the behavior-analytic literature. Bourgeois (1990) taught three husbands to teach their wives conversation skills using memory aids. They found that not only was their method effective in increasing on-topic conversation statements, it could be taught effectively to the husbands. However, they also found that the husbands' interpretations of correct responding were stringent, and while this was a demonstration of high treatment fidelity, it may have inhibited novel responding. By contrast, Adkins and Mathews (1997) did not measure treatment fidelity but reported anecdotally that family caregivers to whom they taught a prompted voiding procedure (to increase using the toilet) were still successfully using the procedure 6 months later. These studies show the utility of behavioral approaches to teach caregivers methods to maintain independent skills in their family member.

Although maintaining independent skills is important, family members may need assistance in managing behaviors that challenge, especially as challenging behavior is the leading reason for a person needing to enter care (Thomas et al., 2004). Behaviors that challenge might be more salient (and problematic) for family caregivers. For example, Bourgeois (1990) found that the husbands in their study did not notice the increases in conversational skills and offered a lack of salience of the changes as an explanation for their finding. Polenick et al. (2020) found that the most commonly reported strategies used by caregivers were general, e.g., humor, social support, and activity engagement. Caregivers also reported modifying their interactions and the care environment; however, there would be clear benefit to enhancing these strategies with individualized, function-based interventions. Currently, there do not appear to be any studies teaching family caregivers to implement functional analyses or function-based interventions for behavior that challenges, despite a body of literature teaching caregivers of other populations (e.g., ASD; Gerow et al., 2019).

Direct Care Staff Professional caregivers (direct care staff) of people with major neurocognitive disorder come from a range of training and education backgrounds and vary across countries and services. Often, professionals with higher levels of education are responsible for overseeing care or for specific elements of care (e.g., medical), while untrained caregivers provide day-to-day care (Hallberg et al., 2016). Although behavior-analytic research is full of examples of training care staff to competency in the intellectual disability sector, there are a number of barriers to training direct care staff to work with people with major neurocognitive disorder. First, there is a paucity of research on training caregivers working with those with major neurocognitive disorder to complete behavior-analytic assessments or interventions. Second, resource constraints mean that staff may be too busy to implement behavioral assessments or interventions. Finally, staff may not contact reinforcement for implementing behavioral assessments or interventions even when they have time to do so, and therefore they do not continue to engage in assessment or interventions.

Staff in residential homes may find that competing contingencies to complete tasks such as cleaning, infection control, meal preparation, and documentation preclude spending time in interactions with people that does not involve direct personal care (e.g., dressing). An adverse outcome of this can be that dependent behaviors are reinforced and independent behaviors either punished or placed on extinction (Baltes et al., 1980; Burgio et al., 1986). That is, it is quicker and easier for staff to complete tasks for people rather than use difficult or time-consuming prompting procedures. Therefore, one goal for behavior-analytic work is to identify problematic contingencies maintaining competing staff behaviors and work with management to change them. Additionally, small environmental changes that preclude the need for more complex interventions can be easily evaluated using direct measures of behavior. For example, Munyisia et al. (2013) introduced an electronic documentation system and measured whether the time staff spent documenting reduced.

Some studies that attempted to train staff to continue the intervention once established (e.g., Engstrom et al., 2015) reported a lack of success. Other studies have found that staff report new practices to be burdensome (e.g., Noguchi et al., 2013). One reason could be because the interventions lack social validity (i.e., are too complex, too time-consuming, or not considered to be useful or effective). Trahan et al. (2014a) called for the social validity of interventions with people with dementia to be explored, which is an area currently under-explored.

There is some evidence that some direct care staff may not find interacting with people with major neurocognitive disorder reinforcing. For example, Brodaty et al. (2003) found that a quarter of the staff they interviewed stated that interacting with the people with major neurocognitive disorder provided no job satisfaction. Similarly, Schnelli et al. (2020) identified staff fear of people with major neurocognitive disorder was a key barrier to addressing behavior that challenges. Factors such as these might mean that the reinforcement for avoiding interactions might be greater than the reinforcement available for addressing behaviors proactively. Similarly, for those who do find reinforcement, it may be that there are reinforcers for "caregiver behaviors" (i.e., ensuring an older person is well cared for) rather than support behaviors (i.e., ensuring an older person has supports in place to maintain independence). There are a number of solutions grounded in behavior-analysis.

The first is to give staff skills to effectively reduce problematic behavior (e.g., using behavioral skills training; Parsons et al., 2012), therefore reducing the aversiveness of interacting with the people for whom they provide care. It would also be useful to use behavior-analytic methods to help staff to build relationships with the people for whom they provide care, for example, by facilitating familiarization (e.g., Parsons et al., 2016) or helping staff to conceptualize the causes of problematic behavior. For example, there is some evidence that staff attitudes (i.e., verbal rules and verbal behavior) toward people with major neurocognitive disorder affect the quality of care and occurrence of problematic behaviors (Gerristen et al., 2019). To enhance staff understanding of problematic behavior, it is important to teach a functional approach. Training should emphasize that the person is not engaging in problematic behavior because they have major neurocognitive disorder, but because their major neurocognitive disorder has changed the way they interact with their environment. Thus, the only way to change the behavior is to change the environment.

In addition to increasing staff knowledge, another avenue is to explore preference-based workplace adaptations (e.g., Task Enjoyment Motivation Protocol; TEMP), a strategy developed by Green et al. (2008). They helped staff to identify nonpreferred work tasks, implemented changes to decrease the aversiveness of the tasks, and found that staff subsequently reported their quality of work life to be better. Behavior analysts are concerned with behavior (both physical and verbal) in context, and therefore there is value in exploring interventions that address a broader range of goals than simply increasing individual caregiver skills.

Use of Technology

Technology is playing an ever-increasing part in the care and support for people with major neurocognitive disorder. The specific type of technology can take many forms, from simple digital alarms that prompt a person regarding the day, time, and important activities (e.g., Nishiura et al., 2019) to more complex virtual reality (VR) programmer to improve physical skills (e.g., Liao et al., 2019). The technology can be used to increase or maintain independence (e.g., the teaching of kitchen skills using VR; Yamaguchi et al., 2012), assist a person to stay in their home (e.g., the use of tele-assistance and automatic light paths; Tchalla et al., 2013), and promote language skills (e.g., Lancioni et al. (2014) used a computer-aided program to facilitate reminiscence conversational skills). Due to the fast pace with which technology advances, becomes more accessible, and is adopted by consumers, the research on the utility of technology must also keep pace. For those with major neurocognitive disorder, the use of technology is relatively new, and even newer within behavioral gerontology research. Much of the drive within the field of behavioral gerontology has come from Lancioni and colleagues. For example, they have produced a range of research that explored the use of automated verbal prompts to teach and maintain a range of activities (Lancioni et al., 2009), the use of pictorial instructions provided by a portable computer to increase activity (Lancioni et al., 2013) or via use of a tablet or smart phone

(Lancioni et al., 2019), motion sensitive sounds and light systems to facilitate independent ambulation (Lancioni et al., 2013), and independent choice of music (Lancioni et al., 2014).

Although Lancioni and colleagues have produced behavioral gerontology research in the technology space, the vast majority of research looking at the effectiveness of technology for people with major neurocognitive disorder would not meet Baer et al.'s (1968) criteria to be considered ABA research. Most of the research in the area lacks a clear behavioral definition of the dependent variable and has poor experimental design, which is indicative of a lot of exploratory research in the subfield. However, the research does appear to meet the criteria for *applied*, with both the behavior change and the intervention being socially valid.

Although technology has the potential to have a large impact on the quality of life for people with major neurocognitive disorder, it should be noted that behavior analysts should not adopt it blindly. Rather, like the models discussed at the start of the chapter, they should consider the mechanisms by which the technology is likely to obtain behavior change. For example, the desirable impact of technology assessed in the non-behavioral literature can often be explained in behavioral concepts, including prompts, increased saliency of natural stimuli, and the provision of natural reinforcers. With this conceptually systematic understanding behavior analysts are well poised to use our skills in measurement and data analysis to assess the impact of the technology impact on the quality of life for people with major neurocognitive disorder.

Conclusion

BF Skinner is regularly quoted as saying "old age is rather like another country, you will enjoy it more if you have prepared yourself before you go." Behavioral gerontology research has provided us with some of the information required to prepare one's self. However, there remains a need for researchers to aid our understanding of the underlying behavioral mechanisms relevant to the aging process for people with major neurocognitive disorder and to continue to provide evidence of the clinical utility of adapted behavioral assessment and intervention methods. Of equal importance is the need to increase the number of behaviorally trained clinicians working with people with major neurocognitive disorder. Despite an ever-growing need within the population, it remains the case that few behavior analysts work with older adults as their primary area of professional emphasis (0.13%; Behavior Analyst Certification Board, n.d.). However, there is good evidence that behavior analysis can contribute to solving problems of ageing, and there is guidance for practitioners interested in expanding their scope of competence to allow them to engage in a meaningful and collaborative manner with others in the sector (Brodhead et al., 2018). Therefore, it is hopeful that future behavior analysts will heed this call. This call is especially important as there will be very few of us whose lives are not touched by living with, caring for, supporting, or at the very least being aware of someone living with major neurocognitive disorder. Behavior analysts are in a strong position to contribute to preparing people for the aging process and ultimately improving the quality of life of older adults, we must just accept the challenge.
