Autism and Child Psychopathology Series

Series Editor

Johnny L. Matson
Department of Psychology
Louisiana State University
Baton Rouge, LA, USA

Brief Overview

The purpose of this series is to advance knowledge in the broad multidisciplinary fields of autism and various forms of psychopathology (e.g., anxiety and depression). Volumes synthesize research on a range of rapidly expanding topics on assessment, treatment, and etiology.

Description

The **Autism and Child Psychopathology Series** explores a wide range of research and professional methods, procedures, and theories used to enhance positive development and outcomes across the lifespan. Developments in education, medicine, psychology, and applied behavior analysis as well as child and adolescent development across home, school, hospital, and community settings are the focus of this series. Series volumes are both authored and edited, and they provide critical reviews of evidence-based methods. As such, these books serve as a critical reference source for researchers and professionals who deal with developmental disorders and disabilities, most notably autism, intellectual disabilities, challenging behaviors, anxiety, depression, ADHD, developmental coordination disorder, communication disorders, and other common childhood problems. The series addresses important mental health and development difficulties that children and youth, their caregivers, and the professionals who treat them must face. Each volume in the series provides an analysis of methods and procedures that may assist in effectively treating these developmental problems.

Preface

This book will be a comprehensive reference for practitioners and practitioners-in-training in the field of child health and mental health. One other, much less comprehensive, volume on the topic was published by Walker and Roberts in 2001. Thus, the present volume is an up-to-date and expanded version of a much earlier text. Topics covered are history, theories, ethics, and diagnostic systems such as the new RDoC criteria. A series of chapters will cover risk factors such as parental stress, divorce, and parental depression. Up-to-date reviews of cognitive variables such as theories of memory, executive function, theories of intelligence, theory of mind, and cognitive tempo will also be discussed. A substantial portion of the book will also cover methods of assessment such as checklist and interviews and methods of treatment such as cognitive behavior therapy, mindfulness, and family therapy. Also, a number of chapters will be devoted to the assessment of specific diagnostic categories such as depression, anxiety, elective mutism, and ADHD. Pediatric issues such as chronic pain, childhood cancer, childhood obesity, and toilet training will be extensively addressed as well. Finally, trending issues will be addressed such as gender diversity, social justice, bullying, internet gaming disorder, and the impact of COVID-19.

Contents

Part I Foundations of Clinical Child Psychology

Part II Cognition and Clinical Child Psychopathology

Part III Testing Methods in Clinical Child Psychology

Part IV Treatment Methods in Clinical Child Psychopathology

Part V Assessment of Neurodevelopmental Disorders in Children

Part VI Treatment of Neurodevelopmental Disorders in Children

Part VII Assessment and Treatment of Pediatric Disorders

Part VIII Assessment and Treatment of Challenging Behaviors in Children

Part IX Assessment and Treatment of Childhood Adjustment

Part X Assessment of Psychopathology in Children

Part XI Treatment of Psychopathology in Children

About the Editor

Johnny L. Matson, Ph.D., is Professor and Distinguished Research Master in the Department of Psychology at Louisiana State University-Baton Rouge. He is the founding editor of the *Review Journal of Autism and Developmental Disorders* and the author of more than 850 publications including 52 books and 22 tests. He has served as major professor for 72 Ph.D.'s.

Part I

Foundations of Clinical Child Psychology

1

History of Clinical Child Psychology

Michaela Brown, Johnny L. Matson,
and Celeste Tevis

Clinical psychology can be defined as the "psychological specialty that provides continuing comprehensive mental and behavioral health care for individuals and families", and it is marked by its comprehensiveness and integration of knowledge from a wide array of disciplines as well as populations served ("Clinical Psychology", 2008). Child clinical psychology uses this comprehensiveness and integration of knowledge and applies it to the delivery of services to children, understanding the social contexts, social-emotional development, overall developmental process, possible psychopathologies as well as behavioral concerns ("Clinical Child", 2005).

Clinical psychology itself included the study of the development, atypical and typical, of children throughout its history. Eventually, child clinical psychology became its own branch of psychology in 1962. At this time, the sections of Division 12, the Society of Clinical Psychology, began to form, with child clinical psychology as Section 1 (Routh, 1994). The study of children has been a critical part of clinical psychology since its beginnings, starting with the turn of the twentieth century.

Though the science of psychology has been in practice since the early 1900s, the term "Clinical psychology" was not commonly used until 1907. Lightner Witmer first introduced the term in the journal entitled *The Psychological Clinic*, with its first issue as "Clinical Psychology", in which he described an interdisciplinary approach of both assessment and treatment, which, in his case, began with the assessment of children (Benjamin, 2005). Witmer founded a psychological clinic at the University of Pennsylvania in 1896, with his first case reportedly being a child with reading difficulties (Routh, 1994).

History

Children played a critical role in the creation of clinical psychology with the advent of intelligence testing. In 1904, Alfred Binet began assessing children with poor academic performance in school using what would become the first metric scale of intelligence (Carson, 2014). The Minister of Public Instruction in Paris wanted children of lower intelligence to also receive an education, placing these children in special classes and removing them from ordinary schooling (Reisman, 1991). In order to

accomplish this, a subjective examination process needed to be developed to assess the intelligence of children.

This subjective process ultimately became the 1905 Binet-Simon scale, a scale composed of 30 items arranged according to increasing difficulty (Reisman, 1991). However, the authors of this initial scale admitted that the 30 items did not effectively assess intelligence, and as such, it was adapted to the more sophisticated 1908 Binet-Simon scale. This scale included 59 tests grouped by age levels, from 3 years of age to 13 years of age (Reisman, 1991). The 1908 scale also introduced the concept of "mental age", which was defined as "the highest age level at which the child completed most tests successfully" (Boake, 2002, p. 386); however, Binet expressed concerns about this concept, for he felt it measured a child's intelligence based on the knowledge gained in schooling, not intelligence overall (Reisman, 1991). Despite these concerns, the Binet-Simon scale became the most widely used scale of intelligence in Europe, with American psychologist Henry Goddard translating it for use in America (Boake, 2002).

However, the criticisms of the Binet-Simon scale led to further improvements and research. Augusta Bronner, who had previously worked in Dr. William Healy's child guidance clinic, discussed later in the current chapter, found that test-taking attitudes could significantly impact scores. She also argued that if a child has certain disabilities, such as the inability to read, the intelligence scale would find an invalid score of intelligence (Reisman, 1991). This, and Bridges and Coler's (1917) findings, led to the question of whether intelligence is primarily affected by hereditary factors or one's environment. This question then led to more variations of the intelligence test, accounting for a variety of ages and abilities (Reisman, 1991).

Soon after Binet's work with intelligence came another era in child clinical psychology; the child guidance movement. This movement started with the idea that antisocial behavior can be treated with psychiatric means, including an emphasis on possible pathology (Watson, 1953). Dr. Healy, a psychiatrist and criminologist, helped to establish the first child guidance clinic in the United States in 1909, called the Juvenile Psychopathic Institute, in which clinicians investigated the causes of delinquency in children (Patrick, 1915). Children with mental health concerns were referred to the clinic for scientific study, and information such as their medical examinations, social histories, and recommendations for treatment was collected and presented for the court (Snodgrass, 1984). Within these clinics, the model of mental health emerged, with the disciplines of psychology, psychiatry, and social work intertwined.

Healy went on to publish *The Individual Delinquent*, in which he found no direct cause for delinquency and no clear-cut psychopathology (1915). He also included intelligence tests, possible trauma, and medical infections as evidence for his theory (Levy, 1968). Using this evidence, he argued that emotional disturbances were causing delinquency in children and treatment was needed in an attempt to eliminate these disturbances (Reisman, 1991). Though this book led to some controversy, the theories discussed brought upon change, leading some legal authorities to favor environmental and psychological explanations for delinquency as opposed to organic and hereditary explanations (Reisman, 1991). Healy and Bronner went on to create the Judge Baker Guidance Center in Boston, Massachusetts, eventually becoming the largest child guidance clinic (Routh, 1994). Child guidance clinics were created to promote mental health by preventing mental illness and focused on the issues children were struggling with, including disobedience, sleep disturbances, and overall problematic behavior (Bakker, 2020).

During this time, child guidance clinics were also forming in Europe, with Alfred Adler organizing the first clinic in Vienna (Reisman, 1991). Adler believed similarly to Healy, for he felt that child guidance emphasized the idea that children with behavioral difficulties were often struggling internally (Adler, 1947). Adler studied the differences between children from varied socioeconomic backgrounds as well as those with disabilities and disorders. He was also interested in topics such as birth order and a comparison between "neurotics" and "the criminal child", for he reported that both demonstrate a lack of social interest as well as an increased concern for their own welfare (Adler, 1947). Adler used these theories to guide his work in his child guidance clinics, which were created along the lines of individual psychology (Seidler & Zilah, 1930). Adler's theory of individual psychology emphasized that neurosis does not originate from a defective body part, but rather from the individual's subjective feelings of inferiority (Reisman, 1991).

Introduction of Clinical Psychology

As discussed in the introduction of this chapter, clinical child psychology became the first section of Division 12, The Society of Clinical Psychology, in 1962 (Routh, 1994). After the development of Section 1, a journal was created to represent the section. The first issue of the *Journal of Clinical Child Psychology* was published in 1971, with an emphasis on child advocacy (Routh, 1994).

However, the first clinical psychologist of note was published much before the advent of the journal. C.M. Louitt wrote *Clinical Psychology: A Handbook of Children's Behavior Problems* (1936), in which he discussed diagnostic methods, mental deficiency concerns, and behavior problems. Louitt attempted to use the child's history as well as other psychological factors to understand behavioral problems, breaking down the section into chapters examining topics such as conduct problems, juvenile delinquency, speech defects, and behavior problems correlated with disabilities (Olson, 1937).

The idea of clinical child psychology continued to make itself known in the psychology world following this publication. In 1941, Charlotte Buhler, a psychologist originally from the University of Vienna, began a class on clinical child psychology at Clark University in Massachusetts (Routh, 1994). Bruno Bettelheim worked with children with autism and psychosis at the clinic he founded, the Sonia Orthogenic School. Here he used milieu therapy, a treatment that included the entire staff for therapeutic interactions at all times during the day, instead of the child receiving treatment over the course of a couple of hours (Marcus, 1999). Milieu therapy consisted of thoughtfully arranged supports, personnel, and general procedures according to the patient's overall mental health and needs (Reisman, 1991). The aim of this therapeutic method was to have every interaction and activity therapeutic by providing learning situations in which the child is taught social skills, daily living skills, and appropriate behaviors, among others (Wolf, 1977). Bettelheim felt that this method supported the child's development by increasing mastery in a variety of skills as well as emphasizing interpersonal relationships (Bettelheim & Sylvester, 1948).

Also, the nature versus nurture debate originated around this time, for which children were used as evidence for each side. Due to the increased use of intelligence measures and a resulting increased debate on what a subjective estimate of intelligence is, schools of thought began to develop between the "nature-heredity-organicists" and the "nurture-stressing environmentalists" (Reisman, 1991, p. 189). Beth L. Wellman (1934) conducted research in support of the nurture position, finding that children who attended preschool demonstrated a significant increase in IQ compared to those who did not. She also discussed the idea that environment can play a role in functioning, lower IQs could come out of more impoverished environments, while higher IQs were seen in those who came from more enriched environments (Reisman, 1991).

On the nature side of the debate, British psychiatrist Lionel Penrose (1935) found two cases of intellectual disability. At the time, this was referred to as "mental retardation", which was thought to be produced by a deficiency of a specific enzyme, leading to difficulties of oxidation for specific amino acids. The nature side found scientific evidence for potential causes of intellectual disabilities, whereas the nature side could not explain all of the cases of disability (Reisman, 1991).

Intellectual functioning continued to be a debate through the mid 1900s. During the civil rights movement in the 1960s, poverty was an important topic. In an attempt to break the cycle, early childhood education was emphasized, with attention placed on children at the preschool age (Reisman, 1991). Additional testing measures were created to assess the intellectual functioning of the age group, such as the Wechsler Preschool and Primary Scale of Intelligence (WPPSI: Wechsler, 1967) and the Bayley Scales of Infant Development (BSID: Bayley, 1969).

Following the increased use of these measures came increased questioning as to why children were not performing well academically. Schools found that children were specifically having difficulties with areas such as arithmetic and reading, and instead of being diagnosed as emotionally disturbed or an underachiever, these children were receiving diagnoses such as brain damage or a perceptual handicap (Reisman, 1991). Eventually the term "learning disability" came into use, becoming a central theme for parents and advocates to gain services for children with learning disabilities (Mercer & Hallahan, 2002).

As time went on, more etiologies of disorders were reexamined. Before the 1980s, psychological disorders, such as schizophrenia and autism, were believed to be genetically determined (Reisman, 1991). However, by 1989, schizophrenia was deemed a disease, with researchers advocating to psychologists to change the classification and overall understanding of this disorder. A similar process occurred with autism, a disorder initially termed as childhood schizophrenia (Rutter & Schopler, 1987). Bettelheim, the psychologist responsible for the previously discussed milieu therapy, also conducted research on autism and publishing several books and articles about his work (Bettelheim, 1959, 1967, 1974). Initially, Bettelheim proposed a psychodynamic explanation for the disorder, stating that autism occurs due to the child's inability to develop his or her ego as well as his object relations, or interpersonal relationships (Helm, 1976). He also went as far as to compare autistic children to feral children, concluding that the behavior of both feral and autistic children is largely due to extreme emotional isolation as well as perceived threatening experiences (Bettelheim, 1959). Leo Kanner, one of the first psychiatrists to publish about autism (Kanner, 1943), shared a similar sentiment, arguing that autistic children were reared in emotional refrigerators by refrigerator mothers, attributing the disorder to a lack of parental warmth (Cohmer, 2014)

However, by the 1980s, few psychologists believed his theory, as demonstrated in the DSM-III's classification of autism as a pervasive developmental disorder, instead saying that autism interfered with the infant's early growth (Reisman, 1991). Rutter and Schopler (1987) took the definition of autism a step further, suggesting that it could be considered a syndrome, similar to cerebral palsy or intellectual disability. However, autism does not present with brain structure abnormalities like these two diagnoses.

Along with these clarifications in diagnoses, the field of clinical psychology continued to see significant changes within the population served and society overall. In his Presidential Address at the Clinical Child Psychology Section's Executive Committee Meeting, Jan. L Culbertson discussed the new trends that the field must face, such as a changing ethnic mix in the U.S. population as well as increased immigration rates (1993). Culbertson (1993) recommended a more comprehensive network of services to meet the children's mental, physical, and social needs, a distribution of these services to areas with less access to mental health services, as well as coordination with the various services involved in child mental health, such as health care, education systems, child welfare, and justice systems. Several models were discussed and suggested, such as "Project Wraparound" (Burchard, 1988), a program in which services were "wrapped" around children with emotional disturbances and were used to support their adjustment to mainstream school. These services consisted of school-based interventions, in which a specialist helps develop and implement the child's individualized educational plan (IEP), and of home-based interventions, in which a specialist develops a support plan with and for the family (Culbertson, 1993). Multisystemic treatment approaches, such as this one, continued to develop, addressing both systemic and individual problems with interventions focusing on communities, schools, and homes (Henggeler & Borduin, 1990; Melton & Abramcyzk, 1989).

Professional Development

In 1892, the American Psychological Association was founded at Clark University by G. Stanley Hall and seven other council members, ranging from psychologists to educators and physicians (Reisman, 1991). Hall, a student of William James, founded one of the first psychological laboratories in the United States at John Hopkins University as well as the first American psychology journal, *the American Journal of Psychology*. Hall founded the APA with the ideas of advancement of psychology as a science as well as an association used to promote relations with other professional organizations (Greenwood, 2017). Within the first decade of formation, the APA grew to about 100 members and worked to make gains in the psychological field, especially within the field of diagnostic testing (Reisman, 1991).

Witmer (1907), the psychologist credited with introducing the term “clinical psychology”, used the term clinical to refer to his teaching method, in which instructors, students, and individuals gathered to study, research, and treat mental disabilities and disorders. He believed the clinical psychologist’s role was not composed solely of clinical examinations of individuals in need, but also teaching to demonstrate procedures for students as well as scientifically collecting data for research from every case (Reisman, 1991). Witmer persuaded the administration at University of Pennsylvania to offer formal training in clinical psychology, with courses offered in psychiatry and neuropathology. Eventually, more courses were offered, such as abnormal psychology, developmental psychology, and child psychology (Reisman, 1991). Witmer’s clinic out of the University of Pennsylvania assessed several children and staffed several different specialties, such as students, PhDs, and social workers (Fernberger, 1931).

The success of this clinic led to the establishments of other psychological clinics, such as the Iowa Psychological Clinic out of University of Iowa in 1908 and psychological clinics at Clark University, University of Minnesota, and University of Washington, with the latter two also offering courses in clinical psychology (Reisman, 1991).

Despite the increase of psychological clinics, there was a shortage of trained psychologists working in the clinical field, such that in 1917, only 16 of the 307 members of the APA worked in the nonacademic application of psychology (Reisman, 1991). J.E.W. Wallin also observed this problem in the psychological field, noticing a lack of trained psychologists who could administer and interpret the intelligence tests schools were desperately needing (Routh, 1994). The United States began enacting compulsory attendance laws for school-aged children, leaving teachers overwhelmed with a wide diversity of students and no clear direction of how to teach to a wide range of functioning abilities (Ferguson, 2014). With the advent of intelligence testing, schools were able to test and place children according to their IQ, leading to a dramatic increase in special education classrooms. By 1922, at least 130 cities in 23 states were stating enrollments of over 23,000 pupils in special education classes (Scheerenberger, 1983).

With this increase of special education classrooms came an increased demand in intelligence testing and clinicians who were trained to administer the measure. Wallin organized a training school in which teachers were taught to administer the Binet-Simon scale (Reisman, 1991). The University of Pennsylvania also worked to achieve this goal by offering courses on the study of intellectually disabled children and remedial teaching, as well as opening clinics that focused on speech defects (Fernberger, 1931).

With this increase in classes specialized in clinical psychology and psychological clinics also came an increase in institutions, such as Boston Psychopathic Hospital, McLean Hospital, and New York Institute for Child Guidance, offering clinical psychology internships (Reisman, 1991). The number of clinical psychologists continued to rise with the opportunities available for them to receive training.

Despite this progress made within special education, the classification system of labeling an individual as intellectually disabled was heavily debated. Wallin helped to create a law in which children had to be assessed individually using a standardized test of intelligence before they were assigned to a school for the “mentally defective”, or “intellectually disabled” in today’s terminology (American Psychiatric Association, 2013). Legislation was also introduced that required a psychologist to be included on the panel of experts that determines whether an individual is mentally ill and should be committed to an institution. However, the psychiatric and medical communities were not in agreement as to whether or not a psychologist could be considered an expert on this issue (Reisman, 1991).

This disagreement led to a split within the psychological community. Those psychologists who believed the APA was not representing them well left to form an independent organization, the American Association of Clinical Psychologists (AACP). Its main focus was to raise professional standards of clinical psychologists and encourage research (Routh, 1994). However, the AACP only lasted 2 years, dissolving in 1919. This dissolution was due to psychologists’ opposition of splinter groups within the psychological community, which appeared to weaken their strength, especially following World War I (Reisman, 1991).

Along with the increase in testing came an increase in improvements in the mental hygiene movement. Psychologists worked to prevent mental illness and support those who suffered from it instead of focusing the majority of resources and training on patients requiring hospitalization (Reisman, 1991). Clinical psychology also broadened its horizons to include a wider range of disciplines, such as medical criminology, disciplinary psychiatry, and a discipline called orthopsychics, which placed emphasis not just on delinquent and intellectual disabled individuals but also on the parent-child relationships of these individuals (Lowrey, 1948). In 1924, the American Orthopsychiatric Association was formed (Reisman, 1991), with orthopsychiatry defined as “an interdisciplinary approach to mental health in which psychiatrists, psychologists, social workers, pediatricians, sociologists, nurses and educators collaborate on the early treatment of mental disorders, with an emphasis on prevention” (American Psychological Association, 2020).

Despite the progress psychology made in the public, during the 1920s and 1930s psychiatrists still continued to oppose clinical psychologists, arguing that intellectual disability was solely a medical diagnosis made by medical personnel, not by psychologists (Reisman, 1991). Shepherd Franz (1906), a psychologist and editor of several psychological journals, attempted to bridge the gap, stating that psychiatrists often need psychologists, for psychologists can determine what symptoms and changes in mental states are of clinical importance. On the opposing side, psychiatrists felt that psychologists should not be involved in either diagnosis or treatment, for leaders in the field such as psychiatrist Abraham Arden Brill published articles stating that psychoanalysis should only be performed by physicians (Alexander et al., 1995). The New York legislature agreed with Brill, passing a bill declaring analysis done by any profession other than psychiatry illegal (Reisman, 1991). However, as time went by, psychology came to be considered a science. Clark L. Hull, the president of the APA in 1937, proposed a model designed to build psychological theories by using operationally defined terms and theorems as well as a theoretical system in which to test hypotheses (Reisman, 1991; Paterson, 1937).

With the debate as to what psychologists were effectively trained to do, clinical psychology continued to grow and develop. In 1924, the Section of Clinical Psychology set standards for clinical psychologists moving forward, stating that clinical psychologists should receive a PhD from an approved graduate school and receive 4 years of clinical training, with at least one of those years focusing on diagnosis (Reisman, 1991; Routh, 2000). More journals in the psychological field began to adapt and come out, such as the *Journal of Abnormal and Social Psychology*, originally the *Journal of Abnormal Psychology*. This journal introduced social psychology as a valid branch of psychology and was eventually gifted to the APA in 1926 (Reisman, 1991).

With this growth in clinical psychology came an increased number of clinical psychologists and their overall dissatisfaction with the APA and current clinical guidelines. The APA considered psychologists to be creators and interpreters of tests, but clinicians wanted more freedom within their roles, for clinical psychologists desired to move onto the treatment of behaviors and personality problems, not just the administration of tests (Tulchin, 1930). In an attempt to resolve this, the Section of Clinical Psychology of the APA established a training program in clinical psychology, forming the Committee on Standards of Training for Clinical Psychologists in 1935 (Reisman, 1991). The committee defined clinical psychology as the art and technology that deals with adjusting problems of human beings and laid out training recommendations for clinical psychologists (Report of Committee, 1935). Though these training recommendations were implemented across graduate programs, clinical psychologists were still unhappy with their limitations within the APA, and the Clinical section of the APA disbanded in 1937, forming the American Association of Applied Psychology (AAAP) (Routh, 1994). The AAAP took over the American Association of Consulting Psychology and organized itself into four sections; consulting psychology, clinical psychology, educational psychology, and business and industrial psychology (Reisman, 1991). Despite its initial success, which included 615 members by 1941, the AAAP still looked to the APA for guidance and leadership (Reisman, 1991). In 1942, the AAAP was incorporated into the APA, creating a more federal association with 18 new divisions, each representing a special interest group (Routh, 1994).

Following World War II, psychology grew in popularity and prestige, with a significant increase in college students studying psychology (Fischer & Hinshaw, 1946). Clinical psychology also became more popular within the APA, with 53% of those affiliated with the association expressing an interest in the clinical field (Hilgard, 1945). The APA Committee on Training in Clinical Psychology (1947) detailed classes required for graduate programs, such as statistics, diagnostic methods, and general psychology.

With the increase of clinical psychology graduate programs came an increase in clinical psychologists in need of legal recognition and certification. Beginning in 1945, states began enacting general certification laws for psychologists (Reisman, 1991). Also, the importance of internship was becoming emphasized and recognized. Clear guidelines were created for the types of supervision and training clinicians should receive, with internships providing opportunities for clinicians to hone clinical skills as well as become acquainted with raw data in the field in order to complete research later on (Raimy, 1950; Foster et al., 1952).

With the increase of clinical psychology students came the discussion of current training models. The Conference on Graduate Education in Clinical Psychology, which eventually became known as the Boulder Conference, concluded with a detailed training model called the Boulder Model (Routh, 1994). The Boulder Model, or the scientist-practioner model, emphasized diagnosis, therapy, and research within graduate training programs for clinical psychologists (Baker & Benjamin, 2000). The practioner model was later introduced in the 1960s, with less emphasis on research and more on practical courses, like treatment and assessment methods. The student would receive a PsyD instead of a PhD and work in five laboratories related to clinical psychology, when a PhD student was only required to work in two (Reisman, 1991).

By the 1970s, clinical psychology became a more recognized scientific field including medical specialties within its reach, with several divisions created within clinical psychology, such as clinical neurophysiology and pediatric psychology and clinical psychophysiology (Feuerstein & Schwartz, 1977). By the 1980s, clinical psychology was the dominant branch of psychology in the United States, with more PhDs being given in clinical psychology than any other field (Reisman, 1991).

Theories

Clinical child psychology also played a significant role in the development of crucial psychological theories. For example, the fundamentals of behaviorism may have found its footing in clinical child psychology. John B. Watson believed that behaviorism was the most objective branch of psychology, for its theoretical background was the prediction and control of behavior (Watson, 1913). He also emphasized that one's environment and training were the fundamentals of behavior (Watson, 1928). Watson, upon studying infants, found that the only unlearned behaviors are those of simple motor responses and emotional reactions, whereas the more complicated behaviors and responses are learned through conditioning (Reisman, 1991).

Watson assessed his theory of conditioning through an experimental study on Albert, a 9-month-old child who initially did not demonstrate any fear towards live animals, including a rat, but did demonstrate a fear response when a loud sound was made behind his back (Harris, 1979). In order to condition the child to fear the rat, the rat was shown to Albert and was immediately followed by the loud sound. Watson continued to pair the two stimuli for several sessions, testing the fear response days later by presenting the rat along with various other objects. Albert displayed a strong fear response to the rat along with other similarly furry animals, such as a dog and a rabbit (Harris, 1979). Watson concluded that children can demonstrate emotional conditioning towards certain stimuli, leading to conditioned fears (Watson, 1919).

Mary Cover Jones, under the supervision of Watson, was also interested in behavior therapy in the treatment of children's fears (Goodwin, 2010). In her studies, Jones took Watson's work a step further, incorporating methods such as social imitation and modeling, for she found that if a child with an existing fear of a rabbit sees other children playing excitedly with the rabbit, his fear response was quickly reduced, and he was able to interact with the rabbit (Jones, 1924).

Jean Piaget, one of the founders of the Gestalt school of psychology, also used child research as foundations for his theory, as he found that children use two different kinds of speech (Reisman, 1991). Children around the ages of 5 and 6 used egocentric speech, in which the child is unable to differentiate his or her perspective from others (Kohlberg et al., 1968) and the child's speech was characterized by a lack of concern about whether others attended to what the child was saying or what the listener may be thinking (Reisman, 1991). The second kind of speech was socialized speech, in which the speaker used language as an intentional way to communicate with others, considering the reactions and perspectives of the listeners (Reisman, 1991). Piaget's work provided significant evidence for developmental psychology as well as methods for data collection for clinical child psychology, for he demonstrated that observations of children done in natural settings can display interesting findings on human functioning (Reisman, 1991).

Child development, a critical component of clinical child psychology, had also been studied years prior to the creation of Section 1, with several psychologists contributing to the field. Arnold Lucius Gesell analyzed the early motor, cognitive, and emotional development of infants, creating a theory of sequences through which children move through (Dalton, 2005). The Gesell Developmental Schedules were made up of 26 age levels of developmental maturity from birth through the age of 5. Four areas of development were assessed: motor, adaptive, language, and personal-social (Gesell & Doll, 1953). These scales were used by parents to assess their child's developmental milestones (Reisman, 1991) as well as in research (Beckwith et al., 1976; Roe, 1978).

Prominent psychoanalysts also contributed to the field of clinical child psychology. Melanie Klein published *The Psycho-Analysis of Children* (1932), in which she described how children demonstrated their unconscious fantasy life through free, undirected play. She collected evidence for this theory via "play therapy" in which she used Freud's analytic therapy of free association, such that the child was instructed to play with simple toys, and the analyst interpreted the play, developed positive and negative effects, and resolved the issue, all through a type of "transference-neurosis" (Klein, 1933).

Play therapy continued to be researched following Klein's work in the area. Frederick Allen, the director of the Philadelphia Child Guidance Clinic, worked to create significant gains in the therapeutic relationship between the child and therapist (Reisman, 1991). Allen emphasized the importance of accepting the child as he or she was at that moment in time and helping him or her understand and accept who he or she is. He also believed in understanding his own limitations as a therapist and did not want his clients to see him as omnipotent (Allen, 1934).

Play therapy became a popular form of treatment for children, for therapists found it was a method for children to be able to communicate through free play. In the 1930s, therapists believed play served two functions; it was considered to be a natural medium through which children could express fantasies and difficulties, and the therapist could use the play to impress the child and gain his or her confidence (Reisman, 1991). David Levy (1939) used play as the basis for his release therapy, in which children acted out or "played" their anxieties, fears, or undesired behaviors in an attempt to understand their own motivation and express their feelings. Levy (1939) also believed play could be used as a diagnostic tool, in which the therapist would create a situation using the toys at hand and encourage the child to interact and react to the scenario. Over the years, play therapy has become an effective form of treatment, with positive effects observed in areas such as social maladjustment, autism, conduct disorder, and speech or language concerns (Ray & Bratton, 2010).

The stages of development also became a popular and important topic of research, following reports of the aftereffects of children raised in orphanages (Reisman, 1991). Harry F. Harlow and Margaret Kunne Harlow (1962) found that monkeys raised without a mother and any physical contact of peers grew to be socially inept, aggressive, and overall unable to function as expected in their daily lives. The authors compared these results to the observations of children deprived of mothering in orphanages, finding similar symptoms of emotional pathology (Harlow & Harlow, 1962).

Mary Ainsworth and John Bowlby took Harlow's work a step further by examining the relationship between mother and child. Bowlby believed that children required a close and continuous caregiving relationship and did not agree with the current explanation for this relationship offered by the psychoanalytic view, in which motherly love comes from oral gratification, or the social learning theory, in which dependency is considered secondary reinforcement (Bretherton, 1992). Bowlby argued that an infant's clinging to and following around its mother was more important for attachment than other behaviors such as sucking and crying (Bowlby, 1958).

Eventually, Bowlby formulated the attachment theory (Bowlby, 1958, 1959, 1960), with Ainsworth contributing and refining it (Ainsworth 1967; Ainsworth & Bell, 1970). The researchers examined how the relationship between mother and infant, and possible separation between the two, impacted the child's development. Ainsworth observed families of unweaned babies, focusing on the signals and behaviors of the child and whether these signals and behaviors were directed towards the mother. She found that infants who securely attached to their mothers cried less and explored more when near their mothers when compared to insecurely attached infants, who cried often and explored little (Bretherton, 1992). She continued to examine this pattern by means of the Strange Situation, a laboratory procedure in which mother and infant interacted in a playroom for a period of time until an unfamiliar woman entered the room. The stranger interacts with the baby, and the mother leaves the room, only to return shortly. The stranger leaves and the mother leaves next, leaving the child completely alone (Ainsworth & Wittig, 1969). Ainsworth confirmed her results, and she and Bowlby used these behavioral findings to create their attachment theory, in which attachment has its own motivation and is not due to other evolutionary processes, such as mating and feeding (Bretherton, 1992). Instead, the attachment figure (i.e., the caregiver) provides a secure base for the child to explore its environment as well as provides a safe haven to return to for reassurance and comfort (Ainsworth 1967; Schaffer and Emerson, 1964).

Bowlby used the work of Piaget to support his argument. After working with Binet on his IQ measures, Piaget became interested in how the child's mind worked, which resulted in his development of stages of cognitive development (Reisman, 1991). The first stage, the sensorimotor stage, occurs in infancy, in which the infant learns through motor activity, and his or her intelligence is based on interactions and experiences. The child begins to develop object permanence and some language skills (Ojose, 2008). The next stage, the preoperational stage, occurs during toddler and early childhood, in which the children begin to use symbols, language, and imagination (Huitt & Hummel, 2003). The child also begins to assume causality and relationships between events, becoming more aware of people and his and her immediate environment (Reisman, 1991). The next stage, the concrete operational stage, occurs in elementary and early adolescence, in which operational thinking occurs and the child begins to learn and understand more logical concepts such as time, constancy, volume, and mass (Huitt & Hummel, 2003). In the final stage, the formal operational stage, occurring during adolescence and adulthood, the individual is able to apply the logical use of symbols to abstract concepts, predict future events, and consider possible circumstances or consequences (Huitt & Hummel, 2003; Reisman, 1991).

Treatment

Following the development of these theories came the development of effective and evidence-based treatments to support children with commonly occurring disorders, such as the two discussed below.

Advancements in Treatment of Child and Adolescent Anxiety

Anxiety disorders represent the most commonly occurring mental health disorder in children (Cartwright-Hatton et al., 2006) and adolescents (Merikangas et al., 2010). Though it was not officially classified as an illness before the nineteenth century, there is evidence that anxiety has been clearly defined as a negative affect and a separate disorder by Greco-Roman philosophers and physicians (Crocq, 2015). Over the years, various treatments have been created for anxiety disorders in children. Ollendick and King (1998) presented the first review of treatments that used the guidelines set by the American Psychological Association (APA) Task Force on Promotion and Dissemination of Psychological Procedures, in order to assess the efficacy of these treatments. The authors assessed specific psychological procedures, such as systematic desensitization, modeling, self-instruction, and cognitive-behavioral interventions, finding that only cognitive-behavioral interventions with and without family anxiety management were efficacious (Ollendick & King, 1998). A decade later, Silverman et al. (2008) conducted another review on anxiety treatments for children and adolescents, focusing on group design studies and named treatments (e.g., *Coping Cat*; Kendall, 1994). The authors did not find well-established treatments, but did find five treatments that were possibly efficacious, and three deemed experimental (Silverman et al., 2008), according to Chambless and colleague's criteria (Chambless et al., 1996, 1998).

Higa-McMillan et al. (2016) conducted a review of treatment outcome studies from 1967 to mid-2013. Out of the 111 treatment outcome studies testing 204 treatment conditions, six were considered well-established status for treating child and adolescent anxiety, eight were considered probably efficacious, two were possibly efficacious, six were deemed experimental, and eight treatments demonstrated questionable efficacy (Higa-McMillan et al., 2016). Overall, CBT and exposure-based therapies were the most efficacious for children with anxiety. The authors surmised that treatment is most effective when it is based upon the child's unique circumstances, such as family characteristics, where the services take place, and type of treatment (Higa-McMillan et al., 2016).

Advancements in the Treatment of Autism Spectrum Disorder

In 1987, O. Ivar Lovaas wrote about the effectiveness of a behavioral-intervention project working to make behavioral gains in young children with autism (Lovaas, 1987). He found that intensive behavioral treatment significantly treated children with autism, for 47% of the experimental group achieved typical intellectual and educational functioning (Lovaas, 1987). The treatment was based on operant conditioning theory and included methods such as ignoring aggressive and self-stimulatory behavior, shaping more acceptable forms and behavior, building compliance, teaching imitation, and then teaching expressive language and interactive play, among other goals (Lovaas et al., 1980). Studies like these and others (McEachin et al., 1993) demonstrated the plasticity of autism and the possibility of significant gains given appropriate intervention. Rogers and Vismara (2008) conducted a review examining the efficacy of early interventions of autism and found that Lovaas' treatment met well-established criteria, no treatments meeting probable efficacious criteria, and three meeting possibly efficacious criteria.

Loovas went on to develop one of the most evidence-supported and popular treatments for ASD, applied behavior analysis (ABA) (Roane et al., 2016). Initially referred to as early and intensive behavioral intervention (EIBI), ABA is conducted 5–7 days a week up to 40 h a week, using discrete-trial training as its main method, in which skills are taught in a repeated and brief fashion with specific instructions. Data are then collected during these trials to determine the child's progress (Lerman et al., 2011). ABA is one of the most accepted forms of treatment for ASD, for the majority of insurance companies require treatments to incorporate the principles of ABA within its model (Roane et al., 2016).

Conclusion

Clinical child psychology, though not an officially used term at the time, played a significant role in the advancement of psychology as a science. Psychology over the decades broke into several branches, one of which was clinical psychology, a hands-on field that psychologists fought to create in order to use their clinical skills to diagnose and treat individuals (Franz, 1906; Tulchin, 1930; Routh, 1994). Children played a role in the creation of these branches within psychology, for they were used to develop the theory of intelligence (Boake, 2002), and the study of their development played a significant role in psychological theories such as delinquency (Healy 1915) and attachment (Bowlby, 1958, 1959, 1960; Ainsworth, 1967). Advancements in public education also help to progress the field of clinical psychology, for the increase in special education classrooms (Scheerenberger, 1983) and the present movements, such as the civil rights movement, which emphasized early childhood education (Reisman, 1991), led to major breakthroughs and developments in education (Mercer & Hallahan, 2002; Ferguson, 2014).

As time went on, clinical child psychology continued to improve upon psychology overall via several avenues, such as encouraging the creation and implementation of multisystemic interventions of children at risk for emotional or behavioral disturbances (Culbertson, 1993) and playing a significant role in the treatment of commonly occurring disorders that often first manifest systems during childhood (Ollendick & King, 1998; Rogers & Vismara, 2008).

Overall, clinical child psychology has held a significant role in psychology's history starting as early as the 1900s. Since the foundation of psychology, field clinicians have fought to be considered clinical psychologists and be allowed and trained to do the work they felt passionate about. Clinical psychology continues to be a popular and powerful branch of psychology (Reisman, 1991) and its inclusion in the study of children has led to significant improvements in the diagnosis and treatment of disorders (Roane et al., 2016).

Developmental Psychopathology

2

Christopher T. Barry, Hyunah Kim,
and Brianna M. Halter

Based on considerable research over the past few decades, it is now well understood that the assessment, diagnosis, and treatment of mental health difficulties in children and adolescents should be conducted through a developmental lens. Throughout this process, ongoing or potential avenues for treatment are determined by whether a presenting problem represents atypical development or an exaggeration of a typical developmental process. Fortunately, the discipline of developmental psychopathology provides an ever-growing, empirically based framework for the consideration of these issues and key concepts grounded in empirical evidence. Important factors in a developmentally informed approach to assessment, case conceptualization, and treatment include age of onset of a psychological difficulty or timing of exposure to a significant/traumatic event, severity of the problem, and intensity of the problem (Costello, 2016). Inarguably, a child's psychosocial functioning must be understood within important contexts such as home, school, peer, community, and culture. As described throughout this chapter, the developmental context is also important for conceptualizing and determining intervention options for child and adolescent maladjustment.

A central contribution of research in developmental psychopathology has been to elucidate developmental pathways and progressions involving adaptive and maladaptive functioning in youth. One such example is highlighting the lack of evidence for assuming one cause/precursor for one psychological outcome or one result from one risk factor. That is, the concepts of equifinality and multifinality reflect the complex realities of psychological adjustment throughout development. They describe processes by which one psychological problem may stem from multiple causal pathways (i.e., equifinality) and how one event or risk factor can result in a variety of outcomes (i.e., multifinality; Cicchetti & Rogosch, 1996). Relatedly, the possible presentations of a specific disorder or problem are tremendously heterogeneous based, in part, on these diverse developmental pathways.

Another cornerstone of developmental psychopathology involves accounting for multisystemic or multilevel variables as possible risk or protective factors during youth and adulthood. Such factors may include identity variables such as race (Anderson & Mayes, 2010; Gutman, 2019) or gender (see Rutter & Srouffe, 2000); supportive or non-supportive systems (e.g., family, Simpson et al., 2018; Womack et al., 2019; school; Fite et al., 2014, Vancraeyveldt et al., 2015; neighborhood, Riina et al., 2013); psychopathology related to the development of further difficulties or impairments; and contex-

tual factors, including socioeconomic status as well as community health and safety (Cui et al., 2018; Jeon et al., 2020; Neal & Neal, 2013; Smokowski et al., 2014). Multilevel conceptualizations are necessarily more complex and nuanced but also more comprehensive for understanding youth adjustment at the individual and population levels. Continued efforts to incorporate these factors into understanding the phenomenology of psychological constructs during childhood and adolescence will also result in more accurate and generalizable information on developmental norms.

Data on developmental norms are critical in developmental psychopathology and allied disciplines. Vast research on normative development guides clinical assessment, diagnosis, and treatment within a developmental psychopathology framework. That is, psychological problems across the lifespan can and should be understood from what is known regarding typical development. For example, hyperactivity is often not a focus of diagnostic assessments or intervention efforts in the preschool years because behavior dysregulation in the form of running around, restlessness, and difficulty remaining seated is considered quite common during that time.

Developmental research underscores the need to make norm-referenced comparisons in childhood based on relatively short periods given the substantial amount of psychosocial development that takes place during each timeframe (Frick et al., 2020). However, this need for a short window of time diminishes as development starts to slow. To illustrate, comparing an adult to other individuals who are 10 years older would not be fraught with nearly as many problems as would comparing a child with other youth who are 10 years their senior.

A further consideration is that when a problem is impairing or at an atypical severity or frequency, that presentation may be qualitatively different than what may be expected at an individual's age or developmental stage. Alternatively, the problem may simply represent an exaggeration in severity or frequency of a typical developmental process. The former is represented by a young child demonstrating symptoms of depression. The latter process is exemplified by adolescent-onset conduct problems, as some degree of rule-breaking or illegal behavior is normative during this period when youth typically attempt to assert their autonomy and commonly experience less parental monitoring as well as more peer engagement (Loeber et al., 2009). Intrafamilial factors, however, may help further explain relative fluctuations in delinquency during adolescence, with greater disclosure between adolescents and parents predicting lower levels of delinquency (Keijsers, 2016).

A clinician must, therefore, have good knowledge not only of developmental norms but also of common developmental processes and tasks throughout childhood and adolescence. To that end, decades of research on developmental psychopathology inform clinical work with children and adolescents through several guiding principles. First, there is *tremendous heterogeneity within diagnostic categories* (e.g., Klein et al., 2005; Masi et al., 2017). Within the *DSM* diagnostic framework, an individual can meet the criteria for a diagnosis through a variety of symptom presentations, expanding the varied ways in which a disorder may present itself. However, perhaps more importantly, there are clear individual differences in how psychopathology is expressed, differential influences of important contexts, and as discussed below, developmental influences on the manifestation of clinical difficulties. Another factor in the heterogeneity of clinical presentations that has been discussed in the context of autism spectrum disorder is *chronogeneity* (Georgiades et al, 2017), which reflects the varied paces at which developmental gains are made within and across individuals, further adding to the complex and heterogeneous forms with which clinical problems present themselves in childhood and adolescence.

Second, *in clinical settings, comorbidity is typical for children and adolescents* (see Drabick & Kendall, 2010; Mash & Hunsley, 2005). More specifically, youth with difficulties in one area of functioning (e.g., ADHD) tend to experience problems in other areas (e.g., learning problems, conduct problems). That is not to say that children and adolescents should routinely receive multiple diagnoses, especially if some areas of concern are thought to be secondary to a primary diagnosis. Instead, clinical assessments and intervention recommendations should encompass a variety of areas of functioning to reflect the reality that youth may struggle across domains. Third, *youth who experience subclinical difficulties in psychosocial functioning can still benefit from targeted interventions* on the construct(s) connected to the most impairment or distress for them (e.g., Jaycox et al., 1994). This conclusion may be especially true for youth who experience subclinical learning or attention problems within school, but may not meet other criteria necessary to receive a clinical diagnosis. For example, reading difficulties are a prevalent concern in young children that teachers are often able to assess (Virinkoski et al., 2018). School-based identification programs may also be of use for intervention of youth and adolescents who are experiencing subclinical academic or mental health difficulties that may have otherwise been missed (Anderson et al., 2019).

Fourth, *in the general population, the distribution of clinical constructs is positively skewed* (Frick et al., 2020). That is, most youth tend to experience relatively low levels of concerns in emotional or behavioral domains. Conversely, the distributions of age-appropriate adaptive skills are negatively skewed (Sparrow et al., 2016), with most youth demonstrating increasingly complex adaptive skills as they get older. Fifth, *the psychological functioning of children and adolescents is heavily influenced by context, and children's behaviors also influence their surroundings* (Frick et al., 2020). Thus, an assessment of the factors that exacerbate or mitigate a child's difficulties should be a focus of assessment and intervention efforts. Lastly, *most developmental processes tend to be continuous rather than discontinuous, with developmental transitions marking the most likely time of discontinuity in functioning* (Cicchetti & Rogosch, 2002). Thus, understanding the trajectory of normative continual changes is important for explaining apparent disconnects. Discontinuity in a child's functioning may point to significant events or risk factors that exacerbate problems or to the implementation of valuable supports.

This chapter will discuss current knowledge and examples concerning the relevance of age of onset, developmental course, and influence of developmental context on the manifestation of child and adolescent psychopathology. As part of this review, we will note important developmental tasks that may also influence conceptualization of typical vs. atypical development for youth, adjustments that often occur at different stages of childhood, and the influence of development on assessment data itself (e.g., early recognition of hyperactivity relative to inattention). The utility of empirical findings from developmental psychopathology will be emphasized as foundational for the assessment, diagnosis, and treatment of children and adolescents. We begin with age of onset as it relates to the conceptualization and potential outcomes of youth psychological problems.

Age of Onset

Substance abuse is perhaps the most striking example of the importance of age of onset for conceptualizing psychological problems in youth. More specifically, a preadolescent or early adolescent onset of substance use is much more unusual, and therefore deviant, than a later adolescent-onset of such behavior. Furthermore, an early onset of substance use and other conduct problems is associated with a more severe and persistent pattern of externalizing behaviors (Moffitt, 1993; Odgers et al., 2008). In contrast, conduct problems that emerge during adolescence are more common and appear to represent a relatively temporary and less severe form of exploration, as the adolescent gains more autonomy, spends more time with peers, and experiences a likely developmental peak of risk-taking (Gardner & Steinberg, 2005; Moffitt, 1993; Monahan et al., 2013; Steinberg, 2010). Simply put, the same problem behavior is viewed quite differently based on the timing of its onset.

Developmental norms also provide insight as to the typical onset of a particular problem. As infants begin to demonstrate age-appropriate motor, cognitive, language, and even social skills, a general developmental surveillance, such as that conducted by a pediatrician, can begin to detect potential delays. To that end, more severe cases of some disorders (e.g., autism spectrum disorder (ASD), Shattuck et al., 2009; intellectual disability, see Patel et al., 2020) are typically detected and diagnosed relatively earlier than less severe presentations. For instance, a young child who does not exhibit age-appropriate expressive language may be evaluated for possible ASD or other developmental concerns earlier than a child whose language skills appear to be normative (Goodwin et al., 2017). It may not be until later that subtle signs of repetitive behaviors or poor social reciprocity are detected in the child with age-appropriate expressive language. As another example, the relative typicality of separation anxiety in early childhood (e.g., Calkins et al., 2015) provides an impetus for parents and others who work with young children (e.g., daycare workers) to develop strategies for dealing with the outbursts and escape/avoidance behaviors that may be present. Those who work with adolescents presumably understand the importance of monitoring for mood symptoms given the increase in depressive episodes during that period of development (Avenevoli et al., 2015).

Importantly, across childhood and adolescence, relatively early onset is associated with a worse prognosis for conduct problems (Silberg et al., 2015), anxiety disorders (Lim et al., 2013; Ramsawh et al., 2011; Rosellini et al., 2013), depression (Hammen et al., 2008), bipolar disorder (Propper et al., 2015), and psychosis (Veru et al., 2016). This general pattern applies to recurrence of symptoms, later adjustment, and the development of more varied, or comorbid, clinical difficulties. Furthermore, age of onset may provide clues as to the underpinnings of behavioral or emotional maladjustment for children and adolescents. More specifically, early onset may point to temperamental or neurobiological factors for constructs such as social anxiety and conduct problems, whereas later onset may be suggestive of critical social context factors or acute events (see McLaughlin & Hatzenbuehler, 2009; Rosellini et al., 2013) that are not stable in comparison to dispositional factors. Although early identification presents an opportunity for early intervention to deviate from a prolonged and severe course, the factors involved in a late onset may be more easily targeted for intervention. Said differently, adolescent psychopathology that is influenced by context may be ameliorated when relevant situational factors are altered or removed.

Within early and late onset trajectories, the developmental course of a problem is influential in a child's functioning. That is, age of onset is but one important factor in the understanding of developmental psychopathology. The developmental course of the child's difficulties has implications for prognosis and response to treatment. Aside from individual differences in the developmental course of psychological difficulties, the typical course may also be tied to the construct itself.

Developmental Course

The apparent trajectory of a psychological difficulty is an important component for case conceptualization and treatment. Here again, differentiating between normal developmental changes in childhood and adolescence and those that may signal meaningful shifts in functioning is crucial. The differential influence of important contexts such as familial and peer influences on the course of a problem must also be incorporated into assessment designs and case conceptualizations. Moreover, as discussed below, there are developmental changes in how some constructs, such as anxiety or depression, present through childhood and adolescence. These different trajectories add complexity to the assessment process, but knowledge of potential developmental changes in the course of psychological difficulties can assist in assessment of key features of a construct, as well as the recommendation and implementation of developmentally appropriate treatment strategies.

Guided by a wealth of longitudinal research across clinical domains, important areas of psychological functioning can be conceptualized as developmentally stable (e.g., Carballo et al., 2010; Morken et al., 2020), escalating in frequency or severity, declining in frequency or severity (e.g., Lahey et al., 2005), developmentally variable, or cascading into the development of different problems (e.g., Kim & Cicchetti, 2010; Nigg et al., 2020). These trajectories may be particularly associated with certain constructs, the onset of the problem (with earlier onset predicting a more stable course as described above), and even factors like child gender (e.g., Dekker et al., 2007; Moffitt, 2018; Yaroslavsky et al., 2013). There may also be important developmental underpinnings, such as early temperament or early important contextual experiences, for these trajectories. For example, temperamental factors may predict the early emergence and escalation of depressive and anxiety symptoms (Côté et al., 2009).

Stable Course Some emotional and behavioral difficulties may run a stable course in childhood. Of course, the term "stable" is considered in relative terms, as child and adolescent functioning can be expected to fluctuate tremendously based on situational or contextual factors. In general, childhood internalizing problems are less stable than many types of externalizing problems (e.g., Van Oort et al., 2009). More specifically, anxiety and depressive symptoms may fluctuate based on contextual or acute situational factors such as the presence of relational problems or stressful events (Jenness et al., 2019; McLaughlin & Hatzenbuehler, 2009), whereas youth who exhibit impulsivity and oppositionality from an early age may be more likely to persist with such behaviors throughout childhood than their same-aged peers (Olson et al., 1999). This pattern is particularly descriptive of youth whose behavioral dysregulation is rooted in genetic or neurobiological factors (Niv et al., 2012). It is important to note, however, that although relative stability may characterize externalizing behaviors, an individual's absolute level of behavior dysregulation tends to decline with age (see below).

Researchers highlight factors that may predict stable courses for internalizing problems in youth. The stability of depression may depend on the accumulated stress experienced during childhood and adolescence; that is, for youth predisposed to negative affect or depressive symptoms, accumulated stress may serve to maintain these difficulties (Whalen et al., 2016). Based on longitudinal research with twins, the stability of trait anxiety appears to be most closely influenced by genetic factors, with the influence of shared environment diminishing across adolescence and into adulthood (Garcia et al., 2013). Similarly, continuous/persistent anxiety during middle childhood is largely related to genetic factors and manifests as social anxiety, separation anxiety, or panic disorders (Trzaskowski et al., 2012).

Lastly, as described in the previous section, children who experience an earlier onset of psychological difficulties, such as conduct problems, tend to exhibit relative stability of such problems across childhood. In this way, a given individual's developmental history, rather than the construct per se, may also lend further insight into their prognosis. Certainly, without early intervention, children with any type of emotional or behavioral difficulties are at risk for increasing problems, particularly in terms of severity, and a worse long-term prognosis.

Increasing Course A common developmental trajectory for psychological difficulties is for them to escalate in severity through adolescence and adulthood. For example, this course often applies to early onset conduct problems (Lahey & Loeber, 1994). For a child with a history of behavioral problems, adolescence brings further opportunities for conduct problems such as substance use or property offenses. That is, such a child may escalate into additional forms of antisocial behavior given the greater opportunities to do so with the increased autonomy of adolescence. Depressive symptoms also appear to markedly increase in adolescence relative to childhood, particularly among females (Silberg et al., 1999).

Moreover, the presence of psychological difficulties early in childhood may set the stage for the emergence of more severe and varied problems. For example, in boys and girls, higher levels of ADHD symptoms at ages 6–12 are related to greater risk for suicidality at ages 13, 15, and 17 (Forte et al., 2020). Callous-unemotional (CU) traits (e.g., lack of empathy, lack of remorse/guilt) serve as such a marker for youth with conduct problems (see Frick & Kemp, 2020). The cooccurrence of anxiety, oppositionality, and CU traits early in childhood is associated with aggression and impairments in executive functioning and social cognition later in childhood (Ezpeleta et al., 2017). In addition, early externalizing problems are predictive of later substance use (Sitnick et al., 2014) and internalizing problems (Moilanen et al., 2010). Such evidence underscores the importance of early identification of psychopathology and the ongoing assessment of a variety of potential cooccurring symptoms.

An important challenge in the assessment of constructs that become more normative or typical in adolescence is determining when the problems become severe or pervasive enough to warrant intervention and/or diagnosis. This issue is central to the field of developmental psychopathology and involves distinguishing between a temporary increase in maladjustment, which is relatively less severe or pervasive, and an issue that serves as an early indication of an enduring problem. Factors that may assist in appropriate decisions and treatment planning include the age of onset (see above), family psychiatric history, comorbidity, and the social context of the psychological difficulty (Frick et al., 2020). Regarding social context, because adolescence is typically a time of increased peer socialization, a lack of such social contact may be cause for concern for internalizing problems (Rudolph et al., 2008). Perhaps ironically, delinquent peer affiliations are a risk factor for conduct problems (Laird et al., 2005), yet acting out behaviors that occur in the context of peer activities during adolescence might be considered a sign of relatively transient behavioral problems (Hamalainen & Pulkkinen, 1996). Assessment of relevant risk and protective factors in a child's developmental context is critical for attempts to circumvent an escalation of psychological problems throughout youth and into adulthood.

Decreasing Course Numerous areas of maladjustment commonly follow a decreasing course during childhood. In such cases, decreasing frequency or severity of a particular problem may be due to improved emotion and behavior regulation as a child gets older (Perry et al., 2018). More specifically, in early childhood, conduct problems typically involve indications of a difficult temperament and behaviors of dysregulation (e.g., temper outbursts, aggression), with these specific types of difficulties diminishing over time (Loeber, 1990), even if conduct problems take different forms for such children during adolescence. Regulation may develop through natural, seemingly spontaneous, developmental processes such as are often described for nocturnal enuresis (Baird & Atchison, 2021) or through learned experiences and environmental modifications such as may be the case for decreased temper tantrums (McCurdy et al., 2006).

As yet another example, hyperactivity/impulsivity tends to decline with age, as do inattentive symptoms, although this latter decrease tends to be more gradual or steady over time (e.g., Biederman et al., 2010; Leopold et al., 2016). Still, current diagnostic nomenclature allows for some persistence of hyperactivity with overall restlessness being a proxy for symptoms such as "acts as if driven by a motor" for older children (American Psychiatric Association, 2013). In general, youth who experience symptoms of ADHD may expect the severity and frequency to decrease as they approach adulthood (Bramham et al., 2012). However, adults, unlike children, have greater autonomy in selecting activities that may play to their personal strengths while not requiring a level of sustained attention and impulse control that might be difficult for them. In this way, ADHD represents one of many areas, which include adaptive and academic skills, as well as emotion and behavior dysregulation, that may be expected to improve with appropriate interventions as children get older. Proper early assessment of a child's specific strengths and impairments can facilitate this process.

Variable Developmental Course Of course, the trajectory of psychopathology at the individual child level most often should be considered variable, despite the evidence just described. Further, the predominant pattern for some clinical constructs may be a variable developmental course. Early temperamental factors may be predictive of different developmental trajectories of a specific disorder (e.g., Lee et al., 2017). CU traits are an example of such a precursor for conduct problems (e.g., Dadds et al., 2005). However, the degree or specific nature of conduct problems that may develop in the presence of CU traits is quite variable. Therefore, the complexity of psychopathology across developmental contexts is generally consistent with the core concept of multifinality.

Trauma, in addition to being arguably the most clear example of multifinality in developmental psychopathology, typically follows a variable path across and within individuals, partly as a function of development (Contractor et al., 2013; Masten & Narayan, 2012). Adolescents can be expected to exhibit more of the cognitive aspects of posttraumatic stress disorder (PTSD) such as intrusive thoughts and emotion cue reactivity, along with dysphoria, than children. On the other hand, younger children may exhibit relatively more frequent hypervigilance and anxious arousal (Contractor et al., 2013). As with many other psychological difficulties, the variable course may be a function of additional external stressors and the individual child's social and cognitive development.

Peer victimization, as another example of multifinality, can result in varied impairments that follow different courses depending on the nature of the victimization, as well as the victim's gender and age (Kretschmer et al., 2015; Roeder et al., 2014). Gender may also play a role in the variable trajectories of some specific psychological difficulties, such as generalized anxiety, with females increasing in these symptoms during adolescence and males demonstrating the opposite pattern (Hale III et al., 2008). For depression, the gender ratio appears to be roughly equivalent prior to adolescence, with females being more likely than males to be diagnosed with depression beginning in adolescence and continuing into adulthood (Hankin et al., 1998). Females are also more represented among adolescents who exhibit a high and stable profile of depressive symptoms (Yaroslavsky et al., 2013).

Lastly, the developmental course of anxiety may vary depending on the type of anxiety or contextual and intrapersonal factors that influence a young person's experience of distress. Overall anxiety and fears may decrease from childhood to adolescence (McLaughlin & King, 2015), particularly depending on individual differences in anxiety sensitivity (Allan et al., 2014). Some findings indicate that panic symptoms and social anxiety decrease from early to late adolescence (Hale III et al., 2008) perhaps as a function of improved emotion regulation or coping strategies. However, others suggest the opposite pattern with social anxiety and panic symptoms increasing later in adolescence, with factors such as the quality of social experiences moderating this trajectory (Weems, 2008). Relative to other forms of psychopathology, therapeutic approaches for anxiety differ based on the specific manifestation or source of the anxiety. Thus, not only is accurate assessment of symptoms essential, but consideration of case-specific moderating factors that might predict an individual's developmental course of anxiety is necessary.

As noted above, developmental changes are often continuous or gradual, but discontinuity can also be observed. This discontinuity is a primary factor in variable courses of psychopathology and can be represented by trauma (Masten & Osofsky, 2010), upheaval in a child's life (Block et al., 1986), significant illness/injury (Northam, 1997), or cultural discontinuity (Causadias, 2013). A variable developmental course, marked by discontinuity, presents an interesting challenge for assessment. On the one hand, clear changes in a child's functioning may be easy for informants to describe and may point to critical events as potential etiological factors. However, on the other hand, variable presentations of a clinical issue or marked changes in functioning may make it difficult to discern a given child's typical functioning or symptom presentation. Variable functioning also presents issues for predicting how a young person may respond to different approaches to intervention and speak to a need for close consideration of relevant risk and protective factors at the individual level.

Cascading Developmental Course Lastly, cascading developmental trajectories reflect the complexity of adaptive and maladaptive outcomes for many individuals and may also inform pathways that lead to continued problems in adulthood vs. limited impairments. Developmental cascades are based on the cumulative risk and protective factors that a child faces, as well as the more specific transactions between a child and their environment (Masten & Cicchetti, 2010). Further, the notion that well-timed and -targeted treatments may promote a positive trajectory underscores the importance of developmentally informed and comprehensive assessments that result in appropriate intervention recommendations (see Masten & Cicchetti, 2010).

Fully capturing developmental cascades requires assessment of both adverse childhood experiences and factors indicative of resilience. The former involves assessment of the child's history of personal and ecological risk factors that vary considerably in the directness of both their impact on the child and their risk to the child's safety or well-being. Adverse childhood experiences (ACEs) include, but are not limited to, abuse, neglect, poverty, family conflict/dysfunction, underfunded schools or community resources, and discrimination (Felitti et al., 1998). Conversely, assessment of resilience at the individual child level "reflects all the adaptive capacity available at a given time in a given context that can be drawn upon to respond to current or future challenges facing the individual, through many different processes and connections" (Masten & Barnes, 2018, p. 99).

An illustration of such a process is the connection between parental verbal abuse in childhood and internalizing problems in adulthood. Although such adverse experiences predict internalizing problems several years later, this connection is mediated by the youth's development of a self-critical cognitive style (Sachs-Ericsson et al., 2006). That is, children who experience verbal abuse from parents may come to engage in self-criticism, which in turn, would increase the risk for later anxiety or depressive symptoms. Of course, not all adverse experiences translate to negative psychological outcomes for youth, as numerous variables serve as important protective factors. For example, social competence and family cohesion are two potent constructs that have been known to play a role in attenuating depressive and anxiety symptoms in adolescents (Skrove et al., 2013). Perceived control over outcomes (Bolger & Patterson, 2001) and social support (Münzer et al., 2017) also promote resilience from maltreatment and are important constructs for clinical assessment. Such variables illuminate the need for clinicians to focus on familial and social support interventions when considering treatment approaches for children and adolescents.

Developmental Influences on Manifestation of Problems

Another consideration for assessment, diagnosis, and treatment planning is the influence of a child's development in the presentation of a particular psychological concern. In this way, a young person's functioning interfaces with typical developmental demands across different periods of childhood and adolescence. For instance, it is typical for younger children to have more difficulty with emotional and behavioral regulation than adolescents. Thus, as noted above, conduct problems early in development are more likely manifestations of dysregulation (e.g., temper outbursts, impulsive acts) than are those exhibited by adolescents. In contrast, because adolescents typically can be expected to go through a process of separation and individuation from caregivers, they experience less supervision (Luyckx et al., 2011). This more limited parental monitoring provides greater chances to engage in misbehaviors of opportunity (e.g., substance use, theft, property destruction) than are available prior to adolescence (Jackson & Schulenberg, 2013).

Two important principles in this regard are *homotypic continuity* and *heterotypic continuity*. Homotypic continuity is the idea that a symptom or behavior may represent the same underlying impairment across development. As might be evident from the above discussion of age of onset, homotypic continuity is not often observed for concerns like conduct problems. On the other hand, continued lack of expressive language acquisition across time may point to underlying intellectual deficits. Heterotypic continuity involves ways in which the same underlying problem may be exhibited differently across development (Cicchetti & Rogosch, 2002). The following examples show a number of ways in which heterotypic continuity is most commonly observed in developmental psychopathology.

For instance, one general trend is that cognitive aspects of psychopathology tend to increase from childhood to adolescence, as a young person's cognitive style becomes much more self-aware, abstract, and complex. These include the cognitive symptoms of depression (e.g., feelings of worthlessness, difficulty making decisions, negative cognitive style; Alloy et al., 2012; Sonuga-Barke et al., 2016), anxiety (e.g., worry, perfectionism; Tyler et al., 2021), and obsessive-compulsive disorder (e.g., more abstract categories of obsessions, mental rituals; Mancebo et al., 2008). Because of these natural developmental progressions in cognitive functioning, assessment approaches need to be modified to incorporate a young person's perceptions in a more detailed, rich manner. These increasingly cognitive manifestations of clinical concerns also open up a wider array of treatment options that more directly involve the young person, as opposed to a predominant emphasis on parent consultation or parenting strategies for younger children. These approaches may target cognitions that maintain or exacerbate distress and impairment (e.g., Lochman et al., 2008).

Research also reveals some symptom presentations during adolescence that may differ from what is typically observed in adults. For example, in depression, vegetative symptoms (e.g., changes in appetite, insomnia, loss of energy) appear to be more common in adolescents than in adults, whereas anhedonia and difficulty concentrating are relatively more common in adults (Rice et al., 2019). Thus, developmental level may influence the heterogeneity within diagnoses, as well as probabilistic explanations for impaired functioning and the presentation of syndromes or disorders (Mash & Hunsley, 2005; Youngstrom et al., 2017). The developmental psychopathology literature further informs assessment in this manner. That is, the key construct of focus may be primarily determined by the description of referral concerns, but can be further shaped by evidence on the common problems encountered at different periods of childhood and adolescence. For example, anxiety and anxiety-related impairments change in their manifestation from early childhood to adolescence. As described above, more cognitively oriented forms of anxiety may be a central focus of adolescent assessments, but not within the typical scope of anxiety assessments for very young children. Alternatively, separation from caregivers is a common source of anxiety for young children, but is quite rare for adolescents and would not be a frontline emphasis in such evaluations.

Youngstrom (2013) highlights the utility of a probabilistic approach to assessment that should be informed, in part, by different symptom presentations at different developmental stages. This approach is necessarily intertwined with an understanding of relatively likely developmental courses of different forms of psychopathology. Moreover, periods of developmental transition may further shape assessment and conceptualization with a greater expectation of adjustment difficulties during such times (Youngstrom et al., 2017). In short, a probabilistic approach capitalizes on the empirical evidence concerning the prevalence of psychopathology at different developmental levels and the typical courses of difficulties across development. It is also consistent with the ongoing need to be cost-effective in assessment and implementation of intervention.

As is evident, the developmental level of a child/adolescent and related contextual factors are crucial for case conceptualization, diagnostic decisions, and treatment planning. Peer influence represents one clear way in which context informs these aspects of clinical practice. This influence is not static across childhood and adolescence, however. Peers may have a decreasing influence on substance use from early adolescence to late adolescence and aggression from childhood to adolescence (Goldstick et al., 2018), presumably as peer conformity decreases (Steinberg & Monahan, 2007). Parenting practices insofar as they reflect developmentally normative degrees of supervision and approaches to discipline also influence the manifestation and conceptualization of youth psychological problems. To illustrate, lower parental knowledge of adolescents' activities in early adolescence is associated with adolescent substance use, but the strength of this association tends to decrease over time (Mak et al., 2020). That is, as it becomes more normative for parents to have less oversight over their adolescent's whereabouts, the relevance of parental monitoring may decline. However, low parental supervision coupled with antisocial peer behavior may place adolescents at particular risk of problem behaviors (Mak et al., 2020).

Lastly, developmental proximity of a problem to adulthood is predictive of the persistence of that problem into adulthood. For example, although a childhood-onset and adolescent-onset of depression are both related to depression during adulthood, the presence of adolescent depression is more directly connected to such difficulties as an adult (Cicchetti & Rogosch, 2002). That conclusion is not to discount the worse long-term prognosis often observed for early onset of psychopathology but rather to highlight that psychopathology, particularly if untreated, can continue to persist independent of onset. Indeed, adolescent onset cases may have less complex presentations than do many youth with a history of psychopathology during childhood, who by extension, may have a variety of neurobiological, familial, and systemic risk factors (Cicchetti & Rogosch, 2002). Still, proper identification and intervention at any point during youth is important for curtailing persistent impairments and negative long-term outcomes.

Conclusions and Future Directions

The above summary of evidence and examples underscores the essentialness of a developmental perspective in clinical work with children and adolescents. As described two decades ago (Cicchetti & Rogosch, 2002), there are clear benefits to the early identification of psychological problems, prevention of negative outcomes for which a young person may be at risk, and interventions that focus on an individuals' strengths and enhancing developmental adaptations such as coping skills. Generally, this approach is construct-driven and, in particular, considers psychopathology as largely dimensional rather than categorical or taxonomic. In essence, the field has long grown toward a consideration of mental health broadly construed rather than only of mental illness (Sameroff, 2000). A construct-driven, rather than diagnosis-driven approach, has particular benefits for working with children and adolescents in that diagnostic labels may be based on inaccurate professional judgments, pejorative for youth in some settings, and tied to factors that may still be malleable through the developmental period. This approach also takes into account the relative strengths and shortcomings of specific tests, as well as the manner in which certain informants may be more likely to observe some forms of youth psychopathology (e.g., externalizing behaviors) than other forms (e.g., depressive cognitions). In addition, continued movement toward practices and terminology that destigmatize mental health issues in youth is evident in the field and will likely continue to gain prominence (cf., Frick, 2020).

Moreover, greater emphasis on a construct-driven approach will allow for individual differences in the expression of psychological problems, the influence of developmental context on these expressions, and the utility of identifying, and intervening with, subclinical concerns before the progress in severity and pervasiveness. Consideration of constructs and important contextual influences on children's adjustment/maladjustment will involve further identification of moderators that will further inform knowledge of equifinality and multifinality. Importantly, research on resilience or protective factors lags behind our identification and understanding of risk factors and represents an important avenue for further inquiry.

Cicchetti and Toth (2009) discussed the need for an interdisciplinary approach in informing further advances in the field and ultimately improving services to youth and their families. Since that time, models for the integration of services across disciplines for child and adolescent assessment and therapy have been increasingly available (e.g., Buchanan et al., 2020; Shahidullah et al., 2018) with professionals who engage in research and clinical work with children and adolescents often working together in primary care or integrated care settings. Importantly, developmental psychopathology should continue to incorporate knowledge of cultural influences (Cicchetti & Toth, 2009) and the role of systems on psychosocial development. For clinical practice and the research on which it is based, it is crucial to challenge assumptions in the field that may have limited applicability for individuals from diverse backgrounds and that have presented potential barriers to equitable and inclusive access to valuable mental health services.

Finally, as evidence-based approaches to psychological assessment and intervention become more common emphases in training and practice, developmental psychopathology will become an even more crucial centerpiece of this work. The evidence base for assessment methods and therapeutic techniques is necessarily bound to the developmental level of the child. That is, the appropriateness of assessment and therapeutic approaches is partially a function of developmental factors. It is anticipated that important individual, contextual, and systemic variables in this work will be increasingly applied to the conceptualization of child and adolescent psychosocial difficulties and subsequent prevention/intervention efforts.

Evidence-Based Practice in Clinical Child Psychology

3

Katherine Wislocki, Nicole S. Keller,
Kelsie H. Okamura, and Emily M. Becker-Haimes

What is "evidence-based practice (EBP)"? This question has sparked debate and controversy for decades, from difficulties conceptualizing what should define "evidence-based practice" to disagreements over what should constitute "evidence" (e.g., outcomes of randomized clinical trials versus clinical expertise and experience). In this chapter, we will provide a historical overview of EBP, its structure, and the importance of EBP as it relates to clinical child psychology. Then, we will discuss different theories, resources, and methodologies that clinicians and researchers can use to reinforce their understanding and guide their selection of the most effective interventions that have been developed. Finally, we conclude with some reflections on continued controversies in youth mental health care and offer thoughts on future directions for the field.

Historical Evolution and Controversies

The concept of evidence-based practice originated in medicine as *evidence-based medicine.* Historically, as the scientific literature on new medical treatments and drugs proliferated, physicians searched for answers on how they could leverage the most up-to-date scientific research literature (e.g., results of randomized clinical trials that tested the efficacy of specific interventions) and apply that knowledge to clinical practice. David Sackett is most famously credited with this modern definition of evidence-based medicine, highlighting it as a *process:* "The practice of evidence-based medicine, then, is a process of life-long, self-directed learning in which caring for our own patients creates the need for clinically important information about diagnosis, prognosis, [and] therapy…" (Sackett & Rosenberg, 1995, p. 622). However, inherent to this *process* is the notion that some treatments have higher evidentiary support for their efficacy and effectiveness than others. Thus, the "evidence-based" terminology is often used interchangeably by many to refer to *treatments* with empirical support, which often goes hand in hand with the notion that the application or delivery of these evidence-based treatments should be prioritized.

Although evidence-based medicine sought to improve patients' overall treatment outcomes by integrating scientific research into clinical practice, widespread misconception led to controversy. Critics worried that the medical field would be reduced to "cook-book" medicine (Sackett, 1997), with overly strict adherence to treatment guidelines, protocols, and/or manuals rather than a personalized treatment plan based on a comprehensive evaluation of a patient's needs. Concerns also were raised that "cook-book" medicine would replace a physician's own expertise and experience.

Despite the controversial debate around evidence-based medicine, the need for the standardization of medical treatment and clinical therapies continued to grow. Other fields in health care, such as public health and psychology, began to adopt and adapt the core values of evidence-based medicine to their own disciplines. Evidence-based practice continues to be a broad term that is often misused and shrouded in confusion (Codd III, 2017). There are many different terms used interchangeably by clinicians and researchers when referring to a treatment supported by scientific research (e.g., "evidence-based approach," "evidence-based treatments," and "empirically-supported treatments;" Codd III, 2017). The extensive, and interchangeable, use of these terms only exacerbates misunderstanding as these concepts maintain distinct definitions from "evidence-based practice."

Given the ongoing confusion related to the terminology mentioned above, it is essential that we remain precise in our use of these terms. As such, throughout the remainder of this chapter, we use the term *evidence-based practice (EBP)* to refer to the evidence-based *process* and collective aspects of the so-called three-legged stool, which denotes that EBP constitutes a combination of the best available research evidence, clinical expertise, and patient preferences (Spring, 2007). We use the term *evidence-based treatment (EBT)* to refer to the mental health treatment protocols with the best available research support, whereas we refer to the specific intervention techniques (e.g., relaxation, exposure therapy) that comprise EBTs as "EBT intervention techniques." Finally, we use the term *evidence-based assessment (EBA)*, a core component of EBP (Jensen-Doss, 2011), to refer to the use of psychometrically supported assessment tools that align with research recommendations to assist the EBP process (Hunsley & Mash, 2007).

To date, the scientific literature has predominantly focused on the "best available research evidence" leg of the three-legged stool (Peterson et al., 2016; Stewart et al., 2018), with some arguing that this EBP component should be prioritized in practice over the others (Lilienfield et al., 2013). As such, we devote the most attention in this chapter to this stool leg.

Stool Leg 1: Best Available Research

We begin by briefly elaborating on how the field has sought to define what constitutes an EBT. Division 12 of the APA defines EBTs as treatments that demonstrate efficaciousness through randomized controlled trials or similarly rigorous methods, a definition which derives from the foundational work of Chambless and Hollon (1998). The term "empirically supported treatment" also has specifically been used to denote treatments that have demonstrated effectiveness with a given population in at least two separate methodologically rigorous studies, which are most typically randomized controlled trials (Chambless & Hollon, 1998).

However, the format of EBTs can vary widely, as we discuss below. We present several formats that EBTs commonly take in child services, including manualized treatments, transdiagnostic treatments, and modular treatments. We also devote time to discussing the role of so-called "common factors" within the context of EBP.

Manualized Treatments The evolution of behavioral health treatments and push towards EBP gave rise to the "manualization" of treatments. Initially, manualized treatments were created to provide a structured framework for treatment; this allowed for scientific comparison between treatments (e.g., through randomized controlled trials). These manuals provide a linear design where client needs are addressed in a fixed and structured order throughout treatment (Higa & Chorpita, 2008). Many manuals provide session-by-session guidance and others offer more formal guidelines for treatment overall. While the structure of treatment manuals can be somewhat rigid, prescribing specific delivery of intervention techniques and proscribing others, many manuals provide intentional opportunities for flexibility (Chambless & Ollendick, 2001).

From inception, manualized treatments have been subject to criticism (Chambless & Ollendick, 2001). While the decreased uptake of EBTs in real-world practice reflects a confluence of issues (Chambless & Ollendick, 2001; McHugh & Barlow, 2010; Beidas & Williams 2019), opponents of manualized therapies purport that they are reductive, impersonal, and antagonistic to more traditional forms of treatment, and unrealistically linear for most clients (Addis & Krasnow, 2000; Borntrager et al., 2009). These critiques are often cited to explain the limited efficacy of manuals and the only marginal benefits they provide when compared directly to non-manualized treatments (Weisz et al., 2006, 2017). As treatment manuals are often developed to be specific to distinct mental health conditions, manuals present additional challenges related to addressing the complex comorbidity profiles commonly seen in youth outside of clinical trials (Ehrenreich-May et al., 2011; Southam-Gerow et al., 2008; Chu et al., 2012). Explicit costs also include training on specific treatments and purchasing the manuals and associated patient workbooks themselves. In addition, manualized treatments can cause "choice overload" for clinicians given that there are often multiple options within diagnoses from which to choose (Chambless & Ollendick, 2001). As such, it is perhaps unsurprising that manual use remains low among mental health clinicians (Becker et al., 2013).

Transdiagnostic Treatments Challenges associated with early manualized treatments contributed to the inception of transdiagnostic treatments, which, unlike their predecessor, do not target specific disorders (Barlow et al., 2004; Chu, 2012; Ehrenreich et al., 2007; Marchette & Weisz, 2017). Transdiagnostic treatments can differ in approach, but ultimately strive to understand and treat mental health issues through a more unified approach than that of previous disorder-specific manuals. Marchette and Weisz (2017) detailed three transdiagnostic approaches, including the (1) "core dysfunction approach" which can be used to construct interventions that can address several issues or disorders through targeting similar etiological, maintenance, and process-related factors, (2) "principle-guided approach" which focuses on the conceptual elements that cultivate therapeutic change and form the basis of effective treatments, and (3) "common elements approach" which combines similar components of evidence-based treatments aimed at specific issues across different disorders. Of note, there is debate about whether this latter category should best be conceptualized as transdiagnostic (Chorpita et al., 2007), and we discuss this approach in more depth in the "modular treatments" section below. While ultimately transdiagnostic protocols are manualized for dissemination, proponents of transdiagnostic treatments argue that they may be able to leverage the most effective components of manualized treatments to create better treatments for youth (Marchette & Weisz, 2017). For example, one of the first transdiagnostic manuals for youth, the Unified Protocol for the Transdiagnostic Treatment of Emotional Disorders in Youth (Ehrenreich et al., 2017), was adapted from an adult version, the Unified Protocol for Transdiagnostic Treatment of Emotional Disorders (Barlow et al., 2011), and focuses on the prevention of anxiety and depression in youth through the "core-dysfunction approach." Several transdiagnostic approaches since have been used to meet a wide range of comorbidities in youth in specific environments like schools (Garcia-Escalera et al., 2019) and inpatient mental health programs (Thompson-Brenner et al., 2019).

Numerous benefits of transdiagnostic approaches have been cited, including the decreased need for multiple disorder-specific treatment models, improved ease of implementation and delivery of treatment, reduced training costs for clinicians/organizations, increased relevance to real-world practice, and higher levels of satisfaction from clients and clinicians (Marchette & Weisz, 2017). Additionally, transdiagnostic treatments have been lauded as especially relevant to youth, as youth are more likely to have comorbid conditions and shifting environmental and clinical needs (Chu et al., 2012).

While relatively new, research focused on transdiagnostic treatments and interventions is increasing. In practice, transdiagnostic treatments have encountered similar criticisms to those raised against treatment-specific manuals, including the increased compartmentalization of transdiagnostic manuals, limited evidence for their effectiveness in diverse populations, and questionable generalizability due to experimental design (Newby et al., 2015; Schaeuffele et al., 2021). Limitations aside, transdiagnostic treatments are a promising innovation for youth mental healthcare and those who provide it (Chu et al., 2012).

Modular Treatments As noted above, modular treatments are sometimes inappropriately grouped with transdiagnostic treatments (Chorpita et al., 2007) as they are both designed with the understanding that youth experience complex comorbidity patterns and that "single diagnosis youth" are relatively rare in practice. However, their underlying philosophies reflect meaningful differences. The foundation of the modular CBT approach is based on a method for synthesizing extant treatment literature in youth mental health: the distillation and matching model (DMM, Chorpita et al., 2005). The DMM model is an example of "chunking" youth treatments in common treatment components (Okamura, Becker-Haimes, et al., 2020a) that helps clinicians synthesize large amounts of information drawn from randomized controlled trials and treatment manuals. Distillation refers to the extent to which researchers can identify specific techniques (herein referred to as practice elements) in existing treatment manuals. Matching refers to the contextual factors, such as setting and client demographics, that can be matched to clinical trial data to identify practice elements that may be effective for a given population or subgroup. DMM relies on the following assumptions regarding practice elements: (a) they can be explicitly defined, (b) they can be reliably coded, and (c) different treatments may share practice elements in common.

The DMM has been used to create clinical decision-making tools for youth therapists since the early 2000s. The first products were developed within the Hawaii State Department of Health - Child and Adolescent Mental Health Division, which is where "Blue Menu" and biennial reports (https://health.hawaii.gov/camhd/clinical-tools/) were published by the Evidence-Based Services Committee on extant treatment literature outcomes and practices for youth. These reports helped to inform clinicians by identifying the best practices for problem areas (e.g., anxiety) by treatment "families" (e.g., Cognitive Behavior Therapy) and practice element profiles. One of the strengths of the DMM is its non-reliance on diagnostic categories as a taxonomic anchor. Instead, literature is coded based on targeted problem area, which is intended to allow for greater external and ecological validity in community mental health (Chorpita et al., 2005).

Early results from modular treatment trials derived from the DMM indicate that this approach is comparable to, or better than, standard manual treatments at improving youth outcomes (Weisz et al., 2012). Additionally, therapists tend to have more favorable attitudes toward the modular approach over time as well as more satisfaction with the flexibility of the treatment approach (Weisz et al., 2012). Subsequent trials also provide support for the modular design in addressing the needs of youth mental health compared to unstandardized treatment protocols (e.g., Chorpita et al., 2017).

Common Factors Unlike the traditional EBPs described above, all of which share elements of packaged sets of intervention techniques, *common factors* refer to the active therapeutic ingredients that underlie *any* successful psychotherapy (e.g., therapeutic warmth, development of therapeutic relationship and alliance, empathy; Wampold, 2015). Common factors models purport that "psychotherapy [is] a socially constructed and mediated healing practice…and a common factors model focuses on factors that are necessary and sufficient for change" (Laska et al., 2014, pp. 469). Specifically, Laska et al. (2014) argue that any treatment that includes all of the following is likely to be efficacious: (1) a strong bond between therapist and patient, (2) a safe, healing space in which therapy takes place, (3) the therapist provides "psychologically derived and culturally embedded" education in response to patient difficulties, (4) the therapist provides adaptive and acceptable explanations for how patients can overcome their difficulties, and (5) that treatment leads the patient to engage in something that is perceived as positive, helpful, or adaptive. Importantly, a common factors model states that improved outcomes will occur in the presence of these components, regardless of any specific theoretical model of change or formal treatment manual (Laska et al., 2014).

While understudied in youth, there is empirical evidence that specific common factors are uniquely associated with improved clinical outcomes within the context of youth psychotherapy (Shirk & Karver, 2003) and are highly valued by practicing clinicians (Bickman et al., 2000; Stewart et al., 2018). However, as with all elements of EBPs, the importance of common factors as a distinct driver of change is not without controversies (Mulder et al., 2017). For example, proponents of Cognitive Behavioral Therapy (CBT), a well-established EBT for youth, will note that these common factors are not only integral to the effective delivery of CBT (Hudson et al., 2014; Kendall & Frank, 2018), but also that it is artificial to attempt to separate out the effects of specific EBT techniques from common factors (de Felice et al., 2019). Consequently, more recent research has aimed to integrate the study of common factors with specific EBT treatment ingredients (Harder, 2018; Lorenzo-Luaces & DeRubeis, 2018); advancing the scientific literature around our understanding of the complex processes of youth psychotherapy is a much-needed next step to optimize youth mental health outcomes informed by the "best available research evidence."

The availability of research evidence to guide clinical practice is central to EBP in clinical child psychology – however, knowing the treatment components alone is likely insufficient to generate meaningful clinical change in youth. This brings us to the next leg of the EBP three-legged stool: clinical expertise.

Stool Leg 2: Clinical Expertise

Perhaps the most underdeveloped in the youth mental health literature, the second stool leg of EBP traditionally refers to clinical expertise. Lilienfield and colleagues (2013) propose that this stool leg can be conceptualized as two distinct parts: clinical *judgment* and clinical *experience.* Regarding the role of clinical judgment in EBP, even the most prescriptive EBTs cannot provide clinicians with a script for every scenario and there may be instances where EBTs are virtually equivalent for a particular presenting problem - as such, clinical judgment is a critical component of EBP. Additionally, clinicians always need to make quick judgments and decisions to effectively proceed in clinical scenarios, regardless of whether there are specific formulae or decision trees to guide them (Lilienfield et al., 2013; Meehl, 1957; Stewart et al., 2018). Clinicians cite factors like client and family characteristics as the most common reason treatment adaptations are made (Barnett et al., 2018), which highlights the potential interrelationship of this EBP stool leg with that of the third leg (patient culture, preferences, and values), described further below. For these reasons, the importance of clinical judgment has been argued by some as being essential for effective EBP (e.g., Fava et al., 2015; Tomba & Fava, 2012).

However, clinical judgment is not infallible. Most notably, when clinicians rely on their clinical judgment to make diagnoses, it is well-established that this leads to high rates of errors in diagnostic accuracy, even when diagnoses are collapsed into broader diagnostic categories (e.g., presence or absence of an anxiety disorder; Jensen-Doss et al., 2013; Rettew et al., 2009). In addition, recent work suggests that statistical models outperform treatment recommendations made by trained clinicians when predicting which EBP an individual patient is most likely to benefit from (von Bronswijk et al., 2021).

There is slightly more support for the role and importance of clinical experience as it relates to the relationship between more experience and improved clinical outcomes. Walsh et al. (2019) conducted a meta-analysis of 22 studies that demonstrated that clinical experience overall was associated with a modest impact on improved patient outcomes (Walsh et al., 2019). Important to note, however, is that Walsh et al. (2019) also found that the relationship between clinician experience and improved outcomes was attenuated when treatments were manualized. This suggests that effective delivery of treatment manuals by less experienced clinicians can potentially achieve comparable clinical outcomes to those obtained by more experienced clinicians.

Taken together, *how* and *when* clinical judgment is most valuable remains a complex question; ultimately, it is both essential, but likely insufficient alone, for optimizing youth psychotherapy outcomes (Waller & Turner, 2016). This underscores the importance of EBP delivery being guided by all three legs of the EBP stool.

Stool Leg 3: Patient Culture, Preferences, and Values

The American Psychological Association (Levant, 2005) defines the third stool leg of EBP as the characteristics, culture, and preferences of patients in the context of delivering treatment. This is particularly nuanced in youth mental healthcare given the many contexts under which youth may receive services (e.g., school-based, community outpatient, publicly funded systems), the multiple ecological environments (e.g., school, their peers, family, community), the rapid developmental changes that take place during youth (Weisz & Hawley, 2002), and the different “stakeholders” involved in a given child’s care (e.g., youth and caregivers; Hawley & Weisz, 2003). A central goal of youth EBP is to maximize patient choice among effective interventions and to acknowledge the many systems that affect phenotypic expression of mental health disorders.

The original APA EBP Task Force (2005) noted a plethora of patient characteristics including “gender, gender identity, ethnicity, race, social class, disability status, and sexual orientation” (Levant, 2005). Patient culture is arguably one of the broadest constructs and is defined as “the distinctive customs, values, beliefs, knowledge, art, and language of a society or a community” (APA, 2021). Patient culture has a profound impact on the effectiveness of treatment, which is particularly consequential since many leading EBTs were initially developed and tested with predominantly white, middle to upper-class samples (Baumann et al., 2015; Cabassa & Baumann, 2013; Mullarkey & Schleider, 2021). Additionally, minority youth have differential access to quality mental health care (Chambless et al., 1996; Hall, 2001), and patient values and culture are known to influence treatment delivery (Maina et al., 2018). Therefore, a systematic approach from assessment to the delivery of treatment is recommended for adapting treatments to be compatible with an individual patient’s culture (Bernal et al., 2009; Lau, 2006).

A unique complexity related to incorporating patient preferences into youth psychotherapy is the challenge of defining “the patient.” Youth, by nature of their age and legal status, rarely seek psychotherapy independently, but rather within the context of their family and community system. Additionally, to accurately understand a given youth’s concerns, a multi-informant (e.g., youth, parent, teacher) assessment approach is usually recommended (De Los Reyes, 2011; Hunsley & Mash, 2007). This can create challenges for shaping the intended goals of treatment when informants do not agree on the youth’s primary presenting issues (Hawley & Weisz, 2003). As many EBTs are designed for specific symptom clusters, it can be challenging for therapists to determine how first to proceed in treatment when these multiple stakeholders hold different priorities.

Finally, while not an exhaustive list, it is important to note that these patient characteristics described above largely refer to the *individual* patient without specific attention to the larger ecological context in which youth function. For youth with severe emotional disturbances, there are often multiple social service systems that intersect and can influence mental health treatment selection (Stroul & Friedman, 1994). The system of care framework is helpful for balancing and addressing the multiple goals and perspectives that may shape a given youth’s treatment. Guiding principles for youth EBP that align with a system of care framework include building a service array around youth to meet their individual needs, finding the least restrictive environment to keep them within their community, providing ease and access to transition and early intervention, and ensuring that services are culturally competent based on the individual youth (Stroul & Friedman, 1994).

In sum, considering individual patient values and the systems in which they reside is likely critical for effective EBP with youth.

Frameworks and Methods for Delivering EBP and Selecting EBTs

So far, this chapter has made clear that there are differing views of what does and should constitute “EBP”; however, EBP is more than merely selecting a specific treatment and delivering it. So, how does a mental health provider begin the process of EBP? To address this complex issue, we present several, non-mutually exclusive, frameworks that youth mental health providers can use to guide the process of EBP. In recognition of the importance of EBT protocols to EBP, we then provide more targeted guidance for how clinicians and researchers can identify what specific treatments for youth mental health constitute an EBT.

Evidence-Based Assessment (EBA) As noted above, EBA is a critical component of EBP, considered by some to be the cornerstone of high-quality youth EBP (Hunsley & Mash, 2018; Jensen-Doss, 2011; Youngstrom et al., 2017). EBA serves two key clinical functions with respect to guiding EBP and is associated with improved treatment engagement (Klein et al., 2010; Pogge et al., 2001) and response (Bickman et al., 2011; Eisen et al., 2000; Jensen-Doss & Weisz, 2008) among youth. Early in treatment, EBA guides initial case conceptualization (described further below) and supports the accurate identification of appropriate treatment targets. This latter point is particularly crucial, as the accurate detection of primary concerns is the "clinical roadmap" that guides clinicians to determine which EBT is the best match for an individual youth (Youngstrom et al., 2015). In addition, after the initial selection of an EBT is made, EBA can guide the monitoring of treatment progress and inform personalization and tailoring to optimize treatment success (Ng & Weisz, 2016; Youngstrom et al., 2015). The use of EBA throughout treatment, also referred to as measurement-based care, refers to the systematic and regular collection of treatment progress measures to inform ongoing clinical decisions (Scott & Lewis, 2015). Collecting and reviewing clinical data throughout treatment can be used to monitor the effectiveness of a current EBT and influence decisions about whether to continue with an initial treatment approach or whether adjustments to the treatment plan should be made.

Science-Informed Case Conceptualization Case conceptualization is one method proposed for supporting EBP delivery by providing a framework for clinicians to systematically integrate research evidence into their clinical practice (Christon et al., 2015). While the importance of case formulation and conceptualization has been highlighted for some time now (e.g., Persons & Tompkins, 1997), the science of case conceptualization for youth is relatively new. Christon et al. (2015) proposed a five-stage model that should guide case conceptualization-driven EBP. Specifically, in Stage 1, clinicians identify and quantify the presenting youth issues, then assess for and identify the causal and maintaining factors associated with those concerns, along with historical context. To be optimally effective, this should be guided by the collection of accurate assessment data that allows clinicians to generate (and subsequently test) hypotheses about the various antecedents and maintenance factors for maladaptive emotions and behaviors in youth (McLeod et al., 2013). This information then guides diagnostic assignment (Stage 2) and the development of an initial case conceptualization (Stage 3). An important component in Stage 3 is generating hypotheses about the interrelationships between the primary presenting concerns and the historical, causal, and maintaining factors; these hypotheses then inform initial treatment selection. For example, a hypothesis that a youth's anxiety and depressive symptoms are largely driven by family conflict may indicate a family-systems EBT would be beneficial. In contrast, hypotheses that anxiety is driven by maladaptive behavioral avoidance and irrational, catastrophic fears may suggest a cognitive-behavioral EBT as a more suitable approach. In Stage 4, the clinician would proceed with this initial treatment plan, and Stage 5 would include ongoing monitoring and revision of the case conceptualization as needed. Ongoing progress monitoring (e.g., through measurement-based care practices) is used to evaluate the generated hypotheses and inform future steps in treatment within Stage 5.

Shared Decision-Making Shared decision-making (SDM) refers to interactions between clinicians and their clients (i.e., youth and families) designed to foster a collaborative approach to making treatment-related decisions (Elwyn et al., 2012). SDM can facilitate EBP delivery by ensuring that a treatment plan is consistent with the patient's values and preferences (i.e., the third stool leg of EBP). Broadly, an SDM approach has promising support for its potential to improve patient engagement and outcomes (Trusty et al., 2019). This is a relatively nascent area in youth mental health; recently, Langer and Jensen-Doss (2018) proposed an illustrative protocol for shared decision-making that begins by identifying who should be involved in the decision-making process (e.g., youth and caregivers, youth alone) and how each stakeholder will be involved in the treatment process over time. The clinician can then facilitate a conversation around identifying the target problems (guided by EBA) and present the most promising treatment options for discussion. The clinician can then engage those involved in the SDM process in a conversation related to the benefits and drawbacks of the various options and work collaboratively to develop an initial treatment plan, ideally informed by the EBT literature. SDM processes can also guide the selection of targets for ongoing progress monitoring (e.g., number of instances of physical aggression in the home, number of days a child misses school per week) to ensure that ongoing monitoring of treatment progress aligns with a family's primary concerns.

Managing and Adapting Practices A direct service model that can also benefit case conceptualization and EBP in youth mental health is the Managing and Adapting Practice (MAP) system (https://www.practicewise.com/Community/MAP). The MAP system was created around the goal of improving outcomes and quality of care for youth and maintained an early foundation based on the DMM (Chorpita et al., 2005) and the Child STEPs effectiveness trial (Weisz et al., 2012). The MAP system provides clinicians with a framework that allows for structured collaboration and information-sharing between coordinating members of the care team around key decision-making with three important tools: (a) the PracticeWise Evidence-Based Services Database (PWEBS) – a searchable database of over 2000 randomized controlled trials that provides information on treatment practices by effectiveness level, problem area, and demographic variables, (b) the Practitioner Guides – step-by-step documents on how to deliver a practice element and clinical processes, and (c) Clinical Dashboards used to track youth progress and outcomes. The MAP system has been studied and used in youth public-sector service systems for many years (Higa-McMillan et al., 2020; Southam-Gerow et al., 2014).

Identifying Specific EBTs All of the above frameworks and systems provide guidance for clinicians to engage in a process of EBP as well as ensure that a clinician has the requisite information to design a treatment plan. However, this still begs the question of how to know whether a given treatment constitutes an "EBT." It is clear that there has been a proliferation of EBT protocols over the past several decades (Okamura, Orimoto, et al., 2020b), making it largely infeasible for practicing clinicians to simply "turn to the literature" to know what the current EBTs are for a client's presentation. *Clearinghouses and inventories* are important resources for organizations and professionals looking to implement EBTs. These resources aim to consolidate and disseminate information on the existence and efficacy of various EBTs to support clinicians, stakeholders, and organizations looking to utilize these practices (Means et al., 2015). Current leading clearinghouses (as of Spring, 2021) include the Blue Menu of Evidence-Based Psychosocial Interventions for Youth (https://www.practicewise.com/Community/BlueMenu), American Psychological Association Division 53 inventory of evidence-based treatments (http://www.effectivechildtherapy.fiu.edu/), and the Substance Abuse and Mental Health Administration National Registry of Evidence-Based Programs (https://www.samhsa.gov/resource-search/ebp).

Of note, the methodological decisions and processes involved with maintaining extant inventories can vary. For example, Walker and colleagues (2017) identified significant differences in the processes and outcomes in their review of prominent research inventories. While there were largely consistent approaches to the initial inclusion of literature (e.g., using unpublished versus published literature, accepting outside literature submissions versus sourcing literature internally), the breadth of evaluation elements varied (Walker et al., 2017). There were also differences as to how updates were made across inventories, including those related to the review process (e.g., number of reviewers per review) and inclusion of literature for updates (e.g., using unpublished literature versus published literature), and many of the inventories that were explored held different areas of focus; unfortunately, agreement on criteria for research inclusion between inventories was observed to be low (Walker et al., 2017). Walker and colleagues (2017) also demonstrated that separate inventories differentially rated the level of evidence for specific EBTs, which complicates one's ability to quickly identify whether a given intervention constitutes an EBT. The variation across inventories was most consequential for practices with less defined and/or established bases of evidence. Encouragingly, more established practices were more likely to consistently be rated as such across inventories (Walker et al., 2017).

Additional weaknesses related to clearinghouses are important to note. There is little consensus on the design, methodology, and data required to be sufficient across inventories dedicated to behavioral health topics (Burkhardt et al., 2015). Many treatments exist on one register only, emphasizing the stark differences in process and scope of behavioral health clearinghouses (Means et al., 2015). These realities make it increasingly difficult not only to have a comprehensive inventory related to behavioral health but also to maintain consistency across inventories. Additionally, many of these inventories cater to certain requirements from specific policymaking bodies. This limits the number of consumers that would be able to use the inventory as clinicians, organizations, and key stakeholders are forced to seek out content most relevant to the policies that most affect them. Some of these difficulties reflect larger limitations in the research, such as the lack of a strong evidence base for a specific treatment based on research involving racially, ethnically, or otherwise demographically heterogenous samples. Additionally, concerns related to sustainability, accessibility, and purpose remain problematic for clearinghouses and those who use them. Funding remains an issue as well, and as most revenue is used for review-related costs, there is little left over to devote to infrastructure and similar resources (Burkhardt et al., 2015). Research on the users of these clearinghouses is limited, which further complicates the objective of meeting the needs of consumers (Burkhardt et al., 2015).

As the push towards evidence-based treatment has become more widespread, alternatives to clearinghouses and evidence registers are also emerging. As an example of this, the Society of Clinical Child & Adolescent Psychology (SCCAP) recently sought to review and publish updates on the evidence base more frequently (e.g., every 10 years) in the Journal of Clinical Child & Adolescent Psychology (JCCAP) and through their website (https://effectivechildtherapy.org/). In each edition, experts are invited to review the previous decade of literature on topics in which they hold expertise. For certain treatments to receive an updated classification (e.g., from probably efficacious to well-established), contributors must demonstrate that there is enough research on each treatment to meet certain criteria involving both methodological quality and outcomes of interest (Southam-Gerow & Prinstein, 2014).

Despite these limitations, existing clearinghouses and evidence-based update series published by leading journals remain an important resource for identifying and selecting EBTs to be incorporated in youth EBP.

Future Directions

In this chapter, we have explored the history and definition of the term *evidence-based practice* (EBP), identified leading EBT models in clinical child psychology for clinicians, and discussed overarching frameworks that support EBP for youth. Our attention now shifts to the remaining controversies, future directions, and implications around EBP for clinical child psychology.

As this chapter describes, there have been many efforts to synthesize information, knowledge, and tools to support EBP for youth. As the youth mental health treatment literature continues to develop, there is a critical need to further enhance knowledge management tools to synthesize information for clinicians (Okamura et al., 2020a). Meta-analytic studies are an important method of understanding youth treatment literature growth that examines the strength of the evidence base for youth psychosocial treatment (Weisz et al., 1995, 2006, 2017). In their most recent meta-analysis, Weisz et al. (2017) examined 447 studies across the span of five decades of youth psychosocial treatment literature and found an overall moderate treatment effect size of 0.46 which was moderated by problem area (e.g., anxiety). Furthermore, long-term outcomes of our best treatments yield only mixed support for the sustained effect of EBTs over time (e.g., Curry et al., 2011; Ginsburg et al., 2018), suggesting the need for additional research aimed at optimizing current treatments and/or identifying novel treatment approaches to optimize outcomes in youth mental health.

A complimentary study examining therapeutic practice growth over five decades highlighted a nuanced perspective relative to literature growth (Okamura, Orimoto, et al., 2020b). Specifically, Okamura, Orimoto, et al. (2020b) examined 689 studies and found that while treatment manuals and randomized controlled trials continued to grow, the number of new discrete practice elements (e.g., exposure therapy, cognitive restructuring) leveled off over time. This has important implications for how youth psychosocial treatment studies are conducted given that, for many problem areas, new practice elements have not been identified for nearly a decade. As such, some argue that the paradigm shift needed to support youth mental health now hinges on researchers' ability to understand the complex process of community-based implementation and how treatments can be tailored to treatment response, rather than a singular focus on treatment development for youth (Okamura, Orimoto, et al., 2020b).

Emerging work is aimed at delineating the clinical skills needed to engage in careful adaptation of EBTs to address unique patient needs and to support youth in coping with unanticipated stressors they may face in their day-to-day lives. Much of the work done in this area has focused on how to deliver EBTs to youth experiencing emergent life events (Guan et al., 2019) including family or peer-related problems (e.g., death of a loved one), major emergencies (e.g., natural disasters), prominent national or local emergencies (e.g., the COVID-19 pandemic), and/or significant problems in the environment (e.g., community violence). Guan et al. (2019) categorized EBT adaptations related to client stressors into two areas: *content* – focused on adapting the actual practice for the current circumstance, and *coordination* – focused on adapting the sequence of the practices. Another clinical guide, the Strategic Flexibility Model, suggests that clinicians integrate clinical expertise with data-driven decision-making to inform systematic adaptations, guided by "Who, What, When, Where, and Why" questions (i.e., for whom should treatments be adapted, what components should be adapted and when, and in which settings; Georgiadis et al., 2020). Further developing systematic strategies for supporting clinicians to engage in appropriate EBT adaptations is an exciting area of future research for the field.

Additional work aimed at generating *practice-based evidence* (Margison et al., 2000) is also needed to better understand how and why clinicians make adaptations to EBTs in clinical practice to inform refinements to current treatment models and guide EBP. Insights from the implementation science field are useful here. Specifically, the Framework for Reporting Adaptations and Modifications-Enhanced (Wiltsey-Stirman et al., 2019) is a systematic reporting framework for researchers to document when clinical adaptations to EBTs are made, determining if they were planned or unplanned (and by whom), what is being adapted and at what level, and reasons for the adaptation covering improved fit, culture, cost, contextual factors, or idiographic/personalization needs. Research and synthesis of treatment adaptation will be critical to ensuring that youth EBP is meeting the needs of youth and families from diverse settings.

Finally, given APA's recent call to the psychology field to promote equity, diversity, and inclusion (APA, 2021), the future of EBP will need to address the longstanding disparities within mental healthcare. As noted by APA (2021) and other researchers in the field (Baumann et al., 2015; Cabassa & Baumann, 2013; Lau, 2006; Mullarkey & Schleider, 2021), psychological research and youth psychosocial treatments have mainly been developed and tested with white participants and published by white researchers. The history of inequity underlying our current healthcare landscape as well as the access, priorities, and procedures for funding treatment research indicates that EBP will undoubtedly undergo changes to meet the unique needs of society and to enhance equity in healthcare. However, the specific skills and treatment components that comprise current leading principles of youth EBP will likely remain fundamental to improving the lives of youth and families with mental illness and behavioral health conditions.

Conclusion

EBP in mental healthcare has much to offer in treating the mental health needs of youth. Just as individual issues are often complex and of multifactorial etiology, so too are the treatments to address youth needs. There is a robust evidence base from which clinicians and researchers can draw to support the delivery of EBP with youth, and there is no shortage of gaps in the literature that future researchers and clinicians can address.

The WHO International Classification of Diseases 11th Revision (ICD-11)

4

John-Joe Dawson-Squibb, Eugene Lee Davids,
Marisa Viljoen, Kirsty Rice, and Dan J. Stein

Introduction

The International Classification of Diseases and Related Health Problems (ICD) is the foundation for the identification of health trends and statistics globally and the international standard for reporting diseases and health conditions (WHO, 2021). The 11th Revision of the ICD (ICD-11) has been approved by the World Health Organization (WHO) and has important implications for practice and research. The update and specifically the chapter on Mental, Behavioural and Neurodevelopmental Disorders is of great interest around the world (Reed et al., 2019).

The ICD has played a major role in modern psychiatric research and practice (Clark et al., 2017). Its unique vision and aim of developing a psychiatric nosology that has clinical utility and can be used globally in multiple settings and by non-specialist health workers is in line with the broader aims of WHO (Clark et al., 2017). The majority of the world's population live in low and middle income

countries (LMIC), and there is a strong emphasis on reducing the global burden of disease, particularly mental health which makes up 14% of that burden (MhGAP, 2021; Murray et al., 2020). The WHO Sustainable Development Goals and the WHO Mental Health Gap Action Programme (mhGAP) demonstrate the commitment of the global community and have been endorsed by all United Nations Member States (Patel et al., 2018). The ICD-11 is aligned with these efforts and represents the latest changes and advancements in the field of psychiatric classification with the aim of improving the delivery of primary health services globally.

This chapter is divided into four broad sections. The first will look at the origins, development, and future directions of ICD, and in particular, the chapter on MBND. This sets the ICD in context, noting its original development as a medical taxonomy under the instruction of the WHO. The classification system's development and progress, from including psychiatric categories to its shift towards global applicability and accessibility, will be detailed. The extensive development process that brought about the ICD-11 and specifically the chapter on mental disorders, including carefully coordinated working groups and large, global field trials, are also described. The second section will outline the overall structure of the ICD-11, with an emphasis on the MBND chapter. With 28 chapters and around 55,000 categories, the ICD-11 has a particular focus on utility and application which is emphasized. The third section gives an overview of the key changes related to mental, behavioural, and neurodevelopmental disorders. Given the global aims of the ICD-11, it also explores cultural considerations in this latest iteration of ICD. The final section will explore the clinical utility of the ICD-11 in more detail and some of the key debates surrounding the MBND chapter. Considerations of the broad status of psychiatric nosology, as well as criticisms relating to the lack of etiological focus, overpathologizing of problems in living, reification, arbitrary thresholds, overlap with DSM-5, and artefactual comorbidity will be covered. The specific inclusion of gaming disorder in the ICD-11 will be used to demonstrate the challenges of including new classification categories because of its relevance to adolescent mental health. There will be a particular emphasis throughout the chapter on the features and diagnostic categories of interest to clinical child psychology.

ICD-11: Origins, Development, and Future Directions

The ICD-11 emerges from a history of nomenclature, nosology, and medical taxonomy. Under the instruction of the World Health Organization (WHO), the development process was extensive, with a lifespan of more than a decade. Issues of mental health have been routinely acknowledged in the ICD, with a designated chapter since the 1940s. Its development is best understood against the broader historical context of the ICD as a medical classification system. Its lineage is traced back to the sixteenth century (WHO, 2004), and the current working version is considered a dynamic and comprehensive tool which may be utilized across health disciplines, emphasizing clinical utility and global applicability.

This section outlines the origins of medical statistics as they are related to the overall development of the ICD, as well as the ICD's multiple revisions throughout the twentieth century, with reference to considerations of mental health. The principal vision, development, processes, and implementation of the current revision, ICD-11, are provided. Development procedures and findings specifically related to the advancement of the current Mental, Behavioural and Neurodevelopmental Disorders (MBND) chapter are discussed, and consideration is given to future directions. This serves to situate the MBND chapter within the broader context of global health, an essential frame of reference when considering the psychological health of children.

Classifying Mortality: The Beginnings of the ICD[1]

The first known statistical records of death originated in sixteenth century England, where deaths "from distinctly medieval purposes" were recorded on a weekly basis by the London Bills of Mortality (ICD-11, 2019, p. 2273). Pioneered by John Graunt, the bills were reported to have been collected and collated by parish clerks who had not necessarily been exposed to the practice of medicine, or statistics (Chute, 2000). Regarding medical classification, very little else was recorded until the mid-nineteenth century (WHO, 2004). Formal use of statistics is evidenced by reports and papers issued by the London Statistical Society from 1838, and the International Statistical Institute in 1853. This was indicative of the increasingly widespread use of statistics at that time, as well as the emergence of more precise data-gathering.

Considered to be the first medical statistician, William Farr, associated with the General Register Office of England and Wales, advocated for a uniform nosology based on statistical principles. His reports were influential, and at the first International Statistical Congress in 1853, he was tasked – alongside Marc d'Espine – with preparing a classification of death with international applicability. The anatomical basis of categories and general arrangement suggested by Farr and d'Espine influenced the ICD architecture.

A major development in the emerging field of medical statistics involved the International Statistical Institute's collaboration with the Statistical Works for the City of Paris in 1891. Jacques Bertillon, a French statistician and social scientist, was tasked with the preparation of a comprehensive classification system to capture causes of death, with applicability to public health. The outcome of Bertillon's efforts, known as the Bertillon International Classification of Causes of Death, was formally adopted by the International Statistical Institute in 1893 and was soon recognized by other countries. Under the jurisdiction of the International Statistical Institute, international revision conferences saw the first three iterations of the ICD developed in 1900, 1909, and 1920, respectively, each reflecting advances in medicine and involving an increasing number of international collaborators. Each version took on the standard title of the *International Classification of Death (ICD).* The brief involvement of the Health Organization of the League of Nations (post-World War I) contributed to the use of tabulation in the ICD, which reflected global developments in the field of statistics. The ICD-4 and -5 were published in 1929 and 1938, respectively.

From Death to Disease

In response to growing public health demands, the Fifth Decennial Revision Conference of the ICD in 1938 acknowledged the potential utility of classification beyond records of mortality. As a result, a resolution to develop a corresponding list of diseases was instated. The need to include morbidity had been identified through the administration of multinational surveys and so it became standard practice to formally engage an internationally representative committee, a gesture suggestive of the inclusive processes that remain today.

The notion that a list of diseases would be beneficial within the health professions was considered by Farr in the early nineteenth century. Further, in parallel to the globally accepted *International Classification of Death,* a Parisian classification of diseases had been in use since 1900. While there were some attempts to integrate non-fatal diseases into the ICD-4 in 1929, these categories were generally omitted in administrative practice due to the existence of localized morbidity lists.

---

[1] Much of this section has been adopted directly from the World Health Organization's 2nd edition of the ICD-10 manual, which provides a comprehensive narrative of the ICD's historical development. References to other sources are provided.

The major turning point in the ICD's implementation and development took place after World War II. The World Health Organization (WHO), founded under the jurisdiction of the United Nations in 1948, was granted responsibility for developing and maintaining the ICD; The recommendation to incorporate disease classifications into the ICD led to the *International Classification of Diseases, Injuries, and Causes of Death,* which was circulated to national governments. This was accepted at the first World Health Assembly in 1948, with the ICD-6, in the same year. The 6th revision comprised two volumes and included a chapter on psychiatric disorders. At this inaugural meeting, members were encouraged to establish national committees which would, in the future, contribute to the ongoing development and revision of the newly titled ICD.

ICD Revisions Under the Guidance of the WHO

The WHO released the ICD-7 in 1957, and the ICD-8 in 1968, setting a precedent for decennial revision (Janssen & Kunst, 2004). Between these revisions, the WHO's Nomenclature Regulations, an international treaty instated in 1967, were endorsed. The Nomenclature Regulations mandated all WHO Member States to instate the most current version of the ICD (WHO, 2021). The implementation of the treaty secured the ICD's status and function as a global communication tool which facilitates the collection of comparable health information (Clark et al., 2017).

The newly formed network of WHO member states, now committed to implementing the ICD, began to level criticism at the ICD, targeting its structure and utility. While the 9th revision (released in 1978) did not initiate structural changes, discussions regarding the future utility of the ICD were ongoing at the time of publication. The standard decennial revision of the ICD was determined to have an insufficient time period to facilitate adequate evaluation processes, leading to the decision to increase the preparation period leading up to the release of the ICD-10.

The ICD-10 was endorsed in 1990, and approved in 1992, but implementation was slow and inconsistent. The ICD-10 was updated almost yearly post-2000, with the most recent version released in 2019 (WHO, 2021). Initial work focused on remodelling the structure of the ICD and led to the WHO Family of International Classifications [FIC]. The 'family' is inclusive of several WHO-developed health and health-care system classification products, which may each be used independently or in conjunction with one another.

Mental Health Classification in the ICD

The ICD-6 chapter "Mental, Psychoneurotic, and Personality Disorders" (Clark et al., 2017) had a total of 26 categories that were put forward with suggested inclusion and exclusion terms. While the categories were broadly grouped into three clusters, no definitions or diagnostic guidelines were provided. As with the other sections of the ICD manual, the changes to this chapter between ICD-6 and ICD-7 were minimal.

Discussions regarding the inclusion of mental health within the ICD often invite comparison to the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM). This is due in part to the extensive collaboration between the WHO and American Psychiatric Association (APA) which led to a high level of consistency between the ICD-8 and the DSM-II, both of which identified psychoses, neuroses (including personality disorders), and "mental retardation" as the major categories for mental disorders. DSM-III included diagnostic criteria, and although these were included in ICD-10, DSM-III became more widely used for research and academic training purposes.

Following the release of the ICD-8, the WHO issued a glossary in which recognition of nosological problems within the psychiatric profession emerged. This was subsequently incorporated into the main statistical body in the ICD-9 (Clark et al., 2017; First et al., 2015). The glossary represented an important step towards the diagnostic guidelines included in later editions. DSM-III and DSM-III-R were developed independently of the WHO and ICD and reflected substantial changes with regard to disorder classification, namely a trend towards more thorough description. A more methodological approach was used to develop the DSM-IV and, apart from additional content, the edition was known for explicitly documenting its use of literature reviews, analysis, and field trials.

The publication of the ICD-10 marked an important step forward with the concurrent release of the *ICD-10 Classification of Mental and Behavioural Disorders: Clinical Descriptions and Diagnostic Guidelines (CDDG),* also known as "the blue book" (First et al., 2015). The CDDG expanded on the previous ICD glossary for mental disorders and was meant to provide diagnostic guidance to clinicians. However, the guidelines provided in the CDDG were often inconsistent in their level of detail, which impacted the CDDG's utility in clinical practice – while it allowed for flexibility, this came at the cost of consistency and therefore, potential global validity (First et al., 2015). This aspect of the CDDG was identified as one of the main areas for revision in the ICD-11 and was informed by work on and discussion of the DSM-5.

For example, an important addition to the CDDG in the ICD-11 expands the previously named 'mental retardation' subdivision (now named 'disorders of intellectual development' and included under the Neurodevelopmental Disorders section) via the provision of guidelines which outline both intellectual and adaptive domains. Children are uniquely considered within the diagnostic guidelines for this category, distinct from adolescents and adults, reflective of the developmental approach adopted by the ICD-11 (Reed et al., 2019). The recognition of the differences in presentation of mental disorders across the lifespan – in which the mental health of children is carefully contemplated – is an important result of the extensive, decade-long development process outlined below.

ICD-11: Vision, Development, and Process

Vision The current version of the ICD was built with the primary objective of overall utility, applicability, and accessibility. The final product needed to be user-friendly and appropriate for integration into the public health sector, while retaining statistical integrity and scientific credibility (Ustun & Jakob, 2009). The key settings identified for implementation included primary care, clinical care, research, and public health.

Development At the outset of development, three broad phases were outlined (Ustun & Jakob, 2009). The first phase, labelled "ICD-10-Plus", consolidated criticisms of the ICD-10, first combining all national modifications and other adaptations before inviting structured proposals for potential changes. The second phase saw the compilation of an "ICD-11 alpha draft". This was compiled by WHO assigned editors and Topic Advisory Groups, who reviewed taxonomic rules, definitions, and diagnostic criteria. Upon completion, the third phase involved the use of a "ICD-11 beta draft" as a field-trial version. This early version of the ICD was tested for feasibility, reliability, and utility through the Global Clinical Practice Network (GCPN) and allowed for direct comparison with the ICD-10.

Process To facilitate the revision of the ICD, the WHO established a comprehensive organizational structure which linked WHO headquarters to WHO's member states. This included a Revision Steering Group, which oversaw the many Topic Advisory Groups (TAGs), each consisting of field experts aligned to each major domain of the classification (e.g., a TAG was responsible for Chapter 5). Each TAG established Working Groups as needed; the working groups were tasked with assessing diagnostic issues within their domain, through a process of review of published literature, revision of the ICD-10 diagnostic categories, and the address of public comments. Following this process, the revised category was then submitted for testing in field trials via the GCPN – an innovative and collaborative web-based platform where members of the WHO-FIC network, NGOs, and interested health professionals with relevant experience participated in quarterly surveys. The GCPN used surveys to collect data which captured how clinicians understood and *used* diagnostic codes and categories. These data informed the revision of diagnostic criteria, and subsequently became the platform through which systematic field trials which allowed comparison between ICD-10 and proposed ICD-11 diagnoses were implemented. This allowed for reliability, validity, and clinical utility to be tested.

Mental Health Classification: The Approach of ICD-11

Major changes in the MBND chapter included a review of chapter structure, the addition and relocation of diagnostic categories, and the standardization of the format of diagnostic guidelines (Gaebel et al., 2020). Part of the restructuring process involved the adoption of a developmental and 'lifespan' approach. Where previously the ICD structure had aligned itself with the one presented in Kraeplin's seminal psychiatry textbook, the current version orders disorder categories from a developmental perspective, beginning with disorders most often diagnosed in childhood, and closing with disorders most often diagnosed in elderly populations (neurocognitive disorders) (Reed et al., 2018a, b). The official use of the term 'neurodevelopmental' is new to the ICD system, significant in its recognition of a group of chronic disorders which have a distinctly early onset and are characterized by lasting difficulties in both cognitive and social-communicate domains (Stein et al., 2020).

Regarding the clinical utility overall, both the core statistical chapter and the CDDG were revisited with a particular aim of enhancing clinical utility (IAG for Revision, 2011). The need for greater clinical utility was highlighted in two provisional surveys, in which only ~60% of mental health clinicians indicated routine use of classification systems, with practical references to the ICD-10 used predominantly for administration purposes (Evans et al., 2013; First et al., 2018). Other considerations identified by the IAG included the definition of mental disorders, the universality of categories, and the application of the system across contexts. The MBND chapter needed to be relevant to three stakeholder groups: governments and administrative bodies, mental health clinicians, and mental health service users and their families. The development process was based on the recommended ICD revisionary process, held the same organizational structure (namely TAGs and working groups), and included systematic literature reviews, country-level analysis, as well as international surveys of mental health professionals. An important function of the working groups was to use uniform 'content forms' in order to standardize the development of diagnostic descriptions for the CDDG (First et al., 2015).

Global collaboration for these processes was ensured through the creation of The Global Clinical Practice Network (GCPN) for mental health. The GCPN is considered the largest practice-based research network in global mental health. It is composed mostly of individual mental health practitioners, who are appropriately diverse and represent different professions (psychiatrists, psychologists, nurses, social workers, and occupational therapists), countries, years of experience, and professional contexts (Reed et al., 2015). As of February 2021, it included over 16,000 members from 160 countries (Socially Responsive Mental Health, 2021). Importantly, 40% of practitioners represent LMIC countries, 92% currently see patients, and a further 58% supervise others. This reflects the diversity of WHO member states, as well as the ICD's global relevance. Registration for the web-based platform was made available in nine different languages.

The primary function of the GCPN so far has been the facilitation of various field trials, which have been utilized throughout all three major phases of development. The field trials included both internet studies and clinic-based studies and were internationally inclusive. The internet-based field studies (surveys) were administered via the Global Clinical Practice Network (GCPN) web platform and were helpful in understanding accuracy, consistency, and clinician diagnostic judgement of the ICD-10 criteria, and formative in revising the overall architecture of mental disorder classification (Reed et al., 2015). One of the major applications of the web-based studies was the review of the newly proposed diagnostic descriptions for implantation in the CDDG. In addition, clinic-based studies used the revised criteria to assess reliability, and clinical utility and applicability (see Reed et al., 2018a, b).

Noteworthy studies included an early project in which over 500 mental health professionals provided input regarding the 'natural' taxonomical use of mental health classification (see Reed et al., 2013). Data from experienced clinicians – representing the diversity of WHO member states – indicated a high level of consistency in taxonomical application, suggesting a surprising level of utility in both the ICD-10 and DSM-IV. In support of this finding, a larger study, the product of a collaboration between the WHO and the International Union of Psychological Science (IUPsyS), which exclusively examined the views of psychologists, went on to highlight specific diagnostic areas requiring attention, as well as issues regarding cross-cultural applicability (Evans et al., 2013). For example, controversies regarding what is currently reflected as autism spectrum disorder, as well as the then 'hyperkinetic disorder' (now attention deficit/hyperactivity disorder in both the ICD and DSM), were identified by psychologists as disorders which were problematic in both validity and utility (Evans et al., 2013).

ICD-11 Field Trials: Relevance for Children and Adolescents

The implementation of ICD-11 field trials was a protracted process which took place over several years. The initial published results have focused on disorders more commonly diagnosed in adulthood, including schizophrenia and schizoaffective disorders (Luciano et al., 2020; Petersen et al., 2019), personality disorders (Kim et al., 2014), gender identity diagnosis (Robles et al., 2016) as well as mood disorders, anxiety disorders, and disorders specifically related to stress (see Keely et al., 2016; Reed et al., 2018a, b). Clinical presentations of relational problems in adults have also been evaluated by mental health clinicians (Heyman et al., 2018).

The disorder categories listed above have received adequate yet limited attention in relation to childhood and adolescence. Relevant *commentary* has focused on gender incongruence *in childhood* (see Drescher et al., 2016) as well as early life complex post-traumatic stress disorder and the restructuring of oppositional defiant disorder. Issues related to gaming disorder are also addressed in this chapter.

Regarding ICD-11 specific *field trials,* an initial child and adolescent study examined diagnoses related to childhood chronic irritability and oppositionality (Evans et al., 2021). In this comprehensive study, the vignette methodology described by Evans et al. (2015) required clinicians to differentiate between chronic irritability and non-irritable oppositionality, episodic bipolar disorder, dysthymic depression, and 'normative' irritability in children. The results were formative in the decision to exclude the DSM-5's DMDD and the reconfiguration of child oppositional and conduct disorders in the ICD-11. The impact of this field trial represents an important step forward in the nosology of this area of child functioning and highlights the utility of the field-trial methodology outlined in the ICD-11's overall vision.

A number of independent studies which reference disorders in children also exist, but ultimately highlight the need for further *field trials*. For example, regarding trauma and stress disorders, the works of La Greca et al. (2017), Murphy et al. (2016), Perkonigg and colleagues (2016), as well as others provide helpful information regarding clinical utility of PTSD and the newly included Complex-PTSD. Yet nosologically, there are still limitations regarding these diagnoses (see Vasileva et al., 2018). Data from completed ICD-11 global field trials, including those that are relevant to disorders impacting on children and adolescents, continue to be processed and analysed. It is expected that results from these trials will be published and provide continued opportunity for refinement and increased understanding of these disorders.

Future Directions

Reception of the ICD-11 MBND chapter has been mostly positive, though not without criticism (Stein et al., 2020). The inclusivity of the revision process has integrated the many demands made of the ICD system, reflecting the aims of clinical utility and global applicability, yet ensuring scientific validity. Ongoing commentary and advances in psychiatric classification and nosology will continue to inform future revisions of the ICD, with hopes that models based on dimensional – rather than categorical – approaches will inform both structure and diagnostic description (Gaebel et al., 2020).

The ICD's vision for the future is that it will remain a work in progress and always provide a global clinical utility which adequately reflects the most current knowledge base and advancements in the health professions. More immediately, issues of distribution, implementation, and adequate training will be prioritized, a process which is expected to be ongoing for several years. The WHO's International Advisory Group will oversee this process: its role is to identify practical next steps and to facilitate operational management, as well to provide consultation for the development of additional resources (such as case books, primary care versions, and assessment tools). This includes mechanisms for evaluating the effectiveness of the MBND chapter and monitoring of implementation progress.

Training in the use of the ICD-11 MBND chapter is crucial in ensuring ongoing utility and is expected to take place both in-person and online. Due to the extent of the current network, this is expected to be a resource intensive project which may have difficulties in scaling. Also, concerns have been raised regarding accessibility. In response, a web-based training academy is currently being both developed and piloted. Development of the online training platform, Global Mental Health Academy – informed by experts – aims to utilize best practices in medical training and is based on the empirical data collected in the field studies referenced above. Upon its completion, it will be available to practitioners, who will receive certificates of completion for each module. The content of the online training is planned to be iterative and will reflect revisions to the ICD-11 as it continues to be developed and updated.

ICD-11: Overall Structure

The ICD-11 consists of chapters, blocks, and categories arranged in a hierarchical manner which allows for different levels of detail to be communicated. This corresponds with the overall purpose of the ICD-11 – to classify diseases in a manner that is practical and clinically useful, while allowing statistical presentation of mortality and morbidity data for research, legislative, and other purposes. ICD-11 chapters are the top-level entities consisting of several categories which are arranged in a hierarchical manner within each chapter. A block is a group of related categories (World Health Organization, 2021) (Fig. 4.1).

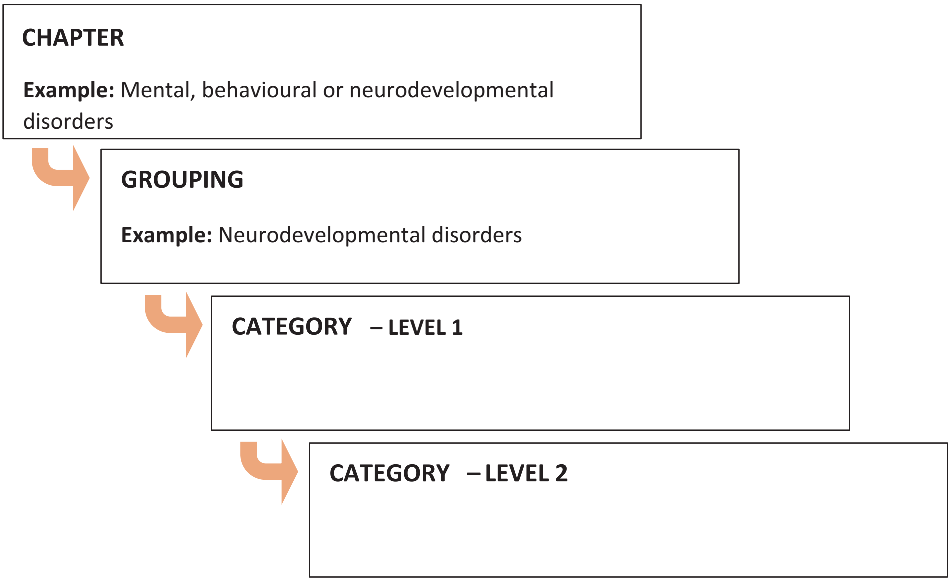

Fig. 4.1 A schematic representation of the ICD-11 showing the increase of detail in each level from the most general (chapter) to the most detailed (category) level

Categories included in the ICD-11 are mutually exclusive and cover the complete range of diseases or morbid conditions. Every disease or condition has a specific and well-defined place, or category, within the ICD-11 framework.

A health condition that meets classification criteria for a specific category is classified under that primary category (known as its primary parent). A unique feature of the ICD-11 is that it allows health conditions to be classified under secondary and even tertiary categories in different ICD-11 chapters. For example, Tourette's syndrome's primary classification is under Chapter 8 (Diseases of the Nervous System – Movement Disorders Grouping); it is however also classified under Chapter 6 (Mental, Behavioural and Neurodevelopmental Disorders – Obsessive-Compulsive Disorders Grouping and the Neurodevelopmental Disorders Grouping). Conditions that cannot be allocated to the specific categories are categorized in residual categories. Every category has a unique, alphanumeric code referred to as an ICD-11 code. Chapters and blocks do not have ICD-11 codes, and are therefore descriptive, and cannot be used for diagnostic purposes. For an entity to qualify as a category, certain criteria were considered during the development of the ICD-11. These include epidemiological evidence, clinical evidence, granularity (the level of detail reported and useful for a specific condition), continuity (relating to previous versions of the ICD), and parsimony (the need to describe and classify a condition in enough, but not excessive, detail) (World Health Organization & WHO collaborating Centre for Capacity Building and Training in Global Mental Health, 2021).

ICD-11 codes can be combined to describe a clinical condition in as much detail as needed. Additionally, unique identifiers can be assigned to category codes if a high level of granularity is necessary, or an ICD-11 category code can be used without identifiers to classify a condition in cases where detail is limited or not needed. The ICD-11 has 28 chapters and roughly 55,000 categories. Chapter 6 – Mental, Behavioural or Neurodevelopmental Disorders will be described in more detail.

The 23 groupings classified under the MNDB Chapter of the ICD-11 (Gaebel et al., 2017; Gozi, 2019; WHO, 2021) are as follows:

- *Neurodevelopmental Disorders*. This grouping refers to disorders that arise during the developmental period and involve challenges with acquisition and performance of specific intellectual, language, motor, and social functions. Examples include autism spectrum disorders, disorders of intellectual development (previously mental retardation and disorders of psychological development), and attention deficit hyperactivity disorder (previously hyperkinetic disorder). This grouping considers presentation across the lifespan and includes indicators for different age groups (early childhood, childhood/adolescence, and adulthood), levels of severity, and adaptive functioning domains (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Schizophrenia and Other Primary Psychotic Disorders*. This grouping includes conditions where psychosis is the primary or core feature. Disorders where psychosis are induced or affective (e.g. mood disorders or psychosis due to substance use) are classified elsewhere. Positive and negative symptoms should occur with sufficient intensity and frequency. Cultural norms are considered. Examples of Schizophrenia and Other Primary Psychotic Disorders include schizoaffective disorder, schizotypal disorder, and delusional disorder (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Catatonia* is a condition of psychomotor disturbances such as mutism, stupor, posturing, negativism, and psychomotor agitation to name a few. Catatonia may occur in the context of other disorders such as mood disorders, schizophrenia, or neurodevelopmental disorders (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Mood Disorders*, Including bipolar disorders and depressive disorders. The ICD-11 emphasizes the importance of a longitudinal pattern of a particular type of mood episodes over time. Examples of mood disorders include Bipolar or related disorder and Depressive disorder (Gaebel et al., 2017; Gozi, 2019; WHO, 2021)
- *Anxiety and Fear-Related Disorders* are characterized by excessive fear and anxiety that results in significant functional impairment. Although fear and anxiety are closely related, they can be clearly differentiated. Fear can be described as a reaction resulting from an impending threat. Anxiety is more future-orientated and relates to a perceived rather than imminent threat. Examples are generalized anxiety disorder, panic disorder, and agoraphobia (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Obsessive-Compulsive and Related Disorders* are characterized by repetitive thoughts and behaviours. Some disorders in the Obsessive-Compulsive and Related Disorders grouping include a cognitive component in the form of obsessions, intrusive thoughts, and preoccupations that is central to the condition. Examples are obsessive-compulsive disorder, body dysmorphic disorder, hypochondriasis, and olfactory reference disorder. Body-focused disorders lack a cognitive aspect and are characterized by recurring and habitual actions. Examples of body-focused disorders included are hair-pulling (trichotillomania) or skin-picking (excoriation disorder) (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Disorders Specifically Associated with Stress* are related to exposure to traumatic or stressful events. An identifiable, causal stressor is necessary for each disorder categorized under this grouping. Examples are post-traumatic stress disorder, prolonged grief disorder, and adjustment disorder (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Dissociative Disorders*, examples include dissociative neurological symptom disorder, trances disorder, and dissociative amnesia. These conditions are characterized by involuntary disruption or discontinuity of identity, sensations, perceptions, affects, thoughts, memories, control over bodily movements, or behaviour (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Feeding and Eating Disorders* involve abnormal eating behaviours that are not developmentally appropriate and cannot be explained by an individual's cultural context. Eating disorders involve preoccupations with food relating to body weight and body shape. Feeding disorders are not concerned with body shape and weight, for example eating non-food substances. Examples of eating

disorders are anorexia nervosa, bulimia nervosa, and binge eating disorder. Pica and rumination-regurgitation disorder are examples of feeding disorders (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).

- *Elimination Disorders* refer to repeated urination or defecation in inappropriate places after a developmental age when continence is expected. Enuresis after 5 years and encopresis after 4 years old are considered atypical. Elimination disorders may be present from birth or occur following acquired continence (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Bodily Distress Disorder* involve disturbances in a person's experience of their body. Examples are body integrity dysphoria and bodily distress disorder (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Disorders Due to Substance Use and Addictive Behaviours* result because of substance use.
- *Impulse Control Disorders* refer to disorders where an individual repeatedly fails to resist an impulse to perform an act that is harmful to either themselves or others. Examples are kleptomania and compulsive sexual behaviour disorder (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Disruptive Behaviour and Dissocial Disorders* are characterized by persistent defiant, disobedient, provocative, or disruptive behaviours. These behaviours violate the rights of others and are not in line with societal norms, rules, or even laws. Examples include oppositional defiant disorder and conduct-dissocial disorder. The onset of these disorders is most often, but not always, during childhood (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Personality Disorders and Related Traits* are characterized by dysfunctional patterns of behaviour relating to the self (e.g. identify, self-worth, or self-view) and/or interpersonal dysfunction (e.g. ability to form and maintain interpersonal relationships). The trait domain includes codes that can be assigned to describe prominent personality characteristic of an individual (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Paraphilic Disorders* refer to persistent and intense patterns of atypical sexual arousal involving others who are not able or willing to consent. Examples are exhibitionistic disorder, voyeuristic disorder, or paedophilic disorder (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Factitious Disorders* are characterized by intentionally feigning, falsifying, inducing, or aggravating medical, psychological, or behavioural signs and symptoms or injury in oneself or in another person (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Neurocognitive Disorders* involve deficits in cognitive functioning that are not developmental but arise later in life and involve a decline in cognitive ability and function. Examples include delirium and dementia (Gaebel et al., 2017; Gozi, 2019; WHO, 2021).
- *Mental or Behavioural Disorders Associated with Pregnancy, Childbirth, or the Puerperium.* These conditions develop following pregnancy, childbirth or the period after delivery, and can occur with or without psychosis. This category can be assigned with another mental disorder if symptoms meet diagnostic criteria for both categories.
- *Psychological and Behavioural Factors Affecting Disorders or Diseases Classified Elsewhere.* This category pertains to psychological and behavioural factors affecting health conditions classified in another chapter. The psychological or behavioural factor should adversely affect the health condition classified elsewhere by, for example, influencing treatment and posing additional risk or exacerbating symptoms. This code should always be assigned with a code from another chapter/diagnosis.
- *Mental and Behavioural Disorders Associated with Disorders or Diseases Classified Elsewhere.* Psychological or behavioural symptoms that are resulting from a health condition not classified under mental and behavioural disorders should be coded here. This category should be used with the diagnostic category for the underlying condition.
- *Other specified mental, behavioural or neurodevelopmental disorders.*
- *Mental, behavioural or neurodevelopmental disorders unspecified.*

Table 4.1 *Categorization of Autism Spectrum Disorder* and Attention Deficit Hyperactivity Disorder

Chapter 6 Mental, behavioural, or neurodevelopmental disorders		
Grouping	Category – level 1	Category – level 2
Neurodevelopmental disorders	6A02 Autism spectrum disorder	*6A02.0* Autism spectrum disorder without disorder of intellectual development and with mild or no impairment of functional language *6A02.1* Autism spectrum disorder with disorder of intellectual development and with mild or no impairment of functional language *6A02.2* Autism spectrum disorder without disorder of intellectual development and with impaired functional language *6A02.3* Autism spectrum disorder with disorder of intellectual development and with impaired functional language *6A02.5* Autism spectrum disorder with disorder of intellectual development and with absence of functional language *6A02.Y** Other specified autism spectrum disorder *6A02.Z*** Autism spectrum disorder, unspecified * 'Other specified' residual category ** 'Unspecified' residual category
	6A05 Attention deficit hyperactivity disorder	*6A05.0* Attention deficit hyperactivity disorder, predominantly inattentive presentation *6A05.1* Attention deficit hyperactivity disorder, predominantly hyperactive-impulsive presentation *6A05.2* Attention deficit hyperactivity disorder, combined presentation *6A05.Y* Attention deficit hyperactivity disorder, other specified presentation* *6A05.Z* Attention deficit hyperactivity disorder, presentation unspecified** * 'Other specified' residual category ** 'Unspecified' residual category

- Each grouping consists of categories arranged in a hierarchical manner. Table 4.1 illustrates the hierarchal categorization of two conditions, autism spectrum disorder and attention deficit hyperactivity disorder, that are categorized under the Neurodevelopmental Disorders grouping.

ICD-11: Overall Application

The ICD-11 is designed to be a versatile, user-friendly tool that can be used across a range of settings and speciality areas by a variety of people. An improvement that adds to the practical feasibility of the ICD-11 is the fact that it is completely digitalized and accessible free of charge online (WHO, 2021). This allows the ICD-11 to be used for many different purposes, including documenting causes of death, recording the incidence and prevalence of diseases, and documenting external causes of disease. The systematic, comprehensive design of the ICD-11 also allows for comparison of health data across different time frames and settings (countries, regions, cities, hospitals). Data gathered using the ICD-11 can be used by researchers, policy makers, clinicians, and financial decision-makers to identify health trends, make financing decisions, identify relevant research areas, and plan intervention strategies (Jones et al., 2018).

Clinical Descriptions and Diagnostic Guidelines for ICD-11 Mental, Behavioural, and Neurodevelopmental Disorders

To provide comprehensive guidelines for implementation in clinical practice, the WHO developed Clinical Descriptions and Diagnostic Guidelines (*CDDG*) for ICD-11 Mental, Behavioural and Neurodevelopmental Disorders. The CDDG version of the chapter contains detailed diagnostic guidelines for clinical application and is unique to the ICD-11 (Socially Responsive Mental Health, 2021; First et al., 2015; World Health Organization & WHO collaborating Centre for Capacity Building and Training in Global Mental Health, 2021). The format includes uniform categories of description in order to comprehensively comment on various features found across the presentation of health disorders.

The Clinical Descriptions and Diagnostic Guidelines for Mental, Behavioural and Neurodevelopmental Disorders contain the following eight sections for each disorder:

1. *Essential or Required Features* are characteristics that a clinician could expect to see in all cases of a disorder. These are listed as a bulleted list of symptoms or characteristics in the CDDG. Although this bulleted list of essential or required features may appear like diagnostic criteria, it is used in a different manner and for a different purpose than diagnostic criteria found in the DSM-5 for example. Essential or required features are intended to provide clinicians with guidance when making a diagnosis. They do not include symptom counts or precise durations and therefore allow for more flexible clinical judgement regarding the presentation of an individual case (First et al., 2015; Socially Responsive Mental Health, 2021; World Health Organization & WHO collaborating Centre for Capacity Building and Training in Global Mental Health, 2021).
2. *Additional Clinical Features* are clinical characteristics that are important and relevant to a specific health condition, but not necessary for diagnosis. This includes features and presentations of a disorder that are commonly associated with the specific disorder, but may or may not be present in a clinical case. These features are necessary to consider as they assist recognition of a condition when it can present in a variety of manners. Additional clinical features also need to be considered for clinical management and may assist in making a differential diagnosis (First et al., 2015; Socially Responsive Mental Health, 2021; World Health Organization & WHO collaborating Centre for Capacity Building and Training in Global Mental Health, 2021).
3. The *Boundary with Normality (threshold)* section intends to help clinicians differentiate between symptoms that are clinically relevant and can be described as a disorder and subclinical symptoms that can be more accurately described as a variation of normal functioning, as opposed to a disorder. Different criteria apply to different health conditions. For example, in some cases the level of functional impairment or distress is used to distinguish disorder from non-disorder (First et al., 2015; Socially Responsive Mental Health, 2021; World Health Organization & WHO collaborating Centre for Capacity Building and Training in Global Mental Health, 2021).
4. *Course Features* contain guidance on the typical prognosis or course the health condition is expected to run. This can include information about typical age of onset; whether the condition is persistent or episodic; duration of the condition; disorder progression or remission over time; and the relationship of the condition to life stressors and other disorders (First et al., 2015; Socially Responsive Mental Health, 2021; World Health Organization & WHO collaborating Centre for Capacity Building and Training in Global Mental Health, 2021).
5. *Developmental Presentation*. Many mental, behavioural, and developmental disorders present somewhat differently in different developmental stages. The developmental presentation section describes how symptom presentation may differ across the lifespan and provides guidance on recognizing health conditions based on their presentation across developmental stages (First et al., 2015; Socially Responsive Mental Health, 2021; World Health Organization & WHO collaborating Centre for Capacity Building and Training in Global Mental Health, 2021).

6. *Culture-Related Features* consider how features of a disorder may manifest in ways that are culturally specific. Taking culture-related features into consideration assists clinicians in making culturally informed and sensitive diagnosis (First et al., 2015; Socially Responsive Mental Health, 2021; World Health Organization & WHO collaborating Centre for Capacity Building and Training in Global Mental Health, 2021).
7. The *Gender-Related Features Section* provides information about gender differences in symptom presentation; base rates of disorders; and in help-seeking behaviours.
8. *Boundaries with Other Disorders and Conditions (or Differential Diagnosis)* describe characteristics that differentiate a specific disorder from a condition with similar features. In some cases, guidance is given regarding comorbidity and whether an additional diagnosis can be considered (First et al., 2015; Socially Responsive Mental Health, 2021; World Health Organization & WHO collaborating Centre for Capacity Building and Training in Global Mental Health, 2021).

The ICD-11 provides a common language and systematic classification system. The simplified coding structure of the MBND chapter adds to the clinical utility of the instrument.

Overview of Changes Related to Mental, Behavioural, and Neurodevelopmental Disorders in the ICD-11

The ICD-11 has received attention from mental health professionals across the globe. The chapter related to mental health in the ICD-11 was among the first truly global participatory processes in the area of mental health, as well as child and adolescent mental health more broadly (Gaebel et al., 2020). The inclusion of both mental health providers and users throughout the entire process of developing the classifications related to child and adolescent mental health made provision for applicability across the globe, scientific validity, and clinical utility (Gaebel et al., 2017, 2020).

The MBND chapter has broadly seen a number of changes (outlined in Table 4.2). One of the broad, overarching changes has been the extensive inclusion of 23 groupings related to mental health in the recent iteration of the ICD (see *ICD-11: overall structure* above), compared with the 11 group-

Table 4.2 Some differences between ICD-10 and ICD-11

ICD-10	ICD-11
Mental, behavioural, or neurodevelopmental disorders found in Chapter 5	Mental, behavioural, or neurodevelopmental disorders found in Chapter 6
Mental disorders examined in 11 sub-chapters	Mental disorders examined in 23 sub-chapters
No specific grouping for neurodevelopmental disorders, instead it makes use of ‘disorders of psychological development’, and ‘mental retardation’	Specific neurodevelopmental disorders grouping included in ICD-11
Autism spectrum disorder and attention deficit hyperactivity disorder could not co-occur in the same individual	Autism spectrum disorder and attention deficit hyperactivity disorder may co-occur in the same individual
Previously included childhood autism, atypical autism, and Asperger syndrome	Childhood autism, atypical autism, and Asperger syndrome are non-existent, but are grouped into one category, namely autism spectrum disorder
Gaming disorder not previously included, it is a new disorder	Gaming disorder included under the new grouping of disorders due to addictive behaviours
The coding system did not allow for a more detailed presentation of patient’s characteristics and features	The coding system makes provision for coding characteristics of patient’s clinical conditions in more detail

Table 4.3 New additions related to mental health in the ICD-11

Catatonia	Catatonia given the status of an independent syndrome. In child and adolescent mental health somatic conditions are more common (Remberk et al., 2020)
Bipolar Type II Disorder	Bipolar Type II Disorder has previously been recognized in DSM-IV, however it is the first inclusion in the ICD
Body Dysmorphic Disorder	The community prevalence of body dysmorphic disorder was estimated at 2.2% among adolescents (Veale et al., 2016). Body dysmorphic disorder has been incorporated into the obsessive-compulsive and related disorders group, noting the characteristic difference in symptomology and similarities to obsessive-compulsive disorder
Olfactory Reference Disorder	The concern about perceived body odour or breath unnoticeable or slightly noticeable to others has been included in the obsessive-compulsive and related disorders group
Hoarding Disorder	Hoarding disorder included in ICD-11 with similar diagnostic characteristics as outlined in the DSM-5 and is also in the obsessive-compulsive and related disorders grouping
Excoriation Disorder	Excoriation disorder, also known as skin-picking disorder, is another disorder included in ICD-11 falling under the obsessive-compulsive and related disorder section
Complex Post-traumatic Stress Disorder	Complex post-traumatic stress disorder makes provisions in the ICD-11 for 'persistent, pervasive, and enduring disturbances, in affect regulation, self-concept and relational functioning' which replaces the category of enduring personality change after a catastrophic experience in the ICD-10. In child and adolescent populations, the presence of multiple or chronic trauma, such as childhood physical or sexual trauma, is more likely to be related to complex post-traumatic stress disorder than post-traumatic stress disorder (Brewin, 2020)
Prolonged Grief Disorder	An added explanation of longer periods following a loss has not been clearly described in ICD-10, but the addition of Prolonged Grief Disorder for periods of grief after loss for more than 6 months has been added to the ICD-11
Binge Eating Disorder	An increase in research related to binge eating supported the inclusion in ICD-11, which previously would have been considered in ICD-10 as a diagnosis of other specified or unspecified eating disorder
Avoidant/Restrictive Food Intake Disorder	To differentiate between anorexia nervosa, the avoidant/restrictive food intake disorder made provision for behaviour that was characterized by inadequate amounts or types of food that does not meet the nutritional requirements deemed adequate but is not concerned with issues related to weight or body shape
Body Integrity Dysphoria	Body integrity dysphoria usually has an onset in childhood or early adolescence and is characterized by a desire to have a specific physical disability (such as amputation or blindness)
Gaming Disorder	In light of global concern, gaming disorder is included in ICD-11 under the new diagnostic group labelled *disorders due to addictive behaviours*. For adolescents, there has been an increase in online entertainment across numerous electronic devices which may be linked to the possible inclusion of this disorder related to child and adolescent mental health concerns (King & Potenza, 2019)
Compulsive Sexual Behaviour Disorder	Compulsive sexual behaviour disorder is when an individual experiences for a minimum of 6 months or more a repeated pattern of failure to control intense, repetitive sexual impulses or urges and this behaviour/activity becomes the focus of the individual's life and has adverse consequences. It has been included under the impulse control disorder section in the ICD-11
Intermittent Explosive Disorder	In the ICD-10, intermittent explosive disorder was grouped under the *other habit and impulse disorders*, the ICD-11 included it in the Impulse Control Disorders section
Premenstrual Dysphoric Disorder	Premenstrual dysphoric disorder is differentiated from premenstrual tension syndrome in the ICD-11 and is cross-listed in the sub-grouping of depressive disorders but is primarily grouped in the diseases of the genitourinary system chapter

ings which were examined in the ICD-10 (Gaebel et al., 2017). The chapter structure of the ICD-11 has attempted to compliment the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5), which was done through a collaborative process between the World Health Organization and the American Psychiatric Association (Gaebel et al., 2017; Reed et al., 2019). In addition to the chapter structure, diagnostic and disorder classification has been grouped according to common aetiology, pathophysiology, and phenomenology (Gaebel et al., 2017).

Discussions and Debates Related to Changes in the ICD-11

The updated version of the ICD-11 has seen numerous changes, particularly in the section related to the classification of mental and behavioural disorders for children and adolescents. Some of these are briefly outlined:

Neurodevelopmental Disorders

The ICD-11 introduced a new grouping on neurodevelopmental disorders, replacing this grouping where the ICD-10 made use of classifications such as 'disorders of psychological development' and 'mental retardation'. Another key development and change seen within this specific grouping is that the ICD-11 recognizes that autism spectrum disorder and attention deficit hyperactivity disorder may co-occur in the same individual. This becomes important for treatment as children and adolescents with a diagnosis of autism spectrum disorder can benefit from treatment with the co-occurrence of attention deficit hyperactivity disorder, such as stimulant medication (Stein et al., 2020; Sturman et al., 2017). The recent ICD iteration also sees the amalgamation of diagnoses such as childhood autism, atypical autism, and Asperger syndrome as being categorized as autism spectrum disorder (Silleresi et al., 2020; Stein et al., 2020).

Disorders of Addictive Behaviours

The ICD-11 presents many clinically relevant changes related to addictive behaviours. The recent iteration of the ICD brings together substance use disorders under the category of addictive behaviours through the grouping of *disorders due to substance use or addictive behaviours*; mental health professionals have applauded the change in the recent iteration of the ICD as it resembles similar changes as seen in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders, highlighting alignment between the two systems (DSM-5) (American Psychiatric Association, 2013). The ICD-11 also contributes to the conceptualization of disorders of addiction by recognizing a group of 'disorders due to addictive behaviours'. These are associated with distress/dysfunction surfacing from repetitive rewarding behaviours rather than from the use of dependence-producing substances (Stein et al., 2020). An advance to this grouping is the inclusion of gambling disorder as well as gaming disorder that may be relevant to child and adolescent mental health, which is a new addition to the ICD-11 classification and can be considered as being related to both online and offline behaviour (Rumpf et al., 2018).

Highlighting New Additions to Mental Health in ICD-11

The MBND chapter has seen new additions to the diagnostic characteristics and guidelines in terms of the revised classification interaction. These new additions included the incorporation of Catatonia as an independent syndrome, as well as the inclusion of gaming disorder and complex post-traumatic stress disorder in the ICD-11. The 15 new additions to diagnosis and disorders related to mental health in the ICD-11 have been outlined by Gozi (2019) and Gaebel et al. (2017) and are outlined in Table 4.3.

Cultural Considerations

The latest iteration of the ICD-11 has brought about a number of new changes, developments, and advances which have prompted numerous debates and discussion. One area is cultural considerations related to the classification system. While it has given an opportunity for global engagement in its development, it is essential to note that child and adolescent mental health and psychopathology takes place within a particular environment that can act as a protective or a contributory factor to mental health disorders. Coupled with the environment is the importance of culture and cultural considerations, particularly related to mental health (Gureje et al., 2020).

Mood, anxiety, and stress-related disorders, for both child and adult mental health alike, are among the most common presentations in mental health services and among the disorders commonly impacted by cultural factors (El Khourv et al., 2020). To account for culture and promote cultural sensitivity in the ICD-11, field studies were conducted in multiple countries to ensure global utility and cultural awareness of child and adolescent mental health. These field studies included diverse settings, including countries such as South Africa, Mexico, Japan, Russia, and Brazil (El Khourv et al., 2020).

The ICD-11 provides an international classification framework for child and adolescent mental health practitioners which can aid in addressing the treatment gap between the need for and access to services but remains culturally sensitive as indicated by the global field studies. While the ICD-11 makes some provision for cultural consideration and sensitivity, having an international classification system which promotes clinical utility and considers all cultural factors in mental health decision-making may be difficult. Gureje et al. (2020) have alluded to the cultural considerations of the ICD-11, noting child and adolescent mental health practitioners have been provided guidance for considering contextual and cultural considerations. This aims to strike a balance between global classification of mental health and the pertinent clinical information which should be geographically and culturally relevant. Striving for cultural consideration and sensitivity is a daunting task for a global classification system; however, clinicians and practitioners should be aware of the complexity of these areas when acting in the best interest of both children and adolescents as users of mental health treatment and services.

Clinical Utility of ICD-11

Clinical utility is regarded as an important priority of the WHO ICD-11 (Clark et al., 2017; Reed et al., 2018a, b). Improving the clinical utility of the ICD-10 is regarded as a major orientating principle in its revision (Reed, 2010).

The WHO has provided a detailed definition of a classification system's clinical utility based on earlier descriptions of the concept (First et al., 2004). In relation to the ICD classification of mental disorders, the clinical utility of a classification system, construct, or category depends on: (a) its value communicating (e.g. among practitioners, patients, administrators, families); (b) its implementation characteristics in clinical practice, which includes its goodness of fit (accuracy of description), its ease of use, and feasibility (e.g. how much time is required to use it); and (c) its usefulness in selecting interventions and in making clinical management decisions (Keeley et al., 2016; Reed et al., 2018a, b).

One of the critical objectives of the ICD-11 is to reduce the disease burden of mental and behavioural disorders by serving WHO Member States. This is emphasized by the International Advisory Group for the Revision of the ICD-10 Mental and Behavioural Disorders (2011) who state, 'People are only likely to have access to the most appropriate mental health services with the conditions that define eligibility and treatment selection are supported by a precise, valid, and clinically useful classification system' (p. 90).

ICD-11 revisions have sought to improve clinical utility with the understanding that this could improve public health (Keeley et al., 2016). If a system is not implemented or used extensively because it is not viewed as clinically useful by practitioners, this can impact in a number of ways. It will not generate valid data that can be used for health statistics; outcome evaluation at the individual level will be limited, resource allocation and needs assessment at the system level will be compromised, as will public health decision-making at many levels, including national and global (Keeley et al., 2016).

The ICD-11's emphasis on clinical utility is based on the challenges faced in this area by previous classification systems. As described by multiple authors, including those involved in the development of the systems (e.g. DSM and ICD), there are several problems with clinical utility (Andreasen, 2007). Reed et al. (2013) describe four primary concerns based on the literature. First, many people with mental health needs meet criteria for more than one disorder (Kessler et al., 2005; Kreuger & Bezdjian, 2009; Krueger et al., 2003). This may indicate that current classification systems are not efficiently capturing the core elements of mental disorders as they present in clinical settings (Reed et al., 2013). Second, a large proportion of mental disorders are recorded as either 'Not Otherwise Specified' (DSM terminology) or 'Unspecified' (ICD). This could indicate that current diagnostic categories are not easily understood by professionals or not accurately descriptive of patients. It may also reflect that the finer descriptions of diagnoses are not regarded as clinically useful by clinicians. Third, diagnostic categories are often poor predictors of treatment needs, particularly for those with severe forms of mental disorders. This is despite specific diagnoses often being used to define service eligibility. Existing diagnostic systems do not assist with the efficient use of often limited treatment resources, at either a clinical or country level (Reed et al., 2013). Finally, certain psychological and pharmacological treatments are effective over a range of mental disorders (e.g. Barlow et al., 2004; Harvey & Gumport, 2015). This suggests that several diagnostic distinctions currently made have limited relevance for clinical practice. In other instances, some disorders are significantly heterogenous, for example, the DSM-5 criteria for conduct disorder require only 3 of 15 possible criteria. Thus, for some disorders, it is possible that individuals with the same diagnosis will not share overlapping clinical features which have direct implications for treatment. These significant challenges in previous classification systems raise concerns about their increasing complexity and clinical utility. The ICD-11 revision has aimed to directly address these challenges.

As described in earlier sections of this chapter, the WHO Department of Mental Health and Substance Abuse conducted major field studies for ICD-11 which focused on improving clinical utility (Reed et al., 2018a, b). The subsequent substantive changes to the Clinical Description of Diagnostic Guidelines (CDDG) for ICD-11 Mental, Behavioural and Neurodevelopmental Disorder are intended for use by mental health professionals in clinical settings. Three main changes sought to improve clinical utility. First, providing consistent and uniform diagnostic information across categories (First et al., 2015). Second, allowing for appropriate clinical judgement and reducing arbitrary cut-offs when not strongly supported by evidence. And finally, the groupings and categories are intended to be more consistent with how mental disorders are conceptualized by clinicians (Reed et al., 2013; Roberts et al., 2012).

There is good evidence that these changes have been favourably received by clinicians. In a paper by Reed and colleagues (2018a, b), the clinical utility of the ICD-11 mental, behavioural and neurodevelopmental disorders diagnostic guidelines was assessed by 339 clinicians in 1806 patients in 28 mental health settings in 13 countries. They found very positive overall clinician ratings for the proposed ICD-11 diagnostic guidelines. The guidelines were regarded as easy to use, corresponded closely to patients' presentations (i.e. 'goodness of fit'), were clear and understandable, gave an appropriate level of detail, took a reasonable amount of time (i.e. about the same or less the clinicians' usual practice), and gave useful guidance in distinguishing normality from disorder. While clinicians rated the guidelines as less useful for assessing prognosis and treatment selection than for communicating with other professionals, all the ratings were nonetheless positive. Though every effort has been made to improve the clinical utility of the ICD-11, and early indications are positive that they have done so, it remains to be seen how the revisions will be taken up as the classification system is implemented globally.

Criticisms and Commentary on ICD-11

While some of the criticisms of ICD-11 relate to the larger status of nosology in psychiatry, others relate to more specific elements of the ICD-11, including the MBND chapter (Stein et al., 2015, 2020; Stein & Reed, 2019). This section will cover seven broad criticisms and attempts by ICD-11 to mitigate them. The status of psychiatric nosology, aetiology, overpathologizing of problems in living, reification, arbitrary thresholds overlap with DSM-5, and artefactual comorbidity will be covered in more detail. Finally, the specific case of gaming disorder will be used as an exemplar for controversies that can arise with the introduction of new disorders into classification system.

First, there are multiple classification systems, for example, ICD, DSM, Research Domain Criteria, and there is some debate regarding the need for more than one (Clark et al., 2017). Stein et al. (2020) argue that different systems are needed for differing purposes. For example, the ICD-11's emphasis on clinical utility and global applicability is designed to ensure it would result in a classification system that is of value for global mental health, ultimately reducing the mental health treatment gap and burden of mental disorder globally.

Second, ICD-11 and DSM-5 have been criticized for not being etiologically based (Gitlin & Miklowitz, 2014); this reflects uncertainty about the psychobiological underpinnings of psychiatric disorders (Clark et al., 2017; Gitlin & Miklowitz, 2014; Drabrik & Kendall, 2010). Not only is there a growing awareness that mental disorders are multicausal, but they are also incompletely understood (Clark et al., 2017; Stein et al., 2020). The ICD-11, and specifically the chapter on Mental, Behavioural or Neurodevelopmental Disorders, acknowledges this complexity and includes aetiology in certain groupings that have similar underlying mechanisms (e.g. addictive behaviours). It further details some diagnoses based on specified causes (e.g. anxiety disorder due to a medical disorder or substance use). Finally, certain causal factors can be classified though they aren't defined as disorders (e.g. chapter on Factors Influencing Health Status and Contact with Health Services) (Stein et al., 2020). Despite these efforts, the ICD-11 emphasizes the continuous need of careful individualized assessment that shows awareness of the multiple causal factors in mental illness and the consequent divergent range of interventions (Stein et al., 2020).

Another challenge for diagnostic systems is the difficulty of setting a proper balance between not overpathologizing human problems and being inclusive enough to ensure the treatment of suffering individuals (Frances, 2014; Gitlin & Miklowitz, 2014). There is a large literature on how nosologies have medicalized problems of daily life (Frances, 2014). On the other hand, it is key for disorders to be listed in ICD-11 to ensure clinical and public health attention.

A further consideration for diagnostic classification systems is that complex symptom profiles of individuals often do not fit neatly into diagnoses (Hyman, 2010). There is a danger that the reification of diagnostic categories may impede our deeper understanding of them (Hyman, 2010). Similarly, there is the temptation to inappropriately regard mental disorders as natural kinds (Stein et al., 2013).

The ICD-11 (and the DSM-5) are fundamentally categorical in design in order to achieve the purposes for which they were developed: clinical communication, allocation of mental health resources, compilation of health statistics, etc. (Clark et al., 2017). To mitigate the potential for reification, ICD-11 uses clinical guidelines rather than pseudospecific criteria sets. In addition, ICD-11 has a more dimensional approach to a range of conditions, for example, personality disorders, schizophrenia, and other primary disorders. In disorders of intellectual development, ICD-11 also moved away from using cut off scores based on standardized tests of intellectual impairment. To determine the appropriate severity-based subcategory in the updated system, clinicians must make judgements on multiple dimensions, considering intellectual functioning and adaptive behaviour across domains of social, conceptual, and practical skills (Clark et al., 2017; ICD-11). While dimensions may have some disadvantages for clinicians, field studies of the ICD-11 indicate that clinicians do find the guidelines acceptable and at least as easy to use as more categorical systems (Keeley et al., 2016; Luciano et al., 2020; Volpe, 2017; Reed et al., 2018a, b). How these revisions are taken up and used more broadly and on a global scale will be determined as the classification system is more widely implemented.

The problem of drawing thresholds is a fraught issue in mental disorders, particularly given the concerns described of inappropriate over-medicalization (Stein et al., 2020). Thresholds in this case relate to both between mental disorders and between disorders and normality. Setting thresholds in mental health disorders is difficult for three primary reasons: (1) the definition of mental disorder is under debate, (2) mental disorders are multidimensional, and (3) there are significant clinical and social ramifications for thresholds of mental disorders (Clark et al., 2017). To manage the potential pitfalls of thresholds and in keeping with its primary goals, the ICD-11 describes the essential features of each disorder, providing guidance about the symptoms that clinicians can reasonably expect to find in cases of the disorder (First et al., 2015). This approach enables more flexible applications of clinical judgement while also allowing for cultural variation in symptom presentation. Unlike the DSM-5 criteria, the ICD-11 guidelines don't contain precise symptoms counts, duration thresholds, or polythetic counts (e.g. a patient must have four of a list of seven symptoms). This puts particular emphasis on that distress and impairment that are associated with symptoms (Stein et al., 2020). Through these changes, the ICD-11 aims to support clinicians in identifying the diagnostic formulation that will be most useful in making treatment and management decisions (Clark et al., 2017). There may still be a temptation to reify the particular boundaries set, potentially overlooking the impact of subclinical presentations or underestimating the resilience of individuals meeting clinical thresholds (Stein et al., 2020).

There is a perennial challenge of comorbidity in the classification of mental disorders. As the current classification systems are not completely based on causality, there is the potential for artefactual comorbidity. Multiple diagnoses in an individual may be the result of an underlying dysfunction rather than an actual range of separate disorders with underlying psychological processes involved (Stein et al., 2020). The ICD-11 CDDG has taken a pragmatic approach to comorbidity and uses the term 'co-occurrence'. It has viewed the assignment of multiple diagnostic codes as sometimes necessary to accurately describe complex clinical conditions (Clark et al., 2017). The ICD-11 also has significantly fewer exclusions rules, although it does note some. For example, developmental language disorder with impairment of pragmatic language should not be diagnosed in the presence of ASD (WHO, 2021). This clinically focused approach by the ICD-11 has the clear advantage of addressing an individual's most prominent concerns. This is consistent with Wilk et al.'s (2006) findings that practicing clinicians often focus on the more problematic aspects of a symptom picture and tend not to document all possible comorbid disorders of an individual patient. On the other hand, it has been argued that the ICD-11 emphasis on primary conditions and utility does have the disadvantage that clinically important comorbid conditions could be overlooked (Clark et al., 2017).

Similarities and Differences with DSM-5

By design, there are many similarities between the DSM-5 and ICD-11. The broad groupings they contain and the order of these groupings resulted from a series of meetings between the APA (who oversee the DSM) and the WHO (Clark et al., 2017). Both systems used a model of working groups to oversee revisions and the ICD-11 working groups, which were developed later, typically included one or more members from parallel DSM-5 groups to facilitate harmonization. Despite their revisions, both remain categorical classification systems and are fundamentally descriptive in nature (Clark et al., 2017).

While there are many similarities, there are a number of distinct differences which are notable. ICD-11 coding is mandated globally and ICD guidelines are therefore used by clinicians around the world. By contrast, DSM is more widely used by researchers, because of its more specific operational criteria. A survey of close to 5000 international psychiatrists in 44 countries reported that 70% used the ICD-10 system in their everyday work, with only 23% using DSM-IV (Reed et al., 2011). Many countries, and WHO member states, have integrated ICD in policies and clinical processes relating to social services, care coverage, and disability benefits (International Advisory Group for the Revision of ICD-10 Mental and Behavioural Disorders, 2011). In addition, WHO member states are now responsible for reporting health statistics (e.g. prevalence, causes of mortality and morbidity) based on ICD to WHO.

Relating to more specific differences in classification between DSM and ICD, the ICD-11 gender identity disorders are substantially revised and renamed to ‘gender incongruence’ (see Reed et al., 2016 for further discussion). Particularly in relation to children, disruptive behavioural and dissocial disorders and impulsive control disorders are grouped in separate chapters, but combined in DSM-5. Complex-PTSD and prolonged grief disorder were recommended for inclusion in ICD-11, but not included in DSM-5. Conversely, DSM-5 has included disruptive mood dysregulation disorder while this is not in ICD-11. Finally, in relation to approaches to comorbidity, there is substantial similarity between the two systems, though the more specified criteria of DSM-5 can perhaps lead more individuals to have multiple diagnoses (Clark et al. 2017; First et al., 2021).

Gaming Disorder

Gaming disorder is a new addition to the ICD-11 and provides a useful exemplar for controversies that can arise with new diagnostic categories. A widely cited article in a peer reviewed journal by a group of authors in the field (Aarseth et al., 2017) reflected their concerns about including gaming disorder. Five main concerns were, (1) that there is low quality of research supporting its inclusion, (2) the operationalization leans heavily on the criteria of other, traditional addictive disorders, (3) there is little consensus among scholars on the symptomatology and assessment of the problem behaviours, (4) concerns around the stigmatization and potentially forced treatment of healthy ‘gamers’, and that (5) such false-positive cases would hinder research needed to better understand the phenomenology of problematic gaming.

A response paper by Király and Demetrovics (2017) reviewed the concerns raised by Aarseth and colleagues and submitted that on balance there were more advantages than disadvantages to the inclusion of Gaming Disorder (Billieux et al., 2021). The authors address all five of the original paper’s concerns; for brevity, only three will be reviewed here. Király and Demetrovics agreed that while the overall quality of research in the field requires improvement (e.g. there are few clinical and longitudinal studies, and survey studies are overrepresented), the qualitative studies there clearly demonstrate that a minority of gamers experience significant functional and psychological impairment related to their excessive gaming. This, they conclude, establishes with certainty that the problematic behaviour exists (King et al., 2019).

In reference to the suggestion that there is little consensus among scholars on the symptomatology, the authors argue that the gaming disorder criteria comprise only the less-debated criteria (behavioural salience, losing interest in, and reducing other recreational activities) and those with strong general support (loss of control continuation of the playing behaviour despite negative consequences, and risking relationships and opportunities). However, work on the ICD-11 revision has given impetus to review the evidence and obtain consensus (Castro-Calvo et al., 2021).

Finally, Kirăly and Demetrovics (2017) address concerns that the inclusion of gaming disorder may stigmatize millions of healthy gamers and could contribute to treatment of many false-positive casers. They contend that moral panic and stigmatization is more likely to originate from media scaremongering and generation gaps (e.g. mentality of younger and older generations) than the existence of a formal diagnosis. They conclude that a formal diagnosis might decrease stigmatization by regarding problematic gaming not as a personal weakness or bad character but rather as a disorder in the same way depression is considered a disorder rather than laziness. However, others have emphasized the public health benefits of including gaming disorder in the ICD-11 (Stein et al., 2018).

The inclusion of gaming disorder is one of several new disorders in the MBND chapter of ICD-11. Each has met with differing amounts of controversy and critique as might be expected. As Kirăly and Demetrovics conclude, ‘the definitions of mental disorders are the products of temporary consensuses among professionals and as such they are dynamically changing entities, there will be the possibility to smoothen or modify the criteria in the future based on new empirical results.’ (Kirăly & Demetrovics, 2017; Stein et al., 2021).

Conclusion

The ICD-11 represents an important advance in psychiatric nosology and global mental health. While there are clear debates around psychiatric nosology broadly and some of the specific revisions in ICD-11, it nonetheless reflects a step forward for psychiatric classification and is likely to impact widely on clinical practice. Three critical advancements are raised by Stein and Reed (2019). First, the ICD-11 has drawn on key strengths of the DSM and other classification systems like the Research Domain Criteria Project. In particular, ICD-11 emphasizes that nosological decision-making should be underpinned by evidence. Close collaboration between DSM-5 developers and ICD-11 Working Groups ensured neuroscience influenced decisions around the structure of the classification systems and that broadly similar structures were adopted (Clark et al., 2017; Stein & Reed, 2019). Second, ICD is available freely across the globe, making it more likely that it will be used in a range of settings, improving diagnosis and treatment (Stein & Reed, 2019). Its emphasis on clinical utility and efforts to ensure it is user-friendly and suited for adoption by non-specialists in primary care settings globally further increases the likelihood it will assist in efforts to reduce the global burden of disease. There are significant implications for clinical child psychology practitioners with the introduction of new diagnoses (e.g. gaming disorder, complex post-traumatic stress disorder) and an emphasis on guidelines and clinical judgement rather than fixed criteria. Finally, despite its revisions, the ICD-11 has maintained its unique identity and vision as a fit-for-purpose instrument (Stein, 2013; Stein & Reed, 2019). Its focus on providing flexible guidance in an acceptable and feasible manner for clinicians in multiple settings makes it more likely to be implemented on a broad scale. While it is too soon to determine the impact ICD-11 may have on global health and its efforts to reduce burden of disease, it is likely to play a significant role in psychiatry, psychology, and the advancement of mental health worldwide.

DSM-5 and Clinical Child Psychology

Allison Smith Dupré and Paul Spano

Introduction

Dominating globally for the past 30 years, the American Psychiatric Association's (APA) *Diagnostic and Statistical Manual of Mental Disorders* (DSM) has been the most widely used and accepted diagnostic manual for psychological disorders in the United States (Demazeux & Singy, 2015; Arbanas, 2015; American Psychological Association, 2013). Since the publication of DSM-III, mental health professionals in over 40 countries have relied on the DSM for teaching, research, and clinical practice (Maser et al., 1991). To date, the DSM-5 (APA, 2013) has been published in 24 languages (DSM-5, 2017) and distributed around the world. For each disorder, the DSM provides an overview of the disorder, symptoms required to meet diagnostic criteria, prevalence rates, associated risk factors, and common comorbidities (APA, 2013). The development of the DSM served as a catalyst that increased the prominence of psychiatry in America (Demazeux & Singy, 2015) and research indicates that the majority of etiological and treatment research for psychological disorders relies primarily on DSM criteria (Castonguay & Oltmanns, 2013). Its utility ranges from clinical and research purposes in psychology to insurance codes and court testimony (Blackman, 2016). In addition to professional use, DSM criteria have been regularly mentioned in newspapers and health magazines in various countries to reference mental health (Demazeux & Singy, 2015).

The DSM has undergone several revisions since its original publication in 1952 (Akram et al., 2017), which have led to changes in how psychopathology has been defined and categorized over the past several decades. While criticisms surrounding the current publication remain, the DSM-5 continues to dominate the field in terms of guiding clinical practice, research, and informing insurance providers with necessary documentation for services. In this chapter, the DSM, its history, and its clinical and practical utility are reviewed and discussed.

Nosology

Nosology, the “discipline and practices that deal with the classification of disease”, has been an interest in the fields of psychiatry and psychology for decades (Akram et al., 2017). The categorization of psychological disorders allows for advances in psychological research and clinical practice. Since the 1800s, attempts have been made to establish a standardized classification system for mental disorders in the United States. The efforts were primarily interested in achieving large-scale data collection and strengthening the legitimacy of the field of psychiatry (Grob, 1991). Endeavors to categorize mental illness have led to questions regarding the methodology of classification. Many have attempted to understand the etiology of psychological disorders in terms of genetics through identification of biomarkers (Van Dam et al., 2017). This research has explored biomarkers related to many psychological disorders ranging from autism spectrum disorder and attention deficit/hyperactivity disorder to major depressive disorder and posttraumatic stress disorder (Kennis et al., 2019; Lehrner & Yehuda, 2014; Rose & Ashwood, 2014; Wallis, 2010). However, unlike medical conditions, the field of psychology lacks an abundance of research pointing to reliable biomarkers.

A Case for Classification

The first step in studying, detecting, and treating psychological disorders is the identification and labeling of diagnoses. In order to successfully communicate within the fields of psychology and psychiatry as well as across other related fields (e.g., medicine) and the public, it is essential to use a common language. This is critical for standardizing classification in a universal and homogenized way (Akram et al., 2017).

Classification of disorders aids clinicians in directing treatment planning, enables researchers to study well-defined groups, and enhances communication among professionals and with the public. Additionally, standardized classification systems provide an organized way to gather information about various disorders and a basis for describing similarities and differences in presentation (Muris et al., 2019). By providing a framework for what is typical versus atypical, classification systems help clinicians determine when and how individuals should be treated. For example, a clinician would recommend and implement a very different treatment plan for an individual with autism spectrum disorder than one with an anxiety disorder. Further, even for diagnoses within the same category, differential diagnosis can inform treatment. For instance, an individual with a specific phobia diagnosis may undergo brief exposure therapy in One-Session Treatment (OST) (Zlomke & Davis, 2008), while an individual with generalized anxiety disorder would likely start a longer treatment plan such as cognitive behavioral therapy (CBT).

By classifying disorders, researchers can then use diagnostic categories to ensure homogenous samples (Tevis et al., 2021; Frances & Widiger, 2012). Additionally, classification provides researchers and clinicians within the field with a common language (Volkmar & McPartland, 2014). Without some formal diagnostic categorization and common language, psychological diagnoses would be left to clinician subjectivity. This would severely impede the reliability and validity of the field of clinical psychology at large, as specific disorders, their etiology, prevalence, symptom presentation, and treatment could not be studied differentially.

Challenges of Classification

Due to limited research of biomarkers at this time, current classification systems are forced to rely on symptomology. Unfortunately, this reliance on reported and observed symptoms can and has led to issues with construct validity, as the construct (e.g., disorder) being studied cannot be directly observed (Tevis et al., 2021). With concern about construct validity comes that of reliability. In other words, if the construct being studied is not measuring what it claims to be measuring, it is likely that the measure (or classification system) will not produce consistent results. Further, using classification systems to diagnose child psychopathology poses additional challenges, as a clinician must rely on the parent's report of their child's symptoms or the child's limited insight.

Research also suggests that psychological disorders are not typically the result of a single cause but are likely a combination of several factors. Etiological research indicates that genetics (Bolton et al., 2006), neurobiology (McClure et al., 2007), child temperament (Hudson & Dodd, 2012), family environment (Bögels & Brechman-Toussaint, 2006), and learning (Chorpita et al., 1996) all play a role in the development of psychopathology in children and adolescents. In addition to each factor's independent effects, the literature supports interaction effects. These gene-environment interactions can determine expressions of genetic or environmental predispositions. The constructs of equifinality and multifinality aid in understanding this process. Equifinality is the concept "in which multiple developmental paths lead to similar behavior" (Youngstrom & Algorta, 2014). This explains how two individuals with very different genetic makeup and environments can both arrive at the same diagnosis. Multifinality, a construct that says one pathway is associated with many outcomes (Kruglanski et al., 2015), can be used to describe how two individuals exposed to the same traumatic experience respond differently. In other words, different factors can result in the same disorder (equifinality) and similar factors can lead to various psychological disorders (multifinality). The etiological complexity of psychology makes it difficult to identify the root of disorders, thus, creating challenges to classification.

Further, child and adolescent psychopathology poses unique challenges to classification. While some behaviors are viewed as typical during development (e.g., defiance or shyness), if these behaviors persist and become severe and impairing enough, they may meet criteria for a diagnosis (e.g., oppositional defiant disorder or social anxiety disorder). To address this, many classification systems have incorporated some form of developmental considerations or age requirements in their diagnostic criteria. Still, those who are skeptical of classification systems argue that labeling disorders can increase stigmatization and pathologize non-Western cultures (Tyrer, 2014). Additionally, some argue that the use of classification systems overestimates psychopathology, as the number of diagnosable disorders grows. While some of this growth could be due to increased interest and study of psychopathology, critics suggest that the prevalence rates are out of proportion. Kessler et al. (2005) found that almost half of Americans meet criteria for at least one DSM disorder over the course of their life.

Despite the shortcomings of classification, all attempts to move away from grouping systems have led to alternate forms of classification or internal reliance on clinician's own internal classification system, leading to a lack of reliability. While imperfect, the advantages to having a universal system are undeniable: to facilitate communication, provide a reference system to be used in practice, and provide homogenous samples for research (Lempérière, 1995). Thus, several systems have been published to eliminate subjectivity and create a common language in the field. Among the most prominent classification systems are American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association, 2013) and the National Institute of Mental Health's *Research Domain Criteria project* (*RDoC*) (Insel et al., 2010).

History

Pre-DSM Nosology

In the nineteenth century, attempts to establish a standardized diagnostic taxonomy in the United States were made primarily to collect data that would inform public policies (Grob, 1991). Though a standardized taxonomy would have little clinical utility at the time, nineteenth-century psychiatrists recognized the value of large-scale data collection; for instance, quantitative research could provide information on recovery rates and bolster the legitimacy of the profession (Grob, 1991). In 1918, the APA published the first standardized diagnostic taxonomy in the United States: *Statistical Manual for the Use of Institutions for the Insane* (Grob, 1991). The manual's many critics cited the fact that it was extremely limited in scope, as it was primarily created to collect data for the United States National Committee for Mental Hygiene. As a result, it had little clinical utility and was ignored by many American psychiatrists who instead continued to rely on their own psychoanalytic conceptualizations. Because there were no effective treatments for many mental illnesses, many American psychiatrists believed that diagnostic precision was not clinically useful. Still, the APA went on to publish nine more editions of the *Statistical Manual* prior to World War II (Fischer, 2012).

DSM-I and DSM-II

The *DSM-I*, as it was called upon publication, reflected the heavy influence of psychoanalysis on American psychiatry. Nearly every disorder included in the *DSM-I* was considered a "reaction," and several were defined by the defense mechanisms that were likely to be used. Diagnoses were made by comparison to brief descriptions of typical presentations, and there were several restrictions on diagnosing comorbid conditions for ease of reporting statistics (Fischer, 2012; APA, 1952). Mental disorders were described as being caused either by organic brain dysfunction or "difficulty in adaptation" (i.e., environmental stressors). Each section opened with a brief description of a disorder, followed by paragraph-long descriptions of relevant psychiatric conditions termed "reactions" (APA, 1952). As would be the case for future editions, the *DSM-1* was considered a live document. The manual's introduction commented on the limits of the "present day descriptive nature of psychiatric diagnoses," noting that future editions should include information on etiology, pathology, prognosis, and even treatment (APA, 1952).

Almost all disorders were of adulthood, with the exception of two childhood "reactions": adjustment and schizophrenic. The latter reaction was characterized by "reduction in external attachments and interests and by impoverishment of human relationships" (APA, 1952). The *DSM-1* also referenced "the disturbance in intellectual development and learning ability" that might result from an organic brain syndrome occurring in utero, infancy, or childhood (APA, 1952). These brief descriptions of childhood psychopathology arguably set the foundation for future conceptualizations of autism spectrum disorders, intellectual disabilities, and other neurodevelopmental disorders.

The publication of the *DSM-II* coincides with the development of the eighth edition of the *International Classification of Diseases* (ICD-8) by the World Health Organization (WHO) in 1948. The APA's Committee on Nomenclature and Statistics sought to update the DSM in order to align it with the ICD (Fischer, 2012). In the 1950s and 1960s, the influence of psychodynamic traditions on American psychiatry had weakened; instead, psychopharmacology revolutionized the field as it underwent a "deinstitutionalization" phase that released many patients with severe mental illnesses into the community. Psychopharmacology, rather than psychoanalytic therapy, proved to be relatively more effective for these individuals (Akram et al., 2017). Published in 1968, the *DSM-II* expanded from the first edition's two divisions (i.e., organic and functional illnesses) to ten categories that were systematically arranged.

Like some modern structured diagnostic interviews, the manual was designed to allow clinicians to consider each category sequentially until they arrived at a diagnosis (Fischer, 2012; APA, 1968). For the first time, the manual devoted a section to "Behavior Disorders of Childhood and Adolescence" and introduced it with the following conceptualization: "This major category is reserved for disorders occurring in childhood and adolescence that are more stable, internalized, and resistant to treatment than Transient situational disturbances but less so than Psychoses, Neuroses, and Personality disorders. This intermediate stability is attributed to the greater fluidity of all behavior at this age" (APA, 1968). Representing a significant shift away from psychodynamic traditions, the term "reaction" was removed from all adult disorders. Still, the *DSM-II* used exclusively psychodynamic concepts to describe childhood psychopathology in the new "Behavior Disorders of Childhood and Adolescence" category. Seven reactions "of childhood (or adolescence)" were included: hyperkinetic, withdrawing, overanxious, runaway, unsocialized aggressive, group delinquent, and other (APA, 1968).

DSM-III and DSM-IV: A Paradigm Shift

In 1980, following intense scrutiny from both within and outside the field, the 132-page *DSM-II* was replaced by the 500-page *DSM-III* (Wilson, 1993; APA, 1980, 1968). An enduring criticism of the *DSM-II* set the stage for the development of the *DSM-III*: "Increasingly," noted two prominent *DSM-III* editors, "there is pressure for the medical profession and psychiatry in particular to define its area of responsibility" (Spitzer et al., 1978). The *DSM-III* is often heralded as a paradigm shift away from psychodynamic traditions and towards biological psychiatry, as the psychopharmacological boom of the 1960s demonstrated that neurobiological factors may underlie the development of psychopathology (Shorter, 2013). Unlike the *DSM-III,* previous editions encouraged diagnosis via comparison to prototypical case examples. Revolutionary to the *DSM-III* was the inclusion of "diagnostic criteria," or symptom lists that attempted to distill the core features of each disorder. This was the first edition to include explicitly defined criteria in an effort to bolster diagnostic reliability (Shorter, 2015; APA, 1980). In an attempt to incorporate the biopsychosocial model of psychopathology, the *DSM-III* introduced the multiaxial system of diagnosis. This system called for the assessment of presenting symptoms, personality characteristics, medical conditions, psychosocial and environmental factors, and general functioning (APA, 1980).

The *DSM-III* included the category of "Disorders Usually First Evident in Infancy, Childhood, or Adolescence," which contained five "classes" of disorders: intellectual, behavioral (e.g., attention deficit disorder [ADD] and conduct disorder), emotional (e.g., anxiety disorders), physical (e.g., eating disorders and stereotyped movement disorders), and developmental (e.g., pervasive developmental disorder). This edition was first to include the diagnoses of ADD, bipolar disorder, posttraumatic stress disorder, and several new anxiety disorders (Shorter, 2015; APA, 1980). Borrowing from European nosology, the *DSM-III* was also the first edition to distinguish between affective disorders based on polarity – and with psychopharmacology in vogue, bipolar disorder quickly became one of the most popular diagnoses and led to heavy marketing of mood stabilizers by pharmaceutical companies (Shorter, 2015). Ultimately, the influence of the *DSM-III* is difficult to overstate: its publication launched hundreds of disorder-specific randomized controlled trials and led to the investment of billions of federal dollars for psychopharmacological research (Kawa & Giordano, 2012). A slightly revised edition, the *DSM-III-R*, was published in 1987, changing ADD to attention deficit/hyperactivity disorder (ADHD), removing the schizoid disorder of childhood or adolescence, and introducing the term "mood disorders" in place of "affective disorders" (Akram et al., 2017; APA, 1987).

Notably, the *DSM-III* was the first to utilize federally sponsored field trials to ensure good diagnostic reliability (Spitzer et al., 1978). Prior editions demonstrated fairly low reliability. *DSM* developers expected that new diagnostic criteria, the use of a multiaxial system, and changes to the grouping of disorders would result in improved reliability. Indeed, the reliability of the *DSM-II* was fairly good for nearly all disorders. Major disorders, such as schizophrenia and major affective disorders, demonstrated the strongest reliability; disorders such as schizoaffective disorder and similar personality disorders demonstrated only fair reliability (Spitzer et al., 1979). Another phase of field trials investigated the utility of the multiaxial system, concluding that clinicians generally find the system useful, though the fourth axis – which asked clinicians to rate the severity of psychopathology – suffered from inconsistent reliability (Spitzer & Forman, 1979). Similar critiques of the multiaxial system persisted until its elimination by the *DSM-5* (APA, 2013).

The *DSM-III* also introduced the use of a specialized task force responsible for the overall research and compilation of the manual. Fifteen experts from various subfields were recruited to increase the precision of diagnostic definitions, update diagnostic criteria in light of new research, and settle debates about the inclusion or removal of certain criteria (Davies, 2017). Essentially, the use of a task force was an early step towards the democratization of the *DSM*; now, diagnostic criteria were developed after a consensus was reached by members of the task force. This represented a significant departure from previous editions, which relied on widely accepted, but not necessarily empirical, definitions (Davies, 2017).

Subsequent editions did not deviate far from the *DSM-III;* each enhanced the specificity of diagnostic criteria while exponentially increasing in size and scope (Akram et al., 2017). Published in 1994, the *DSM-IV* included only minor revisions that sought to clarify certain diagnostic criteria and correct several inconsistencies in light of new research (APA, 1994). A minor text revision, *DSM-IV-TR*, was published in 2000; included was a brief update to the description of Asperger's disorder. A major contribution of the *DSM-IV* was the addition of criteria for the "clinical significance" of each disorder, emphasizing the importance of subjective impairment or distress to the definition of "mental disorder" (APA, 1994). Similarly, the *DSM-IV* included a category for "culture-bound syndromes," recognizing that certain mental disorders may present differently across cultures (APA, 1994). The fourth edition also added Rett's disorder and Asperger's disorder to the pervasive developmental disorder category (APA, 1994), foreshadowing the *DSM-V*'s shift towards a dimensional conceptualization of autism spectrum disorders.

Like the previous edition, the *DSM-IV* was also subjected to rigorous field trials, many of which were directed specifically at disorders of childhood and adolescence. One field trial concluded that, compared to *DSM-III* criteria, *DSM-IV* criteria for ADHD were better able to detect impairment in girls and preschool children (Lahey et al., 1994a). Similarly, field trials were conducted for the diagnoses of oppositional defiant disorder (ODD) and conduct disorder (CD); this trial concluded that, despite loosening criteria, the prevalence of each disorder remains largely unchanged. Each disorder also demonstrated higher internal consistency and test-retest reliability when compared to previous editions (Lahey et al., 1994b). Finally, a field trial of autistic disorder (considered a type of pervasive developmental disorder) concluded that previous *DSM-III* criteria were overly broad and associated with false positives, in part because it failed to address developmental issues (Volkmar et al., 1994). In comparison, the detailed ICD-10 criteria demonstrated fairly high reliability; as a result, Volkmar et al. (1994) concluded that use of modified ICD-10 criteria in the *DSM-IV* would allow for convergence between the two manuals.

Developing the DSM-5

DSM-5 Task Force

Led by a dedicated task force, the development of the DSM-5 was a 12-year process that concluded with publication in 2013 (APA, 2013). Like subsequent editions, the *DSM-5* was informed by 13 work groups, each responsible for a particular diagnostic category (e.g., mood disorders, childhood and adolescent disorders, and ADHD and disruptive behavior disorders). They were tasked with conducting rigorous literature reviews to identify key points of contention. These work groups then drafted diagnostic criteria and accompanying text, before subjecting these drafts to intensive peer and public review (APA, 2013). The APA (2013) noted that, generally, the *DSM* serves as a "historically determined cognitive schema imposed on clinical and scientific information to increase its comprehensibility and utility." In other words, the *DSM-5* is considered a "living document," as it is ultimately a culturally informed, theoretical distillation of available literature. For this reason, conceptualizations are expected to change as the field generates new findings in neurobiology and epidemiology, and as it reckons with the blurred distinction between disorder and normalcy.

DSM-5 Field Trials

The DSM-5 work groups also conducted several field trials to empirically demonstrate the reliability of proposed diagnostic categories, a precedent set by the *DSM-III* (APA, 1980). The DSM-5 field trials were conducted both at large academic medical centers, to establish reliability and clinical utility with a large sample size, and smaller clinical practices, in order to evaluate clinical utility in a routine, everyday clinical environment (APA, 2013).

Field trials concluded that many diagnostic categories demonstrated good to very good test-retest reliability (e.g., ADHD, ASD, PTSD, and adult neurocognitive disorders). Notably, the reliability of major depressive disorder fell within the questionable range, likely due to its comorbidity with several other disorders and the heterogeneity in presentation. These trials also failed to find evidence for a distinct, and newly proposed, "mixed anxiety-depressive disorder" (Regier et al., 2013a, b). As a temporary solution, the DSM-5's conceptualization of MDD includes several specifiers to bolster precision and improve the reliability and validity of differential diagnoses. For instance, the "mixed" specifier suggests prominent features of mania/hypomania, and the "anxious distress" specifier signals the presence of prominent anxiety (APA, 2013).

Major Developments

Dimensional Approach

Prior editions of the *DSM* utilized a categorical approach, conceptualizing psychopathology in terms of distinct, narrow constructs. This approach proved to be problematic, as it did not account for shared symptoms or etiological risk factors. Several DSM-5 field trials provided evidence for the utility of a dimensional approach, which conceptualizes psychopathology on a spectrum of severity (APA, 2013; Regier et al., 2013a, b). Within child and adolescent disorders, this change is best demonstrated by the elimination of Asperger's disorder, last seen in the *DSM-IV*, in favor of a general autism spectrum disorder (ASD). Underlying this change is the idea that all "forms" of ASD, regardless of "severity," share underlying etiological and neurobiological factors. For this reason, Asperger's disorder may be better represented by a diagnosis of ASD, Level one (APA, 2013).

The use of a dimensional approach reportedly serves two purposes. First, this approach ostensibly serves as a "bridge" to novel diagnostic approaches (e.g., those based primarily on neurobiological underpinnings), without significantly interfering with current clinical practices. Second, this approach acts as a framework for researchers to systemically investigate etiological factors and neurobiological similarities between disorders, as they are no longer held to strict categorical bounds (APA, 2013). In line with a dimensional approach, *DSM-5* field trials also informed the *DSM-5*'s distinction between internalizing and externalizing clusters of disorders, as evidence from twin studies suggests that disorders within each cluster are associated with similar genetic and environmental risk factors (APA, 2013).

Developmental and Lifespan Considerations

Disorders in the DSM-5 are arranged developmentally, beginning first with those that often manifest early in one's life. For instance, the manual first describes neurodevelopmental disorders (e.g., ADHD and ASD). Towards the manual's end are descriptions of disorders associated with older adulthood, such as neurocognitive disorders (e.g., cognitive impairments due to Alzheimer's disease). Similarly, disorders within each chapter are also arranged developmentally. For example, the chapter on depressive disorders begins with a description of disruptive mood dysregulation disorder; major depressive disorder and substance/medication-induced depressive disorder are described later in the chapter. This organization is meant to encourage the consideration of lifespan information when making diagnostic decisions (APA, 2013).

Elimination of the Multiaxial System

Finally, the *DSM-5* eliminated the multiaxial system utilized by the *DSM-IV* (APA, 1994). This change was explained by the fact that the *DSM-IV* never formally required the use of this system; rather, its widespread use was to the benefit of insurance and governmental agencies (APA, 2013). Instead, the *DSM-5* combines axis III with axes I and II and offers notations for documenting psychosocial and contextual factors (i.e., axis IV). Axis V, once a measure of global functioning (i.e., GAF scale), was eliminated, as it demonstrated poor construct validity and questionable reliability (APA, 2013).

Implications for Child and Adolescent Psychopathology

Attention-Deficit Hyperactivity Disorder

Like the DSM-IV (APA, 1994), the DSM-5 describes three variants of ADHD (i.e., predominantly inattentive, predominantly hyperactive/impulsive, and combined). Based on longitudinal research suggesting that the *DSM-IV* subtypes are fluid across the lifespan (Wilcutt et al., 2012), the DSM-5 considers each variant a different "presentation," rather than a discrete subtype. In other words, presentations of ADHD are prone to changing across the lifespan. Each presentation is associated with functional difficulties in its respective behavioral domain (i.e., attention or hyperactivity/impulsivity), with the combined presentation still referring to significant levels of both inattention and hyperactivity/impulsivity (APA, 2013).

Obsessive-Compulsive Disorder

Consistent with the *DSM-IV*, the conceptualization of OCD is similar for both children and adults. However, in the *DSM-5,* OCD was removed from the anxiety disorders category and placed into a novel category: obsessive-compulsive and related disorders (OCRD). The category also includes body dysmorphic disorder, hoarding disorder, trichotillomania, and excoriation disorder (APA, 2013). This reorganization is supported by research suggesting that these disorders are associated with similar risk factors, neurocircuitry, comorbidities, and treatment responses (Hollander et al., 2008). In other words, research has shown that these disorders are more related to each other than they are to the various anxiety disorders. Proponents of this change also argue that these disorders have been historically undertreated and underresearched; the inclusion of a dedicated OCRD category should, in theory, draw attention to the screening, diagnosis, and study of these disorders. Others argue that the change is premature, and that OCRDs might be best subsumed under a broader affective spectrum disorders category, which could also include depressive and anxiety disorders (Hollander et al., 2008).

Autism Spectrum Disorder

Perhaps the most controversial change was that made to the conceptualization of autism. Wing (1996) first used the term "autistic spectrum disorders" to suggest that pervasive developmental disorders (PDD) are best organized on a spectrum of severity. In line with Wing (1996) and more recent research, the *DSM-5* eliminated the category of PDD, thereby eliminating the popular diagnoses of Asperger disorder and PDD, not otherwise specified (PDD-NOS). Diagnoses that were once subsumed under PDD demonstrated inadequate inter-rater reliability, and *DSM-IV* criteria were vague enough that many clinicians began to develop personal criteria for making differential diagnoses between PDD subtypes (Lord & Jones, 2012). Ultimately, this dimensional approach suggests that ASD should be classified according to dimensions of its core features (i.e., deficits in social communication and restricted, repetitive behaviors or interests), as the severity of these features tends to predict treatment response (Sheinkopf & Siegel, 1998).

Still, this dimensional approach undermines the *DSM-5's* attempt to group disorders based on distinct neurobiological factors, as literature on these factors and how they relate to each "dimension" of ASD has been relatively inconclusive (Lord & Jones, 2012). Instead, this approach emphasizes practicality and assists with treatment planning. In other word, each "level" of ASD is associated with the level of support required to increase quality of life and, if possible, independence. Level one refers to individuals "requiring support," level two refers to individuals "requiring substantial support," and level three refers to individuals "requiring very substantial support" (APA, 2013).

Posttraumatic Stress Disorder

The *DSM-5* retained the four symptom categories described by the *DSM-IV* (i.e., exposure to a traumatic event, presence of intrusive symptoms, avoidance of feared stimuli, and heightened arousal) and added a fifth symptom category related to negative alternations in cognitions and mood (APA, 2013, 1994). Criteria were also modified to include developmentally appropriate presentations of PTSD symptoms that emphasize observable behavioral symptoms. For instance, in young children, “recurrent, involuntary, and intrusive distressing memories” may be manifested in repetitive play, and dissociative reactions may be manifested as “trauma-specific reenactments.” Additionally, the *DSM*-5 notes that children with heightened arousal may engage in extreme temper tantrums (APA, 2013).

Criticisms

Diagnostic Inflation

A major critique that has persisted for decades is that the widening of diagnostic criteria potentially contributes to overdiagnosis and the pathologizing of typical responses to life experiences. For instance, Kessler et al. (2005) noted that nearly half of Americans will meet *DSM-IV* criteria for a disorder in their lifetime. However, research suggests that changes to *DSM-5* criteria had only a minimal effect on prevalence rates for each disorder. A meta-analysis found that, despite constantly shifting diagnostic criteria for ADHD, the prevalence of ADHD has not significantly changed with each *DSM* edition (Thomas et al., 2015). Similarly, *DSM-5* criteria for binge eating disorder and bulimia nervosa were found to result in better detection without significantly raising the lifetime prevalence rate (Trace et al., 2012). A recent meta-analysis suggested that inflated diagnoses are generally no more common than deflated diagnoses (Fabiano & Haslam, 2020). Still, the largest degree of inflation was observed after the transition from *DSM-III* to *DSM-III-R* and from *DSM-IV* to *DSM-V*, though these trends were weak and unreliable between disorders. In other words, no particular disorder is associated with significant hyperinflation, and authors conclude that concerns of diagnostic inflation with each *DSM* edition are likely “overstated” (Fabiano & Haslam, 2020).

Limited Data on Neurobiological Substrates

In many ways, the ideology behind the *DSM-5* has yet to be fully realized. Editors of the *DSM-5* sought to establish distinct clusters of disorders based on shared neurobiological factors and etiologies (APA, 2013). Kupfer and Regier (2011), two of the *DSM-5*’s editors, suggested that the goals set in their research agenda (Kupfer et al., 2002) would not be entirely met in time for publication of the *DSM-5*. Ultimately, these goals were met to varying degrees. For instance, the *DSM-5* included an autism spectrum disorder, thereby eliminating the *DSM-IV*’s diagnoses of pervasive developmental disorder, autistic disorder, and Asperger’s disorder, to name a few (APA, 2013). This decision was informed by studies suggesting that those *DSM-IV* diagnoses may have a common neurobiological substrate (Kupfer & Regier, 2011). On the other hand, there may be a weaker empirical basis for the addition of a distinct “Obsessive-Compulsive and Related Disorders” category based on shared neurobiological substrates. Though the category ostensibly raises awareness of historically understudied disorders, Abramowitz and Jacoby (2015) noted that the category should be rejected on scientific grounds as it seems partially informed by misinterpreted – and cherry-picked – brain-imaging and treatment outcome studies. Still, editors of the *DSM-5* provided an optimistic commentary: “As we gradually build on our knowledge of mental disorders,” Kupfer and Regier (2011) noted, “we begin bridging the gap between what lies behind use (presumed etiologies based on phenomenology) and what we hope lies ahead (identifiable pathophysiologic etiologies).”

Much criticism surrounding the DSM can be attributed to what is characterized as a disorder. Due to the lack of known biological basis, current psychological diagnoses rely on report and observations of symptoms associated with disorders. Unlike physicians, clinicians cannot depend on blood tests or x-rays to determine whether or not an individual's symptoms meet the clinical threshold for a particular disorder. Classification systems such as the DSM will undergo "continual refinement and modification" (Akram et al., 2017). With this knowledge, scientists are encouraged to maintain a healthy balance of confidence and questioning of the systems in place.

Using the DSM

Structure of the DSM-V

One primary goal in developing the organizational structure of the DSM-5 was to group disorders into "clusters based on shared pathophysiology, genetics, disease risk, and other findings from neuroscience and clinical experience" (Regier et al., 2013a, b). Typically, disorders that are listed in the same cluster or chapter of the DSM are assumed to have shared etiology, have high rates of comorbidity, and share similar methods of treatment. Clustering of disorders can also aid in differential diagnosis. For these reasons, the way disorders are grouped can have significant implications in assessment and treatment (Stein et al., 2011). Attempts to group disorders is a complex process, as many disorders with shared symptom presentations and treatment approaches differ in the neuronal circuits at play (e.g., OCD and other anxiety disorders) (Stein et al., 2010). Efforts to cluster individual disorders proves to be a trying task, as there is an abundance of research showing commonalities and distinctions in disorders. It is an effort to balance the current research including distinctions found in neuroimaging and biomarkers to symptom presentation and treatment response.

The current manual reflects this effort to group individual disorders into meaningful clusters by reordering and reorganizing existing disorders. In the introduction of the DSM-5, the authors state that "the revised structure" should "stimulate new clinical perspectives" and "encourage researchers to identify the psychological and physiological cross-cutting factors that are not bound by strict categorical designations" (APA, 2013). The DSM-5 task force utilized several scientific validators such as shared neural substrates, genetic and environmental risk factors, symptom similarity, and high comorbidity to inform decisions about how to cluster disorders in a way to maximize clinical usefulness and validity (APA, 2013). Additionally, in order to reflect a more developmental approach, the DSM-5 organizes diagnostic categories and diagnoses within each category in order of earliest to latest manifestation. For instance, the first category covers neurodevelopmental disorders such as intellectual disabilities, autism spectrum disorder, and attention-deficit/hyperactivity disorder. Within the anxiety disorders section, the developmental approach is reflected by listing separation anxiety disorder at the beginning, as this disorder typically affects a younger population than the other anxiety disorders.

At the beginning of each chapter (i.e., cluster of diagnoses), there is a brief introduction describing the category of disorders. This provides a reference for clinicians and researchers to understand how the disorders found in the chapter are related. For each individual disorder, the manual lists diagnostic criteria, occasionally including age of onset, duration, and frequency of symptoms (Joyce-Beaulieu & Sulkowski, 2016). Below, various applicable sections follow including: specifiers, diagnostic features, associated features, prevalence, development and course, risk and prognosis, culture-related and gender-related diagnostic issues, diagnostic markers, differential diagnoses, comorbidity, and relationship to other classifications. The sections following the diagnostic criteria provide useful information for clinicians regarding defining characteristics consistent with each disorder, differences in prevalence based on gender, age, and nationality, lifetime patterns of each disorder, and information to help make decisions about ruling a disorder in or out (Joyce-Beaulieu & Sulkowski, 2016).

DSM in Assessment

The DSM-5 is clear about the way in which the manual should be appropriately utilized. Rather than relying on the diagnostic criteria as a checklist to diagnose disorders, clinicians must employ their clinical judgment in order to clearly understand the severity and impairment associated with the symptoms present. The manual should be used as a guide by clinically trained professionals to aid in clinical case formulation. Several measures have been developed based on the DSM's criteria to aid in clinical assessment and research, including structured and semi-structured interviews, questionnaires, and observation-based measures. Using the DSM as their guide, these measures aid clinicians in their diagnostic assessments of various disorders.

Structured and semi-structured interviews based on standardized questions, based on DSM criteria, are popular tools used in assessment (Matson & Hong, 2018). Some of the most common interview systems used for psychological evaluations of youth include: the Child and Adolescent Psychiatric Assessment (CAPA; Angold et al., 1995), the Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS; Puig-Antich & Chambers, 1978), the Interview Schedule for Children and Adolescents (ISCA; Sherrill & Kovacs, 2000), the Child Assessment Schedule (CAS Hodges et al., 1982), the Diagnostic Interview for Children and Adolescents (DICA; Reich, 2000), the Diagnostic Interview Schedule for Children (DISC; Costello et al., 1982), the Structured Clinical Interview for the DSM (SCID; First, 2014), and the Anxiety Disorders Interview Schedule for Children (ADIS-C/P; Silverman & Albano, 1996). While less flexible than other methods of assessment, the major strength of these interviews is the standardized questions (Matson & Hong, 2018). Some of these interviews, such as the ADIS-C/P, have separate versions to administer to parents and children, allowing clinicians to gather standardized information from both the child being assessed and their caregiver, thus, formulating a clearer picture of any diagnostic impressions.

During assessments, clinicians often give various questionnaires to gather information from parents, children, teachers, and other involved caretakers. The DSM has played an important role in guiding the development of these questionnaires, as the goal is to better understand the symptoms present and their severity in order to decide whether one meets for a disorder based on DSM criteria. There are various broadband questionnaires that serve to assess a large number of psychological problems in a short amount of time (Hoffman et al., 2016). Questionnaires such as the Achenbach System of Empirically Based Assessment (ASEBA; Achenbach & Rescorla, 2001) and the Behavior Assessment System for Children (BASC; Reynolds & Kamphaus, 1992) allow for multiple informants (e.g., parents, teachers, child) to answer questions regarding a child's behavior and emotions (Rescorla, 2009). Each of these widely used systems has attempted to mimic DSM criteria on DSM-oriented scales and "facilitate differential diagnosis among DSM psychiatric categories" (Rescorla, 2009).

Additionally, more narrowband questionnaires have been constructed in efforts to evaluate specific categories of diagnoses or individual disorders. Some DSM-based questionnaires include the Revised Child Anxiety and Depression Scale (RCADS; Muris, 2002), the Youth Anxiety Measure for DSM-5 (YAM-5; Muris et al., 2017), and the Questionnaire for Eating Disorder Diagnoses (Q-EDD; Mintz et al., 1997). Further, observation-based methods such as the Childhood Autism Rating Scale (CARS; Schopler et al., 1980) and the Autism Diagnostic Observation Schedule (ADOS; Lord et al., 2000) use diagnostic criteria outlined in the DSM to assess for behaviors related to autism spectrum disorder. Observation-based methods offer more flexibility than questionnaires, accounting for the nuances and various presentations of the diagnostic criteria listed in the DSM. Not only do interview systems, questionnaires, and observation-based methods aid in clinical assessment, but they also provide opportunities for research that evaluates DSM criteria. The ability to continue research through these standardized assessment measures allows for continued improvement of future revisions of the DSM.

DSM in Treatment

In addition to its uses for diagnostic assessment, the DSM's defining of disorders has great implications for treatment services. The DSM provides the coding system that insurance companies rely on to decide what is covered for psychological treatment (Knopf, 2022). Each disorder is assigned a code that is tied to an ICD code in order to facilitate financial reimbursement for services (Joyce-Beaulieu & Sulkowski, 2016). In some cases, certain diagnoses even qualify an individual for their own insurance policy. For instance, a diagnosis of autism spectrum disorder (ASD) qualifies an individual for their own insurance under Medicaid in order to provide "medically necessary" treatments such as Applied Behavior Analysis (ABA). DSM diagnoses also qualify youth to access services in the school system. For example, schools in the United States of America are required by law under the Individuals with Disabilities Education Act (IDEA) to provide children with disabilities free, appropriate education in the least restrictive environment (Individuals With Disabilities Education Act, 2004). This can include 504 accommodations or individualized education plans (IEP) to aid children who qualify based on diagnoses (e.g., ADHD, specific learning disorder, ASD). Further, the DSM guides differential diagnosis, which then directs treatment, as empirically supported treatment plans vary depending on the diagnosis. Lastly, DSM diagnoses can offer validation to children and families of children who receive diagnoses. While there are claims that labeling disorders can have a negative impact, other studies show positive effects associated with labeling. For instance, the use of psychological diagnostic labels is associated with effective help-seeking behaviors (Wright et al., 2011).

Conclusion

As the leading diagnostic manual for psychological disorders in the United States (Demazeux & Singy, 2015; Arbanas, 2015; American Psychological Association, 2013) and beyond (Maser et al., 1991), the DSM has served as the catalyst for advancing American psychiatry (Demazeux & Singy, 2015). Additionally, the majority of research of psychological disorders has been shown to rely on DSM criteria to varying extents (Castonguay & Oltmanns, 2013). Throughout the history of its development, beginning with its first publication in 1952, the DSM has undergone significant revisions in order to create the most reliable and evidence-based manual for clinical and research use. The first edition of the manual did not address childhood disorders, aside from a couple childhood "reactions" (APA, 1952). However, subsequent editions expanded upon this to broaden the extent to which disorders of childhood were represented. For instance, DSM-II included seven reactions of "childhood or adolescence" (APA, 1968) and DSM-III created an entire category devoted to "Disorders Usually First Evident in Infancy, Childhood, or Adolescence", introducing ADD (Shorter, 2015; APA, 1980). Acknowledging developmental and cultural considerations, the fourth edition of the manual allowed for better detection of ADHD in females and younger children (Lahey et al., 1994a). DSM-IV and DSM-IV-TR also adjusted diagnostic criteria to ensure better reliability, better reflect current research, and be in line with the ICD. With the publication of the DSM-5 came changes acknowledging child development and disorders even further. For example, developmentally appropriate presentations of PTSD were included (APA, 2013) and more fluid presentations of ADHD (Wilcutt et al., 2012) and ASD (APA, 2013) were emphasized across the lifespan. However, despite these advances, like any good science, the field of psychology continues to critically evaluate current systems and grow with the current research.

Several criticisms of the DSM and classification systems remain, including diagnostic inflation and limited data on neurobiological bases for disorders. Additionally, critics suggest that labeling can increase stigmatization (Tyrer, 2014). While there is a negative stigma associated with labeling, giving a formal DSM diagnosis can increase treatment motivation, inform more successful treatment, and give validation to children and parents. Another issue associated with the DSM is how to use differential diagnosis and deal with the high rate of comorbid disorders. It is difficult for classification systems, such as the DSM, to accurately guide clinicians to decipher between distinct comorbid disorders. While the field has aimed to move toward a more dimensional approach, abandoning classification altogether would impede clinical decision making in assessments and treatment. There has also been concern surrounding overreliance on the DSM. Some have suggested that since the publication of the manual, there is no longer room for clinical judgment. Demazeux and Springy emphasize that clinicians should use caution not to rely solely on standardized criteria but to incorporate their clinical experience into their case conceptualization (2015). Recognizing the permeable nature of diagnostic boundaries, the authors of the DSM explicitly state that the manual should be used by experienced clinicians as a tool to determine diagnosis (APA, 2013). It was not created to be a checklist for lay persons to identify disorders. Rather, the DSM should be used by trained individuals to guide identification of prominent symptoms and clinical diagnoses. Clinicians should utilize and incorporate various measures, assessment tools, and reporters (parents, teachers) when forming their clinical conceptualization.

NIMH's Research Domain Criteria (RDoC) and Clinical Child Psychology

6

Eugene Cozza, Justin Spring, Carver Nabb,
and Stewart Shankman

Introduction and Rationale

Background

The predominant nosological system in adult and child psychiatry in the United States is based on the Diagnostic and Statistical Manual of Mental Disorders (DSM). The DSM system utilizes categorical diagnoses derived from clinically observable signs and symptoms and, since 1980 (when DSM-III was released), has achieved improved diagnostic reliability (i.e., the rate at which different interviewers agree on the same diagnosis) in clinical practice and research (Spitzer et al., 1980). However, given that DSM diagnoses are etiologically and pathophysiologically agnostic, questions about their diagnostic validity (i.e., the ability of diagnoses to capture "true" or natural phenomena) remained. Evidence for limited validity of DSM diagnoses includes symptomatic heterogeneity not adequately accounted for by DSM diagnostic criteria, leading to frequent use of "not otherwise specified" diagnoses (especially among child patients), as well as diagnostic comorbidity (i.e., the co-occurrence of multiple diagnoses in individual cases) that may reflect a common underlying pathogenic process rather than multiple co-occurring distinct disorders (Goldstein & Schwebach, 2004; Kendler et al., 1992; Reiersen et al., 2007).

The introduction of the Research Domain Criteria (RDoC) by the National Institute of Mental Health (NIMH) in 2009 grew out of this concern regarding the limitations of the DSM approach towards psychiatric research. RDoC also came at a time of growing interest in viewing mental disorders as brain disorders (more specifically, as disorders of brain systems) and bringing psychiatry more in line with the medical model of pathophysiology-directed diagnosis and treatment (Hyman, 2007; Insel, 2005). The incorporation of research findings from genetics and neuroscience into clinical prac-

tice has yet to come to fruition - thus one of the ultimate goals of RDoC is to expedite this advancement (Clark et al., 2017). It should be noted that RDoC is not currently designed to serve as a clinical diagnostic system but rather to organize research efforts and findings and to inform the development and refinement of future diagnostic systems (Cuthbert, 2020).

RDoC Assumptions and Goals

The conception of RDoC was predicated on three assumptions: (1) mental disorders are disorders of brain dysfunction; (2) brain dysfunction can be quantitatively measured using available technology; and (3) brain dysfunction data (and other biomarkers like genetic sequence) can be combined with clinical interview data to yield biosignatures that improve clinical care (Insel et al., 2010). A similar approach using clinical biomarkers is common in other fields of medicine, such as the use of genetic and molecular signatures to direct the diagnosis and treatment of cancers (e.g., Paez et al., 2004).

Built upon these assumptions, a number of short- and long-term aspirations of RDoC have been outlined by others (Cuthbert & Insel, 2013; Insel et al., 2010; Sanislow et al., 2010), summarized here in three goals:

(1) **Develop a research framework oriented to study psychopathology with a focus on underlying mechanisms.** The assumptions of RDoC described above dictate that manifestation of psychopathology is dependent on (dys)functional brain mechanisms, and that study of these mechanisms is necessary to gain better understanding of psychopathology. As is described later in this chapter, RDoC defines *constructs* representing a multitude of functional mechanisms within the brain and associated systems that mediate normal neurobehavioral functioning and, when dysfunctional, psychopathology. A primary goal of RDoC research, then, is to define these constructs, both theoretically and by means of measurable indicators of the constructs (termed “units of analysis” in the RDoC matrix), such as biomarkers, laboratory tasks, and self-report scales/interviews. Once constructs are defined (including ranges of normative functioning), their dysfunction can be mapped to associated problematic behaviors, symptoms, or syndromes. It should be emphasized that the goal here is not to search for mechanisms that *explain* DSM disorders, but rather to define mechanisms underlying dimensions of normal-abnormal functioning – a *bottom-up* approach that may or may not map to DSM disorders. This is in contrast to the *top-down* approach utilized in most DSM-oriented research, in which subjects with a DSM-defined disorder (or disorders) are studied in search of underlying neurobiological mechanism(s) of the disorder, an approach that has yielded limited findings. Considering that there are 227 possible combinations of major depressive disorder criteria that would allow one to meet the DSM-5 threshold for diagnosis (Zimmerman et al., 2015) (and even more if one splits the ‘or’ symptoms, such as worthlessness or guilt), it seems unlikely that a single neurobiological mechanism underlies the heterogeneity of syndromes labeled by DSM-5 as “major depression.” Thus, by starting with the study of mechanisms and working *upwards* toward symptoms and phenotypes, RDoC is poised to bring clarification to the current understanding of psychopathology.

(2) **Develop a research framework that dynamically integrates research findings from genetics, neuroscience, and behavioral sciences.** A major criticism of the current state of clinical diagnosis and treatment of mental disorders is the lack of progress in translating the findings from genetics and neuroscience to improve diagnosis and treatment. By defining neurobehavioral functional constructs using objective biomarker data, RDoC aims to integrate findings across multiple areas of research, such as genetics, neuroscience, and behavioral science, into a unified framework. RDoC is intended to be dynamic rather than fixed, so that it can be updated as new research findings emerge.

(3) **Develop a research framework that ultimately improves prevention and treatment outcomes.** This is the primary goal of mental health research. As is discussed in the final section of this chapter, the RDoC initiative's success will likely be judged based on its ability to deliver improvements in patient outcomes. An illustrative example of such work is a recent study by Wu et al. that showed that treatment response to the selective serotonin reuptake inhibitor (SSRI) sertraline in depressed adults could be predicted using patterns of resting-state electroencephalography (EEG) (Wu et al., 2020). While not yet validated for use in clinical care, these types of biomarker findings provide preliminary evidence that approaching mental disorders as brain disorders with measurable brain (dys)function can result in clinically relevant findings and suggest RDoC may be able to inform clinical assessment in a way that improves patient outcomes.

Structure of the RDoC Framework

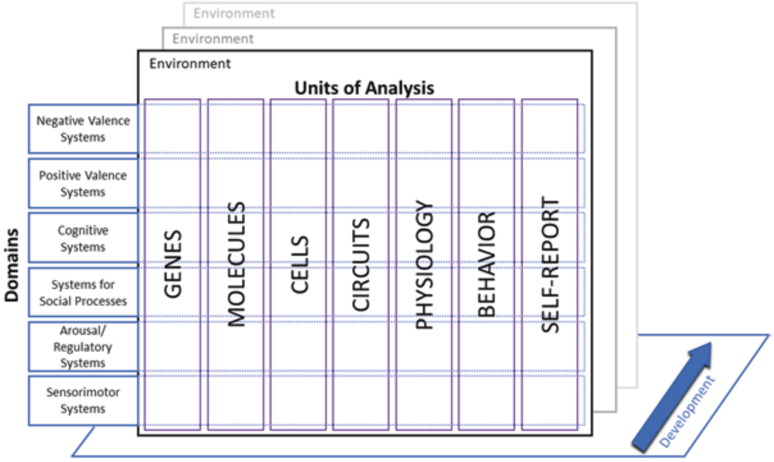
As noted above, the RDoC framework was not initially intended as a clinical diagnostic system per se but rather a research framework to integrate research findings and orient research studies. RDoC was developed through a transparent process coordinated by the NIMH that incorporated expert opinions from leading researchers in various domains (e.g., clinical neuroscientists, behavioral scientists, nonhuman animal researchers, etc.). This section presents the current structure and components of the RDoC framework.

Defining Construct and Dimension

It will aid further discussion of RDoC to first briefly define the terms *construct* and *dimension* as they apply to the study of brain function. A construct is a concept or label that represents an observable brain function or behavior (e.g., general intelligence or risk-taking) that can be measured with specific indicators (e.g., behavioral task, questionnaire, etc.). A construct is considered dimensional (rather than categorical) if it can be measured along a continuum of function (a dimension). While the DSM diagnostic system favors classifying subjects based on categories (i.e., DSM diagnoses), the RDoC framework favors classification based on dimensional constructs that span normal-to-abnormal, such as the RDoC construct *acute threat,* which is conceptualized along a dimension from hypo- to hyperreactivity (to a perceived threatening stimulus) rather than as a dichotomous normal/abnormal diagnostic category (e.g., DSM-defined anxiety disorders).

There are several characteristics to consider when exploring dimensional constructs. First, values along a dimension may be distributed normally or skewed, and the distribution may depend on the population being sampled. Second, the normative range of values should be defined, outside of which values are considered abnormal. Third, it is important to determine whether one or both tails of the distribution are potentially pathologic. For example, an individual's general intellectual ability can be measured and described along a dimension (e.g., intelligence quotient (IQ) of 65) and as a category (e.g., intellectually disabled). As a dimensional construct, IQ might be expected to be normally distributed among a general population of high school students but skewed among students taking advanced placement courses. While a broad "normal" range of IQ scores might be 70–130, only those individuals falling below 70 would be considered pathologic and potentially diagnosed categorically as "intellectually disabled". Meanwhile, individuals with IQ above 130 might be categorized as "exceptional" but not considered pathologic.

Fig. 6.1 The RDoC matrix is depicted with the domains as the rows of the matrix and the units of analysis as the columns. Neurodevelopment is depicted by the arrow proceeding into the page. Environments are shown as cross-sections of the matrix to depict the dynamic nature of the matrix in different environmental contexts



The RDoC Matrix

Dimensional constructs are central to the RDoC framework, which is operationalized as a matrix comprising domains of functioning (the rows) and units of analysis (the columns) at which the domains can be interrogated and instantiated (Fig. 6.1) (Sanislow et al., 2010). The domains are superordinate structures within the matrix that each contains constructs (and subconstructs) intended to represent unique neurobehavioral functions. The RDoC framework proposes that domains – and their (sub)constructs – can be studied across multiple units of analysis, which integrates understanding across research disciplines. The central unit of analysis is the neural circuit, based on the previously mentioned assumption of RDoC that neurobehavioral functioning (and psychopathology) can be attributed to the function (and dysfunction) of neurobehavioral systems comprising neural circuits. Additional units of analysis in the framework include the lower-order components that contribute to neural circuit function (genes, molecules, and cells) and the higher-order components that reflect the products of neural circuit function (physiology, behaviors, and self-reports). Not depicted in the matrix are paradigms, which are standardized laboratory tasks that can assess multiple units of analysis of a given RDoC construct simultaneously (Barch et al., 2016).

The organization of the RDoC matrix encourages researchers to develop sets of prototypical measures for each construct at different units of analysis, while also considering that the constructs occur (and vary) along developmental trajectories and interact with environmental contexts. Collectively, RDoC aims to understand neural circuits and function through the integration of psychiatrically relevant biomarkers and clinical data into a systematic, but flexible, framework that also incorporates the moderating roles of development and the environment.

RDoC Domains and Constructs

The six domains of functioning of the current RDoC matrix include Negative Valence Systems, Positive Valence Systems, Cognitive Systems, Systems for Social Processes, Arousal/Regulatory Systems, and Sensorimotor Systems. Below, these domains are briefly defined. Example constructs are included to illustrate how RDoC constructs may function within the clinical context of well-known DSM disorders.

1. **Negative Valence Systems** underlie neurobehavioral responses to aversive stimuli. Within this domain, one construct is *potential threat* which refers to the neurobehavioral system activated by a perceived threatening stimulus that is not an imminent threat, but rather distant and/or not likely to occur. The repetitive worry observed in DSM-defined generalized anxiety disorder may relate to abnormalities in the potential threat construct (Gillett et al., 2018; Sylvers et al., 2011).
2. **Positive Valence Systems** are responsible for neurobehavioral responses to positive, motivating stimuli, such as reward-seeking behaviors and reward learning. The construct of *reward responsiveness* is responsible for the hedonic responses to impending or received reward. Abnormalities in reward responsiveness are likely to inform the sorts of behaviors that define substance use disorders (Powell et al., 2002) and depressive disorders (Baskin-Sommers & Foti, 2015; Nusslock & Alloy, 2017; Olino, 2016) in the DSM.
3. **Cognitive Systems** include a variety of neurocognitive processes, such as *perception* (e.g., auditory perception) and *language* (i.e., symbolic representations that support thought and communication). The positive (e.g., auditory hallucinations) and negative (e.g., alogia) symptoms of DSM-defined schizophrenia may be understood as abnormal functioning of these constructs (Kelly et al., 2019) .
4. **Systems for Social Processes** underlie neurobehavioral responses to varied interpersonal situations, including but not limited to the constructs of *affiliation and attachment* (i.e., engagement in social interaction and social bonding) and *perception and understanding of self* (i.e., awareness and understanding of one's emotional states, traits, and abilities). Abnormal functioning of these RDoC constructs may provide mechanistic understanding of the maladaptive attachment and unstable sense of self observed in DSM-defined borderline personality disorder (Beeney et al., 2016; Roepke et al., 2012).
5. **Arousal/Regulatory Systems** govern context-appropriate activation of neurobehavioral systems (e.g., arousal to threat) and homeostatic regulation (e.g., energy balance and sleep). The hyperarousal often observed in DSM-defined posttraumatic stress disorder may be understood through abnormal functioning of the construct of *arousal* (Schmidt & Vermetten, 2018), whereas the *arousal*, *circadian rhythms*, and *sleep-wakefulness* constructs each likely inform the psychopathology of DSM-defined bipolar disorder (Cardinale et al., 2018).
6. **Sensorimotor Systems** are responsible for development, learning, and regulation of motor behaviors. Several subconstructs within *motor actions* – i.e., *action planning and selection, initiation, execution* – may help explain the motor abnormalities observed in psychotic or manic states (Walther et al., 2019).

RDoC Approach to Conduct Disorder – An Illustrative Example

The utility of RDoC in understanding mechanisms of neurobehavioral function can be illustrated with a clinical example. Conduct Disorder (CD) is a pediatric disorder conceptualized in the DSM-5 as a "repetitive and persistent pattern of behavior in which the basic rights of others or age-appropriate societal norms or rules are violated" (*Diagnostic and statistical manual of mental disorders*, 2013). The diagnosis is met if a youth displays at least 3 of 15 possible behaviors in the past 12 months, with at least one occurring in the last 6 months. The conceptualization of CD as a categorical construct has been challenged (Lewis et al., 1984). Heterogeneity is a primary issue – not only in terms of the types of behaviors exhibited, but also the severity and age of onset of these behaviors (Brislin et al., 2021; Fanti, 2018; Frick & Nigg, 2012; Klahr & Burt, 2014). Other areas of potential nosological concern include extensive comorbidity with other disorders (Connor et al., 2007), continuity with antisocial personality disorder in adults (Holmes et al., 2001; North & Yutzy, 2018; Zoccolillo et al., 1992), and failing to identify subthreshold pathology due to criterion-based cut-off (Angold et al., 1999; Copeland et al., 2009; Fairchild et al., 2019; Fanti, 2018; Lewinsohn et al., 2004; Raine, 2018). Furthermore, the descriptive approach to CD – i.e., deriving diagnosis (and therefore informing treatment) from observed behaviors – does not specifically characterize the neurobehavioral dysfunction that may mediate these behaviors. In contrast, a dimensional approach rooted in the RDoC framework incorporates domains and (sub)constructs across units of analysis that help to understand the dysfunctional neurobehavioral mechanisms that may mediate symptoms of CD.

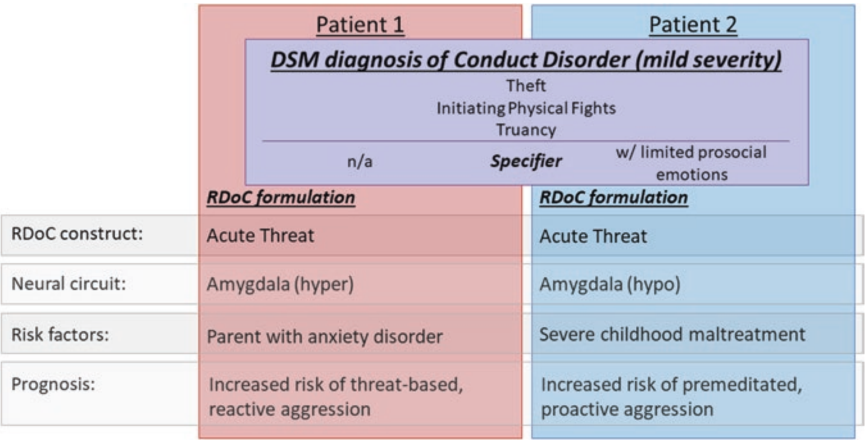
RDoC Approach to Two Conduct Disorder Vignettes

Consider the following two clinical vignettes created to illustrate the advantages of conceptualizing CD in terms of RDoC constructs.

Patient 1 is a 16-year-old male with a history notable for anxiety disorders among first-degree relatives. He is seen for court-mandated evaluation after being arrested for shoplifting. He claims his friends pressured him to steal headphones. Beginning around seventh grade, he often failed to attend school. He explains that his friends skip school so he followed suit. He has also gotten into physical fights with peers, claiming he was provoked. Truancy and fighting have led to several suspensions from school.

Patient 2 is a 16-year-old male with a history notable for severe childhood neglect. He is seen for court-mandated evaluation after being arrested for shoplifting. He states he stole headphones because he lost his other pair. Beginning around seventh grade, he often failed to attend school. He explains that he does not view school attendance as important. He tends to initiate physical fights with peers, offering no justification. Truancy and fighting have led to several suspensions from school.

Features of these vignettes above are depicted in Fig. 6.2. Within the diagnostic framework of the DSM-5, these two cases are nearly identical, containing the same observable behaviors and fulfilling the same criteria for a diagnosis of CD (i.e., theft, initiating physical fights, truancy). However, the differences between underlying mechanisms of these two cases can be more completely understood when examined through an RDoC lens.



DSM diagnosis of Conduct Disorder (mild severity)
Theft
Initiating Physical Fights
Truancy

n/a	***Specifier***	w/ limited prosocial emotions

	Patient 1	Patient 2
	RDoC formulation	***RDoC formulation***
RDoC construct:	Acute Threat	Acute Threat
Neural circuit:	Amygdala (hyper)	Amygdala (hypo)
Risk factors:	Parent with anxiety disorder	Severe childhood maltreatment
Prognosis:	Increased risk of threat-based, reactive aggression	Increased risk of premeditated, proactive aggression

Fig. 6.2 Comparison of RDoC case formulations and prognostic implications for two cases meeting DSM criteria for conduct disorder. Characteristics common to both cases that are sufficient to reach a diagnosis of conduct disorder are listed in the horizontal rectangle. Characteristics specific to the individual RDoC formulations for each case are listed in the vertical rectangles for patient 1 (left) and patient 2 (right)

Patient 1 demonstrates vulnerability to peer pressure (theft, truancy) and a tendency to fight back physically in response to provocation. In this case, these behaviors could be viewed as reactive to an imminent threat and thus as products of the "fight or flight" fear response mediated by the *acute threat* RDoC construct (Blair et al., 2014b; Fairchild et al., 2019). Meanwhile, Patient 2's problematic behaviors seem to arise in the absence of strong negative emotional valence, suggestive of an attenuated acute threat response and consistent with the "callous/unemotional traits" research phenotype that has been identified in a subset of CD patients (Blair et al., 2014a; Fairchild et al., 2019; Fonagy & Luyten, 2018). Indeed, the DSM-5 has incorporated these findings with the "limited prosocial emotions" specifier; however – like the CD diagnosis – this specifier is both descriptive and categorical and does not explicitly consider neurobehavioral mechanisms governing these observations (*Diagnostic and statistical manual of mental disorders*, 2013). Thus, while fulfilling the same three criteria for DSM-5 CD, Patients 1 and 2 may exhibit differential functioning of the acute threat construct.

Acute threat can be interrogated at the level of the neural circuit, wherein differences in amygdala activation during threat perception have been demonstrated among CD patients (Fonagy & Luyten, 2018). These differences suggest that similar problematic behaviors (e.g., aggression) might arise via distinct neurobehavioral mechanisms within the population of CD patients. Aggression that is reactive in nature has been associated with amygdala hyperactivation (i.e., elevated acute threat response, as in Patient 1), while proactive aggression has been associated with amygdala hypoactivation (i.e., blunted acute threat response, as in Patient 2) (Marsh et al., 2008; Viding et al., 2012; White et al., 2016).

An RDoC-based approach to case formulation also affords a more precise understanding of how certain factors may mediate risk for psychopathology. Patient 1 (but not Patient 2) has a family history of anxiety disorders, a category of disorders that are associated with elevated acute threat responses and highly comorbid with CD, in particular among those CD patients lacking callous-unemotional traits (Angold et al., 1999; Blair et al., 2014a; Briscione et al., 2014; Frick et al., 1999; Sumner et al., 2016). These findings suggest that elevated acute threat responses may underlie and hypothetically mediate the association between risk factor (family history of anxiety disorder) and phenotype (CD without callous/unemotional traits). In contrast, Patient 2 experienced early childhood maltreatment, a risk factor that predicts the development of callous/unemotional traits (Joyner & Beaver, 2021). This relationship between childhood maltreatment and callous/unemotional traits has been shown to be mediated by amygdala hypoactivity (i.e., attenuated acute threat response) in children with conduct problems (Lozier et al., 2014). Collectively, these findings suggest that differences in neurobiology, as assessed via RDoC, may underlie phenotypic differences in subsets of CD patients.

Finally, it is important to note how examining CD (or disruptive behaviors more broadly) through the RDoC lens may aid in clarifying prognosis and intervention - for example, by predicting the type of aggression an adolescent with CD is at highest risk to engage in. Research findings to date suggest that functional differences in neurocircuitry underlying acute threat responses among CD patients can predict aggression risk – elevated acute threat (and associated hyperactive amygdala) responses are predictive of threat-based reactive aggression, while attenuated acute threat (and associated hypoactive amygdala) responses are predictive of premeditated proactive aggression (da Cunha-Bang et al., 2019; Lozier et al., 2014; Urben et al., 2018). Distinguishing between these subsets of CD patients by aggression predisposition may have important implications for treatment (Kempes et al., 2005). As illustrated in the case vignettes above, the RDoC approach to case formulation encourages a more mechanistic understanding of patient symptoms, which can aid in determination of prognosis and treatment course beyond that provided by the DSM approach alone.

This section sought to introduce the structure of the RDoC framework, describe the domains of function and constituent constructs and subconstructs, provide clinical context for how constructs may function abnormally and result in psychopathology, and illustrate with case vignettes how consideration of RDoC construct functioning can augment case formulation. The next section aims to provide an overview of the critical role of neurodevelopment in the RDoC framework.

Research Domain Criteria – Development

The study of neurobehavioral development aims to understand how physiologic maturational and environmental experiences that occur throughout the lifespan promote the establishment of neural systems (comprising neural circuits) that then endow an individual with capabilities to detect, interpret, and respond to the complex physical and social environments of human existence. Research into neurobehavioral development promises to provide insight into typical as well as abnormal human development and how the latter may lead to psychopathology. The RDoC framework offers an approach to understand the complexities of neurodevelopment by defining individual developing systems (i.e., RDoC domains and constructs) and attempting to delineate the developmental trajectories of the domains and constructs as well as the factors that promote, delay, or disrupt their development. Better understanding of psychopathology in the context of neurobehavioral development can allow for more accurate assessment of risk and prognosis as well as effectiveness of treatment and prevention.

Developing Neural Circuits

Decades of research have shown that neurobehavioral development is not a linear, continuous, monolithic process, but rather a composite of the development of various neural systems, each with its own rate and trajectory. The structural and functional brain changes along the course of development have been measured. Decades ago, Thatcher et al. showed evidence that cortical development is asymmetric and nonlinear based on longitudinal electroencephalographic studies (Thatcher et al., 1987). More recently, Gogtay et al. used longitudinal MRI to track spatiotemporal structural cortical development in healthy young subjects and showed that areas of cortex that support basic sensorimotor functions (primary motor and sensory cortex, visual cortex, olfactory cortex) matured earlier, while cortical areas that support higher order functions like executive function (prefrontal cortex) matured later (Gogtay et al., 2004). Longitudinal studies have identified changes in resting-state connectivity patterns over the course of neurobehavioral development in children and adolescents (van Duijvenvoorde et al., 2019) and over the course of normal aging in cognitively stable older adults (Oschmann & Gawryluk, 2020). Interestingly, this work with children and adolescents showed that strengthening and weakening of neural connectivity patterns is influenced by factors such as pubertal stage. Thus, studies using structural and functional brain analyses support the idea that measurable brain development proceeds throughout the lifespan.

RDoC and Neurodevelopment

The RDoC framework organizes the complex array of overlapping, simultaneously developing neurobehavioral systems using the RDoC constructs to represent individual developing functions. Notably, RDoC constructs are considered to be dynamic during development; therefore, studies that incorporate RDoC constructs must take care to define the neurodevelopmental timeframe and context of interest, and not just examine the simple effect of 'age' (Bufferd et al., 2016).

To illustrate how the RDoC approach may inform our understanding of the influence of neurobehavioral development on psychopathology, consider the DSM-defined anxiety disorders, which vary in age of peak onset (e.g., separation anxiety in childhood, social anxiety in adolescence, and generalized anxiety in early adulthood) (Lijster et al., 2017). The DSM-informed approach would be to view these as separate, distinct disorders. However, RDoC suggests that these separate categorical diagnoses may actually represent different phenotypical presentations of a single or small number of RDoC constructs (e.g., the *potential threat* construct) that vary based on the neurodevelopmental timeframe. For example, a young child with elevated potential threat sensitivity may be more likely to manifest anxiety in separation from a parent, while an adolescent with the same abnormality may be more likely to develop anxiety regarding social evaluation by a peer (Ahlen & Ghaderi, 2019; Weems, 2008).

Casey et al. (2014) highlight three areas of focus of neurobehavioral developmental research that harness the strengths of the RDoC approach and can improve understanding of developmental mechanisms and potentially improve clinical diagnosis and treatment: (1) developmental trajectories; (2) sensitive periods; and (3) interacting systems.

Developmental Trajectories

Developmental trajectories are the progressions of change in individual neurobehavioral systems across developmental time (i.e., age). Research has shown that neurobehavioral systems (and neural circuit or neuroanatomic correlates) develop with different trajectories. For example, in adolescents, limbic circuits that generate emotional responses to aversive stimuli mature earlier than prefrontal circuits that regulate such responses (Casey et al., 2008). These differences in developmental trajectories between the two systems are considered normal yet also provide tangible explanation for the changes (and challenges) in emotion regulation during the adolescent developmental timeframe. Developmental trajectories can be measured using RDoC units of analysis, such as progression of functional connectivity or performance on standardized laboratory paradigms. Importantly, assessing RDoC constructs across developmental time may require different developmentally appropriate measures – for example, probing the reward learning construct in infants may utilize an eye-tracking paradigm with maternal-cued rewards (Tummeltshammer et al., 2019), whereas probing the same construct in adolescents may utilize a gambling paradigm with monetary rewards (Kwak & Huettel, 2016). Other constructs (e.g., sleep-wakefulness) can be measured throughout the lifespan with the same measures (e.g., 24 h EEG).

A critical impediment to research on trajectories of RDoC constructs is a lack of understanding of the constructs' "normative" trajectory. Studies that define the normative developmental trajectories for each RDoC construct are paramount for comparison to developmental trajectories in subjects afflicted with mental disorders. For example, Shaw et al. longitudinally assessed structural cortical development in subjects with attention-deficit hyperactivity disorder (ADHD) and compared to neurotypical subjects. The investigators found that the developmental trajectories in both groups, as assessed by structural MRI, were similar in pattern but delayed in the ADHD group (Shaw et al., 2007). Further, this delay was most prominent in prefrontal cortical regions that mediate the functions of *cognitive control* (an RDoC construct), disruption of which would be expected to lead to the symptoms of ADHD. A follow-up study showed that trajectories of delayed cortical maturation corresponded with dimensional measures of ADHD behaviors in neurotypical children, providing support for the idea that the categorical diagnosis of ADHD likely identifies individuals at the extreme end of a dimension of normal to delayed prefrontal cortical developmental trajectory (Shaw et al., 2011). However, this conclusion is based on the assumption that the neurotypical children in the study in fact represent ‘normative’ neurodevelopment (defined, in this study, by the absence of psychiatric or neurological diagnoses in the subjects’ histories). It remains possible that the neurotypical sample differed from the general population in other, unmeasured ways. To truly assert that a sample is representative of the general population on objective neurobehavioral measures, the field would benefit from established norms as a basis for comparison, similar to the norms used routinely by pediatricians (e.g., growth charts, hormone levels). Research groups are working towards this goal of establishing normative data sets for neurobehavioral measures (e.g., Imburgio et al., 2020), though concern remains for the current validity of such norms for research aimed at detecting individual-level differences or for clinical application (e.g., Clayson et al., 2021).

Sensitive Periods in Development

Sensitive periods are windows of time during development when the developing neurobehavioral system (or construct) is most malleable to change – in other words, a sensitive period of increased risk for abnormal development but also potentially for therapeutic intervention. By delineating these sensitive periods, researchers can better understand when specific systems are most vulnerable to the disrupting influence of environmental risk factors, potentially providing etiologically relevant information about risk for psychopathology. Such findings can also inform the development of treatment strategies that target abnormal constructs at critical times of highest likelihood for normalization of function. In addition to delineating the boundaries of sensitive periods, research will need to identify which neurobehavioral or environment factors define these periods, as well as which factors can potentially extend or reopen them, allowing for better mechanistic understanding of psychopathology risk and resilience.

As mentioned earlier in this section, in the course of normal adolescent neurodevelopment, there are differences in developmental trajectory between limbic and prefrontal structures. These differences seem to create a “window of risk” or sensitive period in which the system for generating negative emotional responses (limbic) develops before the system for regulating such responses (prefrontal cortex). This developmental window may explain the increased risk for onset of emotional disorders in this developmental stage (Powers & Casey, 2015), a window that seems to tighten (at least to some extent) by adulthood when prefrontal cortical maturation “catches up”. Notably, additional factors beyond developmental trajectories can influence windows of risk, such as environmental stressors in the burgeoning social world of the developing adolescent (e.g., increasing complexity of peer relationships).

Dynamic Interactions in Development

Dynamic interactions refer to the continuous influence that developing systems have on one another throughout development. These systems do not mature in isolation or in complete unison, but rather interact dynamically during development. As discussed previously, studies on cortical development have shown that lower-order systems, like those responsible for sensory functions, develop earlier than those responsible for higher-order functions like complex social interactions. Thus, an early developmental deficit in one system could lead to a cascade of developmental abnormalities in other developing systems. This idea underscores the need for future studies of development to examine multiple systems simultaneously and across developmental time in order to understand how the dynamic interaction of systems influences one another’s development. To illustrate this point, consider the construct of *cognitive control*, the system that modulates operation of other cognitive and emotional systems, in the service of goal-directed behavior (often referred to as "executive functioning"). The construct of cognitive control is thought to be supported primarily by three subconstructs: response inhibition (deliberately suppressing cognitive or behavioral responses to stimulus); working memory (holding and manipulating information in the mind); and cognitive flexibility (considering a single stimulus in multiple perspectives and responding adaptively) (Zelazo, 2020). Davidson et al. investigated whether these subconstructs of cognitive control function independently during development in children and adolescents (Davidson et al., 2006). Overall, their results do not show independence, but rather correlation of the function of these subconstructs, providing support to (but not proof of) the notion that the subconstructs of cognitive control may influence one another during development. Importantly, the extent to which RDoC constructs interact dynamically during development remains largely undefined and requires further study.

RDoC Approach to Developmental Research

To further illustrate the RDoC approach to understanding development and psychopathology, consider the example of motor development and its association with premorbid phases of psychosis (Mittal & Wakschlag, 2017). Developmental abnormalities in the Sensorimotor Systems domain have been found across the clinical stages of psychosis (premorbid, prodromal, acute, chronic) (Cannon et al., 2002; Fish, 1987; Marcus et al., 1985). Early motor abnormalities can provide valuable information about premorbid vulnerability for later psychosis emergence (Walker, 1994). Currently, the predictive value of these motor abnormalities is neither specific nor sensitive, as children who go on to develop psychosis do not always manifest observable motor abnormalities, nor do all children who manifest such abnormalities go on to develop psychosis. Thus, there is valuable, but limited, clinical and predictive utility in currently observable motor abnormalities during development. The predictive value of such motor abnormalities can be enhanced by understanding the neural circuit functioning that underlies motor behavior abnormalities. For example, while analyses of videotapes of early childhood behaviors have shown that those who go on to develop psychosis exhibit more observable motor abnormalities than those who do not (Walker et al., 1994), it is unclear *which* specific children will develop psychosis. By incorporating neuroimaging or other biomarker techniques, it may become possible to differentiate those children who will and who will not go on to develop psychosis. An RDoC-oriented approach to study motor developmental abnormalities could simultaneously and longitudinally assess abnormal motor behaviors (e.g., dyskinesias), psychotic symptoms, and underlying neural circuit abnormalities (for example, in cortical-striatal-pallido-thalamic circuits). While, at present, no pathognomonic neurodevelopmental motor trajectory has been defined that reliably predicts emergence of psychosis, prospective RDoC developmentally oriented studies that define the spectrum of the motor development dimension (and underlying neural mechanisms) are poised to uncover the early developmental events that lead to abnormal motor development in those who go on to develop psychosis, potentially providing clinically valuable prognostic and preventative treatment-directing information. It should be noted that early motor abnormalities are not specific to psychosis, as recent studies have also implicated the role of motor abnormalities in the clinical course of depression in youth (Damme et al., 2022).

To improve reliability of developmental biomarkers like motor behavior abnormalities, groups are working to validate instrumental approaches to measure and track motor abnormalities that are likely more sensitive than traditional observer-based clinical scales. Various assessment methods, from EEG, to grip strength, to handwriting assessments, can be employed at developmentally appropriate stages to interrogate the same underlying neural circuit (Dean et al., 2020; Dean & Mittal, 2015; Perrottelli et al., 2021). These approaches can also be employed simultaneously with functional neuroimaging to assess a given construct at multiple units of analysis. An important consideration in standardizing such instrumental approaches to assess development is that such approaches must be both developmentally appropriate (i.e., one cannot assess handwriting or gait in infants) and also tap into the desired underlying construct (i.e., motor behavior). Mittal and Wakschlag provide an example illustrating how the use of different, developmentally appropriate assessments can track functioning of an underlying neural circuit across developmental time (Mittal & Wakschlag, 2017). In this example, assessment of EEG in infants, hand postures in toddlers, force variability (a measure of muscle contraction patterns, for example in finger tapping) in older children, and task-oriented functional neuroimaging (e.g., during a hand grip task) in adolescents are all instrumental methods to objectively assess functioning of the motor system at various points in development, which collectively can provide insight into trajectories of motor development and associations with psychopathology (Dean & Mittal, 2015; Mittal & Wakschlag, 2017).

In sum, this section sought to introduce the complex process of neurodevelopment and illustrate how the RDoC framework can be used to organize findings and research efforts on neurodevelopment into a unified model. The strength of RDoC here is the ability to separate complex interconnected neural systems (e.g., motor systems, emotional systems) into component parts (i.e., RDoC constructs) that can be assessed at multiple points in development. With this information, the field is poised to define the trajectories, sensitive periods, and interactions of developing RDoC constructs, understand risk and etiology of abnormal development and its association with psychopathology, and potentially direct diagnostic, treatment, and prevention strategies.

Research Domain Criteria – Environment

Converging evidence from decades of research suggests that psychopathology arises from the effects of both internal (e.g., genetic) and external (e.g., environmental) factors (e.g., Kendler & Prescott, 2006). In general, the concept of *environmental factors* is meant to encompass all sources of influence outside the person (e.g., other people, physical environment, social environment). Bronfenbrenner's classic ecological systems theory provides a common model to organize and understand sources of environmental influence during child development (Bronfenbrenner, 1979a, b). This model posits that a child develops within a complex environmental topology that can be defined at multiple levels (or "systems") that differ by their proximity of influence on the child and are nested within one another, commonly depicted as concentric circles with the child at the center. These systems incorporate various external influences on the developing child, including close relationships (e.g., family, peers), neighborhood, and sociocultural expectations. Importantly, this model also accounts for interactions between environmental factors that may indirectly influence the child (e.g., parental unemployment in a troubled economy). The important influence of environment on psychopathology is evident in, for example, the consistent finding that early adverse life events are predictive of psychopathology onset and persistence (Green et al., 2010; McLaughlin et al., 2010a). These early adversities include parental loss, divorce, parental psychopathology, abuse, neglect, serious childhood physical illness, or extreme poverty. Although these relationships between environment and psychopathology have been repeatedly and consistently demonstrated, the mechanistic underpinnings of these relationships remain incompletely understood (March-Llanes et al., 2017).

Environmental Factors in the RDoC Framework

The RDoC framework conceptualizes environment as a separate dimension from the domains and constructs, much like development (Fig. 6.1). This is notable given the bidirectional relationship between neurobehavioral functioning and environment; environment can influence neurobehavioral functioning (e.g., elevated scanning for threats in an unfamiliar environment) and neurobehavioral functioning can influence environment (e.g., seeking a familiar environment when sensitive to threat).

Correlations between RDoC construct functioning and environment can be considered to fall into three categories, similar to how genotype-environment correlations have been categorized: reactive, selective, and passive (Jaffee & Price, 2008). A reactive construct-environment interaction occurs when construct functioning evokes a particular reaction from the environment. For example, a child with limited *cognitive control* may be more prone to impulsive behavior in the classroom, which can evoke negative responses from teachers who have a reciprocal effect on the child (and the child's development). A selective construct-environment interaction occurs when construct functioning influences environment selection. A child with elevated *potential threat* (i.e., sensitivity to uncertain or distant threat) may be less likely to seek out new peer connections, whereas a child with elevated *reward responsiveness* (i.e., hedonic reward response) may be drawn to novel social interactions and thus develop a more robust (and perhaps riskier) social network. These selected behaviors could in turn exert influence on further development of their threat appraisal and reward-seeking systems. A passive construct-environment correlation occurs when both the construct functioning and the environment are the result of a third factor, like genetic influence. For example, consider a child with elevated *reward-delay* (i.e., favoring long-term over short-term rewards) who exhibits high academic achievement and is raised by similarly high-achieving parents in a home environment that promotes delayed gratification. At first, it may appear that the rearing environment promotes elevated reward-delay (and, thus, academic achievement), while in actuality both elevated reward-delay and rearing environment might be genetically determined by genes shared by parents and child. Thus, all construct-environment correlations are not directly causal, and research studies – like those promoted by the RDoC approach – are needed to disentangle whether environmental factors act as moderators (i.e., determinants of construct function and development) that can serve as potential treatment targets, or whether such environmental factors passively correlate with construct function.

Environmental Influence on Psychopathology

RDoC-oriented research studies have attempted to illuminate the mechanisms by which early environmental adversities contribute to lifetime psychopathology by their impact on RDoC constructs (McLaughlin et al., 2020). For example, children exposed to physical or sexual trauma are prone to develop a bias in sensitivity and attention to recognizing facial and other expressions of anger or fear (but not other emotions like happiness or sadness) (Pollak & Sinha, 2002; Shackman et al., 2007). These findings, which can persist beyond childhood, likely correlate with aberrations in RDoC constructs like *social communication* and *potential threat* and have been associated with a broad array of psychopathologies, including anxiety, depression, PTSD, and psychosis (Briggs-Gowan et al., 2015, 2016; Gibb et al., 2009; Masten et al., 2008; Platt et al., 2017; Underwood et al., 2016). Beyond disruptions in attention and processing of potentially threatening stimuli, children exposed to trauma are also at risk of developing emotional problems, such as difficulty recognizing and regulating their own emotions – deficits that map onto RDoC constructs like *perception and understanding of self* (e.g., (Maughan & Cicchetti, 2002)). Similar to deficits in attentional bias and facial interpretation, such difficulties in emotional recognition and regulation have been associated with psychopathologies across the internalizing and externalizing spectra (Heleniak et al., 2016; McLaughlin et al., 2010b; Weissman et al., 2019). While the works cited here illustrate how exposure to trauma in childhood – in particular – may impact neurobehavioral functioning and predict risk for psychopathology later in life, it is worth noting that other aversive environmental exposures (e.g., neglect) may predict risk for psychopathology via differing or overlapping neurobehavioral mechanisms (Milojevich et al., 2019).

The findings presented here converge to suggest that environmental factors (e.g., trauma) can disrupt neurobehavioral development (including RDoC construct function) and increase risk for a broad array of psychopathologies. By dissecting the mechanisms by which environmental factors affect RDoC construct function, RDoC-oriented research is poised to identify those factors that serve as moderators of psychopathology risk and therefore may serve as targets for prevention and treatment of mental disorders.

Research Domain Criteria – Current Status and Future Directions

The evolution of the RDoC framework is ongoing and depends on emerging research findings to reinforce or reshape its structure. The success of the RDoC initiative will ultimately depend on whether this framework satisfactorily integrates research findings from related sciences (e.g., genetics, neuroscience, behavioral science) and promotes better clinical outcomes via prediction of clinical prognosis and/or development of treatment and prevention strategies (Carpenter, 2016; Sullivan, 2016).

RDoC in Clinical Research – Subject Selection

RDoC is promoting change in the design of clinical research studies. Traditional clinical research commonly measures between-group differences using DSM categorical diagnoses as inclusion criteria (i.e., comparing treatment vs. placebo response in major depressive disorder subjects) or utilizes DSM diagnoses as outcome variables (i.e., a prevention trial examining whether subjects develop a major depressive disorder or not). However, the known heterogeneity of research subjects classified by DSM disorders (e.g., lumping subjects with either hypersomnia or insomnia into major depressive disorder) may be obscuring important findings that could be better appreciated by stratifying subjects by construct-oriented symptom dimensions or biomarkers (Hyman, 2011). In other words, rather than dividing research subjects into those who do and do not meet a criterion-based threshold for a DSM diagnosis, researchers can harness the dimensional power of RDoC by recruiting research subjects who vary along symptom dimensions (e.g., mood disorder symptoms) or along the dimension of an RDoC construct. Subjects can be chosen agnostic to any DSM diagnosis, allowing researchers to incorporate subjects with a range of DSM disorders, better accounting for the well-known diagnostic comorbidity and symptomatic heterogeneity and overlap in the DSM system (e.g., (Grant et al., 2004; Unick et al., 2009)). For example, a study may specifically include subjects who report experiencing anhedonia (a manifestation of blunted *reward responsiveness* construct sensitivity that is found transdiagnostically among multiple DSM disorders). Taken further, researchers can forego using symptom report or DSM diagnosis altogether as inclusion criteria, and instead rely on transdiagnostic biomarkers to define subject groups, like performance on a laboratory paradigm to assess reward responsiveness, or genetic variation associated with anhedonia risk (two approaches probing potential mechanisms of anhedonia). In sum, by classifying research subjects using dimensional constructs or biomarkers instead of categorical diagnoses, RDoC-oriented research studies may be better positioned to produce findings directly relevant to the neurobehavioral mechanisms underlying psychopathology.

RDoC in Clinical Research – Variable Selection

Because the RDoC approach is oriented to the study of function of neurobehavioral constructs, clinical research designs can incorporate biomarkers from the units of analysis as outcome variables. This approach allows a divergence from traditional "distal" trial endpoints like diagnostic status or symptom burden (which, as described above, are heterogeneous and not unique to specific DSM diagnoses) and toward more "proximal" trial endpoints like engagement of the biological or behavioral target of interest by the intervention. This approach, termed "fast-fail" at NIMH (Grabb et al., 2020), can allow for both faster trial results (by targeting more proximal endpoints) and a more complete understanding of the mechanism of action of the intervention under investigation. A recent trial is illustrative of this type of study. Krystal et al. published a proof-of-mechanism phase two trial investigating a novel kappa opioid receptor antagonist to target the symptom dimension of anhedonia (Krystal et al., 2020). Instead of focusing on change in anhedonia symptoms as the primary endpoint, the investigators used a validated biomarker of the reward responsiveness construct (reward-related striatal activity as measured by functional MRI) as the primary endpoint. By taking this approach, the investigators were able to show that the novel agent successfully "hit" the therapeutic target (i.e., increased activity in a neural circuit within the reward system). Secondary outcomes, which included self-reported symptoms of anhedonia and behavioral measures on a validated laboratory paradigm of reward-related behavior (the Probabilistic Reward Task), provided some evidence that the neural circuit-level primary outcome (striatal activation) may have relevant clinical effects that are measurable at other units of analysis (self-report and paradigm). Importantly, the investigators note that larger, high-powered trials will be required to investigate whether the observed primary outcome has clinically significant effects on subjects' symptoms or other clinically relevant outcomes. In sum, using RDoC dimensional constructs and units of analysis as independent and dependent variables in clinical research promotes research findings that are more mechanistically informative and transdiagnostically applicable. As research progresses, one can anticipate the clinical utility of such biomarkers (as defined by the units of analysis) to serve as clinical prognosticators and treatment targets.

RDoC in Clinical Research – Incremental Findings over DSM

RDoC-oriented research is already beginning to disentangle neurobehavioral mechanisms and provide clinically relevant data beyond that provided by DSM diagnosis. For example, Whitton and colleagues classified mood disorder subjects by their performance on a laboratory-based reward learning task (highly relevant to mood disorders) and assessed multiple reward-related brain functions via neural biomarkers (Whitton et al., 2021). The authors found that reward learning ability, the independent variable, predicted certain aspects of reward-related brain function better than DSM diagnosis. The authors further found that those same aspects of reward-related brain function could then predict severity of longitudinal mania-spectrum symptoms better than DSM diagnosis alone. Importantly, however, the prognostic relevance of those reward-related brain function biomarkers in this study was restricted to subjects meeting diagnostic criteria for bipolar disorder (but not major depressive disorder), suggesting a potential synergy between psychiatrically relevant biomarkers and categorical diagnoses. Evidence continues to emerge that assessment of RDoC constructs can provide clinically relevant prognostic information beyond what is predicted by DSM diagnoses (e.g., (Stevens et al., 2019; Whitton et al., 2021)).

RDoC in Clinical Assessment

The utility of RDoC may one day extend beyond clinically oriented research and into the realm of clinical assessment. In this vein, Yager et al. reviewed the clinical relevance of the first five RDoC functional domains and curated a set of detailed questions comprising an "RDoC review of systems", which a clinician could use to gain insight into a patient's neurobehavioral functioning (Yager &

Feinstein, 2017). One hope for the future of RDoC is the development of RDoC functional profiling – a standardized battery of assays that can be applied transdiagnostically to generate results that inform investigators (or clinicians) of the objective functional status of a broad swath of RDoC constructs/domains, i.e., an individualized "profile" of overall RDoC construct functioning. Several interesting early applications of such profiling have been undertaken, including development of mobile applications that could be used to screen young children for autism (Dubey et al., 2021) and cognitive developmental abnormalities (Bhavnani et al., 2019). Similarly, investigators at NIMH are developing a battery of RDoC-informed smartphone tasks to be deployed to research subjects as part of the *All of Us* research program at NIH (Gordon, 2020).

In addition to augmenting diagnostic assessment, RDoC-based approaches could also inform predictions of treatment response. Hui (2020) conducted a systematic review of antidepressant trials that incorporated psychometric instruments that probe RDoC constructs in the negative valence systems domain (e.g., acute threat, potential threat, loss). The findings provided preliminary evidence that existing, commonly utilized medication treatments may affect function of specific RDoC constructs. Thus, RDoC-informed clinical assessments, while still nascent, show the potential to provide investigators and clinicians with important information that could augment current diagnostic practices, predict treatment response, and provide a more complete and mechanistic understanding of an individual's neurobehavioral strengths and vulnerabilities.

RDoC in Developing Treatments

The RDoC approach is also being utilized in the development of treatment strategies that specifically target RDoC constructs and related symptom dimensions. For example, Positive Affect Treatment is an investigational psychotherapy developed to target the symptom dimension of anhedonia in depression (Craske et al., 2019). A treatment program for adolescent depression (named TARA – Training for Awareness, Resilience, and Action) has been developed that aligns with RDoC by targeting the sustained threat and arousal constructs, which are thought to play a central role in adolescent depression (Henje Blom et al., 2014). Similarly, a treatment program for late-life depression called Engage has been developed that focuses on reward-related RDoC constructs as the primary source of dysfunction in this population, while also taking into account relevant constructs in other domains (Alexopoulos & Arean, 2014). These examples illustrate how targeting relevant RDoC constructs represents a productive avenue for development of novel psychotherapeutic treatments. In some cases, the dimensional approach of RDoC has been leveraged to develop broadly applicable (transdiagnostic) treatment strategies. The Unified Protocol for the Transdiagnostic Treatment of Emotional Disorders is a cognitive behavior therapy-based psychotherapy protocol developed to target higher-order temperamental dimensions like negative affect that affect patients with a range of emotional disorders (e.g., depressive and anxiety disorders) (Ellard et al., 2010). Similarly, a research project called MATCH has developed a school-based mental health care treatment protocol that employs a dimensional – as opposed to diagnosis-based – approach to treating common mental health problems in school-aged children that requires less training for providers than traditional interventions (Evans et al., 2021; Harmon et al., 2021). Finally, in addition to psychosocial treatments, pharmacologic treatments are also under development that target transdiagnostic functional constructs or symptom dimensions rather than DSM diagnoses, such as the previously mentioned kappa opioid receptor antagonist for treatment of anhedonia (Krystal et al., 2020).

RDoC in Education and Training

The RDoC framework also has important implications for the education and training of mental health clinicians and researchers. Although current clinical training predominantly adheres to the taxonomy of mental disorders put forth in the DSM, the potential role of RDoC in teaching the mechanistic neuroscientific underpinnings of psychopathology is increasingly recognized (Benjamin, 2014; Cozza & Shankman, 2021; Etkin & Cuthbert, 2014). The dimensional orientation of RDoC would encourage learners to understand observable clinical phenomena (e.g., panic attacks) as manifestations of over- or underactivity of normative neurobehavioral systems (e.g., the fight or flight response of the *acute threat* RDoC construct), rather than just discretely abnormal phenomena (as panic attacks are considered by DSM). Such an approach would also introduce learners to innovative techniques to interrogate the functioning of RDoC constructs and measure objective, psychiatrically relevant biomarkers, which will likely become an increasingly valuable component of clinical data in the future. Certainly, the incorporation of the dimensional RDoC framework into trainee education would be a complex process requiring significant supervisor/faculty buy-in for the value of the approach, which may be a challenge given the majority of current faculty supervisors were not themselves trained in RDoC. Nevertheless, if such efforts were successful, developing clinicians and clinician-researchers may benefit and be better prepared to incorporate RDoC-based research findings into their understanding of psychopathology and their approach to clinical practice.

Evolution of RDoC

While the RDoC approach is already driving change in mental health research, it is important to consider that RDoC is a flexible framework to be continuously reassessed and updated based on emerging research findings (Sanislow et al., 2010). Future changes to the RDoC matrix may include the incorporation of new domains of function or constructs, new biomarkers at various units of analysis, a more nuanced understanding of developmental trajectories and their impact on construct functioning, and a more formalized consideration of the role of environmental context to construct functioning. In recent years, based on scientific evidence and expert consensus, the RDoC framework was expanded to include a sixth domain – sensorimotor systems (Harrison et al., 2019; Walther et al., 2019). As evidence continues to emerge, RDoC will evolve to become more comprehensive and aligned with cutting edge neuroscientific understanding and contemporary clinical need.

Much of this change will likely result from an increased emphasis on computational approaches to studying brain-behavior relationships (Cuthbert, 2020; Gordon, 2020; Sanislow et al., 2019). Data-driven efforts will continue to map associations between related biomarkers within a given construct, providing quantitative support to the theoretical notion that biomarkers probing the same neurobehavioral mechanism or construct should associate more closely than those probing disparate mechanisms or constructs. As these relationships are more precisely deconstructed, their functioning can be more accurately represented by mathematical modeling. In addition to computational approaches, the evolution of RDoC will also rely on the development and optimization of tools for measuring the functional domains of behavior/RDoC constructs, from functional neuroimaging to laboratory paradigms to RDoC-oriented psychometric scales (Gordon, 2020).

In summary, RDoC is a research framework developed at NIMH to direct mental health research toward a better mechanistic understanding of neurobehavioral functioning and psychopathology. The overarching goal of RDoC is to integrate findings from related areas of mental health research and inform future research to improve patient outcomes.

Child and Youth Psychopathology: Ethics and Legal Considerations

Gerald Young and Maureen C. Kenny

Working with children and youth experiencing psychopathology is important and rewarding, but the ethical and legal challenges are complex and require careful professional consideration. The areas to consider in these regards cover the full range of work with children, from assessment and psychotherapy to research and consultation. Given children's status as minors, there are many legal considerations in working with them that are not present with adults.

The ethics code of the American Psychological Association (APA, American Psychological Association, 2017) describes the ethical principles and standards that govern ethical conduct in psychological practice, and we refer to it extensively. However, the code does not address special considerations ethically related to children. Therefore, we further consulted the ethics code of the American Academy of Child and Adolescent Psychiatry (AACAP, American Academy of Child and Adolescent Psychiatry, 2014) for an ethics code that applies directly to the topic at hand.

The five main principles of the APA ethics code involve: (a) beneficence and nonmaleficence; (b) fidelity and responsibility; (c) integrity; (d) justice; and (e) respect for people's rights and dignity. Clearly, all five principles apply to children, including in cases of child psychopathology. As we proceed, we indicate which principles and associated standards in the code apply to the ethical requirements of the particular topics chosen in dealing with children and youth with psychopathology. The APA ethics code principles are considered aspirational, referring to values that overarch its obligatory ethical standards. The code includes multiple standards, for example, related to informed consent and other areas related to Autonomy. There are multiple mentions related to law, for example, when the ethics code and the applicable law in one's jurisdiction are in conflict. We rely on the APA code from 2017, but the APA ethics code is currently in revision (American Psychological Association, 2020).

The value of the AACAP (2014) code of ethics is illustrated by its placement of "developmental perspective" as its first principle. Then, it refers to Beneficence and Nonmaleficence as its next two principles. Principle IV and V refer to Autonomy (i.e., respectively, assent and consent, confidentiality, which are embedded in the APA principle E) and the associated Fidelity, which is also in Principle VI on Third Party Influence. Principle VII refers to Scholarship and Research, Principle VIII to

Table 7.1 Comparison of APA and AACAP Ethical Principles

American Psychological Association APA (2017)	American Academy of Child and Adolescent Psychiatry AACAP (2014)
A. Beneficence and non-maleficence	I. Developmental perspective
B. Fidelity and responsibility	II. Promoting the welfare of children and adolescents (beneficence)
C. Integrity	III. Minimizing harmful effects (non-maleficence)
D. Justice principle	IV. Assent and consent (autonomy)
E. Respect for people's rights and dignity	V. Confidentiality (autonomy/fidelity)
	VI. Third party influence (fidelity)
	VII. Research activities
	VIII. Advocacy and equity (justice)
	IX. Professional rewards
	X. Legal considerations

Justice, Principle IX to Professional Rewards (e.g., financial), and Principle X to Legal Considerations. There is much overlap in the AACAP code with the APA ethics code, but topics that are covered in the standards of the APA ethics code are placed as principles in the child psychiatric ones. That said, the AACAP code highlights research and law as separate areas of principled ethics, which are noteworthy additions (see Table 7.1 for a comparison of principles).

While both ethics codes under discussion are fairly comprehensive, there are some important areas that are missing. Young (2017, 2020) has advocated for a principle on science focus, for example, including assessments and evidence-based psychotherapy. The draft of the revised APA ethics code does refer to the principle of Scientific mindedness, which is a noteworthy addition. Young (2017, 2020) has also proposed a principle on Life Preservation that would include dealing with suicidal intent, duty to warn, and the prohibition of participating in or condoning torture. The latter topics are covered in the APA ethics code and standards, but explicit inclusion related to them, as well as science and law, would be helpful. In our review of ethical considerations in dealing with child and youth psychopathology, we add these three topics (life preservation, law, science). Moreover, because we are dealing with child and youth psychopathology, we add the topic of Assessment and Diagnosis. Finally, we include topics such as child maltreatment and divorce as they might be preludes to child psychopathology or complications in its presence and also include ethical and legal issues.

Therefore, this chapter on ethical and legal considerations in child and youth psychopathology includes the following topics: (a) Developmental Considerations; (b) Beneficence/Nonmaleficence; (c) Autonomy and Life Preservation (including child abuse); (d) Assessment and Diagnosis; (e) Research; (f) Divorce; and (g) Law and Science. We consider each of these topics in relation to child psychopathology. The principles in the APA code that we do not mention here are important but are less pertinent to ethical and legal considerations with respect to child psychopathology or would require much more space than we have (e.g., the ethics of cultural considerations), so we have elected to leave them out.

Mental health ethics can be considered from two points of view. First, ethics codes provide obligatory rules and guidelines that must be followed in dealing with patients, research subjects, colleagues, and so on. Second, ethics codes provide insight into how to address ethical conflicts, for example, if one's applicable jurisdictional ethics code conflicts with the law in the jurisdiction. When conflicts seem intractable, various ethical decision-making models exist to help navigate the conflicts (e.g., Pope et al., 2021; Young, 2017).

Our own approach to the question is that psychologists have a duty to their own moral codes as much as to the law and applicable ethics codes, which is illustrated by the torture imbroglio that bedevilled the APA for years (Pope, 2016) and remains not fully resolved. With respect to the question of ethics, law, and child psychopathology, ethical issues will arise that will challenge psychologists in their work, and only full knowledge of the law for the issue at hand can illuminate whether the psychologist has to take a moral stance beyond them. A major law that we deal with in this chapter concerns autonomy, in particular, per the Health Insurance Portability and Accountability Act (HIPAA, 1996). Practitioners should be familiar with all state laws applicable to children, such as family acts, school and educational acts, and juvenile offender acts. We refer to these as required as we proceed.[1]

Ethics

(a) Developmental Considerations

Children are dynamically changing with age, in a developmental process cognitively, behaviorally, socially, and emotionally. They manifest great individual differences in this regard (Young, 2021), from serious developmental abnormalities to being gifted and talented. Epidemiological research indicates that 17% of children will be diagnosed with an impairing central nervous system, brain, or neurodevelopmental abnormality (Zablotsky et al., 2019), with another 13–20% diagnosed with a mental disorder (O'Connell et al., 2009). The most common mental disorders diagnosed in children are Attention Deficit Hyperactivity Disorder (ADHD), behavioral problems, anxiety, and depression (Centers for Disease Control and Prevention, 2021).

Moreover, children are exposed to multiple risk factors for developmental disorders, such as early adversities, child maltreatment, and abuse. These risks impact the neurodevelopmental trajectory and alter the mediating factors in children's adaptive behavior, such as executive function, emotional regulation, inhibition, and self-control (Young, 2022a). Further, these changes alter children's perception or appraisal of their competencies (self-esteem) and variables in the environment that impact them (e.g., having a negative hostility bias, a fear bias in cases of abuse). From an ethical standpoint, the mental health professional needs to be aware of the vulnerabilities of children in these regards. Also, they need to be aware of the family dynamics, which family members provide support, and who potentially perpetrate abuse.

Ethically, we add that workers need to respect and not violate children's fundamental rights. These include those specified by the Nuremberg code (U.S. Government Printing Office, 1949). Specifically, in its 10 principles, the code indicates that the voluntary consent of the person as medical subject must be obtained. The research involved should avoid all possible unnecessary mental as well physical injury and suffering. This ethical proscription applies psychiatrically, as well. Also, we make reference in these regards to the Convention on the Rights of the Child (Convention on the Rights of the Child, United Nations, 1989). It specifies that children have inherent dignity and equal and inalienable rights without discrimination. They are entitled to special care, safeguards, considerations, assistance, and protection. Their best interests should be paramount. They have the right to multiple freedoms, including the freedom of expression (directly or through a representative) in any proceedings about them.

---

[1] Note: as we proceed, we refer to children generally instead of to the cumbersome term of child and youth or adolescence. Currently, the term "developmental psychopathology" is referred to more than that of "child psychopathology," but, either way, we focus on the ethical and legal challenges and obligations in working with children who have psychological disorders that affect their development and outcome.

(b) Beneficence/Nonmaleficence

Beneficence/Maleficence is a primary principle in most ethics codes, including those for psychologists and psychiatrists. According to AACAP, Beneficence concerns optimizing children's welfare, functioning, and development. AACAP continued with describing the mental health worker's obligation to avoid harming children (the principle of Nonmaleficence).

In cases of children with psychopathology, we maintain that the ethic of beneficence (nonmaleficence) becomes even more salient, given children's increased vulnerability. The psychologist should assess the particular developmental issues and disorders involved and determine their impact on the child's welfare, functioning, and development. Work with these children requires increased care and sensitivity because of their vulnerabilities and dependencies. For example, the informed consent process must address the child's psychopathology and its possible impact on proposed assessments and treatments. Assessment and therapy procedures that might be scientifically supported for the normally developing child might not find an evidence base for the child with psychopathology.

(c) Autonomy and Life Preservation

Autonomy concerns having meaningful voice or choice that is not interfered with by others or from limitations that are not accommodated and should be the rule in obtaining informed consent (Greig et al., 2013). Related topics concern maintaining privacy and anonymity. This chapter delineates when breaking confidentiality is warranted, especially in cases of child abuse. Life Preservation concerns dealing with suicidal ideation/intent and the threat of harm to others in particular. These difficult situations require ethical reflection and consideration of intent and severity before confidentiality is breached. This section of the chapter deals with issues such as these with others related to them not considered due to space limitations.

To review, there are three primary reasons considered here for a mental health professional being required to breach confidentiality with minors. These include: (a) suspected harm to the child (abuse or neglect); (b) concern over serious self-harm (suicide; non-suicidal injury; McManus et al., 2021; North et al., 2021) by the minor; and (c) threat of harm to others by the minor (including homicide). These conditions are also typically mandated by law as exceptions to professionals related to children with confidentiality. Given that parents technically and legally hold the right to the child's confidentiality, there is also the need to balance the confidentiality of the child with the parents' desire for information about the child's emotional state and progress in treatment. We will review each of these considerations.

Informed Consent

Fried and Fisher (2019) described that informed consent should be based on having all the relevant information to make a rational decision, and the decision should be made freely or without coercion. This includes not losing normal privileges should participation in the research be refused. For example, participation in research should not be sought using excessive gifts or monies and extant services should not be withdrawn as a penalty should participation be refused. The decision needs to be made by a rational party, which leads to minors requiring parental consent. That said, youth should provide assent for participation in services, therapy, or research. [We discuss some exceptions to this rule below.] The opportunity to provide consent is consistent with giving voice to children and respecting their participation and developing autonomy. Child psychopathology might even undermine the capacity to give assent, which should be discussed with the parents.

For further review of informed consent in the research and pediatric context, consult Hirascau et al. (2014), Noiseux et al. (2019), Powell et al. (2012), and Yao et al. (2021). These articles include international perspectives.

Child Abuse Reporting

In ensuring beneficence, psychologists have a responsibility to do good for others and promote the well-being of others. One way in which this is demonstrated is by being proactive and preventing harm to clients where possible. Protection of a child, in the form of recognizing and reporting child abuse, is a significant ethical obligation for psychologists (e.g., APA, 2017). The notion behind mandatory reporting is that the professional should protect those vulnerable populations who cannot advocate for themselves (e.g., children). Reporting of suspected child abuse and neglect exemplifies this concept and is not only a professional responsibility but also a legal mandate in many jurisdictions. Many countries require reporting of suspected or confirmed cases of abuse including the US, Canada, and Australia (e.g., Mathews & Kenny, 2008).

Given that reporting abuse is required for psychologists and the result is a break of confidentiality, it should be included in discussions with the family as part of the informed consent procedure at the initiation of treatment. Explaining the limits of confidentiality to children must be done in a way that takes into consideration their developmental and cognitive level. The APA Ethical Standard 4.02 Discussing the Limits of Confidentiality recommends that this occur at the start of the relationship. Specifically, the standard states: "(b) Unless it is not feasible or is contraindicated, the discussion of confidentiality occurs at the outset of the relationship and thereafter as new circumstances may warrant" (p. 7). This latter part reinforces the suggestion of these authors that when a situation arises in which confidentiality needs to be broken, such as reporting abuse, the psychologist revisits the discussion. Standard 4.05 Disclosures states, "(b) Psychologists disclose confidential information without the consent of the individual only as mandated by law, or where permitted by law for a valid purpose such as to (1) provide needed professional services; (2) obtain appropriate professional consultations; (3) protect the client/patient, psychologist, or others from harm" (APA, 2017, p. 8). The mandatory reporting of abuse would be applicable as points (1) and (3). While it may be acceptable to disclose without the consent of the individual, good clinical practice would dictate discussion with the child and the family so that they understand the legal requirement and are prepared for a potential visit by child protective services.

If limits of confidentiality are addressed at start of treatment, there will be less of an impact on the therapeutic relationship (Bean et al., 2011; Davidov et al., 2012). In order to minimize anger and damage to therapeutic relationship, it is best to involve the client in the process of making a mandatory report of abuse or neglect. Involving them in the process will also reduce client distrust and demystify the process of reporting. Failure to report may not only violate legal standards but also violate the APA ethical code. Many psychologists fear that breaking confidentiality in the case of child abuse will harm the therapeutic relationship; however, research has not found this to be true. Weinstein et al. (2000) found that 75% of mandated reports have either no effect or a positive effect on the therapeutic relationship (i.e., client expressed relief and increased self-disclosure). However, failure to comply with mandated reporting may have serious negative effects on the abused child, who may continue to be abused and will not receive the proper interventions (see Chapter 52 on Child Abuse and Maltreatment).

These issues are magnified in cases of child psychopathology. The child might have developed trauma reactions, PTSD, complex PTSD, dissociative disorders, depression, and the seeds of bipolar disorder or personality derangement because of the abuse experienced. The psychologist will have to not only report the abuse but handle the repercussions for the child. Early identification and reporting of abuse can facilitate necessary clinical services for the child and family and halt the abuse.

Harm to Self

In the course of treatment with youth, particularly those who are depressed, they may express suicidal ideation or intent. While the handling of this clinically is beyond the scope of this chapter (see Chapter 77 Suicidal Behavior), there is a need to break confidentiality and take several potential actions. Primarily, the parents need to be informed so that they can be involved in the decision-making. Actions that might be taken include referring the child for assessment at a crisis center, informing the parents so they will monitor the child closely, potentially initiating an involuntary hospitalization of the child for a suicide watch, or referral to a psychiatrist for medication (Sori & Hecker, 2015). As with child abuse reporting, this breach is best handled by discussing with the child the psychologist's concern over the child's physical and mental health and the need to keep the child safe from self-harm. Learning of non-suicidal self-injury (e.g., cutting) has the same ethical obligations, depending on the severity.

Harm to Others

There is probably no case that had as large an impact on breaking confidentiality than the landmark case of Tarasoff v. Board of Regents of University of California (Tarasoff v. Regents of University of California, 1976). While this case took place decades ago, its effect on therapeutic confidentiality is undeniable. The outcome of this case in terms of its historical importance is the establishment of what is commonly referred to as the *Tarasoff duty* or *duty to warn*. Duty to warn is ethically warranted when the therapist ascertains that there is a likelihood of physical harm. (In the US, some states have statutes mandating that the threat actually be communicated). While psychologists cannot control the behavior of the client, they have an obligation to the public to protect members of the public from harm. The duty is not warranted without a foreseeable victim. This condition indicates that the identity of the intended victim is known, either through direct statement by the client, (e.g., I am going to kill Hillary Sommers) or through detection (e.g., I am going to kill my math teacher). In this latter case, the psychologist could identify the teacher with minimal effort by contacting the school and determining who is the client's math teacher (Sori & Hecker, 2015).

The concept of duty to warn has been expanded in many states to include duty to protect. This expansion allows for greater latitude in the psychologist's actions. In these cases of harm to others, psychologists would need to check their legal requirement and obligation to warn the intended victim. However, there are other actions that can be taken including removing the threat of the client by initiating an involuntary hospitalization of the client, which would also reduce the threat by removing the client from society for a specified period of time. The psychologist could warn the intended victim, notify the client's family of the potential harm, or notify the police. There are many actions that can be taken to ensure safety.

Balancing Child Privacy with Parental Rights

Legally, all parents have the right to information shared by children in treatment given the youths' status as minors. However, in order to establish a trusting relationship with children and encourage open communication, psychologists will often assure youth of confidentiality. Parents are typically notified of this arrangement by helping them understand the necessity of the youth feeling safe disclosing to the psychologist. Issues arise, however, when psychologists may believe they need to break this agreement to inform the parent(s) about some aspect of the youth's behavior. There is a balancing act for psychologists with ensuring no harm comes to the client and risking damage to the therapeutic relationship. Sullivan et al. (2019) reported that psychologists are likely to encounter this situation because adolescents often engage in risky behavior that may place them in harm's way.

Issues of privacy with youth are difficult due to the often competing interests of the youth and parents. There are many factors to consider before sharing information a child has disclosed with parents (Sori & Hecker, 2015). Technically and legally, parents have the right to information about their child's treatment. There are several ways to manage the issue of confidentiality with minors. One way would be for the parents to have complete access to the content of what the child shared in session. While this may satisfy the parents, the child is not likely to feel comfortable opening up and disclosing, particularly about content the child does not want the parents to know. Another way would be to explain to the parents that you will not be sharing with them what happens in treatment with the child. This approach will probably not be satisfactory for the parents and is not really feasible. Involving the parents in the treatment and keeping them abreast of the child's state is important. We advocate for an approach that seeks to balance these two positions and informs the child before any disclosures are made. In practice, this would entail telling both parties (child and parents) at the outset about the rules you have established for the child's confidentiality. When the time for sharing information with the parents arises, the child and psychologist would talk about what is being shared so it would not come as a surprise or the disclosure occurring in secret without the child's knowledge. Helping the parents to recognize that the child needs privacy and a trusting relationship with the psychologist, but also letting them know you will inform them of certain concerns, is challenging. These difficult topics might include substance abuse, pregnancy, reckless behavior, etc. Psychologists will want to consider the severity of the behavior and the age of the child in determining whether disclosure to parents is warranted (Isaacs & Stone, 2001).

With older children (aged 14–17 years), there may be an increase in risky behavior that may give the psychologist cause to consider breaking confidentiality. Rae et al. (2002) found that pediatric psychologists generally considered it ethical to break confidentiality when health risk behaviors are more intense, more frequent, and of longer duration with adolescents. They concluded that at a certain point the adolescent's health is more important than confidentiality. Sullivan et al. (2019) found a "push-pull relationship" (p. 298) such that the negative nature of the behavior may push one to break confidentiality, whereas maintaining the therapeutic process may pull one away from breaking confidentiality. They recommended that psychologists would be wise to gain a knowledge base of risky behaviors (e.g., sexual activity, substance use, suicide) such that their decisions are not based solely on intuition but on empirical data.

Treatment Without Parental Consent

Some states have allowances for minors to seek treatment without parental consent in the case of emergencies. For example, in the state of Florida in the US, FL §394.4784 (Fla. Stat. §394.4784, 2020) allows for minors age 13 years or older to access services if the provider deems the child is "experiencing an emotional crisis to such degree that he or she perceives the need for professional assistance". The law further states that such services shall not exceed two visits during any 1-week period in response to a crisis situation before parental consent is required for further services. Thus, a child may be seen without parental consent or knowledge but only for a short period of time. The age of 13 may be used as it could indicate an unplanned pregnancy or other crisis situation that the minor may need assistance with and not want parental knowledge. Other issues that a minor may potentially seek treatment for without parental consent could include drug abuse, birth control counselling, sexually transmitted diseases, or sexual assault (Lawrence & Kurpius, 2000). We recommend that while, legally, the psychologist may be able to treat the minor, procuring parental consent as soon as possible is the best option.

We have examined several topics related to Autonomy involving children who require ethical reflection and obligatory practice. These include reporting child abuse, protecting against suicidal ideation/ intent, and reporting danger to specific others. Therapists need to balance children's desire for confidentiality and parents' desire to know details in therapeutic sessions. These issues are magnified in cases of child psychopathology, and the psychologist should be on heightened alert. For example, in cases of child psychopathology, in which psychologists need to deal with suicidal ideation and intent, they must exhibit greater need for caution and should have a lower bar for reporting. As with the findings that treatment will not be negatively impacted by having to report abuse, the obligation to act in cases of suicidality/intent normally should not lead to significant worsening relations with the reporting professional party.

(d) Assessment and Diagnosis

Assessment The APA (2017) ethics code deals extensively with assessment and is complemented by the standards for assessment the APA has cowritten with the American Educational Research Association and the National Council on Measurement in Education (2014). In this section, we review the ethical standards for assessment put forth by the APA, which are ones common to all ages and psychological conditions. In the last section of the chapter on law and science, we list some widely used tests in work with children.

The APA ethics code (APA, 2017) considers assessment in its ninth standard. For bases of assessments (in Standard 9.01), psychologists use information and techniques that are sufficient "to substantiate" their findings. The information and techniques need to support their statements and conclusions; we add that these would often concern their diagnoses, recommendations, and prognoses. The constraints and limitations in the examination, if any, on the adequacy of the assessment process (and the consequent reliability and validity of the assessment) need to be mentioned in the assessment reports. For use of assessments (in Standard 9.02), psychologists use assessment protocols (the instruments, tests, techniques, or interviews, and their administration, adaptation, scoring, interpretation) in appropriate ways for the question at hand according to the research on or other evidence related to them. The tests need to be standardized on a population related to the examinee profile (e.g., racial, ethnic, age), thus assuring that they are reliable and valid for the assessment at hand. If this is not the case, the psychologist describes the strengths and limitations of the instrument results and their interpretation. One such limitation might relate to language.

Standard 9.06 of the APA ethics code concerns the interpretation of test results. It indicates, "When interpreting assessment results, including automated interpretations, psychologists take into account the purpose of the assessment as well as the various test factors, test-taking abilities, and other characteristics of the person being assessed, such as situational, personal, linguistic, and cultural differences, that might affect psychologists' judgments or reduce the accuracy of their interpretations" (APA, 2017, p. 13). They indicate any significant limitations of their interpretations. We would add that age, developmental status, and associated diagnoses, disorders, and psychopathology are part of the critical characteristics of the examinee in test interpretation. Psychologists need to be aware of these variables or risk arriving at incorrect and even harmful interpretations of a child's test results.

Diagnosis The APA (2017) ethics code does not refer to diagnosis except tangentially in one standard. The process of diagnosis is integral to the work of a psychologist with children, especially in cases of child psychopathology, yet the APA ethics code expresses a serious lack by not considering the ethics in diagnosis (Young, 2017). Young (2016) reviewed the criticisms of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5; American Psychiatric Publishing, 2013). The main concerns were that categories might not be valid or have their bar lowered for diagnosis, leading to more psychopharmacological prescriptions for children. Therefore, psychologists should not apply the DSM-5 without reflection or knowledge of its criticisms and the extant literature of the diagnosis/disorder/psychopathology in question.

(e) Research

The United Nations Convention on the Rights of the Child [UNCRC](Convention on the Rights of the Child, 1989) during the 1990s represented a change from viewing children as passive objects subordinate to their parents to viewing them as human beings with their own legal rights (Cater & Øverlien, 2014). Simon et al. (2020) noted that the US is the only country that has not ratified the UNCRC. The UNCRC presents the dichotomy in dealing with children: that they are competent and have the right to be heard (e.g., in Article 12), while also being vulnerable and in need of protection (e.g., in Article 19).

Falch-Eriksen et al. (2021) reviewed the literature with respect to whether children's voices are being heard in child protection service proceedings given the passage of the UNCRC. They found that this was not the case in the multiple countries examined: The children felt that they were not being asked, listened to, or heard, even in unsafe or harmful contexts. Tobin and Cashmore (2020) noted that for it to be effective, countries need to adopt a rights-based approach such that children are involved in decision-making in which their lives are affected; as well as in the research that affects them. This legal tension in children needing to be heard and needing protection is more salient with children expressing psychopathology. Children experiencing psychopathology still should be heard but, granted, they are more vulnerable, including in situations and problems over which they have little to no control. As mentioned, another situation about children's voice involves research; next, we consider the issue of trying to obtain assent for participation, which is accentuated in children with psychopathology.

All research involving children should be reviewed by a research ethics board to ensure the protection of children. The research ethics board must consider the potential benefits, risks, and discomforts of the research to children and assess the justification for their inclusion in the research (Office for Human Subjects Protection, 2016). In assessing the risks and potential benefits, the IRB should consider the demographics and characteristics of the children to be enrolled in the study – for example, their health status, age, and ability to understand what is involved in the research – as well as potential benefits to participants, other children with the same condition, or the greater community. Whatever the level of participation, researchers have responsibilities to ensure that they protect children's and young people's best interests. As Coyne (2010) stated, "Accessing children for research purposes is a process that is governed by strict ethical guidelines and procedures which are meant to safeguard the children from potential harm or exploitation" (p. 227).

Generally, when conducting research, consent is required from participants. Given children's age and lack of legal competency status as adults, they are typically asked to give *assent* while their parents provide *consent* for them. Some important ethical issues emerge when parents may give consent for a child, but the child does not wish to participate in the study. The alternate situation may occur also, in which a child wants to participate but the parent will not provide consent. The notion behind the necessity of parental consent is that the parent is the legal guardian and custodian and viewed as responsible for making decisions in the child's best interests. There is a balancing act between the need to protect children from potential harm in the research with the need to ensure their right to informed consent or dissent is respected.

The APA ethical codes make no consideration of youth in research with regard to the consent process. However, in the section "Informed consent," the principles state: "(b) For persons who are legally incapable of giving informed consent, psychologists nevertheless (1) provide an appropriate explanation, (2) seek the individual's assent, (3) consider such persons' preferences and best interests, and (4) obtain appropriate permission from a legally authorized person, if such substitute consent is permitted or required by law." (p. 7). This dictate would apply to children in that they are legally incapable of giving consent and must rely on their parents to complete this process. Children should be provided with a form (depending on age and reading level) that outlines in age-appropriate terms what the research entails. If capable, they can sign their name to the form to indicate assent. Younger children can be read a statement and their comprehension can be determined by asking if they understand what has been shared. As is true of all forms of consent, children (and parents) have the right to withdraw at any time without penalty (see Chapter 8 for more on Informed Consent).

Parsons et al. (2016) interviewed 32 researchers who work regularly with children. All reported that they use paper and pencil assent forms (as routinely required by university research ethic boards) and most explained the importance of verbal interaction and the development of trust and rapport over time with the child participants. Some used additional attractive and child-centered methods, such as pictures, technology, comics, or images, to portray the information. Many revisited consent over time given that there were concerns about children's comprehension. Technology was recognized as potentially playing an important role in research with children by providing a means to review consent, to show what is upcoming in the research (e.g., next steps), and the use of social network sites to recruit participants. In sum, technology was seen as a way to impart information to children (e.g., tablets, videos) and support autonomous decision-making by children. Given the increased use of technology by children, incorporating this into consent may be a very viable option.

Traditionally, there is a concern about the power differential between the adults conducting research and the youth who are participants in the research. However, there has been a shift toward recognizing children as more competent than previously believed and that their voices need to be heard in research (Clavering & McLaughlin, 2010). This would translate to children having an active voice in the development of research protocols. As Coyne (2010) pointed out, it is unclear if any ethics committees may involve children as members, even though children are the subject of the studies. There may be unintended benefits to children from participation that are not fully understood at the initiation of the research. Woodgate et al. (2017) reported on how, for some youth participants in their research, telling their stories was empowering, and on some occasions therapeutic.

Research conducted with children expressing psychopathology presents even more ethical concerns because of their increased vulnerability, lessened ability to understand the research protocols, and impacted understanding of how the research might benefit them or other children in the public. Researchers need to give special attention to obtaining informed assent and assuring the children of the benign nature of the research, or that the benefits substantially outweigh the risks. Deception in research with this population should be avoided and not supported by IRBs, given their vulnerabilities.

(f) Divorce

Many children come from divorced homes. Research has consistently shown that children from divorced homes exhibit more behavioral problems and evidence greater psychological adjustment than children from intact families (Ahrons, 2004; Kelly & Lamb, 2000). Given the potential subsequent emotional or behavioral issues that may arise for a child, psychologists will have to deal with complex ethical issues in such cases. Typically, the parent with legal custody is the one to consent to treatment. However, in many cases, there is shared parental custody and both parents need to be informed and consent. While one parent may call and initiate treatment for the child, it is best practice to seek to inform (at a minimum) the other parent of the treatment. This can be done by contacting the other parent by phone. While some experts advise that the psychologist should ask for and review the custody agreement, we argue that the onus should be placed on the parent who brings the child to assist in the notification of the other parent. This assistance should come in the form of providing that parents' contact information. Clinically, it is probably best to have the involvement of both parents and every effort should be made to involve both parents. This can reduce issues of loyalty for the child (Sori & Hecker, 2015). (This recommendation is also applicable in any parenting situation, e.g., never married).

Another area of concern when working with children of divorce is the role of the psychologist. Woody (2000) described the various roles of the psychologist including custody evaluator, clinician, and mediator. It is important to not mix roles. For example, if you are the clinician for the child, you are not functioning in the role of custody evaluator, and therefore cannot make comments or recommendations regarding custody of the child. The role of the psychologist should be outlined at the outset of treatment to the parents in order to avoid confusion later on. The APA Guidelines for Child Custody Evaluations in Family Law Proceedings (American Psychological Association, 2010) discuss concepts related to the psychological best interest of the child, making the child's welfare paramount and obtaining appropriate informed consent when conducting custody evaluations. The psychologists involved in child psychopathology and divorce require extra prudence in proper evaluation of the situation and child in order to make informed decisions. For example, conducting custody evaluations in this context requires detailed knowledge of the perception of both parties of the child's status and developmental needs. This leads to the last substantive section of the chapter on ethics and law in child psychopathology.

Law and Science

Law Multiple areas in working with children expressing child psychopathology require detailed knowledge and application of ethics and law, for example, for forensic evaluations for court and working in the school system. Ackerman et al. (2021) conducted an exhaustive review of child custody evaluations (CCEs) that epitomizes the intersection of psychology and law forensically in working with children. They maintained that work in the area requires intimate knowledge of ethics codes, professional child custody and forensic guidelines, and the research literature, as well as applicable law. Work in the area is associated with a notable rate of malpractice suits and board and ethics complaints, illustrating the risk in the area and emphasizing the present authors' emphasis on the need for psychologists to be scientifically informed, for example, with respect to domestic violence, sexual abuse, substance abuse, and parental alienation and abandonment. The tests used in the assessments need to meet expected psychometric standards of reliability and validity and the scientific criteria of the SCOTUS decision *Daubert* (i.e., published and peer reviewed, known or estimable error rate, testability or falsifiability, and general acceptance; *Daubert v. Merrell Dow Pharmaceuticals, Inc.,* 1993).

For children, the Minnesota Multiphasic Personality Inventory-Adolescent (MMPI-A; Butcher et al., 2006), the Personality Assessment Inventory-Adolescent (PAI-A; Morey, 2007), the Child Behavior Checklist (CBCL; Achenbach, 1991), and the Behavior Assessment System for Children-3rd Edition (BASC-3; Reynolds & Kamphaus, 2015) are the most widely used instruments in these regards. About placement decisions (e.g., sole, joint custody), in survey research, across judges, attorneys, and psychologists, the wishes of the child become relevant at about 15 years of age.

This age is consistent with the age at which teenagers should be able to decide whether confidential information should be given to their parents by therapists, everything else being equal. However, it is our opinion that the voice/ autonomy/agency of the child could be heard earlier in decisions about custody as part of the full scope of information gathered in a child custody exam (CCE). Our emphasis for hearing the child in CCEs is consistent with how we underscore that psychologists have the ethical obligation to function from the superordinate principles of being fully responsible in their work, respect the full personhood of the developing client, and advocate for their full participation to the degree possible in decisions involving them.

That said, psychologists should determine whether any preferences in these regards are based on coercion, demand characteristics, or other biasing factors. The parents in CCEs should be assessed in depth and also with reliable and valid psychological instruments, but they should include respondent validity scales, such as the F family of tests in the Minnesota tests (Minnesota Multiphasic Personality Inventory-2; MMPI-2; Butcher et al., 1989)/Minnesota Multiphasic Personality Inventory-2-Restructured Form (MMPI-2-RF; Ben-Porath & Tellegen, 2008/2011), which are referred to as ones used frequently in CCEs by Ackerman et al. (2021). The MMPI-3 (Minnesota Multiphasic Personality Inventory-3; Ben-Porath & Tellegen, 2020) and its similar family of F scales will be making inroads in the instruments used in these regards. Ackerman et al. (2021) argued against use of projective type tests with children because of psychometric issues. In testing children for CCE, intelligence tests are used often, as well. For other work on ethics and law related to CCEs, see Geffner et al. (2018), who gave, for example, a vignette on how testing can be biased.

In these COVID times (McGee et al., 2021), remote telehealth and tele-assessment are taking place much more frequently. But the virtual environment presents multiple difficulties in the informed consent process, the quality of the medium, limitations when face-to-face testing is required, and eventual challenges in court on its reliability and validity (Brown et al., 2021; Dale & Smith, 2021; Dickinson et al., 2021; Goldenson & Josefowitz, 2021; Thibodaux et al., 2021; Young, 2022b). These difficulties would be compounded with children experiencing child psychopathology.

Science The three themes in this chapter related to being scientifically informed in working with children expressing psychopathology involve: (a) evidence-based practice; (b) reliable and valid tests in assessments; and (c) empirically supported diagnostic categories. We have examined the latter two topics in prior sections and focus here on evidence-based practice. Therapists are obligated to help and do no harm, which is especially true for children, who are vulnerable, and doubly true for children with psychopathology, who are even more vulnerable.

The American Psychological Association endorsed the value of evidence-based practice in 2006 (American Psychological Association, 2006). Blease et al. (2016) advocated that psychologists need to conduct assessments, offer diagnoses, and implement therapy with professional competence, which depends on keeping up to date with the current research and effectively evaluating the evidence involved. That said, patient values and preferences need to be considered, as well as sociocultural factors. Current science does not mean only randomized control trials, for example, as they might not be representative of the general population. Young (2022c) reviewed the literature, documenting lack of representativeness in research for race/minority status, gender, age, vulnerability, etc. These deficits would apply to children in research, as well.

Given the prevalence of emotional and behavioral disorders in children and the potential for lifelong struggles related to these conditions, psychologists need to become trained in evidenced-based practices. Evidence-based practices (EBPs) have been shown to be both efficacious and cost effective. Cook et al. (2017) reported that one of the main goals of EBP psychotherapy is to allow for patient choice about treatment options. Clinical decisions are made collaboratively with the client, thereby increasing autonomy. Blease et al. (2016) argued that in order for practice to be ethical, it is imperative that it is guided by the relevant data. Thus, the inclusion of EBPs into clinical practice and their reliance on research enables psychologists to use research-driven evidence as opposed to relying solely on personal opinion or preference. The APA evidence-based guidelines (American Psychological Association, 2006) strongly encourage including clinical expertise and judgment into applicable practice of evidence-based psychotherapies, so that a balanced approach is achieved. However, children experiencing psychopathology need special considerations in implementing any therapy.

Barnett et al. (2019), Crane et al. (2021), Dutil (2019), Jensen (2021), Pegg et al. (2021), Powell et al. (2020), and Whiteside et al. (2021) have described factors and difficulties in this regard for traumatized youth and other youth requiring psychotherapy. For example, Barnett et al. (2019) and Jensen (2021) referred to difficulties in reaching children who need treatment, while Dutil (2019) emphasized difficulty in reaching Black and Latinx youth in these regards. Pegg et al. (2021), Powell et al. (2020), and Whiteside et al. (2021) referred to the difficulties in funding and implementation, respectively.

Conclusions

Working with children experiencing psychopathology is ethically challenging and requires expert knowledge of the law for the children involved. This chapter on ethics and law in relation to working with children experiencing child psychopathology has covered topics: (a) Ethics, (b) Developmental Considerations, (c) Beneficence/Nonmaleficence, (d) Autonomy and Life Preservation (including child abuse), (e) Assessment, (f) Diagnosis, (g) Research, (h) Divorce, (i) Law, and (j) Science. Following from these topics, the areas in the chapter considered include informed consent, confidentiality, child abuse reporting, duty to warn, assessment, child custody evaluations, research, and evidence-based practice.

The APA ethics code (APA, 2017) and its principles and standards have provided the starting point in our consideration of ethics in relation to child psychopathology. However, it barely mentions children and development, so we consulted the AACAP ethics code, as well, which starts with a developmental principle. The chapter considered the professional applicable ethics code as a starting point in practice, provision of service, and research, with local jurisdictional laws as especially relevant, too. There are also practice guidelines to consider. At the same time, understanding that ethics is dynamic and changing, such that any ethics code or practice guideline does not supply pat answers to be applied in a cookbook fashion. This dictum especially relates to vulnerable children, such as those with psychopathology.

Parental Stress in Raising a Child with Mental Health and Behavior Problems

8

Songtian Zeng, Lynn Yuan, Yujin Lee,
Yiyang Guan, Katherine Volk, Margaret O'Riordan,
and Angela K. Stone-MacDonald

Raising a child with mental health and/or behavior problems can be challenging. Providing care for a child with mental and behavioral problems is a significant source of stress for parents and caregivers (Angold et al., 1998; Brannan & Heflinger, 2001; Taylor-Richardson et al., 2006). Furthermore, the stress associated with caring for a child with emotional and behavioral difficulties may be compounded by factors at the parent, family, and broader social and community levels. Other factors such as low socioeconomic status (and its accompanying stressors) and lower educational levels can further compact parental stress. In this chapter, we will describe the biological, physical, and mental aspects of stress; synthesize how stress may affect parenting and family functioning; and discuss the associated factors that may contribute to the development of parental stress. Intervention and policy recommendations will also be discussed.

What Is Parental Stress?

Parental stress is distinct from the stress arising from other roles and experiences—from the workplace stress, interpersonal conflict within the family, and general psychological distress. Deater-Deckard (2004) defines parental stress as "a set of processes that lead to aversive psychological and physiological reactions arising from attempts to adapt to the demands of parenthood (p. 6)." Parental stress can arise when parents encounter stressors in the parenting role and perceive them as threatening or burdensome. According to the parental stress literature (Nomaguchi & Milkie, 2020; Pearlin, 1989), parental stressors include *role overload* (i.e., parents' perceived parenting demands exceed their capacity and available resources), *interpersonal conflict* (i.e., problems and difficulties evoked between parent and child), *role captivity* (i.e., parents feel stuck with caregiving and parenting tasks), and *interrole conflict* (e.g., work interference with fulfilling parental responsibilities to meet the needs of their children).

Any parent or caregiver of a child faces these stressors and experiences parental stress to some extent at one time or another. However, raising children with mental health and behavioral needs has

been found to add another layer of burden and challenges to parents, which often result in higher parental stress (Neece & Chan, 2017). To be specific, providing care for children with special needs imposes time, financial, and psychological burdens that are far beyond the burdens faced by those without special needs (Nomaguchi & Milkie, 2020). For example, parents of children with intellectual and developmental disabilities may experience greater caregiving demands and arrangement of care, which imposes time burdens (Miller et al., 2015). Also, having a child with a disabling health condition tends to have more unsecured debt, and the rise persists longer for those with more severe disabilities, perhaps due to the higher cost of more intensive care (Houle & Berger, 2017). Finally, parents with mental health and behavioral challenges are at increased risk of psychological distress. During daily encounters with people around the family—neighbors, friends, school officials, strangers, and health care professionals—people's stigmatizing attitudes and adverse reactions may serve as parents' psychological stressors (Farkas et al., 2019). In response to these stigmatizing or stressful daily encounters and social exchanges, parents tend to blame themselves for their child's conditions and experience increased social isolation and role captivity (Beernink et al., 2012; Moses, 2010).

Parental Stress Assessment

Although parental stress has been conceptualized in several ways in the parental stress literature (e.g., Abidin, 1992; Belsky, 1984; Crnic & Greenberg, 1990; Crnic & Low, 2002), two predominant theoretical frameworks have influenced parental stress measures. The first framework is conceptualized by the work of Abidin et al. (1992) and Belsky (1984) and is often called Parent-Child-Relationship theory (P-C-R theory; Deater-Deckard, 2004). P-C-R theory posits that parental stress arises because of stressors arising from the parent domain (e.g., depression, anxiety), child domain (e.g., behavioral problems, disabilities), and parent–child relationship domain (e.g., relationship conflict between parent and child). The other framework conceptualized by the work of Crnic and Greenberg (1990) and Crnic and Low (2002) is the Daily Hassles theory (DH theory). What makes it distinct from the P-C-R theory is that the DH theory mainly focuses on typical parental stress stemming from a broad array of minor daily stressors that most parents face daily or weekly. In contrast, P-C-R theory focuses on parental stress stemming from stressful circumstances or life events, such as parent depression, child disabilities, economic hardship, and relational problems in the family (Deater-Deckard, 2004).

One of the most widely used parental stress assessments, the parental stress Index (PSI) is grounded in the P-C-R theory. This parent self-report measure is available in a long form (101 items) and a short form (36 items). The long version consists of two general domains—the child and parent domains—and the optional life stress domain. The child domain contains six subscales (i.e., adaptability, reinforces parent, distractibility/hyperactivity, demandingness, mood, and acceptability) measuring various child-level factors that may affect parent–child relationships (Abidin, 1995). The parent domain contains seven subscales assessing various parent-level stressors (i.e., competence, isolation, attachment, health, role restriction, depression, and spouse (Abidin, 1995). The PSI short form (PSI-SF) is similar to the long form, except questionnaires are recategorized into three subscales: parental distress, parent–-child dysfunctional interaction, and difficult child (Abidin, 1995). Notably, the validity and reliability of the PSI for parents with special needs have been documented in a small body of research (Barroso et al., 2016; Tomanik et al., 2004; Zaidman-Zait et al., 2010). For example, Barroso et al. (2016) examined the psychometric properties of the English and Spanish versions of the PSI-SF among 58 mothers of 12- to 15-month-old infants with elevated levels of behavior problems from predominantly Hispanic, low-income backgrounds. Their findings provide empirical evidence that the PSI-SF may be an effective and appropriate measure to assess parental stress among parents of children with behavioral concerns from minority and disadvantaged backgrounds (Barroso et al., 2016). Tomanik and colleagues' work (2004) also supports the applicability of using the PSI-SF in parents of children with autism spectrum disorders (ASD).

Another measure grounded on the P-C-R theory is the Parental Stress Scale (PSS). The PSS is a self-report measure that captures both the joys and demands of parenting (Berry & Jones, 1995). Importantly, the PSS was designed to measure parental stress in particular by differentiating parental stress from general stress and avoiding confounding parental and marital stress (Louie et al., 2017). Example items are "I feel close to my child(ren)," "I enjoy spending time with my child(ren)," "the major source of stress in my life is my child(ren)," "having children has been a financial burden," "the behavior of my child(ren) is often embarrassing or stressful to me," and "having children has meant having too few choices and too little control over my life."

Louie et al. (2017) reviewed 21 studies in which the PSS was utilized as a parental stress measure. Their review showed that the PSS had been tested in many countries and diverse samples, including parents of children with and without ADHD, physical disabilities, behavioral problems, and clinical levels of psychopathology (Louie et al., 2017). In one study, the responses of 233 parents of children with special needs, 95% of the participants demonstrated strong internal consistency ($\alpha = 0.83$) and 6-week test-retest reliability ($r = 0.81$), as well as robust convergent validity with the Perceived Stress Scale ($r = 0.41$). In another study based on 43 parents of children with special needs, the Parental Stress Scale strongly correlated with the parental stress Index, $r = 0.75$. The PSS was also shown to correlate with constructs related to parental stress, such as loneliness, anxiety, marital satisfaction, and social support ($-0.29 < r < -0.44$) in a sample of 746 parents of children with and without special needs. Finally, discriminant validity was shown by differentiating between 116 mothers of healthy children, 51 socio-demographically matched mothers of children receiving treatment for behavioral problems, and 78 parents of children with neurodevelopmental disabilities receiving special education (Berry & Jones, 1995). Furthermore, the PSS is brief, ideal for routine use in pediatric medical clinics.

The Parenting Daily Hassles scale (PDH), on the other hand, was designed to assess the frequency, intensity, and impact of 20 typical day-to-day parenting hassles experienced by parents and caregivers of children (Crnic & Greenberg, 1990). Its subscales include challenging behavior, parenting tasks, and the burden of meeting children's expected or legitimate needs. This parent self-report measure asked parents to score each of the 20 potential hassles in terms of frequency (ranging from rarely to constantly) and intensity (1 = low to 5 = high). Potential hassles listed include "being nagged, whined at, complained to," "sibling arguments or fights require a referee," "the need to keep a constant eye on where the kids are and what they are doing," "the kids get dirty several times a day requiring changes of clothing," "having to run extra errands to meet the kids' needs," and "babysitters are hard to find."

Parental Stress and Children with Special Needs

Parental stress is greater when child care demands are higher. Parents whose children have emotional and behavioral challenges face additional care demands related to the child's symptoms. Children with chronic health conditions are more likely to experience emotional and behavioral problems than their healthy peers (Long et al., 2008). Parent–child relationship quality, parenting behavior, and family functioning are critical to healthy development (American Academy of Pediatrics, 2003). In theory, Lazarus proposes there is a reciprocal relationship between parental stress and child behavior problems, and parental stress is derived from parents' perceived ability to fulfill their parenting role (Morgan et al., 2002). Child behavior problems are thought to be a causal agent of stress, and parental stress may have detrimental effects on child well-being and affect parents' sense of parenting efficacy (Chang & Fine, 2007). Parental stress has been linked to less responsive, more authoritarian, and more neglectful parenting (Belsky et al., 1996). In turn, poor parenting has been associated with poorer developmental outcomes for the child (Deater-Deckard & Scarr, 1996). For example, children with problem behavior may elicit increasingly harsh discipline from their unskilled caregivers, and in turn, these poor parenting practices could worsen children's adverse behaviors.

A considerable body of research further supports the theory that parental stress was elevated among parents with children with emotional and behavioral problems (Crnic et al., 2005; Mackler et al., 2015; Rothbaum & Weisz, 1994). Parenting knowledge, perceived competence, and emotional and instrumental support can all influence parents' levels of parental stress. The literature suggests that sources of parental stress are multidimensional, including child characteristics, parent characteristics, qualities of the parent–child relationship, demands of parenting, and contextual life events within the parent–child system (Abidin, 1995; Deater-Deckard, 1998).

One line of research that advanced in the past decade has focused on the challenges of raising children with special health care needs or emotional and behavioral problems. For example, parents tend to find obsessive compulsive disorder (OCD) symptoms in their child distressing to observe (Amir et al., 2000; Peris et al., 2008), and so it is unsurprising that studies indicate high rates of symptom accommodation (e.g., participating in rituals, providing reassurance, changing family routines) among parents of children with OCD to reduce the child's distress and the parents' own emotional reactions toward it (Allsopp & Verduyn, 1990; Peris et al., 2008; Shafra et al., 1995; Storch et al., 2007). Family members are also motivated to engage in accommodation to avoid angry reactions from the child with OCD if they do not accommodate and reduce the duration of compulsive activity (Calvocoressi et al., 1999). It is evident that parents find themselves in a bind that is likely to affect their well-being: They report symptom accommodation to be distressing (Amir et al., 2000; Peris et al., 2008), do not believe it is helpful (Calvocoressi et al., 1999), and yet often face aggressive outbursts or distress from their child when they refuse to accommodate (Storch et al., 2007).

Accommodation is positively correlated with relatives' anxiety and depression (Amir et al., 2000). It can affect family relationships in that the burden imposed, either by engaging in accommodation or attempting to resist it, can lead to feelings of blame toward the child (Peris et al., 2008). Arranging and providing care for children with special health care needs imposes time burdens (Miller et al., 2015) as well as financial costs (Stabile & Allin, 2012) far beyond the time and money required to raise healthy children. Primary caregivers of children with special needs tend to reduce or stop paid work activities, which, in addition to children's health care costs, places these families into lifelong financial deprivation. Using the National Longitudinal Study of Youth 1979 (NLSY79), Houle and Berger (2017) found that mothers whose children had a disabling condition by age 4 were more likely than those whose children did not have disability to have unsecured debts (i.e., debts that are owed to banks, stores, hospitals, and other institutions and are not tied to an asset) that they were unable to repay for decades following the birth of a child with a disability.

Social stigma, referring to people's adverse reactions that often involve stereotypes, prejudice, and discrimination, is another major stressor. Parents raising children with physical disabilities or mental disorders must endure daily encounters with medical professionals, school officials, neighbors, strangers, and friends (Farkas et al., 2019). In response to other people's stigmatizing attitudes, parents tend to blame themselves for their children's conditions and isolate themselves and their families from social interactions (Moses, 2010). Having a child with emotional problems or aggressive behaviors increases mothers' parental stress (Vaughan et al., 2013) because it increases mothers' social isolation and role captivity (Beernink et al., 2012), and it affects the mother–child relationship negatively.

Studies investigating child symptomatology on parental stress have primarily focused on developmental disorders (Britner et al., 2003; Long et al., 2008), but they also include studies of child mental health symptoms (Anderson, 2008; Deater-Deckard, 2004; McDonald et al., 1997; Tzang et al., 2009).

Primarily, the research on parental stress has focused on the relationship between parental stress and subsequent child psychopathology (Abidin et al., 1992; Costa et al., 2006; Nelson et al., 2007) and has demonstrated that higher levels of parental stress are related to higher levels of child symptomatology. Research investigating the relationships between child symptoms and parental stress has found that child symptoms predict parental stress (Anderson, 2008; Deater-Deckard, 2004; McDonald et al., 1997; Tzang et al., 2009). For example, McDonald et al. (1997) found a direct relationship between externalizing behaviors and caregiver-reported stress. Deater-Deckard's (2004) research demonstrated increased stress among parents caring for children with anxiety and depression.

Researchers have suggested that the experience of parental stress may vary based on the specific diagnosis of disability of the child due to the associated behavioral phenotype, which are the expressions of behaviors related to a diagnostic label (e.g., intelligence, social skills, agreeableness; Dykens & Hodapp, 2001; Hodapp et al., 1998; Seltzer et al., 2004). Researchers commonly report that families of children with ASD experience more parental stress than families of typically developing children (Dabrowska & Pisula, 2010; Rao & Beidel, 2009) or those diagnosed with other disabilities. Due to the core symptoms of ASD (e.g., social interaction deficits, repetitive behaviors, and restricted interests and activities), parents raising children with ASD experience more mental health issues and more parental stress than parents with typically developing children or children with other disabilities (Gardiner & Iarocci, 2014).

One study showed associations between parental stress and severity of ASD symptoms, adaptive skills, and IQ (Rivard et al., 2014). Further, parents of children with ASD show more psychiatric disorders, more autistic symptoms, and more problems in social communication themselves (Brei et al., 2015). Particularly, among families of children with ASD compared to families of children without disabilities or with other types of disabilities, child challenging behaviors are highly predictive of parent stress (Falk et al., 2014). These challenging behaviors include self-injury, social interaction difficulties, and emotional dysregulations. In a broader context, Hayes and Watson (2013) reexamined the research using comparison groups to investigate parental stress and conducted a meta-analysis to pool results across studies. The experience of stress in families of children with ASD versus families of typically developing children resulted in a larger effect size. Comparisons between families of children with ASD and families with other disabilities also generated a large effect size. In other words, the findings of a meta-analysis suggest that parents of children with ASD experience more parental stress than those of children who have typical development or another disability (Hayes & Watson, 2013).

Consistent with the proposition that parental stress and children's disruptive behaviors are reciprocally related (Burke et al., 2008), several studies have demonstrated that elevated parental stress is associated with children's higher externalizing and internalizing problems in both clinical and nonclinical groups (Labella & Masten, 2016; Levendosky et al., 2003; Rothbaum & Weisz, 1994). Moreover, parents of children with disruptive behavior disorders (DBDs) reported experiencing considerably higher parental stress than those of children without behavior disorders (Crnic et al., 2005; Podolski & Nigg, 2001; Ward et al., 2016). When experienced in childhood, ADHD adversely impacts the family system (Johnston & Mash, 2001). In addition to experiencing significantly more parental stress than parents of typically developing children (Theule et al., 2013), parents of children with ADHD are reported to experience greater levels of parental stress than parents of children with autism (Miranda et al., 2015) and physical conditions such as HIV infection or asthma (Gupta, 2007). These data suggest either that neurodevelopmental disorders contribute to parental stress to a greater extent than other significant medical conditions or that having a child with a neurodevelopmental disorder is correlated with the tendency for increased stress. Increased parental stress is associated with numerous negative outcomes for children with ADHD and their parents, including the worsening of a child's ADHD symptoms, reduced response to intervention, reduced quality of the parent-child relationship, and decreased parental psychological well-being (Johnston & Mash, 2001; Modesto-Lowe et al., 2008; Theule et al., 2013). Parental stress may impact children via a number of pathways, including poor monitoring of children's activities and whereabouts and increased use of corporal punishment and controlling rather than supportive parenting strategies (Deater-Deckard, 2004; Rogers et al., 2009a, b).

Another factor that may contribute to the amount of parental stress is the type or severity of the child's emotional or behavioral symptoms (Angold et al., 1998; Bussing et al., 2003a, b; McDonald et al., 1997). Tang et al. (2009) investigated ADHD subtypes and parental stress in a Taiwanese sample. These authors found that parents of children with the combined subtype (inattentive and hyperactive impulsive) of ADHD reported more parental stress than those parenting children with inattentive type. Anderson (2008) investigated child, parent, and contextual predictors of parental stress and found that youth problem behaviors were related to more stress. Data from one large study showed that child behavior of preschoolers was associated with increased levels of parental stress (Williford et al., 2007). Further, parental stress was positively related to externalizing problems during preschool over time (Bayer et al., 2008) and from infancy to middle childhood (Benzies et al., 2004). Together, these studies suggest that different patterns of child symptoms may yield stress and strain in different domains and that caregivers of children with symptoms in both externalizing and internalizing domains may experience more parental stress when compared with those caregivers of children with symptoms in one domain.

Parental Stress, Family Support, and Quality of Life

Families of children with special needs experience daunting challenges and daily high workloads in parenting their children (Davis & Carter, 2008; Hu et al., 2019). Examining the outcomes of children with mental and or behavioral problems and their families' experiences are important for the broader fields of social welfare and disability-related services. Parental stress can affect family-level outcomes, such as family quality of life (FQOL). FQOL refers to "a dynamic sense of well-being of the overall family unit, collectively and subjectively defined and informed by its members, in which individual and family level needs interact" (Zuna et al., 2010, p. 262). FQOL was grounded on the family system approach and emphasizes measuring the holistic outcome of family life for children with disabilities. In the past two decades, there has been an exponential increase in international disability research focusing on FQOL of children with disabilities (e.g., Pozo et al., 2014; Schlebusch et al., 2017).

The family is a dynamic, interconnected, and interacting set of relationships, both between the members of the family and with the wider society. The overarching purpose of promoting FQOL research is to shift the focus of family support or services from the child with disabilities to the whole family as the target (Turnbull et al., 2007). Currently, FQOL has been identified by service providers and researchers internationally as one key factor and outcome measure for family and disability-related services, therefore leading to enhanced service delivery and policy development (Kober & Eggleton, 2005; Kyzar et al., 2016), because the family is the primary setting in which most children and adults with disabilities reside. Previous research has primarily focused on exploring the overall FQOL of families who have children with ASD and related disorders, as well as the possible predictors. In a study of Turkish parents with intellectual disabilities and ASD, Meral et al. (2013) indicated that high emotional support predicted better FQOL. Pozo and his colleagues (2014) found that mild ASD symptoms and better social skills are related to better FQOL.

Family support is a significant factor in reducing parental stress in raising children with disabilities. Spouse or partner support is reported as the most important source of family support (Hsiao, 2018). Poor marital relationships may contribute to increases in stress (Hall & Graff, 2011). Also, lack of extended family support can also lead to higher levels of stress (Mancil et al., 2009; Preece & Jordan, 2007). Moreover, social and governmental policy support can significantly alleviate the financial burden in caring for a child with special needs. However, in developing countries like China, current federal policies have not yet authorized formal family support programs. Informal social support to families of children with mental health and behavior problems is usually provided in three ways: counseling services and information support from the registered parent support organizations; professional support on parenting skills from special education schools; and emotional support and information sharing from self-organized parent-to-parent support groups (Zeng et al., 2020).

Parental stress can have a mediating role in family support and FQOL. In investigating the dynamic causational variables of parental stress, Abidin (1990) put forward a stress model stating that parental stress was created by a mismatch between parental roles and the available family support to meet the demands associated with parenting a child with disabilities. Family support is defined as a set of strategies directed to the family unit to ultimately benefit the family member with disabilities (Hecht et al., 2011). Conceptually, there are four types of family support: emotional support, physical support, material/instrumental support, and informational support (Kyzar et al., 2012). The parent stress model validates that parental stress is associated with the type of family support families can obtain (Deater-Deckard, 1998). Previous research demonstrated that mothers' perceptions of family support were negatively associated with parental stress. Specifically, the more family support parents obtained, the less stress they experienced, and the more likely it was that parents could provide positive parenting to their children, especially for those with ASD (Deater-Deckard, 1998; Dyson, 1997).

Using a structural equation modeling approach, Zeng and his colleagues (Zeng et al., 2020) further demonstrated that family support is critical in promoting FQOL and helps to buffer the negative effect of stress deriving from raising a child with ASD. Family support had a direct effect on parental FQOL. This finding supports the hypothesis that family support is critical in promoting FQOL, consistent with research done in the United States (Davis & Gavidia-Payne, 2009), and applies in the Chinese context. Moreover, there is a significant mediating effect of family support on parental stress and FQOL. Together, these findings support the unified theory of FQOL (Hsiao et al., 2017; Kyzar et al., 2012; Zuna et al., 2009). Although previous studies suggest raising a child with ASD can be stressful for parents and can negatively impact their FQOL, if robust family support is available to meet the demands associated with parenting a child with ASD, the stress can be mediated (Abidin, 1990).

Socioeconomic Status and Parental Stress

Parental stress is also tied to family socioeconomic status (SES) and has particular relevance to families with a child who faces mental health challenges. As noted earlier, families with children with special needs face additional financial burdens associated with the child's care and limitations on adult caregivers' ability to have a job outside the home (Stabile & Allin, 2012). When these stressors are compounded by already-low socioeconomic status, the stress becomes that much more intense. Among families struggling to meet basic needs (e.g., food, shelter, and health care), the likelihood that those families include a child with a disability is higher than families who are not materially struggling. Children with disabilities are significantly more likely to live in poverty (Parish & Cloud, 2006). For example, studies examining families who experience homelessness/housing instability have demonstrated that approximately 20–25% include a child with a medical, physical disability and overlapping learning/emotional challenges (Glendening et al., 2018; Hayes et al., 2013).

Families with lower SES may also struggle with access to adequate food, both in quality and quantity. Kursmark and Weitzman define food security as “having access, at all times, to enough food for active, healthy life, including the ready availability of nutritionally adequate and well-tolerated foods and the ability to acquire such foods in a socially acceptable way (Kursmark & Weitzman, 2009).” Food insecurity occurs “when the availability of nutritionally adequate and well-tolerated food, or the ability to acquire such foods, is limited or uncertain” (Rose & Bodor, 2006). Although more research is needed to determine exact rates of food insecurity among children with disabilities, a few things are clear: Parents often restrict their own food intake so that their children may eat (Coleman-Jensen et al., 2017); parental disability status may lead to household food insecurity (Sonik et al., 2016); and access to consistent and quality nutrition is essential to the well-being of children with disabilities, whose health is often more vulnerable and whose developmental trajectory less certain than children without disabilities (Sonik et al., 2016).

Understanding the ecology of children living in poverty is essential to supporting their overall well-being and caregivers. However, the context in which a child lives is often left out of screening and assessment processes (DeCandia et al., 2021). When this happens, key factors influencing the well-being of children—in this case, the well-being of their caregivers—may be missed, and with it, an opportunity to support the family. When considering stress among caregivers of children who have disabilities, their SES and accompanying ecology must be considered. These include housing stability, access to healthcare, caregiver well-being, food security, trauma exposure, and much more.

Gender Difference and Parental Stress

Family systems are dynamic and interconnected systems in which one family member (e.g., emotions and behaviors) is affected by other family members (Bronfenbrenner, 1979; Nelson et al., 2009; Turnbull et al., 1984). For instance, studies by Hastings et al. (2005) and Kayfitz et al. (2010) found that fathers’ level of stress with children with ASD is strongly associated with mothers’ stress levels. One parent’s failure to cope with their emotions may influence the relationship between the other parent and the child (Rodriguez et al., 2019). Parental stress may be decreased by couples sharing child-rearing responsibilities and giving more support to each other (Abidin & Brunner, 1995). Family members’ needs are also more likely to be met through couples sharing the demands and needs of children with disabilities, contributing to improved FQOL (Davis & Gavidia-Payne, 2009).

According to Bronfenbrenner’s (1979) ecological systems and Turnbull et al.’s (1984) family systems theory, the family is a dynamic and interconnected system, and the members are affected by each other. The family system emphasizes the interaction between fathers and mothers (Turnbull et al., 1984). The particularly important role of co-parenting relationships within families of children with ASD has been investigated (Thullen & Bonsall, 2017). Research suggests that fathers and mothers have interactive effects on each other and the child and family outcomes. For example, Sharabi and Marom-Golan (2018) conducted a study in which they compared mothers’ and fathers’ involvement in family support (e.g., educational services, disability-related services, health care support) and perceptions of both formal and informal social support in Israel. They reported significantly higher levels of maternal involvement and that maternal involvement was associated with higher levels of parental distress. Furthermore, they found the level of social support and parental education level as the contributing factors associated with the level of fathers’ involvement.

Similarly, Hartley and Schultz (2015) found that mothers in their study reported a higher number of needs that were unmet than did fathers, and fathers were often more satisfied than mothers with current support services. Further analysis suggests child age, co-occurring behavior problems, an intellectual disability, parent education, and household income were associated with mothers’ and fathers' different support needs. Researchers also found that fathers with low socioeconomic status perceived more basic and immediate support needs. Another study by Pozo et al. (2014) reported other contributing factors (e.g., problem behaviors) on fathers' and mothers' discrepancy of coping with children with disabilities.

Although historically, mothers have been the primary caregivers of children with disabilities and the participants in research on children with disabilities, fathers are increasingly included in research on children with disabilities (Huang et al., 2012). Additionally, research has indicated the particularly important involvement of fathers and the role of co-parenting a child with special needs (Hu et al., 2019). However, collecting data from one individual family member and studying the entire family unit is problematic because the conclusions drawn at the family level using the data collected from one individual family member might not be accurate. Therefore, it is imperative to involve both parents in research on the FQOL of children with special needs.

Most studies examining child behavior problems and parental stress have included only mothers. However, fathers can form different relationships with their children (Phares, 1996), have different opportunities to observe them (Hay et al., 1999), and have different experiences and associated outcomes of parental stress (Roggman et al., 2007). Studies using descriptive analysis suggest that mothers may experience significantly higher stress levels than fathers (Ang & Loh, 2019). Meanwhile, fathers reported fewer social interactions with family, friends, and health professionals than mothers (Hickey et al., 2018). A recent study (Pozo et al., 2014) attempted to explore how fathers' and mothers' social support and psychological well-being are related to FQOL using separate path analysis models. Findings suggest high agreement among mother and father report of behavioral problems in children ages 3 and 4 years, particularly among the parents of children with delays, and similar relationships between child behavior problems and parental stress for mothers and fathers (Baker et al., 2002, 2003).

A more recent study (Zeng et al., 2021) suggests a strong actor effect of family support on decreasing stress and improving FQOL for both mothers (total effect = 0.650) and fathers (total effect = 0.444), respectively. This study further validates this claim and indicates that both mothers and fathers may benefit from a strong family support system. Although raising a child with ASD can be stressful for both fathers and mothers (Harper et al., 2013; Rivard et al., 2014), robust family support can alleviate parental stress and change their perception of FQOL (Abidin, 1990).

When considering fathers as the actor and mothers as the partner, fathers' FQOL are positively associated with fathers' perceived support and mothers' perceived support (Kenny & Cook, 1999). That is, fathers' FQOL (Y) is associated with as much by their own perceived support (X) as with their partners' perceived support (X'). This would occur if the person were as concerned with the partner's outcomes as with his or her own outcomes (Kenny & Cook, 1999). In other words, mothers' perceived support may accurately represent fathers' priority in family support. Mothers could know better about the family needs and priorities since parenting largely falls on the mother's side (Johnson & Simpson, 2013).

In contrast, when considering mothers as the actor and fathers as the partner, mothers' FQOL are positively associated with their own perceived support but negatively associated with fathers' perceived support. This is defined as the contrast pattern (Kenny & Cook, 1999). In contrast to the couple-oriented case, where the partner's success is valued as much as one's own outcome, the contrast social comparison typically involves dissatisfaction with the partner's success. In other words, what the father perceived as the priority for family support may not accurately represent mothers' perceived priority and preferences. This discrepancy may reflect the traditional family roles. Specifically, this finding may reflect that fathers are not as involved as mothers in daily caregiving for the child with ASD. The level of services needed and specific types of support that fathers perceive as highly valuable may not be valued equally by mothers (Wang & Michaels, 2009). Yet, research has shown that fathers' involvement is essential to promote mutual support (Flippin & Crais, 2011). Therefore, it is important to use a family-centered approach and involve both fathers and mothers in the support plan and implementation process. Meanwhile, the contrasting pattern (opposite direction of the effects) suggests large discrepancies in perception, which may be a source of family conflict (Hu, 2022).

Intervention and Policy Recommendation

Parents of children with mental health and behavior problems reported a higher level of parental stress than their peers (Baker et al., 2002, 2003; Brobst et al., 2009). When parents experience stress, they may be less responsive to their child's needs and exhibit punitive or negligent parenting (Belcher et al., 2007). Major factors contributing to the parental stress of raising children with disabilities include the child's behavioral problems, parents' coping skills, and family support. Practitioners could provide parents with appropriate and applicable behavior management skills and recommendations to work with their child's problem behavior at home and in the community. Also, organizing counseling groups can be an effective way to help parents develop new and positive coping strategies and gain support from outside of their family and school, thus reducing parental stress and leading to the child's success with disabilities. Meanwhile, it is worth noting that practitioners need to cautiously consider all other factors and characteristics of the families and their children's disabilities (e.g., the negative social stigma associated with the child's disabilities, socioeconomic status of the family) when helping parents reduce their stress.

Many children and adolescents with severe emotional and behavioral challenges are served by systems of care. A system of care was first defined in 1986 by Stroul and Friedman as "a comprehensive spectrum of mental health and other necessary services which are organized into a coordinated network to meet the multiple and changing needs of children and their families." Youth with emotional and behavioral challenges present to these systems of care with various mental health diagnoses, including externalizing disorders such as oppositional defiant disorder, conduct disorder, or substance use disorders and internalizing disorders such as depression and anxiety (Liao et al., 2001). Family support (e.g., advice on problems specific to their child, help with child care) is a consistent predictor of most dimensions of parental stress (Guralnick et al., 2008). Practitioners can play an important role in helping parents of children with disabilities gain more support from outside of their families.

A systematic family support network should be provided for both mothers and fathers to enhance the overall FQOL. Research indicates that family support adequacy can significantly predict FQOL for families of children with ASD. The local government in charge of affairs for children with ASD (i.e., local association for people with disabilities) should provide formal family-centered services (i.e., information support; professional support, respite care) to prepare families in responding to stress and build resilience (Hu et al., 2019). The possible programs can include weekend respite care services, psychological counseling, mental health services, and information support on education and healthcare services for children with ASD. Respite care and parent-to-parent programs for families with ASD found promising effects in reducing parental stress. Furthermore, informal support (i.e., emotional support, parent-to-parent groups, respite care) could be a cost-effective and efficient way to help families deal with parenting challenges and meet the healthcare needs of their children with ASD (McCabe, 2008). With regard to developing informal support, government and NGOs could design and provide parent-to-parent programs, hotline services, and home visits by relatives or community members to families of children with ASD. Moreover, support providers should assist parents in realizing the potential benefits of seeking support outside of family members. Community members, friends, and relatives are sources of informal support, exerting a positive role in providing emotional support.

Teaching coping strategies to parents can help alleviate some of the parental stress (Hall & Graff, 2011; Lyons et al., 2010; Zablotsky et al., 2013). Coping refers to behavioral or cognitive efforts that individuals use to minimize their level of distress or stress (Zablotsky et al., 2013). Parents often lack strong coping skills to solve real problems: Many of them use emotional coping or avoidance-oriented coping, which lacks effectiveness and leads to higher levels of stress (Pottie & Ingram, 2008; Zablotsky et al., 2013). However, research suggests that parents with more effective coping skills experience lower levels of parental stress (Raphael et al., 2010). For example, short-duration (1–3 months) mindfulness-based interventions and cognitive behavioral therapy in clinical settings are recommended for socioeconomically disadvantaged parents to reduce stress. There are several ways that parents may adopt to cope with stress: (a) using task-oriented coping to solve problems through specific strategies that minimize the influences of problems; (b) using emotion-oriented coping by reacting to the stress or problem through emotional responses, such as self-preoccupation or performing fantasizing reactions; (c) using avoidance-oriented coping to avoid a stressful situation through escaping; and (d) using distraction by engaging in a substitute task (Lyons et al., 2010). Providing support or parental education for parents to learn more effective coping strategies is important and beneficial for families of children with disabilities (Hsiao, 2018).

Moreover, the discrepancy in fathers' and mothers' perceived priority and support is needed to improve their FQOL. On the one hand, more services should support fathers' involvement in parenting children with ASD. Also, it is important to promote mutual communication and shared understanding for the couples through marriage consultation or other services. Diverse support should be available for both fathers and mothers to choose because they shoulder different roles in parenting children with ASD. Exploring needs from both fathers and mothers will be helpful for support providers to design and develop individualized family support and services. Moreover, as parent-delivered interventions become pervasive (Clark et al., 2019), practitioners should take the distinct needs and benefits of in-home interventions from fathers and mothers into careful consideration, respectively. Also, it is important to involve both fathers and mothers in the support plan and implementation process.

Families demonstrated the lowest level of satisfaction with emotional health, consistent with past research. While this finding is likely due to the stress of caring for a child with special needs within a context with limited support for families, it points to the need to provide more services to address emotional health. One implication is that families should have greater access to mental health professionals and family support counselors. With greater access and use of these professionals for support, it is possible that emotional health would be better and support more positive outcomes for families. Furthermore, more personnel preparation is needed for educators, medical staff, and mental health professionals working with children with special needs families. In the educator preparation programs, courses on family-professional partnerships should be integrated into the curriculum to help new educators better work with families with their unique needs. While educators, medical professionals, and mental health professionals are all trained in their specific disciplines, they are often not trained in working with families with additional FQOL concerns, such as having a child with autism. Instead, we advocate that more attention should be allocated to preparing professionals working with families with children with mental health and behavior problems to address their unique needs for family support.

Conclusion

Providing care for a child with serious emotional or behavioral difficulties is a significant source of stress for parents and caregivers (Angold et al., 1998; Brannan & Heflinger, 2001; Taylor-Richardson et al., 2006). Furthermore, the stress associated with caring for a child with emotional and behavioral difficulties may be compounded by factors at the parent, family, and larger social and community levels. This chapter has synthesized the biological, physical, and mental aspects of stress and how stress may affect parenting and family functioning. We discuss the associated factors that may contribute to the development of parental stress.

Parental Substance Use

Janina Dyba, Diana Moesgen, and Michael Klein

Introduction

The misuse and dependency of psychoactive substances is a worldwide phenomenon and of substantial health concern. It is estimated that 1.4% of the global population (107 million people) suffer from an alcohol use disorder (AUD) and approximately 0.9% have a drug use disorder (71 million people). Throughout the world, an estimated 271 million people had used illicit drug in the past year, especially cannabis and opioids (Dattani et al., 2021), while the global use of the socially accepted substance alcohol is of course even larger. Thus, substance use disorder (SUD) is one of the most frequently occurring mental health issues and significantly attributes to the global burden of disease (Degenhardt et al., 2018). According to the Substance Use and Mental Health Service Administration (SAMHSA) (2020), 20 million people in the United States were diagnosed with a SUD in the past year. Of these, 71.1% had a past year AUD, 40.7% had an illicit drug use disorder, and 11.8% had both an AUD and illicit drug use disorder. In the context of illicit substances, a continually high prevalence of opioid use is reported, with 4.0% of the population in North America misusing this type of substance (United Nations Office on Drugs and Crime, 2019).

While there are no precise numbers available that could determine the exact amount of children affected by parental substance misuse, it is assumed that many of the alcohol and drug using community are parents to minor children. Estimations of federal institutions in the United States report that an average of 8.7 million children under the age of 17 years lived with a substance-using parent in the past year (Lipori & Van Horn, 2017). One in 10 children (approx. 7.5 million) are living with a parent misusing alcohol, and 1 in 35 children (approx. 2.1 million) are living with a mother or father who uses illicit substances. The overall assumption that over 12% of all US children across different age groups and thus in varying developmental stages grow up with a substance using parent underlines the severity of this public health concern (Lipari & van Horn, 2017).

Parental substance use is known to impact children's development significantly, yet understanding the effects of parental substance use on families and children is a complex matter. Existing theoretical models provided in this field vary largely with regard to their specificity. Beekman and Neiderheiser (2013) point out that in the context of parental substance use, the multidimensional nature of trans-

generational transmission and children's problematic development need to be accounted for. This includes genetic aspects, effects of prenatal substance exposure, and disruption of parenting and family processes. Hence, the following chapter will focus on the social environment and parenting practices in families affected by parent's SUD and present developmental outcomes under consideration of risk and protective factors for children growing up in these families. Additionally, support needs and existing interventions for both parents and children are outlined and discussed.

Family Environment

When families are affected by parental substance use, the psychosocial living situation tends to be unfavorable and thus the developmental setting for children is often compromised. Aspects of social marginalization, a low socioeconomic status, and high rates of unemployment are observed significantly more often than in families without problematic substance use (Serec et al., 2012). Here, the interaction between unfavorable social conditions and the substance use of the parent can result in highly dysfunctional family patterns, such as pronounced disharmony and high numbers of and intense conflicts between parents. Thus, children frequently experience domestic disputes and sometimes become involved in these themselves (Templeton et al., 2009). Affected children can develop varying emotional responses to this disharmonious setting, from aversion to the substance-involved parent up to worries and attempts to protect them (Klein, 2005). Domestic violence within the family further complicates the situation of affected children, since they are more likely to witness and become victims of family violence than children from families not affected by parental SUD (Ellis et al., 1997).

In addition, parental separation or divorce, or even the death of a parent, is experienced more frequently by children from substance-involved families than by children from unaffected families (Waldron et al., 2013). This results in higher life stress for the children through unanticipated relationship breakdowns with the caregiver. Frequent (and sometimes repeated) out-of-home placements of children by child welfare services, parental inpatient treatment(s), or incarceration(s) can further destabilize the parent-child relationship and thus promote insecure attachment patterns or even traumatization (Klein, 2006).

This situation is often aggravated by adverse family dynamics such as secrecy, denial of the substance use problem, and parental role reversal or role confusion (Kroll, 2004). Additionally, strong feelings of shame and isolation shape the children's behavior, which can lead to attempts to keep their family situation a secret from others, and eventually lying or inventing fantasy stories (Backett-Milburn et al., 2008). Tabooing the family problem of substance use is therefore a reaction in which affected children might actively participate in, without a conscious decision or alternative behavioral strategy.

It should be noted that growing up in a family with substance use problems often means an undesirable accumulation of stress for the children, which endangers their well-being in the short- and long-term. This is usually even more intense when illicit substances are involved. Here, lifestyles of parents who use drugs are more often characterized by little structure, poverty, and illegal activities (Straussner & Fewell, 2015). These living circumstances can be shaped by the drug-subculture (e.g., prostitution, delinquency, or incarceration) and volatile partner relationships within the substance-using community (Klein, 2006; Straussner & Fewell, 2015). Frequent constellations of both parents using substances and children's young age tend to complicate the situation at an early stage in child development (Klein, 2006; Straussner & Fewell, 2015). In addition, long-term drug use is often associated with poorer physical health and illnesses of the parent, the transmission of blood-borne viruses such as hepatitis C and HIV, and comorbid mental health problems (Straussner, 2011). Generally, there is a more pronounced risk social isolation and societal marginalization in these families and thus children often suffer from the consequences of stigmatization (Klein, 2006).

Parenting

In addition to problems in the overall family environment, the relationship and direct interaction between caregiver and child is often compromised by the parental misuse of alcohol or drugs. When parents suffer from a SUD, their priorities frequently shift to consumption and acquisition of the substance, while parental responsibilities are neglected. Parenting capacities, such as basic care for the child, ensuring child's safety, emotional warmth, stimulation of development, guidance and boundaries, co-regulation, as well as providing a stable environment, tend to be negatively affected by the parental substance use problem. (Cleaver et al., 2011).

With regard to parenting practices, less positive parenting behaviors have been observed in parent-child interactions (Arria et al., 2012) and parents with a SUD have been found to show less emotional engagement, encouragement, warmth, and less responsiveness with their young children (Chaplin & Sinha, 2013). On the other hand, negative parenting behaviors by parents with a substance issue are often predominant. These include more punitive and harsh practices to discipline and control children and less parental monitoring (Calhoun et al., 2015). When children approach adolescence, maternal substance use has also been linked to more authoritarian, commanding, and overinvolved parenting (Solis et al., 2012).

Generally, in the course of substance use and intoxication, parental behavior and moods tend to be erratic (Templeton et al., 2009), which further challenges the child's formation of a secure attachment pattern toward the parent. The common effects of specific substances also shape parental behavior. Mayes and Truman (2002) suggest that the type of substance primarily used by the caregiver may be associated with specific behavioral tendencies in parent-child interaction (Slesnick et al, 2014). While alcohol, marijuana, or opioids are linked to stronger withdrawal and depressed moods, stimulants such as cocaine or methamphetamine may be accompanied by behavior toward activity, impulsivity, and intrusion. Children's predominant experiences will thus differ in families affected by different substances, ranging from parental withdrawal and decreased responsiveness to unpredictable activity and agitation (Mayes & Truman, 2002).

Parental intoxication is often noticed by the child and expresses itself through different ways such as inadequate language and communication, shifts between physical proximity and rejection, or unpredictable reactions ranging from permissiveness and overreactivity. The resulting lack of continuity and age-appropriate boundaries can leave the child disoriented, overwhelmed, and insecure (Dyba et al., 2019a).

Furthermore, parents with SUD have been found to be at increased risk for inappropriate and harmful behaviors when interacting with their children (Forrester & Harwin, 2011) and lifetime substance use has been linked to tendencies toward child abuse (Ammermann et al., 1999). Here, children are at an increased risk for experiencing violence and physical abuse, sexual abuse, and neglect (Famularo et al., 1992; Walsh et al., 2002). Thus, the involvement of child welfare services in this target group is high, which can further strain the family dynamics.

The specific aspect of neglect often includes lack of provision for basic needs and care, but also the lack of adequate emotional nurturing in terms of closeness, attention, and love (Hill, 2013). When parents do not exercise their responsibilities and day-to-day tasks, children tend to take on these responsibilities. As a result, children may face tasks or are left with decisions and responsibilities that are inappropriate for their age and developmental level. The phenomenon called "parentification" describes this slowly developing role reversal and results in the children taking care of the family, for example, by providing for younger siblings, managing household chores, or even taking care of the parent (Pasternak & Schier, 2014). As parentifying behaviors become chronic, children continuously fulfill duties that the parents themselves can no longer fulfill. This leaves children tremendously overwhelmed in the long term, since they cannot adequately cope with the age-inappropriate tasks and burden (Wolfe, 2016).

The predictors and causes of parental tendencies toward a neglectful behavior in substance-affected families have been studied extensively. Dunn et al. (2002) summarize that a parental SUD is directly linked to increased neglect and that their own experiences of childhood neglect in their family of origin moderate this relationship. Thus, transgenerational transmission of parenting models and behaviors, especially in terms of neglectful parenting, needs to be assumed here. Furthermore, comorbid psychiatric parental disorders as well as drug-induced neuropsychiatric symptoms can contribute to increased neglectful behavior by the parent (Dunn et al., 2002).

The described adverse or even traumatic experiences in the family, principles of social learning, and the lack of adequate prenatal role models largely contribute to the risk of ongoing problematic cycles of transgenerational transmission of SUD and/or other mental health problems in substance-affected families.

Children Affected by Parental Substance Use

The research on particular effects on children with a substance-using parent is fairly large (for an overview see Salo & Flykt, 2013; Straussner, 2011). Parental substance use can affect a variety of developmental areas such as cognitive and academic functioning, socio-emotional development, physical development, and behavioral adjustment (Solis et al., 2012). The specific effects of the parental SUD are associated with the age of the child and can present themselves differently at specific developmental stages in life (Straussner, 2011). Furthermore, the extent of the children's exposure and the severity of the parental problem need to be considered when focusing on children's developmental risks (Velleman & Templeton, 2016). Generally, the developmental setting for children involved is more disadvantageous, the more the adversities are present in the family (Velleman & Templeton, 2016).

Prenatal Exposure to Substances

Starting even before the child's birth, maternal substance use during pregnancy is frequently related to severe consequences for children. Prenatal exposure to alcohol or drugs is linked to a variety of pre-, peri- and postnatal problems for both mothers and children, including increased numbers of miscarriages, premature child birth, children's low birth weight, smaller head circumference, increased irritability, and further developmental impairments.

Despite political attempts to reduce maternal substance use during pregnancy, numbers of infants born with prenatally acquired impairments remain high. Globally, nearly 10% of women use alcohol during pregnancy, resulting in 119.00 children born with a fetal alcohol spectrum disorder (FAS-D) each year (Popova et al., 2017). A systematic review indicates that around the world, 15 in 10.00 people suffer from a FAS-D (Popova et al., 2017). In the United States, maternal alcohol use and binge drinking during pregnancy have been rising within the past decade (Denny et al., 2020).

FAS-D manifests in severe symptoms such as craniofacial anomalies, growth retardation, neurological abnormalities, cognitive impairment, and birth defects (Wozniak et al., 2019). Resulting from the damage to the central nervous system, mental retardation can frequently occur.

Besides FAS-D, neonates may suffer from withdrawal symptoms, primarily after maternal opioid use, resulting in the critical neonatal abstinence syndrome (NAS). In the United States, the number of NAS in newborns has increased dramatically by 433% between 2004 and 2014 (Jilani et al., 2019) and is still rising (US Department of Health and Human Services, 2021). As a result, approximately every 15 seconds a child with a NAS is born in the US (Jilani et al., 2019). The NAS is characterized by hyperactivity of the central and autonomous nervous system in the newborn as well as gastrointestinal complications and requires intensive care treatment directly after birth (Sanlorenzo et al., 2018). Similar patterns of infant drug withdrawal can be observed in children affected by maternal methamphetamine during pregnancy. Newborns exhibit significantly enlarged stress levels at birth and a strong activation of the central nervous system, while also showing pronounced lethargy (Smith et al., 2008). A NAS after maternal methamphetamine use is therefore described as heterogenic, between lethargic and overstrained behavior of the newborn (Mühlig et al., 2017). Prenatal methamphetamine-exposure has also been linked to neurobiological and neuroanatomical anomalies (Kwitakowski et al., 2014) and thus is frequently associated with cognitive, social, and emotional deficits in course of the children’s development (Abar et al., 2013; Twomey et al., 2013).

Next to prenatal risks, children from substance-involved families often exhibit developmental and mental health problems, deriving from the above-described maladaptive family environment and associated problematic interactions with their caregivers. Effects of prenatal substance exposure and postnatal adverse living situations are intertwined and prenatally acquired impairments often interact with risk factors present after birth in complex ways.

Mental Health Problems

Children from substance-involved families are considered as a high-risk group for the development of an own SUD. Early substance use is the most frequently investigated subject in the research field of “children with parents with a substance use disorder“(Rossow et al., 2016). Numerous studies have demonstrated that children from substance-affected families are more likely to.

(a) start using substances at a younger age (Waldron et al., 2014),
(b) experience first intoxications earlier (Wong et al., 2006),
(c) exhibit more binge drinking (Weitzmann & Wechsler, 2000), and
(d) make a faster transition from the first substance use to substance abuse and dependency than children from unaffected families (Hussong et al., 2008a, b).

Explaining the mechanisms of transmission of parental SUD to their children is complex. In the case of alcohol problems, both genetic (Sørensen et al., 2011, Palmer et al., 2019) and psychological factors such as model learning (e.g., substance use for self-medication, coping with negative feelings) (Cleveland et al., 2014) or the transmission of positive alcohol expectancies (Smit et al., 2019; Waddell et al., 2020) are regarded as relevant factors in this context. In adulthood, coping with the adverse and/or traumatic childhood experiences through use of alcohol or drugs must also be considered (Zobel, 2017).

Apart from or in addition to the risk for the transmission of the substance use disorder, children from substance-involved families often develop other severe mental health problems (Raitasalo et al., 2019). Children from substance-involved families are at increased risk for externalizing behaviors, such as conduct disorders (Molina et al., 2010) or attention-deficit/hyperactivity disorder (ADHD) (Parvaresh et al., 2015). Externalizing tendencies can appear at all ages of childhood and adolescence or later in adulthood (Park & Schepp, 2015). Moreover, children from substance-affected families tend to exhibit higher rates of internalizing behaviors as well (Hussong et al., 2008a, b). Research findings demonstrate that there is statistically significant difference between children from alcohol-involved families and unaffected children with regard to anxiety, depression, low self-esteem, separation anxiety, social phobia, and obsessive compulsive problems (Hill et al., 2011; Fuller-Thomson et al., 2013; Omkarappa & Rentala, 2019) in childhood, adolescence, and later in adulthood (Park & Schepp, 2015). Moreover, recent studies indicate that a parental history of AUD may be associated with posttraumatic stress symptoms in their offspring children (Bender et al., 2021). Both externalizing and internalizing disorders may be regarded as risk factors for the development of a SUD in adolescence or adulthood (King & Chassin, 2008).

Health Behavior

In addition, general health behavior is often decreased in this group, especially in children from families with parental alcoholism (Forrester & Harwin, 2011). Affected children tend to spend more time with electronic media (television, smartphone, or computer), exercise less, and exhibit overall unhealthier dietary behaviors. This may on one hand serve to reduce stress in the children and on the other hand can represent model learning effects of unhealthy parental behavior. These adverse health behaviors may be regarded as predictors of later mental health problems and can lead to stigmatization (e.g., for obesity) and bullying in school and other peer contexts.

Protective Factors and Resiliency

The development of SUD or other mental health problems in children from substance-affected families cannot be explained by the parental SUD only. The development of children from substance-involved families rather depends on the extent of presence of the various risk factors mentioned above on the one hand and protective factors that can be child- or environment-related on the other. Since substance-affected families often have a high incidence and accumulation of risk factors, counteracting environmental protective factors and individual resilience are of particular importance.

Velleman and Templeton (2016) reviewed and summarized the following protective factors for children from families with a substance-using parent. Here, factors specific to the family and parenting behavior, other environmental and social factors, as well as individual traits can be distinguished.

Factors Related to Parenting and Family Environment Are

- Supporting and trusting relationship with a stable (non-substance misusing) adult (e.g., outside the primary family).
- Close positive bonds with at least one adult in a caring role (e.g., other parent, siblings, grandparents).
- Early and compensatory relationship experiences with primary caregiver(s) in first years of life.
- Low levels of separation from the primary caregiver in the first year of life.
- Affection from members of extended family.
- Parental self-efficacy and good parental self-esteem.
- Traditions and rituals (cultural, religious, familial) within the family.
- Consistency and stability in everyday family life (e.g., social life, rituals, roles, routines).
- Families spending time together.

- Openness and good communication within the family, including open and appropriate discussion of family problems.
- Child having family responsibilities.
- Small family size, larger age gaps between siblings.
- Adequate finances, employment opportunities/income; physical home environment.
- Constructive coping styles and deliberate parental actions to minimize adversity for children.
- Knowledge of protective factors.
- Strong family norms and morality.
- Characteristics and positive parenting style of parents (a balance between ‘care’ (parental support, warmth, nurturance, attachment, acceptance, cohesion, and love) and ‘control’ (supervision, monitoring, clarity about family rules and boundaries, parental discipline, punishment)).
- Parents having high expectations of the child, and clear and open communication of both expectations (about alcohol use/nonuse and also generally) and potential disapproval, if expectations are not met.
- Parental modeling of the behaviors expected of or wished for from their children.
- Absence of domestic violence/abuse, family breakdown, and associated losses.

In direct relation to the parental substance use disorder, Velleman and Templeton (2016) point out that parental SUD of low intensity and shorter duration as well the parent receiving treatment may also serve as important protective factor for affected children. Furthermore, children are less likely to be affected by a parental SUD, if drug paraphernalia and substance use behaviors are kept away from children and outside the home. In addition, the presence of one non-substance-using parent is essential here.

With regard to the social environment and community, factors of relationships outside the family, a supporting community, and culture are especially relevant.

Protective Community/Environmental Factors Are

- Cultural connectedness, values, and identity.
- Support from an adult/adult role model (e.g., teacher, neighbor).
- Strong friendships and relationships with peers with opportunities to talk to about the problems at home.
- Living in a community where there is a sense of caring, mutual protection.
- Community engagement and supportive social networks; strong bonds with local community/community involvement.
- Positive school experiences and influences; opportunities through education and employment – out-of-school/community activities.
- Attendance at school, achievement, monitoring of progress, and acknowledgment of success.
- Teachers’ expectations and discipline.
- Positive opportunities at times of life transition.
- Support from key community services such as healthcare.

Furthermore, each child’s individuality attributes to his or her specific resilience to the adverse family circumstances.

Individual Resilience Factors Are

- Internal locus of control – a sense that they can make a difference to their circumstances and have the power to change their situation.
- 'Active agency' in adopting coping strategies, seeking support and choosing what to share about their circumstances and with whom
- Personal qualities and social skills (e.g., expression of feelings, knowledge, life choices, self-reflection, easy individual temperament/disposition, emotional regulation, self-efficacy).
- Having a hobby or a creative talent or engagement in outside activities or interests (e.g., sport, singing, dancing, writing, drama, painting) – anything that can provide an experience of success and/or approbation from others for the child's efforts.
- Self-monitoring skills and self-control.
- Coping and problem-solving skills – ability to think about and make decisions about coping.
- Plans for the future/yearning for a better future.
- Intellectual capacity.
- Sense of humor.
- Sense of self-strength with regard to the parent's problem (i.e., resisting overidentification with, and maintaining psychological separation from parental problem).
- Perceptions of 'substance misuse' behavior, good knowledge, and understanding of the parental problem(s).
- Not taking drugs or drinking.
- Achieving a balance between supporting the parent(s) and looking after themselves.
- Religion or faith in God.

Wlodarczyk et al. (2017) also conducted a systematic review on protective mental health factors in children of parents with alcohol and drug use disorders and were able to replicate and specify the findings from Velleman and Templeton (2016). According to their study, the following child-related, family and parental, and environmental factors can be confirmed as protective factors for children at risk: The child's ability to engage with adults, secure parent-child attachment, strong family cohesion and adaptability, low parenting stress, an accepting mother, and high social support for the child. Wlodarczyk et al. (2017) were also able to identify biological protective factors, that is, increased activation in the orbital frontal gyrus and left insula as well as blunted activation of the mesolimbic reward circuitry.

It should be noted, though, that resilience factors are not related to individual only, but the family system as a whole. First approaches to systematize family resilience factors were conducted by Walsh (2003), characterizing family resilience by shared belief systems, organizational patterns, and communication/problem solving within the family. Walsh's model has been supported in the context of parental alcohol use and higher family resilience has been associated with more positive parenting behavior (Coyle et al., 2009) and reduced parenting stress in high-risk families (Kim et al., 2020).

The identification of risk and resilience factors is essential and serves the conceptualization of preventive and therapeutic measures for children.

Interventions and Support

The illustrated impact of parental substance use on families and children calls for systematic approaches to improve the living situation and developmental setting for children involved, foster protective factors, and strengthen parental child-rearing competencies. Repeating cycles of transgenerational transmissions of maladaptive parenting, adverse family dynamics, and substance use disorders need to be interrupted permanently. Promising approaches include targeted preventive measures and interventions for both substance using mothers and fathers and their offspring children.

Interventions for Parents

Primary support for substance-using parents generally focuses on the individual and prioritizes treatment of the SUD. So far, the issue of parenting does not appear to be frequently integrated into the treatment of parental SUD, despite a documented need for tailored services for this group and a variety of existing trainings (Arria et al., 2013). Especially in the US, the range of existing interventions for parents with SUD is significantly broader than in other countries. Several systematic reviews have discussed issues of conceptualization, methodology, and outcomes in recent years (Heimdahl & Karlsson, 2016, Moreland & MacRae-Clark, 2018, Neger & Prinz, 2015, Peisch et al., 2018). The existing programs have been demonstrated to be effective with regard to reduction of substance use, improvement of parenting practices, decrease in child maladjustment, and improvement of psychosocial outcomes and parent-child-interactions among others (Moreland & McRae-Clark, 2018, Neger & Prinz, 2015). The most recent systematic reviews on parenting intervention integrated in substance use treatment by Moreland and McRae-Clark (2018), who identified seven interventions with effectives validated through randomized controlled trials, are presented below.

- Mothering from the Inside Out (formerly known as “The mothers and toddlers program”) [MIO]: The individual, outpatient intervention for females consists of 12 sessions and follows a mentalization-based approach. Results indicated an increase in reflective functioning and representational coherence and mother-child interaction was improved in terms of sensitivity and reciprocity (Suchman et al., 2017) after participation.
- Focus on Families [FOF; now known as “Families Facing the Future”] is an outpatient group intervention with 53 sessions for parents in methadone maintenance treatment and addresses the entire family, including children. The extensive family-focused intervention had positive long-term outcomes, especially with regard to parenting skills, parental drug use, or family management (Catalano et al., 2002).
- Engaging Moms Program [EMP] is tailored for mothers involved with family drug court and enhanced the probability of positive child welfare dispositions 18 months after drug court enrollment (Dakof et al., 2010).
- Relational Psychotherapy Mothers Group [RPMG] is an outpatient supportive group intervention for females with substance abuse and is comprised of 14 sessions. Results indicated short-term effectiveness in children’s emotional adjustment and reduction of depression as well as mothers’ reduction of substance use and child maltreatment (Luthar et al., 2007).
- Parent Skills and Behavioral Couples Therapy [PSBCT] addresses males entering outpatient alcohol treatment and their female partners. It includes topics of parenting, substance use, and relationship conflict within 24 outpatient sessions. Evaluation results revealed significant improvement with regard to substance use, parenting, and the involvement of child protective services (Lam et al., 2009).
- Attachment and Biobehavioral Catch-Up [ABC] is tailored for mothers in residential substance use treatment and follows an attachment-based approach. After completion of the 10 sessions, supportive parenting behaviors were significantly improved (Berlin et al., 2014).
- Family Behavior Therapy [FBT] addresses in mothers referred with drug abuse and / or involvement with child protective services. After 20 in-home sessions, results revealed reduction of child maltreatment and hard substance use (Donohue et al., 2014).

Even though some of the effects found in the experimental studies were small, they are of potentially great importance for the target group of substance using parents. A systematic promotion of parenting skills and family processes can prevent children's out-of-home placement, enhance parental sensitivity for children's needs, and strengthen confidence in mothers and fathers in their parental role.

Yet further research on the efficacy and feasibility of appropriate interventions remains necessary, especially in countries outside the United States. While the existing parenting programs can certainly help to shape interventions in other countries, language barriers, cultural specificities, and variations in organizational and financial structures of the welfare system might complicate a direct adaption outside North America. Furthermore, current parenting interventions integrated into substance use treatments are aimed primarily at mothers, and thus fathers with SUD are largely ignored (Heimdahl & Karlsson, 2016). Yet, from a developmental perspective, the father plays an essential role in the healthy upbringing of children. This concerns all phases of the children's development and includes aspects of emotional development and attachment, motor skills, promotion of autonomy, or the stimulation of cognitive development (Seiffge-Krenke, 2016). Hence, the involvement of fathers in parenting and family-oriented trainings should be considered regularly and evidence for this target group needs to be generated. Father-specific programs include "Dads too" (MacMahon, 2013) or "Fathering for Change" (Stover et al., 2018). The latter was able to achieve promising effects regarding emotion regulation, anger and aggression, and co-parenting relationships and was highly accepted among the participants. Once again, this underscores the need for opportunities inherent to father-specific approaches in prevention and treatment for men with SUD. In addition, existing evidence-based interventions focus primarily on alcohol and opioids, while other drugs remain largely unattended. Hence, there is a need for interventions tailored to the characteristics of parents using cannabis or stimulants, since substance-specific parenting characteristics need to be assumed. Following this approach, the German SHIFT-Parent Training for mothers and fathers using methamphetamines can be mentioned. The resource-oriented intervention is the first to address the substance specificity and foster parenting and family resilience (Dyba et al., 2019a, b).

Since functional parenting behavior is one of the greatest deficits in families with substance use problems, the offer of suitable interventions for substance using parents and their children urgently needs to be strengthened and established as a regular offer of substance use treatment and child welfare services. With regard to exposed children, this can be an important and effective preventive measure. The topic of parenting and children's needs should be integrated more strongly into the treatment of parents with SUD since it can represent, on one hand, an everyday-challenge for mothers and fathers. On the other hand, it can serve as an essential motivation for abstinence and treatment.

Interventions for Children

Procedures that encourage parents to enter substance use treatment and consider their parenting role as a part of their recovery process help to reduce the effects of parental substance use disorders on their children (Lipari & van Horn, 2017). However, there is also a substantial need for services that are targeted directly at children from substance-involved families and that address their psychological and developmental needs. Approaches include primarily school-based trainings, community-based trainings, and family-based interventions across different age groups.

A comprehensive systematic review conducted by Bröning et al. (2012) identified and summarized the outcomes and evaluation results of nine selective preventive interventions in childhood and adolescence targeted at children from substance-involved families. These programs were researched in 13 studies; that is, seven randomized-controlled trials, two controlled or quasi-experimental studies, three descriptive studies, and one qualitative study. Of these nine programs, the following eight exist in English:

School-Based Interventions

- The Stress Management and Alcohol Awareness Program [SMAAP] is a group program for 4th-, 5th-, and sixth-grade students with problem-drinking parents. Focus is set on self-esteem, coping behaviors, alcohol expectancies, problem solving, and social support. After the training, participants showed improved emotions-focused coping, problem solving skills, and social competency. (Short et al., 1995).
- Friends in Need addresses primary school students from drug-involved families. The program focuses on self-esteem, coping behavior, perception of emotions, group affiliation, and the "4 C's" ("you didn't cause it, you can't control it; you can't cure it, you can be okay"). Findings demonstrate reduced physical aggression for the intervention group compared to controls. (Dore et al., 1999).
- School-Based-Support-Groups [SBSG] are offered for students from grades 9 through 12 and focus on knowledge on substance abuse, family relations, and coping strategies. Results were able to demonstrate improved addiction-related knowledge in the study group as well as improved coping strategies and social integration in female participants (Gance-Cleveland, 2004; Gance-Cleveland & Mays, 2008).
- Children Having Opportunities in Courage, Esteem and Success (CHOICES) is a three-component program for 3rd- and fourth-grade students and included the following components: 1. "School Support Group": group meetings. 2. "Healthy Lifestyle Peer Mentors": ongoing mentoring program for participants; peer mentors received training and attended group meeting. 3. private lessons / homework assistance. Focus was put on emotions, identity and family, and coping strategies. Significant results for participants were increased self-esteem when the group program was combined with peer mentor training and increased social skills when the program was combined with peer matching. Attitudes toward substance use also improved significantly. Moreover, improvement in isolation, loneliness, coping skills, school, performance, and social behavior was observed (Horn & Kolbo, 2000a, b).

Community-Based Intervention

- Teen-Club is aimed at female teenagers from drug-involved families with a lack of social and family support. Contents of the program include problem solving, health education, social behavior, and home visits for crisis intervention. As a result, the study group went to school significantly longer, had a better chance of getting a job, showed fewer depressive symptoms, and had fewer unwanted pregnancies (Tuttle et al., 2000).

Family-Based Interventions

- Focus on Families [FOF see above as part of parenting intervention] is a family-based program for families with methadone-treated parents and contains sessions with family members and children. After the training, improved family behavior could be observed in the study group. For male participants, there was a reduced risk of developing substance use problems (Catalano et al., 1999, 2002).
- Strengthening Families Program [SFP, Utah Version] is a Canadian adaption of the SFP 6–12-year family-based program developed by Kumpfer & DeMarsh (1983) and was tested with children aged 9 to 12 with at least one parent addicted to alcohol in Ontario and Buffalo, NY. The program focuses on strengthening individuals as well as family structures. After the training, there was a

reduction in Oppositional Defiant Disorder Symptoms in the study group (Maguin & Safyer, 2003).

- Save Haven Program is an adaptation of the SFP (Utah version) for inner city African-American substance-using families with children aged 6 to 12. Focus is put on parenting training and children's and family skills training. In the high drug use group, improvements were observed with regard to both internalizing and externalizing behaviors. In the low drug use group, fewer school problems were reported for children. The total sample exhibited improved family cohesion and less parental drug use (Aktan, et al., 1999).

Intervention duration and intensity of these eight programs do not vary much. Most programs last between 8 and 14 weeks, including weekly sessions of approximately 60–90 minutes. Group sizes are not always reported, but mostly range from 8 to 12 children. As described above, findings suggest that these eight evidence-based interventions may be effective in reducing high-risk children's problems and improving positive behaviors, coping skills, and feelings.

It is up to future work to broaden the body of research on programs for children from substance-affected families. Besides testing new approaches for prevention across different age groups and settings, researching low-threshold and cost-effective methods such as web-based programs and counseling can be promising. Online support for this target group can increase the range of children and adolescents reached through anonymous ways, which might serve to reduce isolation and shame in them.

Generally, the support for children affected by parental substance is aimed at reducing the outlined risk factors and at fostering resilience and protective factors for each individual child. This includes measures of psychoeducation on substance and health education. Also, the promotion of self-esteem, coping skills, problem solving, and emotion perception and regulation are frequently considered as part of targeted interventions. Here, it is important to underline the need for non-stigmatizing approaches that are tailored to the age and developmental level of each child or adolescent.

Apart from evidence-based group programs, many more resources are available to help children when a parent uses substances or has an SUD. For example, SAMHSA (2021) provides online resources for professionals, including information for policy and practitioners, trainings and webinars, and local and state examples and projects.

Conclusion

Parental substance use disorders can have serious effects on children at any age and can lead to severe developmental issues in the short- and long-term, such as decreased cognitive and academic functioning, impaired socio-emotional and physical development, or restricted behavioral adjustment and social skills (Solis et al., 2012). The difficult situations within substance-affected families call for an implementation of systematic support for both parents and children. When a parent has an SUD, every family member should be involved in the recovery process and might need support himself. (Lipari & van Horn, 2017).

Here, early identification and timely engagement with substance use treatment services should be emphasized, potentially even before the birth of a child. It appears necessary, yet challenging, to develop routes to reach parents with limited or no history of service engagement. Low-threshold support should be made available to this group, while associated professions need to be educated on issues related to parental substance use.

In order to buffer the problematic influences for the children in the best possible way, individual and family protective factors should be promoted, especially when there is an accumulation risk factors within the family. A wide range of preventive measures, which should be offered as early as possible, can reduce the risks for the children. Yet, if these interventions are unsuccessful and a threat to the welfare of the child is imminent or already exists, child protection measures should be taken promptly and in coordinated ways.

Parental Separation and Divorce: Risk and Protective Factors and Their Implications for Children's Adjustment

Karey L. O'Hara, C. Aubrey Rhodes,
Rana N. Uhlman, Irwin N. Sandler,
and Sharlene A. Wolchik

Parental separation/divorce is a significant life stressor for many children. In this chapter, we review the prevalence and public health impact of parental separation and divorce, as well as their associated consequences for children. We highlight the heterogeneity of post-separation/divorce outcomes for children and discuss how nonmodifiable and modifiable factors explain differences in children's adjustment. We end with a brief overview of how clinicians can support children after parental separation/divorce.

Prevalence of Parental Separation/Divorce

A large number of children in the United States and around the world experience the divorce of their parents. Recent estimates indicate that in the United States more than 20 million children under the age of 21 live with a custodial parent while their other parent lives elsewhere (Grall, 2020) and that roughly one million children have experienced parental divorce every year since the 1970s (Kreider & Ellis, 2011). A review of national prevalence statistics of adverse childhood events placed parental divorce as the second most common for children in the United States, following economic hardship (Sacks et al., 2014). In addition to children who experience their parents' legal divorce, many more experience the separation of their parents who never married. Research from the Fragile Families study showed that children were five times more likely to experience parental separation if their parents were cohabitating instead of married at the time of their birth (Osborne et al., 2007). Regardless of parents' marital status, children's experience of family disruption, whether it be separation or divorce, is likely to be a stressful life event that confers risk for the development of problems across multiple domains.

There are some documented differences related to income, education level, and race/ethnicity in the prevalence of parental separation/divorce. Researchers have documented that women from economically disadvantaged backgrounds are more likely to divorce and also experience reductions in income as a result of divorce (McLanahan & Percheski, 2008). Women with less education are also more likely to divorce (Martin, 2006) and a recent study found that divorce exacerbated economic inequalities related to education, especially for mothers, even after accounting for child support (Hogendoorn et al., 2020). Divorce was unrelated to poverty for fathers. Race/ethnicity is related to parental separation, with Black and Hispanic children being more likely to experience parental separation during childhood than White children (Kennedy & Bumpass, 2008). Thus, given the institutional inequality existing in the United States, the difference in separation/divorce distribution suggests that divorce may be one mechanism through which racial economic inequality is maintained and exacerbated (McLanahan & Percheski, 2008).

Consequences of Parental Separation/Divorce in Childhood, Adolescence, and Adulthood

Decades of research have shown that parental separation/divorce puts children at risk for a host of negative outcomes. Researchers have shown that parental separation/divorce confers risk for the development of children's mental health and substance use problems (Amato, 2000, 2001; Barrett & Turner, 2006; Furstenberg Jr. & Teitler, 1994; Hoffmann & Johnson, 1998; Jackson et al., 2016; Kasen et al., 1996; Strohschein, 2005; Tebeka et al., 2016), poor physical health (Bzostek & Beck, 2011; Schmeer, 2012; Troxel & Matthews, 2004; Yannakoulia et al., 2008), difficulties with social relationships (Amato, 2001; Kunz, 2018; Vandewater & Lansford, 1998), and academic underachievement (Amato & Anthony, 2014; Strohschein et al., 2009). Further, compared to those whose parents remain married, youth who experience their parents' separation/divorce demonstrate lower levels of subjective well-being and academic success in adolescence (Cherlin et al., 1991; Lansford et al., 2006; Størksen et al., 2006). They are also more likely to leave home prior to age 16 (Goldscheider & Goldscheider, 1998) and have children during adolescence (McLanahan, 1999). The two meta-analyses, which together reviewed more than 150 studies conducted through the 1990s (Amato, 2001; Amato & Keith, 1991b) on outcomes associated with parental separation/divorce, found small but reliable effect sizes (i.e., children from separated/divorced families scored about ¼ standard deviation lower than children from married families, on average, across outcomes).

The risks associated with parental separation/divorce in childhood can persist for many years, conferring higher rates of negative outcomes into adulthood. Adults who experienced parental separation/divorce in childhood or adolescence are more likely to report mental health problems (e.g., depression, anxiety, suicidality; Afifi et al., 2009; Alonzo et al., 2014; Amato & Sobolewski, 2001; Auersperg et al., 2019; Chase-Lansdale et al., 1995; Cherlin et al., 1998; Kessler et al., 1997; Rodgers et al., 1997; Zill et al., 1993), physical health problems (Amato & Keith, 1991a; Kraft & Luecken, 2009; Lacey et al., 2013; Maier & Lachman, 2000; Schwartz et al., 1995), substance use problems (Barrett & Turner, 2006; Huurre et al., 2006), and marital instability and dissatisfaction (Amato & Cheadle, 2005; Amato & Sobolewski, 2001; Tallman et al., 1999). They also report lower well-being (Sobolewski & Amato, 2007), have lower levels of educational, economic, and occupational success (Amato & Cheadle, 2005; Biblarz & Gottainer, 2000; Hetherington, 1999; Sun & Li, 2008; Zill et al., 1993), and report worse relationships with their parents, siblings, and romantic partners (Hetherington, 1999; Webster & Herzog, 1995; Webster et al., 1995; Zill et al., 1993). Further, they have higher early mortality (Martin et al., 2005; Schwartz et al., 1995). Two recent meta-analyses (Auersperg et al., 2019; Sands et al., 2017) that documented the outcomes in adulthood associated with parental separation/divorce in childhood showed small, reliable effect sizes (OR's ranging between 1.12 and 1.64, depending on the outcome).

Public Health Burden Associated with Parental Separation/Divorce

Given the high prevalence of parental separation/divorce in the United States and the wide range of negative outcomes associated with it, this family disruption has significant societal costs. As discussed above, parental separation/divorce puts individuals at higher risk for a wide range of problematic outcomes like depression, anxiety, teen pregnancy, conduct problems, and substance use. These problems translate into costs to society related to involvement in the juvenile and criminal justice systems, unemployment and lost productivity, and use of medical, mental health, and social services (Herman et al., 2015). Illustratively, the treatment of depression, a well-documented outcome related to parental separation/divorce, costs the U.S. more than $83 billion annually (Greenberg et al., 2003). Similarly, problematic substance use is associated with over $740 billion annually in costs related to crime, lost work productivity, and health care expenditures (NIH: National Institute on Drug Abuse, 2021).

Wolchik and colleagues (2006) explored the public health burden of parental separation/divorce by applying the concept of population attributable fraction (PAF), an index that can be translated to show the percent of cases that could be prevented by removing a risk factor and its consequences. They examined the impact of reducing the negative consequences associated with separation/divorce, such as mental health problems, academic underachievement, substance use, and teenage pregnancy in the United States. Based on relative risk and odds ratios calculated from national probability samples (Furstenberg Jr. & Teitler, 1994; Kessler et al., 1997; Zill et al., 1993), researchers found that 36% of mental health problems in young adulthood, 30% of teen pregnancies, 23% of school dropouts, and 20% of drug dependence could be prevented by eliminating the risk associated with parental separation/divorce (Wolchik et al., 2006).

Putting the Consequences of Parental Separation/Divorce in Perspective

Although experiencing parental separation/divorce increases risk of deleterious outcomes that can persist from childhood through adolescence and adulthood, it is important to note that the vast majority of children do *not* develop long-term problems. In fact, most children show incredible resilience after a one- or two-year adjustment period (Amato, 2001; Amato & Keith, 1991b). One longitudinal study documented that only 25% of children who experienced parental divorce developed serious, long-lasting behavioral and mental health problems (Hetherington & Kelly, 2002). In other words, nearly three quarters of children did *not* experience serious mental health problems. However, the rate of significant problems for children who experienced parental divorce was significantly higher than the rate for children whose parents remained married (25% vs. 10%). Similarly, a large epidemiologic study of adults found that the prevalence of psychiatric disorders in the group of adults who experienced parental divorce in childhood was significantly higher than in the group that did not experience parental divorce (66.2% vs. 51.3%; Tebeka et al., 2016). Because of this heterogeneity in outcomes, researchers have put much effort toward studying how, why, and for whom parental separation/divorce confers increased risk for multiple deleterious outcomes.

Theoretical Perspectives of the Effects of Parental Separation/Divorce on Children

A few prominent models have emerged as theoretical frameworks for understanding children's post-separation/divorce adjustment. Amato's (2000) divorce-stress-adjustment model has a few key features. First, parental separation/divorce is viewed as a process that involves events and interactions among family members that happen before, during, and after the decision to separate or divorce. Second, separation/divorce often involves a host of stressful changes (e.g., moving to a different home, changing schools, decreasing economic resources, having less contact with one or both parents) and emotions (e.g., feeling scared or uncertain about the future, blaming oneself for the divorce). Third, the number and nature of stressful events, the quality of the child's relationships, and the nature of the interactions among family members that occur during the process of separation/divorce are seen as influencing one's risk for adjustment problems in the short- and long-term. For example, children exposed to high levels of interparental conflict after the separation/divorce are at the highest risk for developing mental health and related problems (Kalmijn, 2016; Long et al., 1988; O'Hara et al., 2019a). Conversely, high-quality parenting is a robust factor that protects against mental health problems and promotes well-being (Sandler et al., 2012; Wolchik et al., 2000).

In Sameroff's person-environment transactional model (Sameroff, 1987), the features of stressful events and children's access to protective resources are also important determinants of post-divorce adjustment. This model highlights the role of children's perceptions of divorce-related changes and events and posits that whether children experience the divorce-related events and interactions as stressful or benign depends on both specifics of the situation and the individual's personal history and characteristics. For example, children who are prone to experiencing strong, negative emotions may feel particularly overwhelmed when the parent whom they do not live with cancels a visit for the third time in a row. On the other hand, children who are dispositionally calm and have strong coping skills may feel disappointed about canceled visits but quickly recover to think about how to spend the afternoon with the parent with whom they live.

Understanding Variability in Children's Post-divorce Outcomes

Understanding which children are at greatest risk for negative outcomes associated with parental separation/divorce requires a comprehensive look at both modifiable and nonmodifiable factors. In the following sections, we first review the research on how historical and demographic factors, including children's pre-existing problems, gender, age, and race/ethnicity, relate to risk for maladjustment after separation/divorce. Next, we will focus on modifiable risk and protective factors, such as individual resources (e.g., coping) and family processes (e.g., parenting quality, interparental conflict), that influence children's adjustment after separation/divorce. Importantly, children often have unique combinations of these risk and protective factors that must be understood in context with one another. Thus, we discuss studies that have jointly examined risk and protective factors to better understand how they may interact to influence childrens's adjustment.

Nonmodifiable Risk and Protective Factors

Pre-existing Problems A number of prospective studies that followed children from pre- to post-separation/divorce provide evidence on whether mental health problems that predate the separation/divorce account for the higher incidence of children's post-divorce problems (e.g., Block et al., 1986;

Cherlin et al., 1991, 1998; Morrison & Cherlin, 1995). For example, Cherlin et al. (1991) demonstrated that controlling for pre-divorce adjustment at age seven significantly reduced the negative effects of a divorce on behavior problems and academic achievement at age 11; this effect was particularly strong for boys. Similarly, another study showed that for boys who evidenced post-divorce behavior problems, the problems observed at age 18 were detectible up to 11 years earlier (Block et al., 1986). A later study by Cherlin et al. (1998) examined trajectories of emotional problems of children from both divorced and continuously married families from age seven through age 33. They found that children whose parents were divorced had elevated emotional problems prior to the divorce. However, the emotional problems of children whose parents divorced increased from childhood to early adulthood, whereas they did not for those in the continuously married group (Cherlin et al., 1998), indicating that post-divorce emotional problems were not solely attributed to pre-existing problems.

Several other studies showed that the effect of divorce was significant above and beyond pre-divorce child problems (Chase-Lansdale et al., 1995; Furstenberg Jr. & Teitler, 1994; Needle et al., 1990). Illustratively, Chase-Lansdale et al. (1995) found that young adults were more likely to show clinically significant psychological problems at age 23 if their parents divorced in childhood, and accounting for their problems prior to the divorce at age seven only negligibly reduced the effect of divorce (i.e., 48% vs. 39% increased odds). Another study by Strohschein (2005) found that children whose parents would later divorce demonstrated higher levels of anxiety/depression and antisocial behavior prior to the divorce than children whose parents would remain together. However, the divorce itself was associated with increases in anxiety and depression. There was also a significant interactive effect between parental divorce and pre-divorce family dysfunction on children's antisocial behavior; divorce was associated with a decrease in antisocial behaviors if the marriage was highly dysfunctional. Taken together, these studies suggest that pre-existing problems place children at a disadvantage but do not fully account for the effects of separation/divorce on children's problems. In other words, pre-existing problems are likely a vulnerability factor rather than a full explanation.

Other scholars have examined whether dysfunctional processes that predate the separation/divorce, most notably interparental conflict and parent-child relationship problems, account for the development of children's problems after the separation/divorce. Multiple studies have found that youth's post-divorce depression (Aseltine, 1996; Cooney & Kurz, 1996), behavior problems (Tschann et al., 1990), school-related problems, and delinquency (Hanson, 1999) can be partially explained by pre-divorce levels of family conflict. In contrast Booth and Amato (2001) found that high pre-divorce conflict was *positively* associated with post-divorce child-well-being (i.e., composite of general happiness, life satisfaction, and self-esteem). Other researchers have found that children who experience high levels of interparental conflict before the divorce do better on average after the divorce compared to children who live with highly conflictual married parents as well as children whose parents had low marital conflict prior to divorce (Amato et al., 1995; Booth & Amato, 2001; Jekielek, 1998). Examining longer-term outcomes, a longitudinal study showed that young adults who experienced high levels of interparental conflict in childhood were less likely to divorce if their parents divorced rather than stayed married (Gager et al., 2016). These studies support the notion that ending a high-conflict marriage can result in benefits for children.

Other researchers have examined whether post-divorce adjustment can be explained by pre-existing parenting problems (Block et al., 1988; Shaw et al., 1993; Strohschein, 2012). Shaw and colleagues found that pre-divorce maternal rejection in early childhood was related to boys' post-divorce adjustment problems in adolescence and early adulthood (1993). For girls, inconsistent discipline prior to the divorce was related to post-divorce adjustment problems in adolescence (Shaw et al., 1993). Similarly, a more recent, large longitudinal study found that the effects of parental divorce on children's mental health problems were attributable to higher levels of family dysfunction (i.e., problems with trust, communication, and support) assessed prior to the divorce (Strohschein, 2012). These findings align with another study indicating that post-divorce parent-child relationship problems are in part related to parenting problems present prior to the divorce (Amato & Booth, 1996). Given that post-divorce parenting is a robust predictor of children's adjustment, it may be the case that many pre-divorce parenting problems remain stable after the divorce and thus, children miss out on an important protective factor.

Genetic Influences A few studies have investigated how genetic influences may play a role in explaining children's post-divorce adjustment. Amato and Cheadle (2008) used data from a national survey to compare outcomes between adopted and biological children from the same families. They found that parental divorce and marital conflict were similarly associated with behavior problems for both biological and adopted children. These data support what they called the "standard family environment" model where interparental conflict and divorce explain children's increased problems, as opposed to a model where genetic transmission explains the associations. Robbers and colleagues (2012) found that the impact of environmental influences on child internalizing and externalizing problems was higher in children from divorced families than children from married families, and that heritability of genetic influences was lower in the divorce sample. These findings align with those of other studies supporting the changes that occur during the divorce experience, not genes, as the primary explanation for the association between parental divorce and adjustment problems (e.g., Burt et al., 2008).

Another large study found that genetics may play a differential role depending on the outcome being studied. The results of this study indicated that shared genes accounted for increased risk of internalizing problems, whereas the divorce itself accounted for increased risk in substance use problems (D'Onofrio et al., 2007). Similarly, results from a study by O'Connor and colleagues suggest that genetics explained post-divorce academic and social problems, whereas the divorce explained increased psychopathology (O'Connor et al., 2000). One study found that the oxytocin polymorphism, which is related to empathy, attachment, and nurturance, in children whose parents had divorced significantly moderated the relation between parental divorce and depression in young adulthood. Young adults with the oxytocin genotype experienced twice as many depressive symptoms as those with other genotypes (Windle & Mrug, 2015). Finally, using data from the Fragile Families and Child Wellbeing Study of unmarried parents, researchers found that boys with genetic sensitivity (i.e., composite of dopamine and serotonin system polymorphisms) had worse behavior problems after separation than boys with less sensitive genes (Mitchell et al., 2015). Taken together, these findings suggest that although genetics affect offspring's post-divorce adjustment, they do not tell the whole story.

Demographic Factors – Child Sex, Age, Race/Ethnicity

Sex Multiple meta-analyses conclude that both boys and girls are negatively affected by separation/divorce (Amato, 2001, 2010; Amato & Keith, 1991a, b). However, there is some evidence that gender effects differ depending on the particular domain of maladjustment and the developmental period being studied. For example, results of meta-analyses showed that the effect of divorce was larger in magnitude for boys versus girls with regard to social functioning (Amato & Keith, 1991a), conduct problems (Amato, 2001), and major depressive disorder (Kasen et al., 1996). On the other hand, researchers studying adolescents and young adults who had experienced parental divorce found that females were more likely to drop out of high school than males and although they were similarly likely to have children in their teenage years, females were more likely to experience adverse effects of single parenthood (Hetherington et al., 1998; McLanahan & Sandefur, 1994). Another study found that parental divorce in childhood was associated with decreased intimate relationship quality in adulthood for women, but not for men. Further, women from divorced families had lower satisfaction with social support and lower self-esteem than women from married families; this association was not observed for men (Mustonen et al., 2011).

Age Although parental separation/divorce negatively affects both younger and older children (Amato, 2001), some age differences occur for specific domains of adjustment. One meta-analysis found that the effects of separation/divorce on academic achievement varied by age; more negative impact on school functioning occurred for children in elementary and high school compared to preschool or post-high school youth (Amato & Keith, 1991b). Another meta-analysis showed that post-separation/divorce academic and parent-child relationship problems were most prevalent in middle childhood, whereas adolescents showed more mental health problems (Amato, 2001).

Although some aspects of post-divorce adjustment differ as a function of children's age or sex, most of these effects are not large in magnitude. Further, one study found that when children's age and sex were considered in the same model with life events, parenting, and interparental conflict, these environmental and familial factors were stronger predictors of post-divorce adjustment than age and sex (Stolberg et al., 1987).

Race/Ethnicity Very few scholars have examined how race and ethnicity affect how children adjust to parental separation/divorce. Some studies have shown no meaningful differences in the relation between family structure[1] and children's outcomes based on race or ethnicity (e.g., Broman et al., 2008; Heard et al., 2008), whereas others show significant differences (e.g., Heard, 2007; Sun & Li, 2008). For example, in a large, longitudinal study of adolescents, Heard (2007) found that negative consequences on academic achievement of living for more years in a family structure other than with two biological parents were weaker for minoritized youth (i.e., Black and Non-white Hispanic). However, Black youth suffered a larger drop in grades than White youth if they experienced a recent change (i.e., in the last year). The author theorized that racial/ethnic-specific social resources and family practices that were developed, in part, as adaptations to a long history of structural inequalities, such as extended family social support and strong connections to community institutions, as well as less stigma associated with non-two-biological parent families, may buffer stress related to changes in family structure. Sun and Li (2008) found that parental separation/divorce between 10th and 12th grade predicted negative outcomes in several domains of functioning (e.g., test scores, education aspiration, homework completion, locus of control, behavior problems, teacher-reported problems) for White, Asian, and Black/African American youth. However, White youth experienced negative effects of parental/separation divorce in more domains of functioning compared to Asian and Black/African American youth. In contrast, Hispanic youth showed no negative effects of parental separation/divorce on any outcome. In fact, Hispanic youth who experienced parental separation/divorce showed a higher level of academic readiness than their peers residing with continuously married parents. The authors conclude that the results support the theory that because children from minoritized groups face many societal inequities and disadvantages, parental separation/divorce may only come at minimal additional cost to their well-being. Given the small number of studies, it is difficult to draw conclusions about the relations between race/ethnicity and post-divorce adjustment.

---

[1] Note that some studies examined racial/ethnic differences related to family structure more broadly (i.e., two biological parents, single parents, parent and step-parent), as opposed to parental separation/divorce per se.

Modifiable Risk and Protective Factors

A large body of work has focused on modifiable individual- and family-level risk factors, such as stressful events, and protective factors, such as high-quality parenting, as determinants of adjustment to parental separation/divorce. Given that children are likely to have both risk and protective factors, examining these factors together sheds light on important contextual nuances in understanding post-separation/divorce adjustment.

Separation/Divorce-Related Stressors Many of the changes that occur in the family after a separation/divorce are stressful for children. Some of the most common stressors are moving to a different home, changing schools, having fewer economic resources, having less contact with one or both parents, witnessing one or both parents' emotional difficulties, and being exposed to frequent interparental conflict. A study examining the stressfulness of various divorce-related events found high agreement that the most stressful events from the children's perspective include being exposed to interparental conflict and being blamed for the divorce (Wolchik et al., 1986). Other researchers have demonstrated that the number of negative events or degree of environmental change occurring in the child's environment predicts post-divorce adjustment problems (Kurdek & Blisk, 1983; Stolberg et al., 1987; Walsh & Stolberg, 1989). Research by Sandler et al. (1991) illuminated two main factors that influence how events are experienced by children and influence their adjustment: (1) the valence of the divorce-related events (i.e., positive versus negative), and (2) the stability of the events (i.e., no change, change for the worse, change for the better) (Sandler et al., 1991). Stable positive events were associated with positive outcomes for children, whereas negative events or events that changed for the worse were related to poor outcomes for children.

Consistent with children's perception of interparental conflict being one of the most stressful divorce-related events, research has shown that it is the most well-documented stressor that confers risk for children's adjustment problems (Amato, 1993; Amato & Keith, 1991b; Grych, 2005; Hetherington & Kelly, 2002; Shaw & Emery, 1987; Vandewater & Lansford, 1998). Exposure to high levels of interparental conflict has been associated with a range of negative outcomes, including mental health problems (Elam et al., 2019; Kalmijn, 2016; Long et al., 1988; Noller et al., 2008; O'Hara et al., 2019a, 2021), maladaptive coping and low self-esteem (Bing et al., 2009; Noller et al., 2008), academic and social problems (Forehand et al., 1994; Long et al., 1988; Vandewater & Lansford, 1998), risky behavior (O'Hara et al., 2019a; Orgilés et al., 2015), and physical health problems (Fabricius & Luecken, 2007). The negative effects of conflict can be exacerbated if it is frequent, intense, and involves child-centered topics (e.g., child support, children's academic, or extracurricular activities) or if the child is put in the middle of the conflict (Buchanan et al., 1991; Cummings & Davies, 2010; Johnston et al., 1987).

Parenting High-quality parenting (i.e., high warmth, low coercion, consistent and effective discipline, positive communication, supportiveness) by mothers and fathers is consistently associated with positive outcomes in separated/divorce families (Adamsons, 2018; Adamsons & Johnson, 2013; Amato & Gilbreth, 1999; Forgatch et al., 1988; Kelly & Emery, 2003; O'Hara et al., 2019b; Sandler et al., 2012; Simons et al., 1999; Wolchik et al., 2007). The limited research that has considered both parenting by mothers and parenting by fathers has found that they each independently predicted lower levels of children's post-divorce mental health problems (Buchanan et al., 1991; King & Sobolewski, 2006). Importantly, research has found that children benefit from high-quality parenting only when they have sufficient time with that parent (e.g., approximately 10 overnights per month; Sandler et al., 2013).

Several programs have focused on promoting children's mental health and well-being after parental separation/divorce through parenting interventions (Cookston et al., 2007; DeGarmo & Jones, 2019; Forgatch & Degarmo, 1999; Tein et al., 2004; Wolchik et al., 1993). Studies of one intervention, the New Beginnings Program, have shown that bolstering the quality of the parent-child relationship confers benefit for children across many domains of adjustment, including mental health and substance use problems (Tein et al., 2004; Wolchik et al., 2016; Zhou et al., 2008), academic and occupational functioning (Sigal et al., 2012), and adaptive coping (Vélez et al., 2011). Demonstrating the lasting power of improving parenting, the benefits of this 10-week intervention delivered during middle childhood lasted into subsequent developmental stages (Wolchik et al., 2002a; Wolchik et al., 2009, 2013). Using a developmental cascades perspective (Masten & Cicchetti, 2010), which posits that program-induced changes can initiate positive and compounding effects over time, Wolchik and colleagues assessed their sample in middle childhood, adolescence, and early adulthood. They found that intervention-induced improvement in the parent-child relationship reduced children's mental health problems in middle childhood, which led to reductions in mental health and substance use problems as well as increases in self-esteem and school performance in adolescence, which in turn reduced mental health and substance use problems in young adulthood (Wolchik et al., 2016).

In addition to improving positive parenting, decreasing negative parenting behaviors after separation/divorce is especially important. A recent meta-analysis (van Dijk et al., 2020) found that negative parenting behaviors, such as hostility and parentification, were more strongly predictive of children's post-divorce adjustment than positive parenting behaviors.

There is also some evidence that the quality of coparenting after divorce predicts children's post-divorce adjustment (Lamela & Figueiredo, 2016). Coparenting is often defined as a multidimensional construct comprising concepts such as respect, cooperation, communication, trust, valuing, agreement, and conflict (Macie & Stolberg, 2003; Saini et al., 2019; Teubert & Pinquart, 2010). There are very few studies that have examined unique effects of coparenting dimensions, making it difficult to parse out how much of the general effect of coparenting is accounted for by interparental conflict or quality of parenting by mothers or fathers. However, a few studies have found that different dimensions of coparenting predict different outcomes. For example, one study that included young adult from both married and divorce families found that after accounting for the effects of mother and father parenting, parental hostility predicted overall mental health whereas parental cooperation predicted problems with intimacy and work ethic (Gasper et al., 2008). Another study used cluster analysis to examine differences in adjustment for children in "cooperative parenting," "parallel parenting," and "single parenting" families. Comparing "cooperative parenting" and "single parenting" – both relatively low on interparental conflict – the results indicated that children with cooperative coparents had the lowest level of behavior problems in adolescence and the highest level of perceived closeness to fathers in young adulthood (Amato et al., 2011). It is important that future studies assess the unique effects of positive coparenting (e.g., cooperation), above and beyond the well-documented effects of interparental conflict on children's post-divorce adjustment.

Children who experience high-quality parenting are less negatively impacted by separation/divorce-related stressors. For example, one study found that children whose mothers provided high levels of consistent discipline and/or high acceptance/warmth were less likely to be negatively impacted by divorce-related stressors, measured by a composite of events such as witnessing interparental conflict, a parent missing visits, and losing important possessions, such as pets and toys (Wolchik et al., 2000). The opposite was true for those children whose mothers provided inconsistent discipline combined with high levels of rejection; for these children, the association between divorce-related stressors and mental health problems was magnified (Wolchik et al., 2000). However, a couple of studies have found that high-quality parenting does not buffer (i.e., reduce or mitigate an otherwise negative impact; protective against) the negative impact of *all* separation/divorce-related stressors. Lutzke and colleagues found that although high-quality parenting and interparental conflict both had independent relations to child mental health problems; high-quality parenting did not mitigate the deleterious impact of interparental conflict on children's post-divorce mental health problems (Lutzke et al., 1996). In a larger and more diverse sample of children from separating/divorcing families, high-quality parent-child relationships similarly did not buffer the deleterious effects of interparental conflict on children's fears of abandonment (O'Hara et al., 2021).

Findings of studies that included the quality of parenting by both parents demonstrate the complexity of the associations between parenting and divorce-related stressors. For example, Sandler and colleagues (Sandler et al., 2008, 2013) observed a "compensation effect" in families with high levels of conflict; high-quality parenting by one parent protected against child internalizing problems when the other parent provided low-quality but not high-quality parenting. On the other hand, families with low levels of conflict showed a "facilitation effect;" high-quality parenting by one parent enhanced the positive effect of high-quality parenting by the other parent (Sandler et al., 2008).

Social Support Supportive relationships with important people in a child's life, other than their parents, can also serve as a protective factor against negative outcomes. One study showed a protective, stress-buffering effect of supportive nonfamily adults on children's adjustment problems after divorce (Wolchik et al., 1989). Results of another study showed that children's social support from peers was associated with positive post-divorce adjustment (Teja & Stolberg, 1994). In one study, the relation between peer support and children's outcomes was moderated by age; older children benefitted from peer support, whereas younger children did not (Lustig et al., 1992).

Individual Resources Children's individual characteristics and capacities can increase or decrease their risk for adjustment problems. Researchers have examined how these factors relate to their post-divorce outcomes as well as how they interact with other risk and protective factors.

Studies have shown that the way children appraise (i.e., perceive, think about) divorce-related stressors is associated with their post-separation/divorce adjustment. In one study, threat appraisals (e.g., harm to others, negative self-appraisal) of divorce-related stressful events predicted mental health problems both cross-sectionally and 5 months later (Sheets et al., 1996). Wolchik and colleagues (2002a, b) found that fear of abandonment, a common divorce-related threat appraisal, mediated the associations between divorce-related stressors and children's mental health problems. In another sample, researchers showed that interparental conflict predicted fear of abandonment, which in turn predicted children's mental health problems 10 months later (O'Hara et al., 2021). Another study asked children to rate the likelihood of having different kinds of thoughts in response to hypothetical divorce-related stressful events. Children's reports of positive thoughts (e.g., "I know my dad loves me") predicted lower mental health problems, whereas negative thoughts (e.g., "My mom does not want to spend time with me") predicted higher mental health problems (Mazur et al., 1992). Generally, problematic beliefs related to parental separation have been shown to be related to child maladjustment (Kurdek & Berg, 1987). Other researchers have shown that children's positive appraisals about their self-worth (Sandler et al., 2000a, b) and the extent to which they think they can control events in their life (Fogas et al., 1992; Sandler et al., 2000a, b) are positively related to their mental health after parental separation/divorce.

Children's coping is also an important predictor of post-separation/divorce adjustment. Avoidant coping (i.e., avoidant actions, cognitive avoidance) predicts higher mental health problems (Armistead et al., 1990; Sandler et al., 1994), whereas more active coping (i.e., problem solving, positive reappraisal) predicts lower mental health problems (Sandler et al., 1994, 2000a, b). Several researchers have studied associations between coping and adjustment in the context of other child characteristics. For example, Lengua and Sandler (1996) found that for children higher in self-regulation, active coping predicted lower anxiety, whereas for children lower in self-regulation, avoidant coping predicted higher anxiety. Understanding the role of coping efficacy is particularly important for understanding children's post-divorce adjustment. Coping efficacy, or the child's general belief that they can handle stressful situations, has been shown to mediate the effect of adaptive coping behaviors on mental health problems (Sandler et al., 2000a, b). In other words, the positive effects of active coping (e.g., cognitive restructuring, problem solving) occurred by increasing coping efficacy, which in turn, led to mental health benefits.

There is some research demonstrating that coping behaviors interact with divorce-related stressors to affect children's post-divorce adjustment. For example, one study found that children who reported positive interpretations (e.g., "I know my parent loves me") of divorce-specific vignettes were protected against the negative effects of the divorce-related stressful events they had experienced with regard to their self-reported depression and mother-reported externalizing problems (Mazur et al., 1999). On the other hand, older children who reported negative interpretations (e.g., "It's my fault that my parents are fighting") showed stronger associations between stressful events and both self- and mother-reported internalizing and externalizing problems. Another study found that divorce-related stressors and conduct problems were positively associated only for children who reported low active coping (Sandler et al., 1994). A later study found that although positive cognitive coping and coping efficacy were beneficial for all children with regard to protecting against post-separation/divorce internalizing and externalizing problems, positive cognitive coping was especially important in protecting children exposed to high levels of interparental conflict from marijuana use in adolescence (O'Hara et al., 2019a, b). Problem-focused coping protected children exposed to high interparental conflict from internalizing problems. On the other hand, avoidant coping was especially problematic for increasing the risk of externalizing problems in adolescence for youth exposed to high levels of chronic interparental conflict (O'Hara et al., 2019a, b).

Children's general tendencies toward emotional experiences, conceptualized broadly as temperament, are also implicated in their post-separation/divorce adjustment. Hetherington (1989) found children with difficult temperament (rated by nurses when the children were between 6 months and 2 years old) were more likely to have post-divorce behavior problems. Similarly, a study found that children who had higher levels of emotional intensity were more likely to have higher internalizing problems after parental divorce (Kurdek, 1988). Another study of children from divorce families found that children higher in negative emotionality were more likely to endorse threat appraisals, which in turn increased the likelihood of engaging in higher levels of coping (both active and avoidant coping behaviors) and reporting higher levels of internalizing and externalizing problems (Lengua et al., 1999). In the same study, children higher in positive emotionality perceived lower threat in response to stressful events, engaged in more active coping behaviors, and had lower levels of internalizing and externalizing problems (Lengua et al., 1999). One study that focused on the interaction between children's temperament and post-divorce parenting found that positive emotionality and low impulsivity were protective against adjustment problems associated with harsh or ineffective parenting (i.e., high rejection, inconsistent discipline) (Lengua et al., 2000).

Conclusion and Implications for Clinical Practice

In this chapter, we reviewed the prevalence and public health impact of parental separation/divorce. This change in family structure occurs in one million children in the United States each year. The public health impact of parental separation/divorce on healthcare and criminal justice systems is substantial (Herman et al., 2015). We also reviewed the consequences of divorce for children's adjustment. The majority of children do *not* develop significant problems after their parents' separation/divorce. However, a sizeable subgroup experiences higher levels of problems in multiple domains of adjustment, including mental health problems, physical health problems, and decreases in well-being. For some children, these effects persist into adulthood. Risks for developing short- and long-term problems vary as a function of nonmodifiable characteristics, such as age and gender, as well as modifiable risk factors, such as interparental conflict, and protective factors, such as positive parenting and effective coping. There is compelling evidence that interparental conflict is damaging to children's post-divorce adjustment and that positive parenting has the power to protect children from post-divorce adjustment problems. Although less well-researched, there is growing evidence to support the role of individual resources, such as effective coping strategies and adaptive appraisals, in promoting positive adaption to parental separation/divorce. A growing body of literature has demonstrated that modifiable factors, as opposed to nonmodifiable factors like genetics and child sex, have the largest impact on children's post-separation/divorce adjustment. Of course, environmental, genetic, individual, interpersonal, and demographic factors interact in complex ways to impact children's post-divorce adjustment.

It is important that clinicians working with separating and divorcing families remember that divorce is a process that occurs within a family system. Children do not live their lives in laboratory conditions; understanding their experiences in context is vital. Thus, gathering information about many aspects of a child's context, including changes brought on by the separation/divorce and the nature of the family environment, will help clinicians formulate effective treatment plans. The most effective ways to promote children's adaptation to parental separation/divorce include working with parents to improve aspects of positive parenting (i.e., warmth, communication, effective discipline) and decrease interparental conflict, while working with children to enhance individual resources, such as effective coping.

Irritability

11

Emily Hirsch, Margaret Benda, Robert W. Garvey,
and Amy Krain Roy

Pediatric irritability is a transdiagnostic symptom associated with significant functional impairment that results in a large proportion of child mental health referrals (Carlson & Dyson, 2012; Peterson et al., 1996; Vidal-Ribas et al., 2016). Though no formal definition exists, irritability is typically conceptualized as a proneness to anger and low tolerance for frustration that contribute to tonic (i.e., cranky mood, touchiness) and phasic (i.e., temper outbursts) components. Over the past 20 years, there has been a dramatic rise in empirical interest in pediatric irritability, which has led to significant advances in neurocognitive models and the development of improved assessments and interventions. The aim of the present chapter is to provide the reader with a summary of the historical context behind this increase as well as the current state of the field in six sections: (1) Brief History, (2) Irritability in Normative Development, (3) Etiology and Neurobiology, (4) Diagnostic Considerations, (5) Assessment, and (6) Treatment.

Brief History of Current Conceptualizations of Pediatric Irritability

Irritability has received increased clinical and empirical attention in recent years, mostly as a result of the controversy surrounding pediatric bipolar disorder (BD) in the late 1990s and early 2000s (Leibenluft, 2011). During this time, there was a 40-fold increase in pediatric BD diagnoses in outpatient settings, and a four-fold increase in inpatient settings (Blader & Carlson, 2007; Moreno et al., 2007) along with a dramatic rise in the use of psychotropic medications, particularly antipsychotics (Comer et al., 2010; Moreno et al., 2007; Olfson et al., 2006). Given that risk factors for pediatric BD did not change and this escalation only occurred in the United States, the sharp increase was likely due to changes in the clinical conceptualization of pediatric BD, in which irritability played a critical role (Brotman et al., 2017a; Leibenluft, 2011; Roy & Comer, 2020; Roy et al., 2014). Specifically, this marked increase in diagnoses coincided with the idea that pediatric BD may be characterized by chronic and continuous irritability (Biederman et al., 2004; Wozniak et al., 1995), which conflicted with traditional adult definitions of mania as reflected by acute and episodic euphoria or irritability as well as the criterion of bipolar disorder found in the Diagnostic and Statistical Manual of Mental

Disorders, Fourth Edition (DSM-IV), which required a “distinct period” of a change in mood (American Psychiatric Association [APA], 1994). Notably, while DSM-IV included irritability as a criterion or associated feature of several psychiatric diagnoses, it did not include any that specifically captured severe non-episodic irritability.

To address the bipolar disorder controversy and facilitate research on severe non-episodic irritability, researchers at the National Institute of Mental Health (NIMH) developed criteria for a broad phenotype of pediatric BD, which became known as severe mood dysregulation (SMD) (Leibenluft, 2011; Leibenluft et al., 2003). The hallmark symptom of SMD was irritability, which was operationally defined by two components: severe temper outbursts and a negatively valenced mood between outbursts. Hyperarousal was also included as a symptom of SMD to fully capture youth who were receiving BD diagnoses (Leibenluft, 2011; Leibenluft et al., 2003). Longitudinal, family history/heritability, and neuroimaging studies provided clear evidence that SMD and DSM-IV BD were distinct phenotypes and that chronic irritability did not comprise a developmental presentation of BD (Leibenluft, 2011).

The need to address the overdiagnosis of pediatric BD and related increase of antipsychotic medication use, coupled with data supporting SMD as a unique syndrome, led to the addition of disruptive mood dysregulation disorder (DMDD) in the fifth edition of the DSM (DSM-5; American Psychiatric Association [APA], 2013). Discussed in more detail below, DMDD is characterized by severe irritable mood and recurrent temper outbursts and is included in the Depressive Disorders section of DSM-5, highlighting its conceptualization as a mood disorder and distinction from BD. However, the diagnosis of DMDD brought additional controversy. First, when adapting SMD to DMDD, changes were made to the criteria, including the removal of the hyperarousal symptom; thus, research findings related to SMD were not directly applicable to the new diagnosis. Moreover, DSM field trials, analyses of retrospective data, and prospective studies showed that the diagnosis of DMDD had limited reliability, lack of psychiatric consensus, significant overlap with other psychiatric conditions, and limited longitudinal stability (Axelson et al., 2012; Freeman et al., 2016; Mayes et al., 2015a; Regier et al., 2013).

While investigations of SMD were underway, researchers were also considering an irritable dimension of oppositional defiant disorder (ODD). Though several models of ODD have been evaluated, varying in the number of dimensions and the items that comprise them, researchers have consistently identified an irritable dimension that is differentiated from the other dimensions through its robust association with anxiety and depression (Burke et al., 2014; Evans et al., 2017; Stringaris & Goodman, 2009a, b). This research informed the organization of ODD within the DSM-5 whereby ODD symptoms are subdivided into three dimensions, including an “Angry/Irritable Mood” one (APA, 2013), which consists of the symptoms: often loses temper, often touchy or easily annoyed, and often angry and resentful.

Growing concerns about the diagnosis of DMDD, increased attention to the irritable dimension of ODD, and research showing that DMDD has no incremental validity or utility beyond a diagnosis of ODD (Axelson et al., 2012; Freeman et al., 2016) led some to argue that youth with irritability be captured by an ODD specifier rather than a standalone DMDD diagnosis (Evans et al., 2017; Lochman et al., 2015). Indeed, in its Eleventh Revision of the International Classification of Diseases and Related Disorders (ICD-11), the World Health Organization (WHO) chose not to include the DSM-5 DMDD diagnosis and instead added a specifier of “with chronic irritability-anger” to ODD (World Health Organization, 2019). However, proponents of the DMDD diagnosis have argued that such specifiers are often not used by clinicians, so do not add clinical utility (Brotman et al., 2017a; Stringaris et al., 2018). Further, DMDD captures youth with the most severe levels of irritability who are more impaired and require more services than youth with ODD; thus, there were concerns that an ODD diagnosis with a specifier would not adequately address this level of severity (Brotman et al., 2017a).

These controversies have led to a surge of research on pediatric irritability, including its developmental presentations, underlying mechanisms, diagnostic classification, assessment, and treatment, all of which are discussed in the following sections of this chapter.

Irritability in Normative Development

A major challenge associated with the diagnosis and treatment of childhood irritability is distinguishing between developmentally appropriate and clinically significant presentations. Since irritability, primarily in the form of temper tantrums or outbursts, is a hallmark feature of typical development in early childhood, it can be difficult for parents, teachers, and clinicians to know when children's behaviors are of clinical concern and would benefit from intervention (Wakschlag et al., 2012). Indeed, pursuing treatment early in development is critical, given that atypical levels of irritability can be indicative of risk for future psychopathology (Eyre et al., 2017; Savage et al., 2015; Stringaris et al., 2009, 2018; Vidal-Ribas et al., 2016). Additionally, what constitutes normative irritability changes across development, further contributing to difficulty in identification, diagnosis, and treatment of atypical presentations (Copeland et al., 2015; Potegal, 2019). To better understand clinically significant irritability and potential links to psychopathology, it is important to consider the behavioral profile of irritability in normative development.

One of the most common manifestations of irritability in typically developing children is temper tantrums, also known as temper outbursts, which can be defined as verbal and physical outbursts of anger, often precipitated by frustration or when an expected reward is not attainable (Potegal, 2019). In a study of nearly 1500 3- to 5-year-olds, Wakschlag et al. (2012) found that more than 80% experienced at least one temper outburst in the past 30 days. While temper tantrums may seem inappropriate or maladaptive, they provide young children with the opportunity to learn how to regulate emotions, a key developmental task of early childhood (Cole et al., 1994; Kopp, 1989). When toddlers exhibit temper tantrums, they are overwhelmed by their natural, emotional reaction to a frustrating or uncomfortable situation and do not yet have the emotion regulation or executive control skills to sufficiently inhibit maladaptive responses (Kopp, 1989). Over time, children learn to inhibit these responses and find other ways to achieve their goals as they realize that responding to frustration with a temper tantrum does not lead to goal attainment (Brotman et al., 2017b).

Successful mastery of emotion regulation leads to decreased occurrence of temper tantrums and irritability, allowing young children to move on to other advanced developmental tasks. In middle childhood and adolescence, the prevalence of both tonic and phasic irritability generally decreases (Copeland et al., 2015). At the same time, adolescent episodes of tonic irritability occur for significantly longer durations than younger children's, further indicating a change in the behavioral profile of irritability from childhood to adolescence (Copeland et al., 2015). These prolonged periods of tonic irritability may be particularly salient as adolescence is a time when internalizing disorders often onset (e.g., mood and anxiety; Kessler et al., 2007). Thus, while adolescents do not experience temper tantrums to the extent or frequency that toddlers do, they still may experience episodes of frustration and anger, often colloquially referred to as "moodiness," that are normative.

In summary, normative developmental shifts in phasic and tonic irritability can provide a guide for determining typical versus atypical behavior. For example, daily temper outbursts in toddlers may be normative but are of clinical concern in adolescents. Conversely, prolonged episodes of low levels of tonic irritability may be observed frequently in teenagers but would not be expected in younger children. Thus, to understand irritability as it relates to psychopathology, it is crucial to consider these various developmental contexts.

Etiology and Neurobiology

Over the past decade, there has been a dramatic increase in research examining etiological and neurobiological factors that contribute to pediatric irritability (Roy & Comer, 2020). Both genetic and environmental factors have been implicated. For example, heritability estimates have been found to range from 30% to 40% (Coccaro et al., 1997). Parent psychopathology is also associated with child irritability (Dougherty et al., 2013; Wiggins et al., 2014), which may point to genetic or environmental influences. Parents also play a key role in their child's development of effective emotion regulation by modeling and supporting adaptive emotion coping and through operant conditioning processes (Cole et al., 1994; Patterson, 1982). For instance, parents may inadvertently reinforce displays of irritability such as tantrums by providing something rewarding (e.g., attention or a desired object) or allowing the child to avoid or escape something aversive (e.g., by reducing demands) in order to reduce the child's distress. This increases the likelihood that the child will display such a response in the future (Patterson, 1982; Stringaris et al., 2018). Adverse life events and exposure to trauma may also contribute to irritability. Indeed, following exposure to trauma, children may exhibit increased anger as a result of increased activation of a "survival mode" of functioning, which facilitates a threat response (Chemtob et al., 1997). This is consistent with the view that irritability reflects an aberrant response to threat (Brotman et al., 2017b), as described below. Trauma in childhood also disrupts the development of emotion regulation capacities (Dvir et al., 2014), which may increase the risk of irritability.

The current, most widely accepted pathophysiological conceptualization of pediatric irritability identifies aberrant reward and threat processing as the core neural components of severe irritability (Brotman et al., 2017b). The key element that links aberrant reward processing to irritability is frustrative non-reward (FNR), which posits that when an expected reward is not attained, organisms respond with increased motor activity and aggression (Amsel, 1958). FNR is particularly relevant to irritability, as temper outbursts are commonly an explicit reaction of anger and frustration to a blocked goal or reward. Evidence suggests that frustration is associated with altered responding in cortical, regulatory regions as well as subcortical, emotion generation regions of the brain. For example, the dorsolateral prefrontal cortex (DLPFC) shows altered responding to frustration in children with normative levels of elevated irritability as well as in clinically irritable samples. Studies using functional near infrared spectroscopy (fNIRS) suggest that in preschoolers, the DLPFC response follows an inverted U curve, with low and clinically elevated levels of irritability associated with lower activation and moderate levels of irritability associated with greater activation (Grabell et al., 2018; Perlman et al., 2014). Alternatively, a recent functional magnetic resonance imaging (fMRI) study of older children (ages 8–18) from various diagnostic groups as well as healthy controls found positive associations between irritability levels and frustration-related activation in the DLPFC (Tseng et al., 2019). The anterior cingulate cortex (ACC), a region implicated in error processing and emotion regulation, also shows irritability-related alterations in reward- and frustration-related activity as well as functional connectivity. For instance, irritable children have been shown to exhibit reduced activation in the ACC and middle frontal gyrus during frustration but increased activation in these two regions during reward compared to their non-irritable peers (Perlman et al., 2015). Using resting state fMRI, Roy et al. (2018) found reduced intrinsic functional connectivity (iFC) of the anterior midcingulate cortex (aMCC) with surrounding areas of the ACC and increased iFC with the precuneus in children with severe irritability as compared to healthy controls and non-irritable children with ADHD. Together, these findings of alterations in DLPFC and ACC activation and functional connectivity associated with clinical irritability support the putative role of atypical top-down emotion regulation.

Due to its role in processing reward (Delgado, 2007), the striatum has also been a focus of neuroimaging studies of pediatric irritability. In clinically irritable children (ages 6–9), activation in the striatum during frustration has been shown to be negatively correlated with parent-reported levels of irritability (Perlman et al., 2015). Contrary to these findings, a study of adolescents (ages 9–19) found a positive association between irritability and striatal activation, during both reward anticipation and feedback conditions of a monetary incentive delay task (Kryza-Lacombe et al., 2021). In this study, irritability was also associated with decreased functional connectivity between the left striatum and ACC. In a study of healthy preschoolers using the same task, the opposite association was found between irritability and functional connectivity between the left ventral striatum and several posterior cortical regions during successful versus unsuccessful trials, regardless of the presence of a reward (Dougherty et al., 2018). Together, these studies suggest that pediatric irritability is associated with disruptions in activity and connectivity of the striatum; however, such disruptions may vary depending on age.

The second aspect of the pathophysiological model of irritability, aberrant threat processing, is characterized by increased orienting to threat, hostile attribution bias, and deficits in emotion face processing (Brotman et al., 2017b). This model theorizes that clinically irritable individuals have a tendency to overestimate threat in their environments and subsequently react to that threat with anger and rage (Brotman et al., 2017b; Carver & Harmon-Jones, 2009). Behavioral and EEG studies provide evidence for aberrant threat processing in clinically irritable children and adolescents. For example, irritable youth demonstrate an increased attention bias towards threatening facial stimuli (Hommer et al., 2014; Salum et al., 2017) as well as atypical profiles of emotion recognition and labeling (Guyer et al., 2007; Rich et al., 2008). Recent studies using event-related potentials (ERP) demonstrate positive associations between irritability and heightened attention to threat as well as to emotional stimuli, more broadly (Deveney et al., 2020; Martin et al., 2021). These studies suggest that irritable youth attend to emotional stimuli more quickly than their non-irritable peers and then may have difficulty shifting their attention away from these stimuli and towards task-relevant information.

Neuroimaging studies of aberrant threat processing in irritability have focused primarily on the amygdala due to its role in threat perception. Adolescents with SMD exhibit greater amygdala activity in response to angry, fearful, and neutral faces as compared to healthy controls (Thomas et al., 2013) as well as decreased amygdala activation when rating their fear levels to neutral faces compared to healthy control, ADHD, and BD groups (Brotman et al., 2010). Irritability has also been associated with decreased functional connectivity between the amygdala and prefrontal cortex during passive viewing of angry faces (Stoddard et al., 2017). A resting state fMRI study of adolescents with ADHD found higher parent-reported emotional lability, a construct similar to irritability, to be positively associated with amygdala- rostral ACC iFC, but negatively associated with iFC between the amygdala and posterior insula/superior temporal gyrus (Hulvershorn et al., 2014).

In summary, significant advances have been made regarding the etiological and neurobiological mechanisms underlying pediatric irritability. There is clear evidence of genetic and environmental contributions, as well as of disruptions in cortical and subcortical regions involved in reward, frustration, and threat processing.

Diagnostic Considerations

As mentioned above, irritability is a transdiagnostic symptom found in both internalizing and externalizing disorders. In the DSM-5 (APA, 2013), tonic and/or phasic irritability is included as a diagnostic criterion, associated feature, and functional consequence of many psychiatric conditions that present in children and adolescents. Irritability is considered a primary symptom of DMDD, ODD, and intermittent explosive disorder (IED). Other psychiatric conditions include irritability as one of many possible symptoms, or are associated with, or lead to, irritability. Examples include BD, major depressive disorder (MDD), persistent depressive disorder, Anxiety Disorders, Trauma- and Stressor-

Related Disorders, attention-deficit/hyperactivity disorder (ADHD), and autism spectrum disorder (ASD). This section briefly reviews the presentation of irritability in psychiatric conditions common to children and adolescents, starting with disorders in which irritability is a defining feature followed by those in which irritability is either one of many symptoms, an associated feature, or a functional consequence of the core symptoms. Of note, irritability is also associated with many disorders not discussed here, such as obsessive compulsive disorder (Storch et al., 2012), Tourette's disorder (Ashurova et al., 2021), conduct disorder, and anorexia nervosa (APA, 2013).

Disorders Characterized by Irritability

Disruptive Mood Dysregulation Disorder As discussed above, DMDD was added to the DSM-5 to address concerns about the overdiagnosis of pediatric BD. The core feature of DMDD is irritability, and a diagnosis requires chronic irritable mood as well as severe recurrent temper outbursts that occur at least three times a week and are out of proportion to the situation and developmental level. The irritable mood and temper outbursts must be present for at least one year and across at least two settings, and their onset must occur before age 10. The diagnosis of DMDD cannot be given to individuals younger than 6 years of age or older than 18 years of age, or to those with a diagnosis of ODD, IED, or BD (APA, 2013). Notably, evidence suggests that DMDD can be observed in children younger than 6 years if one considers different features of irritability and symptom thresholds in this age range (Wiggins et al., 2021). Some have argued for the need for more precise and objective criteria that vary by developmental level as the current criteria depend on subjective judgement (Laporte et al., 2021; Wiggins et al., 2021).

In an early study, compared to youth with other psychiatric conditions, youth who met criteria for DMDD were more likely to have continued comorbidity, increased risk for anxiety and depressive disorders, and poorer health, educational, legal, financial, and social outcomes in adulthood (Copeland et al., 2014). It could not be determined whether these outcomes were specific to DMDD or simply resulted from greater symptom severity and/or higher rates of comorbidity. However, in a more recent study, Dougherty et al. (2016) found that DMDD at age 6 was predictive of psychopathology and functional impairment at age 9, even after controlling for demographic variables and baseline diagnoses, suggesting that the poor outcomes of DMDD are not simply due to comorbid conditions.

As mentioned above, there are concerns surrounding the reliability and validity of DMDD (Axelson et al., 2012; Freeman et al., 2016; Mayes et al., 2015a; Regier et al., 2013), which in part, stem from the high comorbidity with other psychiatric diagnoses (Althoff et al., 2016; Copeland et al., 2013, 2014) and lack of diagnostic specificity, leading some to suggest that DMDD has no symptoms that are unique to it (Axelson et al., 2011). For example, there was poor agreement between clinicians on DMDD diagnoses in the DSM-5 field trials (Regier et al., 2013), and a study of children aged 6–12 showed that DMDD had low longitudinal stability and could not be differentiated from ODD and conduct disorder (Axelson et al., 2012). There are also concerns about the treatment of DMDD. Specifically, some have noted that DMDD's exclusion criteria and placement in the Depressive Disorders section may keep youth with externalizing problems from receiving the services they need (Evans et al., 2017). Further, there have been concerns that DMDD will simply replace pediatric BD, with clinicians overutilizing antipsychotics and other psychotropic medications (Axelson et al., 2011; Evans et al., 2017; Lochman et al., 2015).

Oppositional Defiant Disorder ODD is a heterogeneous disorder characterized by a pattern of irritable mood, argumentative and defiant behaviors, and vindictiveness (APA, 2013). To meet diagnostic criteria for ODD, children must exhibit four of eight symptoms for at least six months during interactions with at least one individual who is not a sibling. Except for the spiteful/vindictive symptom, symptoms should occur most days for children under the age of 5 years, and at least once a week for children age 5 years or older (APA, 2013). Relevant to the current review, three of the ODD symptoms (often loses temper, often touchy or easily annoyed, and often angry and resentful) comprise an Angry/Irritable Mood dimension. While it is possible for youth to meet diagnostic criteria for ODD without demonstrating irritability, this is relatively rare, and most youth with ODD have at least one of these symptoms (Rowe et al., 2010). Thus, many children with ODD demonstrate a pattern of both tonic and phasic irritability, similar to DMDD, making differential diagnosis a challenge. As a result, many youth with DMDD symptoms also meet criteria for ODD (Mayes et al., 2016), although according to the DSM-5, if a child meets criteria for both ODD and DMDD, only a diagnosis of DMDD should be given (APA, 2013). This stipulation has been somewhat problematic because a DMDD diagnosis does not convey other important symptoms that children with ODD may have, such as oppositionality and noncompliance.

The irritability symptoms of ODD are predictive of unique developmental trajectories. For example, in a longitudinal study of youth with ODD from early to middle childhood, those with high-persistent and increasing irritability had a poorer prognosis than those with decreasing irritability (Ezpeleta et al., 2016). Specifically, those with high-persistent and increasing irritability showed a greater continuity and severity of ODD, greater comorbidity, a higher prevalence of additional disruptive behavior disorders, more internalizing and externalizing problems, and increased difficulties with emotion regulation. Finally, as mentioned above, studies examining the irritable dimension of ODD have found that it most strongly predicts internalizing problems as well as greater difficulties with emotion regulation and more severe symptomatology (Drabick & Gadow, 2012), while the other dimensions of ODD more strongly predict ADHD and conduct problems (Burke et al., 2014; Evans et al., 2017; Stringaris & Goodman, 2009a, b).

Intermittent Explosive Disorder IED is characterized by phasic irritability, namely, recurrent behavioral outbursts that are out of proportion to the provocation or precipitating psychosocial stressor and are not premeditated or exhibited to achieve a tangible objective (APA, 2013). These outbursts are manifested by either verbal or physical aggression around two times per week for approximately three months that does not result in damage, destruction, or physical injury; or three outbursts within a 12-month period that result in damage, destruction, or injury. As such, outbursts in IED generally involve greater levels of aggression than those seen in ODD. Like DMDD, IED cannot be diagnosed in children under the age of 6 years (APA, 2013). IED is differentiated from DMDD in that it does not include symptoms of tonic irritability, as supported by a study that showed that adults with IED spent less than 50% of their time between outbursts feeling angry (Coccaro, 2018). Further, IED has different frequency and duration thresholds and can be diagnosed in those who display symptoms after the age of 10 years and in adulthood. If children meet criteria for both IED and DMDD, only a diagnosis of DMDD is given.

IED is significantly understudied in youth (McLaughlin et al., 2012), likely because it was rarely applied to children prior to DSM-5. However, a study in adolescents found that IED is persistent and highly impairing, co-occurs with many psychiatric conditions, and is significantly undertreated (McLaughlin et al., 2012). Further, a study of large samples of adolescents and adults suggests that individuals with IED and a comorbid externalizing disorder (i.e., ADHD, ODD, CD) have the greatest levels of aggression, followed by those with IED alone, those with other psychiatric disorders, and healthy controls (Radwan & Coccaro, 2020). This suggests that the presence of IED is particularly associated with elevated aggression, with or without a comorbid externalizing disorder.

Disorders Associated with Irritability

Here, we discuss several disorders in which irritability is one of many symptoms or may be an associated feature or consequence of core symptoms.

Bipolar Disorder As described earlier, the role of irritability in pediatric BD has been the focus of significant controversy and research. According to the DSM-5, youth with BD may present with irritability both during manic or hypomanic episodes and major depressive episodes. Manic (lasting at least one week) or hypomanic (lasting at least four consecutive days) episodes are characterized by a distinct period of abnormally and persistently elevated, expansive, or irritable mood as well as increased activity or energy. If these episodes are primarily irritable rather than elevated or expansive in nature, individuals must meet criteria for four rather than three additional symptoms (APA, 2013). For the major depressive episode, youth must experience a depressed or irritable mood, or loss of interest or pleasure in activities, as well as an additional four symptoms that are present during the same two-week period and represent a change from previous functioning. Importantly, in the DSM-5, irritability in BD, whether in children or adults, is episodic rather than chronic in nature (APA, 2013). This stands in contrast with the previous notion, described above, that pediatric BD may be characterized by chronic and continuous irritability.

Major Depressive Disorder and Persistent Depressive Disorder Depressive disorders are characterized by sad, empty, or irritable mood along with somatic and cognitive changes (APA, 2013). While symptoms of depressed mood or loss of interest are required for adults, the DSM-5 specifies that children and adolescents may exhibit irritable instead of depressed mood. However, a study of youth ages 9–16 with depression suggests that irritability rarely occurs without low mood in this population and thus, may not be a developmental presentation of depression (Stringaris et al., 2013). Rather, evidence suggests that irritability in depressed youth may be indicative of comorbid disruptive behavior disorders, especially in males (Stringaris et al., 2013). In addition to being a symptom of depression, irritability in childhood is also predictive of the development of depression in adolescence and adulthood (Vidal-Ribas & Stringaris, 2021). As such, several models suggest that irritability and depression are related due to shared risk factors, including genetic liability, family history of depression, temperamental and personality characteristics, and negative parenting styles (Ezpeleta et al., 2019; Stringaris et al., 2012b; Vidal-Ribas et al., 2016; Vidal-Ribas & Stringaris, 2021; Whelan et al., 2015; Wiggins et al., 2014).

Anxiety Disorders The DSM-5 lists irritability as one of six symptoms of generalized anxiety disorder (GAD) and indicates that children with specific phobia or social anxiety disorder may exhibit tantrums when feeling anxious or afraid (APA, 2013). Indeed, evidence suggests that such anxiety-related outbursts may be reinforced over time when, in response to outbursts, others help anxious youth avoid distress or provide support and attention (Walkup et al., 2021). There is clear empirical support for irritability in a wide range of anxiety disorders. For example, youth with GAD, separation anxiety disorder, and specific phobia have higher levels of self- and parent-reported irritability compared to those without any psychiatric conditions (Stoddard et al., 2014), and among youth with anxiety disorders, irritability is associated with anxiety severity, even after controlling for comorbid depressive disorders and ODD (Cornacchio et al., 2016). Compared to children with anxiety who are not irritable, those with both anxiety and irritability have greater symptom severity and functional impairment (Shimshoni et al., 2020) as well as different neural connectivity patterns (Stoddard et al., 2017). Longitudinal work showing that irritability in childhood predicts anxiety disorders in adulthood also supports a link between irritability and anxiety (Savage et al., 2015; Stringaris et al., 2009; Vidal-Ribas et al., 2016).

Trauma- and Stressor-Related Disorders Irritability is a symptom of several Trauma- and Stressor-Related Disorders in the DSM-5, including posttraumatic stress disorder (PTSD), acute stress disorder, and reactive attachment disorder (APA, 2013). In addition, patterns of comorbidity further demonstrate the association between irritability and trauma. For example, youth with DMDD are more likely to have a Trauma- and Stressor-Related Disorder diagnosis than youth with MDD or persistent depressive disorder (Benarous et al., 2020). Likewise, justice-involved youth with DMDD are more likely to meet criteria for PTSD than justice-involved youth with disruptive behavior disorders (Mroczkowski et al., 2018). Other research suggests links between irritability and trauma history, even in the absence of a formal trauma-related diagnosis. For example, exposure to trauma in childhood has been associated with the development of IED in adulthood (Nickerson et al., 2012). Also, youth with ASD who have a history of trauma have been shown to have higher levels of irritability and a greater likelihood of aggression and temper outbursts compared to those without trauma histories (Brenner et al., 2018; McDonnell et al., 2019). These associations are consistent with etiological models described above.

Attention-Deficit/Hyperactivity Disorder DSM-5 lists irritability as an associated feature of ADHD, reflecting its prevalence in this population and association with greater comorbidity and impairment (Ambrosini et al., 2013; Eyre et al., 2017; Galera et al., 2021). The high co-occurrence between ADHD and irritability has led to the proposal that irritability should be considered a core feature of ADHD (Riglin et al., 2017; Shaw et al., 2014) or that it may represent a distinct subtype of ADHD (Karalunas et al., 2019). Further, some have suggested that the presence of irritability in ADHD may be a marker of future depression risk (Eyre et al., 2017, 2019). Evidence indicates that irritability may be higher in children with ADHD, Combined Presentation compared to those with ADHD, Predominantly Inattentive Presentation (Mayes et al., 2015b). Further, highly irritable youth with high levels of ADHD symptoms exhibit greater phasic irritability than those with moderate ADHD symptoms, with no group differences in tonic irritability (Cardinale et al., 2021), suggesting that phasic irritability may be especially relevant to ADHD.

The co-occurrence of ADHD and irritability may result from shared risk factors, such as alterations in underlying neural circuitry, genetic liability, temperament, environmental variables (e.g., parenting), and deficits in emotion regulation (Faraone et al., 2019; Nigg et al., 2020; Riglin et al., 2017; Shaw et al., 2014; Steinberg & Drabick, 2015). For example, deficits in self-regulation and executive functioning often observed in children with ADHD are also associated with emotional impulsivity, low self-control, and poor behavioral inhibition, which may contribute to emotion regulation deficits and increase risk for irritability (Faraone et al., 2019; Shaw et al., 2014). Irritability may also be a consequence of ADHD whereby symptoms of ADHD evoke negative feedback from the environment, leading to irritability (Deault, 2010; Patterson, 1982; Steinberg & Drabick, 2015). Or, alternatively, irritability may influence the development of ADHD as supported by research showing that irritability predicts subsequent ADHD, even after controlling for baseline ADHD symptoms (Dougherty et al., 2016; Leibenluft et al., 2006).

Autism Spectrum Disorder Although it is not a symptom of ASD, irritability, especially temper outbursts, is common in those with ASD (Keluskar et al., 2021; Mayes et al., 2011). In line with this, Mayes et al. (2015b) found that youth with ASD had significantly higher levels of DMDD symptoms compared to youth with other psychiatric conditions. In fact, irritability is so problematic in youth with ASD that they are the only population for which the United States Food and Drug Administration has approved medications to treat irritability (Fung et al., 2016). Children with ASD have high baseline levels of negative affect and demonstrate difficulties regulating their emotions, which may partially explain high rates of irritability (Keluskar et al., 2021; Mazefsky et al., 2013). Alternatively, elevated irritability may result from specific challenges faced by these children. For example, temper outbursts frequently occur in response to environmental stimuli that are related to the core symptoms of ASD, such as rigidity and sensory sensitivities (Keluskar et al., 2021; Mayes et al., 2015b). Children with ASD may also exhibit outbursts due to difficulties communicating effectively (Manning et al., 2019); however, empirical support for this is mixed (Mayes et al., 2017). Research suggests that non-compliance in youth with ASD, which often arises in instances of perceived or real blocked goals, is strongly related to irritability (Kalvin et al., 2021). In addition, youth with ASD are at an elevated risk for psychosocial stressors, such as victimization and parent stress, which may contribute to irritability (McGuire et al., 2016).

Summary

In sum, irritability plays a role in many psychiatric conditions. For some, it is a core feature, and these disorders can be differentiated by the presence of tonic versus phasic irritability as well as frequency, duration, and pervasiveness criteria. For others, it is one of many symptoms, an associated feature, or functional consequence of the core symptoms. Importantly, irritability's prominence in the DSM-5 highlights its transdiagnostic nature and the continued struggle to adequately conceptualize this construct.

Assessment

Historically, irritability was traditionally assessed as a single symptom of psychiatric illness rather than as a multidimensional construct. Thus, initial research on childhood irritability examined individual items from disruptive behavior, mood, and anxiety disorders sections of diagnostic interviews or used them to derive irritability scales. Over the past 20 years, irritability has become a focus of growing empirical and clinical interest leading to the development of measures that specifically aim to assess irritability in youth. This section describes the most widely used measures of childhood irritability. Some assess irritability exclusively, while others are more broad assessments of child psychopathology or disruptive behavior with subscales that specifically assess irritability.

Clinical Interviews

Preschool Age Psychiatric Assessment and Kiddie Schedule for Affective Disorders and Schizophrenia The Preschool Age Psychiatric Assessment (PAPA; Egger et al., 2006) and Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS; Kaufman et al., 1997) are diagnostic interviews that aim to identify the presence of a range of disorders based on DSM criteria and have been used to assess irritability-related constructs in preschool- and school-age children (Copeland et al., 2015; Eyre et al., 2017) and adolescents (Melvin et al., 2018). Prior to the development of irritability-specific measures, researchers created ad hoc irritability scales utilizing items from relevant psychiatric disorders (depression, ODD, DMDD) derived from these interviews. This allowed for initial studies of irritability in preexisting cohorts that examined diagnostic comorbidities, associated impairments, and developmental trajectories, laying the foundation for future work. Of note, in a recent item response theory analysis, Dougherty et al. (2021) found that the PAPA was unable to produce reliable assessments of childhood irritability at all severity levels, but the K-SADS provided sufficient measures of severe irritability in early adolescence.

The Early Childhood Irritability-Related Impairment Interview The Early Childhood Irritability-Related Impairment Interview (E-CRI; Wakschlag et al., 2020) is a semi-structured clinical interview that assesses irritability's impact on typical social functioning from infancy to toddler-aged children. Clinicians ask parents a series of open-ended probe questions to ascertain the presence of irritability and associated impairment over the past three months; if applicable, clinicians then follow up with a series of more comprehensive probes linking irritability to functional impairment and its variation across six contexts, including home, with peers, and in school or daycare. Ratings of impairment severity are determined by the examiner based on multiple variables including frequency, intensity, and duration as well as consideration of how irritable mood/behaviors disturb typical activities and routines. While many assessments of pediatric irritability have been developed, this is the only one that includes a robust measure of functional impairment.

Wakschlag et al. (2020) tested the E-CRI's validity and reliability in early childhood using a multitrait-multimethod (MTMM) framework to account for the variation of individual items by trait and context. A two-factor model was identified with separate tantrum and irritable mood impairment factors. When examined individually, tantrum- and mood-related impairment were significantly associated with measures of internalizing and externalizing psychopathology. However, when entered into a model together, tantrum-related impairment continued to be associated with both domains of psychopathology, while mood-related impairment was only associated with internalizing problems.

Rating Scales

Child Behavior Checklist Many researchers have assessed irritability using select subscales or items from the Child Behavior Checklist (CBCL; Achenbach & Ruffle, 2000), a well-established measure of child psychopathology. The CBCL is available for three different informants (child self-report, parent report, and teacher report) and in school-age and preschool versions (CBCL/6-18; Achenbach & Rescorla, 2001; CBCL/1.5-5; Achenbach & Ruffle, 2000). The versions differ slightly in length (ranging from 100 to 118 items) but share the same eight syndrome subscales. Respondents answer a series of items evaluating the child's behaviors over the past six months using a 3-point Likert scale. Items are totaled and converted to standardized T scores derived from normative samples.

Researchers using select subscales of the CBCL to measure irritability have primarily used the CBCL Dysregulation Profile (CBCL-DP), which was initially developed to assess pediatric BD (e.g., Diler et al., 2009; Mbekou et al., 2014) and has been found to be an effective tool for evaluating dysregulation and irritability in children and adolescents (Aitken et al., 2019; Papachristou et al., 2016). The CBCL-DP is a composite of T-scores from three CBCL syndrome subscales: Anxious/Depressed, Attention Problems, and Aggressive Behavior (Althoff et al., 2010). In nonclinical samples, children with composite T-scores ≥180 demonstrate more depressive and ODD symptoms, greater temperamental negative affectivity, and lower effortful control than children with composite scores below 180 (Kim et al., 2012). Similarly, a composite T-score ≥180 predicted the development of DMDD in childhood in a large community sample of young children (Dougherty et al., 2014). In clinical samples, a composite T-score ≥210 indicates severe dysregulation as evidenced by increased risk for the development of ADHD and mood disorders in adolescence (Masi et al., 2015), although some have proposed more stringent criteria in which each of the three subscale T-scores must be ≥70 to signify severity (Aitken et al., 2019). Moreover, Deutz et al. (2016) found the CBCL-DP to fit a bifactor model with a general factor of Dysregulation that predicted self-harm and suicidal ideation better than the individual subscales.

To examine childhood irritability more efficiently, others have made use of just three individual items from the CBCL ("temper tantrums or hot temper," "stubborn, sullen or irritable," and "sudden changes in mood or feelings") (Stringaris et al., 2012b; Tseng et al., 2017; Wiggins et al., 2014). The raw scores of these items are summed to create a total irritability score, which has a single-factor structure with strong internal consistency (Stringaris et al., 2012b; Wiggins et al., 2014). This scale also demonstrates strong construct and external validity, being associated with concurrent anxiety and depression and predicting future depression, attention problems, and delinquency (Aebi et al., 2013).

Affective Reactivity Index The Affective Reactivity Index (ARI; Stringaris et al., 2012a) was developed to assess irritability without inclusion of aggressive or antisocial behaviors found in previous measures (e.g., Burney & Kromrey, 2001; Snaith & Taylor, 1985). Specifically, the ARI is a brief measure, completed by either the parent (ARI-P) or child (ARI-S), that assesses the threshold for an angry reaction, frequency of angry feelings/behaviors, and duration of feelings/behaviors over the past six months. The scale further distinguishes itself for its brevity, using just six items related to symptomatology and one assessing impairment due to irritability. Items are rated on a 3-point Likert scale, and ratings of the six symptomatology items are summed for a possible score of 0–12. The ARI demonstrates strong internal consistency and a single-factor structure in both parent and self-report versions across clinical and community samples (Stringaris et al., 2012a). Further, the ARI maintains strong validity as evidenced by increased irritability scores in children and adolescents with SMD as compared to BD and healthy controls (Stringaris et al., 2012a). Since the initial development and psychometric evaluation of the ARI, investigators have evaluated its use across age groups, cultures, and informants. For example, the ARI is validated for a wide variety of ages, ranging from preschool to adulthood (Mulraney et al., 2014; Sugaya et al., 2021) and translated versions of the ARI have been developed and validated for use in both clinical and research settings worldwide (DeSousa et al., 2013; Pan & Yeh, 2019). Evidence shows the ARI may also be effective when teachers serve as reporters (Ezpeleta et al., 2020), and a clinician version of the ARI, the CL-ARI, has been developed, showing strong psychometric properties (Haller et al., 2020).

Multidimensional Assessment of Preschool Disruptive Behavior As indicated earlier in this chapter, assessing disruptive behaviors in preschool-aged children is made difficult by the need to differentiate between normative temper outbursts and atypical ones indicative of psychopathology (Wakschlag et al., 2012). The Multidimensional Assessment of Preschool Disruptive Behavior (MAP-DB; Wakschlag et al., 2014) addresses this issue by examining preschool disruptive behavior with greater acuity for behavior frequency, quality, and context. This 111-item, primary caregiver-reported assessment evaluates behavior frequency over the past month using a detailed 6-point Likert scale with objective frequency ratings (e.g., "some [1–3] days/week"), improving on previous ambiguity resulting from subjective measures of frequency ratings (e.g., "sometimes," "often,") and allowing for more accurate assessment and identification of children with atypical levels of outbursts. The MAP-DB assesses behavioral context across two categories: interactional (e.g., with parents, other children) and situational (e.g., "to get something they wanted," "for no reason or out of the blue"). Finally, items vary across the four-dimensional spectrums of preschool disruptive behaviors of interest: (1) Temper Loss, ranging from normative tantrums in response to distress to frequent, dysregulated tantrums; (2) Noncompliance, ranging from refusal to follow directions to provocative disobedience; (3) Aggression, ranging from reactive aggression to hostile aggression; and (4) Low Concern for Others. Since its development, the MAP-DB has been adapted for use with various age groups, ranging from infancy to adolescence (Biedzio & Wakschlag, 2018).

Wiggins et al. (2018) identified two items from the Temper Loss scale of the MAP-DB that best predicted functional impairment in a clinical sample of preschool- age children at high risk for persistent and future DSM disorders: “become frustrated easily” and “break or destroy things during a temper tantrum, fall-out, or meltdown.” The investigators then determined that a sum score of 3 points on these combined items serves as an effective cutoff for behaviors to be deemed clinical, with strong sensitivity (73%) and specificity (83%). Preschool-aged children (mean = 4.66 years) meeting the irritability cutoff had a higher probability of irritability-related DSM disorders at early school age (mean = 7.08 years).

Behavioral Observations

Disruptive Behavior Diagnostic Observation Schedule Clinician-administered assessments of disruptive behaviors in children often suffer from inadequate ecological validity because the clinical environment lacks specific stimuli that trigger problem behaviors in the child’s daily life. The Disruptive Behavior Diagnostic Observation Schedule (DB-DOS; Wakschlag et al., 2005), a clinical assessment of early childhood disruptive behaviors, addresses these concerns by observing behaviors with the examiner alone and with the parent. By including parent-child interactions, clinicians are more likely to observe disruptive behaviors triggered by parental behaviors. Observing children’s behaviors without parents present allows clinicians to account for variation in parents’ proficiency in de-escalating their child’s emotions or their tendency to exacerbate their child’s oppositional behaviors (Biedzio & Wakschlag, 2018). Accordingly, the DB-DOS is split into three modules, each of which includes compliance, cleanup, and frustration tasks: two with the examiner (Module 1 & 2) and one with the parent (Module 3) (Wakschlag et al., 2005). In Module 1 (Examiner Present), the child’s behaviors are observed while the examiner remains engaged and involved in all tasks. In Module 2 (Examiner Busy), the child is provided with a series of independent tasks to complete with minimal engagement from the examiner. During both modules, the examiner allows full expressions of disruptive behaviors to occur and systematically provides scaffolds (e.g., prompts, redirections) for the child to modulate behavior. This allows the examiner to observe disruptive behaviors and assess the threshold of support needed for the child. In contrast, during Module 3 (Parent Present), the examiner provides no prompts or redirections to the child; instead, parents are encouraged to respond to their child’s behaviors as usual. The demands of the task are changed to provoke disruptive behaviors while observing the child’s response to parental behaviors.

After the observation, each observed behavior is coded on a 0–3 scale ranging from normative, regularly occurring behaviors to clinically relevant, less common ones. More severe behaviors are weighted more heavily, even if they occur at the same rate as less severe ones. Behaviors are coded using 21 total codes organized into two domains, anger modulation and behavioral regulation, in all three observational contexts for a total of six scores (Wakschlag et al., 2008b). The DB-DOS has strong internal consistency and is well validated for identifying disruptive behavior in young children (Wakschlag et al., 2008a, b). The anger modulation domain demonstrates clinical and predictive utility for assessing pediatric irritability (Massey et al., 2020; Wiggins et al., 2018), and anger modulation scores are associated with low morning cortisol in children, which is an indicator of increased risk for the development of emotion regulation difficulties (Frost et al., 2018).

Summary

In sum, several recently developed assessment tools have greatly improved the measurement of pediatric irritability. These include brief measures, such as the ARI, as well as more comprehensive ones, such as the MAP-DB or DB-DOS. These new tools have had a direct impact on irritability research, allowing for reliable assessment and consistency of measures across studies. They have also directly impacted clinical practice by providing a more thorough understanding of irritability and its impact, which in turn, informs treatment planning and assists in the evaluation of outcomes.

Treatment

As with assessment measures, treatments aimed specifically at reducing irritability are relatively new. Traditional interventions such as parent management training (PMT)/ behavioral parent training (BPT) were designed to reduce disruptive behaviors by targeting maladaptive parenting strategies through parental education. See Chap. 36 for an overview. Alternatively, cognitive-behavioral therapies (CBT) were developed to address children's emotion regulation difficulties, typically within the context of anxiety or mood disorders. See Chap. 3 for a comprehensive review of CBT. Thus, while these interventions likely reduced irritability, it was not the specific target of treatment. Recently, intervention models have been developed to directly treat irritability rather than disruptive behaviors or internalizing problems more broadly, utilizing PMT/BPT and CBT components in tandem. Other interventions, such as dialectical behavior therapy (DBT) and transdiagnostic treatments, have also been tested with irritable youth or have undergone adaptations to address the unique needs of these children. This section outlines contemporary treatment practices and their empirical support and provides a brief overview of pharmacological treatments.

Psychotherapy

While CBT has traditionally been used to treat emotion regulation difficulties in the context of anxiety or mood disorders, it has since been adapted for the treatment of anger outbursts and aggression, which makes it germane to the treatment of pediatric irritability. CBT for anger and aggression typically targets relevant difficulties, such as inappropriate expression of anger, hostile attribution bias, and social issues (Sukhodolsky et al., 2016). It also includes a parenting component, teaching parents how to support skill generalization and use parent management techniques to increase adaptive behaviors and decrease maladaptive behaviors. CBT has been found to be effective in treating anger and aggression in youth (Sukhodolsky et al., 2016) and is therefore a promising treatment for irritability.

Cognitive-behavioral treatments have also been adapted to directly target irritability. Two group treatment programs that incorporated CBT and PMT were found to reduce parent-reported irritability in youth with comorbid SMD and ADHD (Waxmonsky et al., 2016) and in youth with chronic irritability (Derella et al., 2020). Another adaptation of CBT for youth with irritability places a stronger emphasis on exposure therapy techniques. This treatment is based on the pathophysiological model of the development and maintenance of pediatric irritability discussed earlier (Brotman et al., 2017b; Kircanski et al., 2019). In alignment with this model, the intervention utilizes graded in vivo and imaginal exposures to non-reward and/or threatening stimuli with the aim of teaching children that non-reward and threat stimuli can be tolerated or are not as adverse as predicted (Kircanski et al., 2019). In turn, biases towards expected adverse outcomes are reduced. The intervention also includes parent training to reduce parents' reinforcement of their child's bias towards expected adverse outcomes (Brotman et al., 2018). Preliminary data for this exposure-based CBT in youth with a DMDD diagnosis are promising (Linke et al., 2020), but randomized controlled trials (RCTs) are needed to demonstrate efficacy.

In addition to CBT and PMT, other treatments, such as DBT, have also been used to treat pediatric irritability. DBT is a comprehensive evidence-based treatment that balances behavioral change and acceptance strategies and specifically targets emotional and behavioral dysregulation (Linehan, 1993). Perepletchikova et al. (2017) adapted DBT for use with preadolescents (DBT-C) with irritability and behavior outbursts associated with DMDD. Like standard DBT, DBT-C consists of individual therapy, group skills training, telephone coaching, and therapist team consultation. However, it also includes caregivers in these modes and introduces a parent training component. A randomized trial comparing DBT-C to treatment as usual found that those who received DBT-C demonstrated lower dropout rates, higher treatment satisfaction, greater symptom improvement, and greater remission rates that were sustained three months after treatment (Perepletchikova et al., 2017).

Recently, transdiagnostic treatments, which were initially developed to accommodate the heterogeneity, comorbidity, and tendency of symptoms to shift across settings in children and adolescents, have been applied to youth with clinical irritability. These include the Modular Approach to Therapy with Children with Anxiety, Depression, Trauma, and Conduct Problems (MATCH; Chorpita & Weisz, 2009) and the Unified Protocol for Transdiagnostic Treatment of Emotional Disorders in Children (UP-C; Ehrenreich-May et al., 2018). MATCH is a modular treatment that includes evidence-based practices organized within 33 treatment modules that can be delivered flexibly and tailored to the needs of individual clients. These include 12 BPT modules (e.g., Active ignoring, Time-out, Giving effective instructions) in tandem with eight CBT strategies (e.g., Graded exposure, Addressing unhelpful thoughts, Problem-solving) that are particularly relevant to irritability (Evans & Santucci, 2021). Following an initial evaluation, clinicians provide these modules flexibly in accordance with developed flowcharts based on presenting problems and modify the time dedicated to each module in response to the patient's progress. For example, a child with comorbid irritability and depressive mood might first complete behavioral activation or problem-solving modules to address depressive mood prior to BPT modules to address irritability-related difficulties such as temper tantrums and oppositionality (Evans & Santucci, 2021). In a recent clinical trial, MATCH outperformed standard manualized treatments and usual care in the reduction of irritability symptoms and predicted fewer posttreatment DSM diagnoses in youth with severe irritability and mood dysregulation, supporting its efficacy as a treatment for chronic irritability (Evans et al., 2020).

UP-C is a transdiagnostic intervention that addresses the underlying mechanisms contributing to the development and maintenance of internalizing disorders. Skills are presented in a group format to parents and children, targeting children's difficulties with neuroticism, emotion regulation, information processing, cognitive flexibility, distress tolerance, and ineffective behaviors (Ehrenreich-May et al., 2018). A modified version of UP-C adapted for use with clinically irritable youth teaches these skills with a particular emphasis on irritability, anger, low frustration tolerance, and aggression (Hawks et al., 2020). The parent component involves PMT strategies that are especially relevant to pediatric irritability, including consistent command-punishment procedures and modeling of healthy emotional coping. Finally, each session contains a joint parent-child experiential activity that involves a series of frustrating or anger-inducing stimuli to provide parents and children time to practice the skills taught in their respective groups while receiving therapist coaching. In a small sample of children with irritability and/or disruptive behaviors, Hawks et al. (2020) reported significantly low dropout rates and a decrease in parent-reported irritability, lending credence to this intervention's use for the treatment of chronic irritability.

Pharmacology

Currently, the only FDA-approved medications for the treatment of irritability are the antipsychotics risperidone and aripiprazole, which are approved exclusively for use with children with ASD (Fung et al., 2016). There are no medications with an indication for use with non-ASD youth with clinically elevated irritability. Several studies have examined the efficacy of other medications, including mood stabilizers and stimulants, to reduce irritability in pediatric samples. One RCT exploring lithium's efficacy in treating irritability demonstrated no clear benefit of lithium over placebo (Dickstein et al., 2009). For children with ADHD, there is evidence that stimulants reduce symptoms of emotion dysregulation, including irritability (Shaw et al., 2014). Reanalysis of data from the Multimodal Treatment Study of Children with ADHD (MTA Study) showed that youth who received a combination of behavioral therapy and stimulants had a greater reduction in irritability than those who received community care or behavioral therapy alone (Fernandez de la Cruz et al., 2015). Likewise, in children with ADHD and SMD, treatment with a stimulant and behavioral therapy resulted in a reduction in externalizing symptoms (Waxmonsky et al., 2016). Moreover, in an open-label study, the combination of aripiprazole and methylphenidate significantly improved irritability, externalizing symptoms, depression, anxiety, attention, social problems, and reaction time variability in a clinical sample of children and adolescents with comorbid ADHD and DMDD (Pan et al., 2018). In adults, selective serotonin reuptake inhibitors (SSRIs) have been found to reduce aggression and explosive outbursts in the context of depression, IED, and premenstrual syndrome (Coccaro et al., 2009; Dimmock et al., 2000; Fava & Rosenbaum, 1999). Although a systematic review demonstrated some improvement in irritability symptoms with antidepressants (Kim & Boylan, 2016), more RCTs are necessary to determine SSRI's efficacy on irritability in children and adolescents, and in fact, data suggest that they may increase irritability in youth with mood disorders (Leibenluft, 2011; McClellan et al., 2007).

Summary

In sum, psychotherapeutic treatments are currently being developed for youth with irritability with promising results, but there has been less research on psychopharmacological treatments to specifically treat irritability in children without developmental disorders.

Conclusions

In recent years, there have been significant advances both in our understanding of irritability–including its developmental presentation, etiology and neurobiology, and role in psychopathology–and in the development of assessments and treatments that specifically address it. It has become clear that irritability is associated with functional impairment and predictive of negative outcomes even when taking other comorbid symptoms into account. Thus, there is a need to continue empirical investigations of irritability in order to understand its presentation across diagnoses and developmental periods with the ultimate aim of improving the nosology, and consequently the treatment of these impaired youth.

A Crisis in the Opportunity to Learn: Addressing the Causes and Consequences of Missing School

J. Jacob Kirksey and Joseph Elefante

Absenteeism and Accountability

Definitions of Chronic Absenteeism and Truancy

Each state in the U.S. constructs its own definition of chronic absenteeism, although they are mostly similar across states. The overwhelming majority of states and the District of Columbia define it as a student missing 10% or more of a given school year. Montana's threshold is 5%. Arizona, Arkansas, and Hawaii follow the U.S. Department of Education's (U.S. Department of Education, 2019) delineation of a student missing least 15 days over the course of one school year. By their definition, 16% – about 1 in 6 students nationwide – was chronically absent in the 2015–2016 school year (U.S. Department of Education, 2019). States' individual chronic absenteeism rates in that same year ranged from as low as 9.5% in North Dakota up to 26.9% in Washington (U.S. Department of Education, n.d.).

Although stakeholders often conflate chronic absenteeism with truancy, the terms differ. Where absenteeism applies to students missing school for any reason, excused or unexcused, truancy refers to unexcused absences only. As with chronic absenteeism, each state devises its own definition of truancy. In California, for example, truancy means a student has missed or is at least 30 minutes late to class three times without a valid excuse. Maryland uses the term "habitual truancy" for students who miss 20% or more of the school year (Attendance Works, 2016). Further, truancy carries legal consequences, sometimes resulting in suspensions for students and fines or even jail time for parents (Attendance Works, 2016).

History of Attendance and Accountability

Over time, schools have assumed an increasing responsibility over whether students show up for school. Newmann (1981) argues that schools have a responsibility to keep students engaged through

stimulating coursework, opportunities for leadership, and strong relationships with faculty. Finn (1989) illustrates this phenomenon via the participation-identification model, writing that from the first years of schooling students should be encouraged to participate in a wide variety of activities such as extracurricular opportunities, school decision-making, responses to educational needs, and other initiatives.

Attendance has been of concern to school leaders and policy makers from the beginning of the common school era. As early as 1838, Horace Mann argued that collecting accurate attendance data should be one of Massachusetts's chief responsibilities (Hutt, 2018). This idea grew more popular with the establishment of compulsory schooling in the U.S., at which point schools became more than just places of learning. Since that time, schools have also provided broad-based social services and helped to ensure children's safety and well-being. Absent students do not just miss academic curriculum, but basic services like food and medical care. Average Daily Attendance (ADA) became one of the earliest measures of school quality and accountability. Accordingly, school leaders put a high priority on getting kids into school (Hutt, 2018).

The federal government began using attendance as a marker of school accountability nationwide with the passage of No Child Left Behind (NCLB), the 2002 reauthorization of the Elementary and Secondary Education Act (ESEA). Specifically, NCLB identified attendance as an indicator in Adequate Yearly Progress (AYP) for elementary and middle schools (Spencer, 2009). Additionally, the passage of the Every Student Succeeds Act (ESSA), the 2015 reauthorization of ESEA, has pushed the issue of attendance to even greater prominence, as ESSA identifies absenteeism as one possible measure of school quality in state accountability systems (Every Student Succeeds Act, 2015). ADA remains an important metric to this day, as it factors into many states' school funding formulas (Dayhoff, n.d.).

Current Context of Attendance and Accountability

School Funding Formulas

Attendance often plays a significant role in how schools are funded. States usually use either total student enrollment from the previous year or ADA to calculate funding proportional to the number of students a school serves (Blagg et al., 2021). Seven states – California, Idaho, Kentucky, Mississippi, Missouri, New York, and Texas – use ADA, or the average number of students attending a given school per day over a predetermined period. These time periods are determined at the state-level (Dayhoff, n.d.). As poor attendance rates obviously have a negative effect on ADA calculations, it behooves school leaders to focus on improving student attendance.

Absenteeism and ESSA

In the United States, states are required to report their chronic absenteeism rates to the federal government (Jordan, 2019). The Office for Civil Rights of the Department of Education (ED) collects this information annually, then reports it every two years as a part of the Civil Rights Data Collection release. States must also include chronic absenteeism on their annual school report cards (Attendance Works, 2020). As of its passage in 2015, the Every Student Succeeds Act (ESSA) mandates that states choose at least one nonacademic metric with which to measure school quality in their state accountability systems (Every Student Succeeds Act, 2015). To date, 37 states and the District of Columbia have selected chronic absenteeism as one of their School Quality Student Success (SQSS) indicators (Jordan, 2019).

Out of these 37 states and D.C. come different models for incorporating absenteeism into state accountability systems. The California Department of Education employs an interactive School

Dashboard designed "to help parents and educators identify strengths and areas for improvement." The Dashboard includes a K-8 Chronic Absenteeism Indicator (CA Department of Education, 2019). Connecticut incorporates a K-12 chronic absenteeism accountability measure which includes a goal of reducing all chronic absence rates statewide to 5% or lower, with an emphasis on early prevention. Indiana includes an indicator in its state accountability system for students who have improved their attendance. Additionally, it rewards schools based on their percentage of "model attendees." These can be either students with with exemplary attendance or who have significantly improved their attendance. In Virginia, where the pre-ESSA chronic absenteeism rate was 18.3%, chronic absenteeism is now an SQSS indicator in all grade levels. The state has set a long-term goal of reducing the chronic absenteeism rate for all students and all subgroups to 10% or lower by 2024 (Kostyo et al., 2018).

Importance of Regular School Attendance

Absenteeism from school is a crisis having considerable negative consequences on the development of children and adolescents. Until recently, the assumption that typical students—those who are not suffering from illness or experiencing extreme circumstances—were attending class regularly was so widespread that most school districts and principals could not identify how many students were chronically absent (Balfanz & Byrnes, 2012). Recently, organizations like Attendance Works have worked to equip school districts with the necessary data tools to better understand, address, and prevent high rates of chronically absent students (Attendance Works, n.d.).

Conversations about school absenteeism have been largely centered around the academic implications, as students miss out on the opportunity to learn from their teachers and peers. For many students, these opportunities are not replaced in the home, and missing academic content in the formal school settings may disrupt students' engagement with their academics and learning environments. One explanation for this established link between absences and achievement might be that by receiving fewer hours of instruction over the course of the school year, absent students receive unequal opportunities to learn and do not perform as well on exams (Chen & Stevenson, 1995; Connell et al., 1994; Finn, 1993; Nichols, 2003). Instructional time has shown to positively predict student achievement for various student populations. For example in analyzing the Early Childhood Longitudinal Study – Kindergarten cohort, Bodovski and Farkas (2007) and Georges (2009) illustrate that greater time spent on procedural mathematics instruction associated with higher math performance of students. Additionally, Heatly et al. (2015) found that a combination of procedural and conceptual instruction led to higher math achievement for fifth graders. Thus, missing school, and thus instructional time, might limit the opportunity to learn for students, and as a result, students suffer academically.

Who Is Missing the Most School?

With better data being collected on student attendance as well as better tools to evaluate common patterns and trends, researchers and policymakers have identified several groups of students considered to be of greater risk of missing school. Students in poverty, for example, are two to three times more likely to be chronically absent from school compared to their peers (Attendance Works, n.d.). Students of color and students with disabilities are also more likely to experience greater absenteeism from school.

Additionally, it is well-established that children with health problems also struggle to maintain regular school attendance. Students can be absent due to seasonal or short-term illness (i.e., cold, flu, etc.), and schools consider these absences excused absences who are sick (i.e., cold, flu, etc.). There are other aspects of students' health that have been linked to greater frequency of missing school. McConnell et al. (2010) examined traffic and pollution data from parents of kindergarteners and first grade students to illustrate its connection to childhood asthma, which has a well-documented relationship to absenteeism from school (Doull et al., 1996; Fowler et al., 1985, 1992; Silverstein et al., 2001; Taras & Potts-Datema, 2005). Other research has concluded that physical health issues are also related to student absenteeism, including obesity, oral health, daily hygiene habits, and nutrition (Basch, 2010; Geier et al., 2007; Nandrup-Bus, 2011).

Whether children miss school for excused or unexcused reasons, the research is clear that both forms of absence can result in academic and nonacademic consequences for students. Next, we review some of this large body of literature illustrating the various declines associated with not being in school.

Consequences of Missing School

Many would argue that absenteeism has garnered so much local, state, and national attention given the large and growing body of research that links missing school to wide ranging short and long-run consequences for students. Missing school has been tied to numerous academic and nonacademic consequences across the grade span. Much like other education risk factors, absenteeism has been shown to put students at serious risk for lower achievement rates, disengagement from schools, and increased risk for dropout (Chang & Romero, 2008; Epstein & Sheldon, 2002).

Direct Effects to Academic Performance

Unsurprisingly, researchers have unveiled several ways in which absenteeism affects students' academic performance. The most direct and frequent measure of academic declines is evident through declines in standardized test scores. Focused on elementary and middle school grades in Philadelphia, Gottfried (2010) shows that students missing school more frequently experience declines in math and reading achievement. Specifically, Gottfried (2011) compares attendance rates among siblings and shows that, even after controlling for family-level factors, siblings who were more absent tended to perform worse on standardized exams compared to their peers. Kirksey (2019) extends this analysis into high school grades and finds that missing school is tied to poorer academic performance in both standardized testing and class grades.

Some researchers have begun to explore the extent to which missing school may only be a problem if students miss a significant amount. Gershenson et al. (2017) and Kirksey (2019) examine the cumulative effect of absenteeism and finds that the academic harm for every one day of school missed is the same for students with higher and lower rates of absence. This suggests that schools should focus on promoting positive attendance behaviors for all students, as every day matters with respect to promoting student learning. Gershenson et al. (2017) also note that, while both excused and unexcused absences can be linked to achievement declines, unexcused absences are nearly twice as harmful as excused absences. The authors also found that low-income students and English learners were disproportionately affected academically when they missed school.

Non-testing Outcomes

Students with higher rates of absences tend to face a higher risk of grade retention (Neild & Balfanz, 2006), and they are also more likely to drop out of school (Rumberger & Thomas, 2000). Kirksey (2019) examines how high school absenteeism links to the probability that students drop out of school and demonstrates that absenteeism in every high school grade increases students' probability of dropping out. The author shows that absenteeism in eleventh and twelfth grade was most directly linked to school dropout.

These effects from excessive absenteeism on school dropout are not only observed for high school students, but several longitudinal studies have also linked early attendance patterns from elementary school to school dropout. For example, Barrington and Hendricks (2013) found that even as early as elementary school, it was possible to identify high school dropouts by their previous absence patterns: students who dropped out were twice as absent in fifth grade and three times as absent in ninth grade. Hess et al. (1989) found that 90% of school dropouts in the Chicago Public School system could be identified by their absence patterns in the second, third, and fourth grades.

Beyond putting students at risk of dropping out of high school, researchers have linked excessive school absenteeism to future social and economic declines. Students who miss school frequently are more likely to experience declines in their social-emotional development (Gottfried, 2014). They are also more likely to be unemployed once they are in the workforce (Alexander et al., 1997; Broadhurst et al., 2005; Kane, 2006). In their recent study, Liu et al. (2021) showed that having 10 absences across all subjects in ninth grade reduced the probability of on-time graduation as well as ever enrolling in college by 2%.

The research is clear. Missing school results in serious learning loss for students that can have a profound impact on students' academic, social, and economic well-being. While some absenteeism is unavoidable when considering illness (Basch, 2010; Geier et al., 2007; Nandrup-Bus, 2011) or traumatic household or community events (Gershenson & Tekin, 2018; Kirksey, 2020; Kirksey et al., 2020; Kirksey & Sattin-Bajaj, 2021), districts and educators can help bridge the home-to-school gap and promote positive attendance behaviors by considering malleable push and pull factors that research suggests drive student absenteeism.

The Role of the School: Considering Push and Pull Factors Driving Student Absenteeism

Policy initiatives and resources are meant to strengthen the impact schools have on known factors that affect student attendance. Yet underlying these policies and resources geared toward reducing absenteeism, there is a theoretical assumption that schools play a significant role in whether a student is present. Newman (1981) designates schools as having a role to keep students engaged via relevant curriculum, student participation in management-decisions, and strong student-staff relationships. Finn (1989) encompasses this obligation of school engagement in the participation-identification model, illustrating that from the first years of schooling students should be engaged in a variety of participatory activities such as after-school activities, decision-making within schools, class-related initiatives, and responses to educational needs. This participation then leads to successful outcomes for students and a stronger school-going identity. Additional policy-driven frameworks of school attendance include classifying absences as being caused by push or pull factors; "push" factors indicate school-level factors that force students out of school and "pull" factors are community or home-based factors that keep students from attending (Youth Justice Board, 2013). Moreover, Kearney and Graczyk (2014) and AttendanceWorks (n.d.) advocate for the adoption of a Response to Intervention (RtI) model for addressing absenteeism in schools, where there exists a hierarchy of evidence-based strategies for keeping students in schools that ranges from universal support to targeted efforts.

There are several commonalities among these various models for understanding how to keep students in school. One is that there are contextual factors that impact student attendance. Contextual factors are defined as characteristics that relate to the demographic composition of schools and classrooms, the quality of the education being delivered, and the learning environment for students. These influences include but are not limited to teacher, peer, and school-level factors, all of which have been thoroughly discussed in the empirical research on school attendance.

Yet the way researchers conceive of absenteeism in elementary school is vastly different than the conceptions of secondary school attendance. For example, elementary students are usually not solely responsible for physically getting themselves to schools, they do not have the same transitions between classes, and they are often in self-contained classrooms with the same teacher(s) and the same peers for the entire school day. Moreover, as Corville-Smith (1998) notes, patterns of absenteeism start early in elementary school but tend to be exacerbated by the same contextual factors as students transition into secondary schools. Thus, a comprehensive discussion of these contextual factors and how they exist differently in elementary and secondary schools is necessary. As such, this review focuses on teacher, peer, and school-level factors that appear to drive student absenteeism for elementary and secondary students.

Elementary Absenteeism

Considering that in the U.S. most students spend a vast majority of their time in the same classroom with the same teacher, the teacher qualities that influence whether a student attends school are important to consider. Teachers establish the meaning and culture of school attendance for their students (Chang & Romero, 2008), and there is an underlying importance in how teachers respond to students who are absent from school. Bruner et al. (2011) discuss how often teachers take inaccurate roll of their elementary classes, which makes it difficult to respond to absenteeism if teachers are not aware of frequently absent students. Ken Reid has established a line of research documenting the necessity for preparing teachers (and school staff more generally) for appropriately reengaging students in school (Reid, 1983, 2003a, b, 2007, 2008, 2012). The discussed characteristics include ways to handle students returning to classrooms after missing schools as well as identifying patterns of absenteeism using data. Teachers should possess accurate data on absenteeism and have the capacity to use data-driven strategies, because unresponsiveness to absenteeism sends a signal to students and parents that missing school is acceptable (Chang & Romero, 2008). This is a key contextual characteristic of teachers that has a significant influence on student attendance. Moreover in regards to teacher-related context, it should be noted that a decline in academic engagement- a potential result from unresponsive teachers- is directly tied to absenteeism (Bealing, 1990; Broadhurst et al., 2005; Reid, 1983; Southworth, 1992). This implies that if teachers are not academically engaging their students, these students might begin to exhibit lower attendance rates.

Second, while elementary students spend a great amount of time with their teachers in schools, they arguably spend an even greater proportion with their peers. Current research has documented several key characteristics of peers that tend to associate with better or worse school attendance. First, there is a body of research illustrating potential negative outcomes that occur when a student has certain peers. Using urban district data from Philadelphia, Gottfried (2013) found that having a greater percentage of peers who were retained in the previous school year was associated with higher rates of unexcused absences for other students in the present year. Similarly, Gottfried et al. (2016) used nationally representative data (ECLS-K) to investigate whether having classmates with behavior disabilities influenced student absenteeism. They found that students who had a classmate with an emotional and behavioral disability were more frequently absent, aligning with prior research that students with disruptive classmates are more likely to experience school disengagement (Juvonen et al., 2003) and miss school (Bealing, 1990; Broadhurst et al., 2005; Giallo et al., 2010; Gottfried et al., 2016; Harte, 1995; Lehr et al., 2003; Reid, 1983; Southworth, 1992). It should also be noted that students who feel socially alienated from their classmates are more likely to be absent (Ekstrom et al., 1986; Finn, 1989; Johnson, 2005; Newmann, 1981).

There is also research to suggest that peers can have a positive impact on student attendance. Kirksey and Gottfried (2018) examined district-level data from California to determine whether having consistent peers associated with better attendance for students. They found that students who had classmates carry over from the previous school year tended to have fewer unexcused absences that year and were less likely to be chronically absent. Kirksey and Elefante (2020) also found that students who shared classrooms with more familiar peers were less likely to miss those classes. More generally and qualitatively, (Barth, 1984) discusses specific intervention strategies and notes how students with poor attendance can improve their attendance with the encouragement and persuasion of peers in their classrooms. These findings seem to suggest that peers clearly factor into students' capacity for attending school.

Finally, in addition to each student's general classroom experience, there is an added layer of school-level factors that relate to elementary student absenteeism. Musser (2011) examined the academic performance and attendance of over 64,000 students in New York and concluded that schools that perform lower academically often have higher rates of absenteeism among their students. Nauer et al. (2014) followed 87,000 students from kindergarten to third grade in New York and concluded that there were several qualities that were consistent among schools with high rates of absenteeism: scores on standardized exams in math and reading were below city averages and most students in the schools were living in high-poverty areas with high rates of crime, homelessness, and unemployment. Finally, Kerr et al. (2012) found that the presence of school nurses reduced absenteeism for elementary students. While there are certain aspects of school nurses that do not directly relate to school context, it is logical that having school nurses might promote a healthy school culture (i.e., students wash their hands regularly), which is certainly a contextual characteristic. These studies suggest that the compositional effects of schools matter for student attendance. From this, it can be concluded that students have better attendance when schools have a student body that exhibits more positive school behaviors.

Secondary Absenteeism

While much research has been dedicated to what teacher characteristics associate with secondary student achievement, very little empirical work has examined which teacher factors impact absenteeism in secondary schools. De Wit et al. (2010) explored a large sample of ninth to tenth grade students for determinants of absenteeism, and the authors find that as students progress through high school, they received less and less support from their teachers. This lack of support associated with lower rates of attendance. In a study of eight schools, García-Gracia (2008) examined the holistic pedagogical approach for addressing absenteeism in schools among different teaching staffs. There were several findings of this study that relate to teaching staff characteristics influencing student attendance. First, schools with higher rates of absences among students had higher rates of turnover among their teaching staff. Additionally, teachers who were seen as pedagogically responsive to diverse student needs experienced less absences from students.

There are also several qualitative studies that guide current research on the teacher-related contextual factors of absenteeism. Reid (1983) conducted interviews with secondary students from 1977 to 1980 and established a baseline of factors at the teacher and school levels that aided more recent empirical efforts to establish quantifiable relationships. First, students who were frequently absent from school claimed to have little authoritative support within the schools when dealing with problems with school curriculum, peer relations, and personal issues affecting their ability to be in attendance. Specifically, when discussing problems that students had with their respective schools, teachers and schools were used interchangeably, highlighting the vital role of the student-teacher relationship as a contextual factor for school attendance. Marvul (2012) assessed the impacts of a small-scale intervention at a high school with 40 students. After conducting interviews with students, the author concluded that negative outlooks and relationships from teachers likely influenced students' decisions not to come to school. Additionally, other studies have qualitatively assessed that having strong teacher support and years of experience positively associates with better attendance patterns and a lower likelihood of dropping out of school (Blue & Cooke, 2004; Dalton et al., 2009; Hébert & Reis, 1999).

At the peer level, research suggests that secondary students may perceive the peer culture of their school as antagonistic. In the aforementioned study from De Wit et al. (2010), the authors found that students who perceived their peers as more hostile were less likely to attend school. Similarly, Gastic (2008) utilizes a sample of tenth graders from the Educational Longitudinal Study of 2002 to examine the impact of bullying on student attendance and finds that students who were victims of bullying were more likely to miss school. Conversely, support from peers in secondary schools has shown to positively associate with school attendance. Specifically, peer acceptance, or peers' willingness to engage with a student, is correlated with greater levels of academic readiness, engagement, positive school perceptions, and sense of belonging at school; this acceptance is negatively correlated with school avoidance and dropout (Adelabu, 2007; Espelage et al., 2013; Ladd et al., 1997; Royer et al., 2008; Vandell & Hembree, 1994). It is clear that even during secondary schooling, peers play a crucial role in supporting student attendance.

At the school level, Wagner et al., (2004) examined a sample of eighth to tenth grade student for trends related to absenteeism in Germany, and the authors conclude that the most significant correlation between school practices and absenteeism was grade retention. That is, students who were held back a grade during high school were more likely to be absent from school. Additional school contextual factors that tend to influence student attendance relate to school violence, school size, and overall school climate. Using nationally representative data from Israel, Astor et al. (2002) found that student-reported fear of attending school due to prevalent school violence related to higher rates of absenteeism for the student body. Brookmeyer et al. (2006) used data from the National Longitudinal Study of Adolescent Health to determine what school-level factors contributed to absenteeism from school. The authors find that large class and school sizes were inversely correlated to school attendance. The authors also used a scale for school climate to establish a relationship between the general school context for students and absenteeism. Unsurprisingly, the authors find a strong correlation between school climate and school attendance.

Given the clear consensus that school climate is related to absenteeism, the disciplinary policy and practices within a school certainly influence the overall climate. In fact, several studies have shown strong associations between more punitive disciplinary policies and absenteeism. For instance, Flannery et al. (2012) used data from 31 states in the U.S. to examine the role of out-of-school suspensions on the likelihood of truancy. The authors used survival analysis and hierarchical linear modeling techniques to conclude that consistent exposure to out-of-school suspensions was associated with higher rates of truancy among ninth grade students. It should be noted that this was the only statistically significant relationship found in the study- race, school percent minority, class sizes, urbanicity, student-teacher ratios, and all other controls become statistically irrelevant when including out-of-school suspensions.

Possible mechanisms of this relationship between disciplinary action and absenteeism have been posited by qualitative researchers. Namely, Torrens Armstrong et al. (2011) interviewed school staff and nurse personnel and found that these authority figures in the schools made qualitative distinctions between "sick absences." For students with lower locus of control, less demonstrated parental awareness and parental control and more victimization were designated as "school phobics" or "frequent fliers," and disciplinary actions were more frequently taken against these students. Other qualitative studies have similarly illustrated how perspectives of school staff on student discipline is harsher for certain groups of students, and these students tend to be more absent from school (Jonasson, 2011;

Strand & Cedersund, 2013). Unfortunately, when students are subjected to perceived unfair rates of disciplinary actions in schools, it is unsurprising that these students tend to view school as a hostile environment, and as a result, they do not attend (Elliott, 1999; Evans, 2000). This body of empirical work on school climate and school climate furthers the notion that the environment in which students receive their education is fundamental to their decisions of whether to attend school.

Strategies to Reduce Absenteeism

Although school absenteeism is certainly a cause for concern, research points to strategies that have been successful at improving students' attendance. These strategies, typically implemented by individual schools or districts, can work on the school, classroom, or family level. Below are examples of each that have proven effective in recent years.

School Level

Research has shown that schools can take measures to meaningfully improve student attendance. Effective interventions can be as simple as supplying a second meal within the school day. Kirksey and Gottfried (2021), examining administrative data from Colorado and Nevada schools, discovered that serving breakfast after the school day began reduced chronic absenteeism rates by 3% in elementary and middle school and 7% in high school.

Successful interventions are often broader-based. Balfanz and Byrnes (2018) researched a pilot program established in 2010 to improve attendance in 100 New York City schools and found that one aspect, the NYC Success Mentor Corps, was particularly effective at improving chronic absence rates among the participating students. These mentors came from existing school staff, partners like AmeriCorps, social work students, retirees, and twelfth-grade peer leaders. The success of this program relied on one-on-one communication with students struggling with attendance, including greeting them at school, calling home, regularly meeting with them individually or in small groups, diagnosing the causes of their absenteeism, connecting students and families to external resources if necessary, and celebrating when students achieve success in attendance or otherwise.

The authors of the above study were careful to point out that this mentoring program was part of a larger effort that included careful tracking of absenteeism, diagnosing reasons for poor attendance and making efforts to address them, relationship-building with students with low attendance and their families, reward and recognition of good attendance, and a commitment to continually assess and modify the program. Moreover, this program used existing school staff and resources and required only a modest financial investment.

Overall school quality, even in seemingly unrelated factors, plays a role in getting students to school more often. Studying 165 traditional and public charter schools in Detroit, Lenhoff and Pogodzinski (2018) determined that schools that scored higher on the 5Essentials surveys of organizational effectiveness had substantially lower chronic absenteeism rates. Specifically, the survey measures that most correlated with reduced chronic absenteeism were expectations for postsecondary education, safety, parent influence on decision-making in schools, parent involvement in school, teacher-parent trust, academic press, quality of student discussions, program coherence, teacher influence, teacher-principal trust, classroom disruptions, classroom rigor, reflective dialogue, school safety, socialization of new teachers, student responsibility, teacher safety, collective responsibility, school commitment, and teacher-teacher trust.

Classroom Level

There are also strategies at the individual classroom level that have helped improve student attendance. In addition to increasingly sophisticated data on teachers and students, access to period-level attendance data is revolutionizing how researchers analyze school absenteeism. For one thing, it is becoming clear that attendance at the middle and high school level often varies throughout the day. Half the time secondary students miss a given class, they attend other classes that same day (Whitney & Liu, 2017). These granular data also allow researchers to look at specific characteristics of teachers and students that predict attendance.

One factor that researchers increasingly look at is demographic representation. There is evidence that students are more likely to enjoy success in school – including attendance – if they attend classes with teachers that look like them. Gottfried et al. (2021), studying administrative data from a high school district in California, found that students were 10% less likely to miss a class taught by a teacher of the same race as them. This effect was most profound for Latinx students. Holt and Gershenson (2019) looked at administrative data from students in Kindergarten through grade 5 in North Carolina and found that students with other race teachers were 4% more likely to be absent and 6% more likely to have an unexcused absence from that class.

Teachers can have other characteristics that improve their students' attendance. Studying 11 years of longitudinal administrative data from a medium-sized urban school district in California, Liu and Loeb (2019) determined that, much like value-added to student academic achievement, teachers can have a similar effect on attendance. The most successful teachers in this regard engage students in class content and motivate the students to achieve academically. Teachers' value-added to student attendance tends to remain consistent over multiple years and classrooms. The effect is more pronounced for students with previously high rates of absenteeism, chronic absenteeism, and dropout.

Researchers have studied peer factors as well. One such factor is the concept of "familiar faces," or peer consistency across multiple years. Kirksey and Gottfried (2018) explored this connection using four years of administrative data from a small urban district in California. In this instance, they estimated an elementary student who had 100% familiar faces from the previous year in their current year's classroom would have −1.08 fewer unexcused absences. Further, that student would be 73% less likely to be chronically absent.

Kirksey and Elefante (2021) conducted a similar analysis of high school data, where period-level attendance data allowed them to look at the association of absences and familiar faces in individual classes. In this study, an increase of 20% familiar faces in a course resulted in 0.84 percentage point decrease in a student's absence rate for that course. Substantially increasing the number of familiar faces in those classes is a workable intervention. For 26% of the students in this study, each classroom consisted of less than half familiar faces.

Family Level

Targeting attendance improvement efforts at families has also proved effective. Aware that families prioritize school attendance differently, Robinson et al. (2018) sent mailers to over 10,000 families of medium- and high-absence elementary students in California. Drawing on the expectancy-value model (Eccles & Wigfield, 2002), the authors assumed that families would value attendance more if they perceived it having a tangible benefit later in life. They sent six mailers home to students' families between November and May. The personalized mailers highlighted the value of attendance in early grades and detailed how many days the families' children had been absent. In addition, some mailers included an insert that encouraged families to communicate with "attendance supporters," which can be friends, family, or school or community members who can help parents with attendance issues. The students whose families received the mailers with the insert missed an average of −0.535 fewer days of school than those who did not. Further, those students' chronic absenteeism rate decreased by 15% (Robinson et al., 2018).

Aiming to reduce chronic absenteeism and improve attendance among kindergarteners in a Pittsburgh school, Smythe-Leistico and Page (2018) designed a program called Connect-Text, a two-way text-messaging system connecting the school and families. About once a week, the school sent preprogrammed, personalized messages to the students' families. The school created messages intended to increase awareness of the importance of attendance, address obstacles to attendance, and provide families with resources to help them improve their children's attendance. Individualized messages provided families with specific feedback on their children's attendance. Importantly, the tone of these messages was always positive.

The program proved successful. By the end of the year, the chronic absence rate at the targeted school declined to 13.3%, compared to 24.4% in a synthetic control group of other Pittsburgh public schools. Overall absence rates improved as well, with target school students missing 5.9% of school days, compared to 7.6% in the synthetic control group. The Spanish language messages were especially effective, reducing the absenteeism rate of students from Spanish-speaking families to that of non-Spanish-speaking families, which was not the case for the control group (Smythe-Leistico & Page, 2018).

Conclusion

This chapter brings the problem of excessive school absenteeism in the U.S. into stark relief. It also points the way forward by highlighting measures that have been successful in recent years at mitigating the problem of absenteeism. To be sure, future research on the causes of and, hopefully, solutions to excessive absenteeism will equip education stakeholders with even more tools to manage this growing crisis.

Executive Function in Children and Adolescents: A Concept in Need of Clarity

Gillian England-Mason and Deborah Dewey

Conceptualization of Executive Function During Childhood

In developmental psychology, "executive function" (EF) is an umbrella term used to refer to a broad range of cognitive processes that are required for the conscious control of actions, thoughts, and emotions. Although definitions of EF vary, there is a general consensus that the psychological construct of EF refers to higher-order cognitive processes that are coordinated by the prefrontal cortex (Best & Miller, 2010; Zelazo & Müller, 2010). The field of EF suffers from some terminological inconsistencies, as different terms are often used interchangeably to refer to the construct of EF (e.g., executive control, central executive, executive attention). These terminological inconsistences are further obscured by the conceptual overlap between EF and some other broad psychological constructs, such as self-regulation (i.e., a general term referring to the management and modulation of physiological, attentional, emotional, behavioural, cognitive, interpersonal, and social processes) and effortful control (i.e., the intentional management and modulation of thoughts, attention, emotions, and behaviour; particularly in emotionally salient contexts) (Müller & Kerns, 2015). To better appreciate the current conceptual and methodological strengths and challenges in the study of EF as they pertain to the practice of clinical child psychology, it is first helpful to understand its historical underpinnings.

Brief History

Converging evidence from primate research and clinical observations led to the current conception of EF as the controlled (or "non-routine") processing of mental processes by the prefrontal cortex. Perhaps the most well-known clinical vignette associated with EF is that of Phineas Gage, a railroad worker who was impaled by an iron bar and suffered severe damage to one of his frontal lobes, with documented resultant changes in personality and behaviour (Harlow, 1868). Although medical reports of other patients from the same era did not definitively link lesions in the frontal lobes to any personality changes (Welt, 1888), the difficulties with inhibition (e.g., impulsivity, loss of social responsibility) often found in individuals with damage to the prefrontal cortex prompted researchers to further investigate the role of the frontal lobes in cognitive processes. In the early twentieth century, primatology research noted that lesions in the frontal lobes were associated with memory deficits (Jacobsen, 1936). The concept of EF was not introduced until the 1970s, with seminal work describing the prefrontal cortex in primates as the "executive" of the brain (Pribram, 1973). In the following decades, there was an explosion of theoretical and empirical work, leading to a better understanding of the different components considered to be "executive functions", the neural architecture supporting EF, factors that bolster or hinder the development of EF, and the associations between impairments in EF and different clinical manifestations. It is noteworthy that these historical origins in neuropsychology and frontal lobe injury are likely contributors to the conflation between the term EF and the functions of the prefrontal cortex (Barkley, 2012).

Theoretical Considerations

The concept of EF has received increasing attention over the past four decades and is a cross-disciplinary construct investigated by various disciplines, including psychology, developmental science, neuroscience, and psychiatry. Across disciplines, development of EF is defined as progressive improvements in domain-general components (i.e., cognitive abilities that influence performance over a range of tasks and contexts such as working memory), which in turn are supported by development of the prefrontal cortex (Diamond, 2013; Miyake et al., 2000). However, it is important to acknowledge that there are several divergent ideas regarding the conceptualization and operationalization of EF that make this construct particularly challenging to define and measure. Herein, to provide a comprehensive review of the current state of knowledge on EF as it pertains to child clinical psychology, we discuss and synthesize the following: models of EF; development of EF from infancy through to adolescence; neural underpinnings of EF; the influence of genetics and the prenatal and postnatal environment on EF development; associated impairments in EF in children with neurodevelopmental, behavioural, and mental disorders; assessment of EF; clinical interventions to address EF deficits; and future directions for research that focus on the promotion of healthy development of EF from the prenatal period through to early adulthood.

Models of Executive Function

Executive function is commonly described as consisting of the following three core domain-general components: (i) working memory (also referred to as "updating"; updating and monitoring information), (ii) inhibitory control (also referred to as "inhibition"; inhibition of a prepotent response), and (iii) cognitive flexibility (also referred to as "shifting"; mental set-shifting) (Best & Miller, 2010; Miyake et al., 2000). These core components were delineated in seminal work by Miyake et al. (2000);

they examined the structure of EF using latent variable analysis, a statistical approach that uses multiple observed measures to infer a mathematical model of a latent variable, which is thought to tap into the underlying construct of EF. This work identified three separate factors that mapped onto distinct experimental tasks (i.e., "updating" on the Operation Span Task, "shifting" on the Wisconsin Card Sorting Test (WCST), and "inhibition" on the Tower of Hanoi) and a common underlying construct (Miyake et al., 2000). Thus, individual differences in EF assessed by simple laboratory tasks were recognized to demonstrate both "diversity" (i.e., separability of components) and "unity" (i.e., correlations between components indicative of a shared construct); reflect significant genetic heritability; relate to various clinically significant behaviours and diagnoses; and show developmental stability (Miyake & Friedman, 2012). At about the same time, the child development literature identified three analogous components of EF: "working memory" (updating), "inhibitory control" (inhibition), and "cognitive flexibility" (shifting) (Diamond, 2006). Although similar, this model did not hypothesize that these components contributed to a common underlying construct and instead hypothesized that these core components worked together to build "higher-order" EFs (e.g., reasoning, problem-solving, planning/organizing) (Diamond, 2006, 2013). Tri-component models that define working memory (updating), inhibitory control (inhibition), and cognitive flexibility (shifting), as the core components of EF are the most commonly examined models applied to research with preschool children, school-age children, adolescents, and adults. Further, there is moderate support in the research literature for the existence of these three separable components of EF, which appear to become more differentiated with age (Karr et al., 2018).

Despite the common acceptance of the tri-component view of EF, current conceptual and operational inconsistencies raise questions as to whether EF should be reduced to these three processes. For example, the tri-component view has been criticized due to reports that laboratory tasks of EF do not consistently correlate with self-regulation measures; the limited evidence that training targeting one or more of these components improves EF in non-targeted components; and limited research showing that performance on simple EF tasks correlates with other outcomes that are thought to be associated with EF (e.g., theory of mind) (Doebel, 2020). In addition, neuroimaging research has reported that performance on tasks of working memory, inhibitory control, and cognitive flexibility is associated with activation of shared frontal and parietal areas, but also unique frontal and/or posterior areas, supporting both the "unity" and "diversity" of these three components of EF (Collette et al., 2005). Further, the results of a systematic review, which analysed 106 studies published between 2008 and 2015, found 39 different components or processes described as EFs (Baggetta & Alexander, 2016). The authors noted that the most frequently examined component of EF was inhibitory control (68% of studies), followed by working memory (35% of studies), then cognitive flexibility (31%); other components such as "planning" (12% of studies) and "attention" (10%) were studied less frequently (Baggetta & Alexander, 2016). A brief, but not exhaustive, overview of additional components often identified as EFs includes: reasoning, problem-solving, planning/organizing, decision-making, emotional control, delay gratification, and verbal measures of EF (e.g., verbal fluency) (Diamond, 2013; Eslinger, 1996). Taken together, it appears that the tri-component view of EF that has greatly shaped the field warrants reconsideration.

In addition to the tri-component view of EF, other models are being investigated. One classifies EF into "hot" affective processes that are associated with the ventral medial prefrontal cortex (VM-PFC) and anterior cingulate cortex (ACC) and "cool" cognitive control processes associated with the dorsolateral prefrontal cortex (DL-PFC) (Zelazo et al., 1997, 2005). This model differentiates hot EF based on the emotionally and/or motivationally significant consequences (i.e., meaningful rewards or losses) of the problem or event. Hot EFs are required for problems or events that involve the regulation of basic functions of the limbic system (i.e., affect and motivation), including those related to the self and social understanding (Zelazo et al., 1997, 2005). Thus, hot tasks involve stimuli, decisions, and outcomes that are motivationally salient (e.g., delay gratification), compared to the cool aspects of EF, which involve more abstract, decontextualized problems or events (e.g., shifting between sorting rules on the WCST) (Zelazo & Carlson, 2012). The distinction between hot and cool EFs is developmentally meaningful, as there are relatively consistent correlations between performance on measures of cool EFs (e.g., working memory, cognitive flexibility) during childhood and adolescence, and this performance shows significant improvements with age. In contrast, for hot EFs (e.g., delay gratification, affective decision-making), the associations between measures are more complex, as these measures are not consistently correlated and age-related improvements are more gradual and occur at later ages (O'Toole et al., 2018; Prencipe et al., 2011).

Another model, the bidirectional model, is becoming increasingly used in the field of EF. It attempts to provide a more reciprocal account of the regulatory skills important for school readiness and other positive outcomes during childhood and throughout the lifespan. This model of EF describes how the parallel development of brain areas that underlie EF reciprocally interacts with those associated with the automatic aspects of self-regulation, such as executive attention, the regulation of emotion, and the stress response system (Blair & Ursache, 2011). Within this bidirectional model, the ACC plays a critical role. The ACC is associated with executive attention (i.e., which registers conflict between stimuli or between stimulus and response options). It sends signals to the prefrontal cortex to initiate activity in the dorsal and ventrolateral regions associated with EF, as well as linking limbic areas associated with emotional processing, which in turn can trigger a stress response and increase neuroendocrine activity in areas such as the hypothalamic-pituitary-adrenal (HPA) axis (Blair & Ursache, 2011). In brief, the processes of EF and self-regulation interact in an adaptive feedback loop in response to the environment and are highly influenced by experience. Further, in this model, EFs are thought to serve as a critical higher-level, or top-down, mechanism in regulating the automatic aspects of self-regulation (Blair & Ursache, 2011). Research, which has examined the development of the bidirectional processes of EF and self-regulation, suggests that children may be "early developers" (i.e., show high initial levels of self-regulation and earlier gains), "intermediate developers" (i.e., show low initial levels of self-regular on followed by rapid gains), or "late developers" (i.e., show low initial levels of self-regulation followed by slow gains), with this heterogeneity in developmental trajectories pinpointing a need for individualized intervention options (Montroy et al., 2016).

Development of Executive Function

In this section, we briefly review research on the development of EF beginning in infancy and then progress into toddlerhood, the preschool years, middle childhood, and through to late childhood and adolescence. Although a variety of biological, environmental, cultural, and lifestyle factors shape EF development across the life span (Wiebe & Karbach, 2017), herein, we focus on a few select factors that are particularly pertinent to each stage of development.

Infancy

The rudiments of EF begin to emerge in the first year of life. From birth, infants will preferentially attend to human faces over other visual stimuli (Farroni et al., 2002). Between 6 and 9 months of age, the cognitive capacities supporting attentional allocation develop to allow infants to participate in dyadic face-to-face social interactions and engage in joint attention (i.e., monitoring another person's focus of attention in order to coordinate one's own focus of attention toward the same external object or event) (Morales et al., 2005; Striano et al., 2006). Also, around 6 months of age, infants begin to demonstrate rudimentary response inhibition (e.g., an ability to not touch something), which is followed at 8 and 12 months of age by the ability to maintain focus on a task despite brief distractions and the emergence of detour reaching (i.e., reaching around physical barriers, which requires inhibiting the tendency to reach straight for a desired object) (Diamond, 1991, 2006). The antecedents of working memory first become evident around 7–9 months of age through capacities such as object permanence (i.e., the ability to understand and remember than unseen people and objects are still there), which is followed by the ability to perform simple means-to-ends tasks and two-step tasks around 9–10 months of age (Diamond, 1991, 2002). These burgeoning attention, inhibitory control, and working memory capacities also converge to support more complex abilities, such as the ability to hold in mind where a desired object has been hidden for progressively longer periods of time (e.g., as shown by reductions in the A-not-B error in infants from 5–6 months to 8–10 months) (Cuevas & Bell, 2010; Diamond, 1990b). The rudiments of cognitive flexibility tend to emerge latest in infancy, at around 9–11 months of age, and involve the ability to seek out alternative methods to retrieve objects that are not directly in view (Diamond, 1991). The emergence and development of these rudiments of EF rely primarily on the circuits and systems of the prefrontal cortex. Activity of pyramidal neurons and increased levels of dopamine in the DL-PFC are thought to be particularly important for supporting these cognitive advances during the latter part of the first year of life (Diamond, 2006).

Toddlerhood

During toddlerhood, the rudimentary aspects of EF continue to develop and become more complex; however, limited research has examined EF development in toddlerhood compared to pre-verbal infants and preschool children. There is wide variability in EF abilities among toddlers, which could be due to variable and rapid rates of development in language skills and vocabulary knowledge, which have been associated with a EF (Schonberg et al., 2018). During the second year of life, an important advancement in the development of EF is an improvement in understanding the physical connections between objects and abstract rules (Diamond, 2006). Around 20–21 months of age, toddlers acquire recognition memory and a basic understanding of abstract rules (e.g., success on the Delayed Non-Matching to Sample task requires a toddler to displace a novel stimulus to retrieve a reward) (Diamond, 1990a). Then, beginning as early as 2 years of age, young children may also begin to shift their actions according to changing rules (e.g., put on shoes for dry weather and boots for rain) (Best & Miller, 2010; Diamond, 2006). The third year of life is an important time for the development of symbolic representations, including language and symbolic play, which is paralleled by developments in the social cognition correlates of EF (e.g., rudiments of theory of mind and moral reasoning) (Diamond, 2006; Panesi & Morra, 2021). Although there are a multitude of factors (e.g., genetics, risk factors such as socioeconomic disadvantage, child temperament) that strongly predict EF development in these few first years of life (Leve et al., 2013; Raver & Blair, 2020), positive and warm caregiving characterized by high levels of support and secure caregiver-child attachment are significant drivers of healthy EF development (Blair, 2016). The child-directed and reciprocal nature of early interactions is important for long-term EF development, and factors that diminish the quality of these early interactions, such as the interference caused by the use of technology (e.g., cell phones) by caregivers and increased screen time in toddlers, predict poorer EF development later in childhood (Anderson et al., 2017; McHarg et al., 2020).

The Preschool Years

The preschool years are one of the most well-studied eras of EF development and represent a pivotal period when core components and processes first become evident. However, this is also the time when difficulties with EF may start to appear. Working memory is one of the earliest EF components to emerge. Preschool children's working memory abilities progress from being able to hold in mind two rules and act based on those rules (e.g., correctly sorting a card with a red rabbit based on colour during the Dimensional Change Card Sort (DCCS)) at around 3 years of age (Zelazo, 2006) to being able to hold previously known information in mind and construct new concepts in order to develop their understanding of representational change and false beliefs (e.g., a sponge that is painted to look like a rock is actually a sponge) by between 4 and 5 years of age (Gopnik & Astington, 1988; Tomasello, 2018). Preschool children's planning abilities also become more complex and flexible with age. Children generally progress from having rudimentary planning abilities (e.g., motor sequencing) at around 3–4 years of age (Carlson et al., 2004) to more complex abilities such as thinking ahead about the future consequences of an initial action (e.g., correct responses on Tower tasks and Route-Planning tasks) at around 4–6 years of age (McCormack & Atance, 2011).

Between the ages of 3 and 5 years, there are dramatic improvements in inhibitory control and cognitive flexibility, especially the abilities needed to regulate impulsivity and to flexibly change perspectives (Diamond, 2006). Children's capacity for inhibitory control typically becomes apparent between 3 and 4 years of age; their ability to inhibit their physical impulses is denoted by significant improvements in accuracy (i.e., being able to inhibit imitating an action) on Luria's Tapping Test (Luria, 1966) and the Hand Game (Hughes, 1998), which usually occur between 3½–4 years of age. At 4–5 years, children can demonstrate inhibitory control in verbal contexts (e.g., say "night" for the sun card and "day" for the moon card on the Day/Night Stroop) (Carlson, 2005) and delay gratification in order to resist temptation and obtain a larger reward following a temporal delay (e.g., delay eating one marshmallow in order to get two marshmallows after 5 min) (Mischel et al., 1989). By 5 years, children display fewer perseveration errors (i.e., they do not persist with the same response strategy after the rule has changed) and can follow an arbitrary rule to produce a response that differs from the natural, prepotent response (e.g., sort coloured cards by shape rather than by colour) (Best & Miller, 2010). Also, during the later preschool years, cognitive flexibility develops and children are able to shift their behaviour according to context (e.g., they take off shoes at home but leave them on at school) and switch back and forth between rules (e.g., switch between sorting by colour and sorting by shape on the DCCS) (Diamond, 2006; Zelazo, 2006). Given that cognitive flexibility has been theorized to draw on other EFs such as working memory efficiency and inhibitory control, children's cognitive flexibility performance depends on the task type (i.e., inductive word-learning tasks such as the Flexible Induction of Meaning test versus rule-switching tasks such as the DCCS) and the "task impurity problem" (i.e., many tasks of cognitive flexibility also assess verbal inhibition, response speed, and/or abstract reasoning); thus, cognitive flexibility can demonstrate significant intra individual variability and tends to develop later in the preschool years (Deák & Wiseheart, 2015; Diamond, 2006).

These marked improvements in the core components of EF (i.e., working memory, inhibitory control, cognitive flexibility) during the preschool years are also predictive of social cognition, such as theory of mind (i.e., understanding of one's own and other people's mental representations) and moral development (Diamond, 2006; Perner & Lang, 2000). For example, EF abilities at 3 and 4 years of age are strongly correlated with theory of mind, over and above the influence of language ability and sex, suggesting that the relation between EF and theory of mind increases during the preschool period (Müller et al., 2012). Similarly, preschool children's EF and theory of mind capacities are significantly associated with their moral reasoning abilities, and thus EFs are thought to be foundational for mental representation (Baker et al., 2021).

During the preschool years, environmental factors remain strong predictors of children's skills. Predictors of improved EF development include positive parenting behaviours and styles (e.g., sensitivity, responsiveness, autonomy support) and socioeconomic advantage (e.g., parents attended college/university, middle class or higher); while predictors of EF difficulties include adverse home environments (e.g., maltreatment), caregiver mental health symptoms (e.g., depression, anxiety), and socioeconomic disadvantage (e.g., poverty, housing instability) (Ackerman & Friedman-Krauss, 2017; Raver & Blair, 2020). A variety of prenatal factors, such as preterm birth and extremely low birthweight, and health conditions such as fetal alcohol spectrum disorder (FASD), are also significantly associated with poorer EF in preschool children (Ackerman & Friedman-Krauss, 2017). A current focus of the field of EF is applying this knowledge about risk and protective factors within community contexts, particularly in the early years, and in preschool programs, to create community-embedded solutions to racial and economic inequalities in order to support children's long-term neurocognitive health, emotional well-being, and academic success (Raver & Blair, 2020).

Middle Childhood

There are some notable improvements in EFs during middle childhood. Beginning in middle childhood, there are significant age-related improvements in working memory, inhibitory control, and cognitive flexibility (Diamond, 2006). For example, around 6–7 years of age, children start to perform at adult levels on learning to ignore irrelevant information (i.e., can inhibit their strong tendency to look toward the target during anti-saccade tasks and are able to look in the opposite direction) and this performance continues to improve over the next few years (Best & Miller, 2010; Diamond, 2006). Unlike the preschool period where the components and processes of EF emerged and research has focused on pinpointing developments at particular ages, during middle childhood there are incremental improvements in EF abilities and the specific improvements and associated ages are sensitive to task difficulty and demands (McCormack & Atance, 2011).

While parents and other caregivers are children's primary social partners during the first 5 or 6 years of life, middle childhood marks the period when peers begin to take centre stage and become a significant influence on EF development. Children begin to form larger social groups and face the need to manage their place in peer hierarchies, form stable friendships, and organize their behaviour according to shared rules (e.g., cooperation, competition) (National Research Council (US) Panel to Review the Status of Basic Research on School-Age Children, 1984). Thus, middle childhood is a critical phase for the development of social cognition and the "hot" aspects of EF, including emotional control and regulation. Specifically, children's improvements in EFs during middle childhood are associated with increases in understanding complex mental states and higher-order theory of mind abilities, such as second-order false beliefs (e.g., the ability to understand another person's thinking about a third person's perspective) (Bock et al., 2015). These improvements in social cognition are also paralleled by advancements in emotional control (i.e., a child's ability to modulate their emotional responses), and children acquire a greater variety of self-initiated strategies to manage their emotions. They rely less on caregivers for external support; are able to accomplish increasingly complex social and personal goals; and can start to adapt their emotional responses to be contextually and culturally appropriate (Thompson et al., 2008).

Late Childhood and Adolescence

There continue to be age-related improvements in EF processes across late childhood and into adolescence, many of which do not reach peak performance until late adolescence or early adulthood (Diamond, 2006). Children's inhibitory control capacity develops to enable them to flexibly switch between a central focus and peripheral stimuli (e.g., focus on riding a bike or driving and attending as needed to road signs and pedestrians) later in childhood and during adolescence; it reaches its pinnacle in adulthood, which enables individuals to consistently respond in a situationally appropriate manner (Best & Miller, 2010; Diamond, 2002). Adolescents continue to improve on assessments of cognitive flexibility and demonstrate increases in accuracy in switching between different foci and adapting to changing rules (e.g., decreased errors on the WCST), until these abilities reach maturity in adulthood, resulting in individuals being able to revise their actions and plans in response to quickly changing demands and circumstances (Best & Miller, 2010; Diamond, 2006). During adolescence, there are also marked improvements in higher-order EFs, such as problem-solving. These improvements are linked to the maturation of the prefrontal cortex and changes in the reward circuitry of the brain, such as the limbic system (Blair, 2017). Adolescence is also characterized by other cognitive and behavioural changes, such as increases in autonomy and risk-taking behaviours (Nelson et al., 1999), and pubertal maturation which contributes to sex differences in the organization and function of the brain and EFs (Nguyen et al., 2017). Both male and female adolescents also demonstrate significant improvements in the motivational and affective aspects of EF (i.e., "hot" EFs). Specifically, adolescence is characterized by improvements in affective decision-making (i.e., the ability to make informed choices under conditions of uncertainty) and abstract reasoning (i.e., the ability to think about and understand complex concepts that are not tied to concrete experiences) (Best & Miller, 2010; van Duijvenvoorde et al., 2010). Longitudinal analyses using a prototypical "hot" EF task, the Iowa Gambling Task, show that affective decision-making abilities aren't strengthened until later in the teenage years (i.e., 16–18) (Almy et al., 2018; Smithers et al., 2012). During late childhood and adolescence, all the previously mentioned factors (e.g., genetics, parenting, preterm birth) continue to predict pathways of EF development, with the child and family risk factors (e.g., socioeconomic disadvantage, caregiver mental health) that were present in early childhood also playing a significant role in determining EF performance at this time (Berthelsen et al., 2017).

Neural Basis of Executive Function

Executive function development has been closely linked to brain development. The frontal lobes and prefrontal cortex have typically been associated with EF; however, recent imaging studies suggest that posterior brain regions, including the temporal, parietal, and cerebellar regions, are also involved. The emerging view is that EFs demand large-scale brain networks and that the different components of EF – working memory, inhibitory control, and cognitive flexibility – are associated with partially separable and partially overlapping processes at the neural level. This is consistent with the integrative model proposed by Miyake and collaborators (Miyake et al., 2000).

Much of the neuroimaging research has focused on the prefrontal cortex (PFC), which consists of approximately two-thirds of the frontal cortex and is divided into three principal frontal-subcortical circuits: (i) the dorsolateral PFC (DL-PFC), (ii) ventromedial PFC (VM-PFC), and (iii) orbitofrontal PFC (OF-PFC). Functional and structural neuroimaging research implicates these three circuits with EF processes (Alvarez & Emory, 2006). The DL-PFC projects primarily to the dorsolateral head of the caudate nucleus and has been associated with a variety of EFs, including working memory, inhibitory control, cognitive flexibility, planning/organizational skills, and problem-solving (Alvarez & Emory, 2006; Moriguchi & Hiraki, 2013). Functional connectivity of the DL-PFC has also been examined and implicated in these EFs (Panikratova et al., 2020). However, the roles of the other two frontal-subcortical circuits, the VM-PFC and OF-PFC, in EF have received less attention, perhaps due to their overlapping contributions to lesser examined social-emotional components of EF, such as emotional control. The VM-PFC begins in the anterior cingulate and projects to the nucleus accumbens and has been associated with social-emotional aspects of EF, such as motivation and empathy (Nejati et al., 2021; Robinson et al., 2014). The OF-PFC projects to the ventromedial caudate nucleus and has been linked to inhibitory control, attentional control, and emotional processing (Bryden & Roesch, 2015; Kuusinen et al., 2018). Although these three circuits may be associated with specific EFs, they are interconnected, and together they support the various components of EF.

With respect to the tri-component view of EF (Diamond, 2006; Miyake et al., 2000), evidence from lesion studies, neurochemical research, and functional neuroimaging provides support for both the "unity" and "diversity" of the three core EF components in adults (Friedman & Robbins, 2021). Emerging evidence also supports the unity and diversity of the neural substrates of these components in children and adolescents (Fiske & Holmboe, 2019; McKenna et al., 2017). Functional neuroimaging studies have reported that laboratory tasks that assess working memory activate areas in the DL-PFC, ACC, and the superior and posterior parietal cortex (Collette et al., 2005; Marklund et al., 2007). Tasks that assess cognitive flexibility have been shown to activate the right interparietal sulcus, right supramarginal gyrus, left precuneus, left superior parietal cortex, and left middle and inferior frontal gyri (Collette et al., 2005). Finally, tasks that assess inhibitory control have been shown to activate areas such as the right inferior frontal gyrus, right orbitofrontal gyrus, and the right middle and superior frontal gyri (Banich & Depue, 2015; Collette et al., 2005). The common networks implicated in all three core components of EF are the right intraparietal sulcus, the left superior parietal gyrus, and the lateral PFC.

Attention is an important component of EF and the brain networks involved in alerting, orienting, and executive attention overlap those associated with EF. The alerting network deals with the aspect of attention related to how an individual achieves and maintains an alert state and involves input from the norepinephrine system, primarily the locus coeruleus, which modulates frontal and parietal structures (Rosario Rueda et al., 2015). The orienting network deals with selective mechanisms operating on sensory input and has been shown to involve the frontal eye fields, the inferior frontal cortex, and areas of the superior and inferior parietal lobe (Rosario Rueda et al., 2015; Vossel et al., 2016). It has been associated with two separate brain networks, one involved in focusing attention voluntarily using top-down mechanisms (i.e., the dorsal attention system) and a second that reorients attention to task demands (i.e., the ventral attention system) (Corbetta et al., 2008; Corbetta & Shulman, 2002). Finally, the executive network, which is involved in the regulation of thoughts, feelings, and behaviour, has been shown to involve the anterior cingulate and anterior insula (operculum) (Posner et al., 2014; Rosario Rueda et al., 2015). These networks are present from infancy and develop through childhood, and although their anatomies are distinct, they interact to influence attention performance and potentially EF (Mullane et al., 2016; Xuan et al., 2016).

Some researchers have suggested that sex and/or gender differences do not play an important role in determining developmental trajectories of EF (Grissom & Reyes, 2019a, b). However, evidence from a recent systematic review showed that there are significant sex differences in the neural networks underlying performance on laboratory tasks associated with working memory, inhibitory control, and cognitive flexibility (Gaillard et al., 2021). It is important to note that there may be more within-sex variability than between-sex variability in EF, which may speak to the importance of experience and contextual factors in shaping EF development (Grissom & Reyes, 2019a, b). Research that considers how sex and/or gender differences contribute to structure and function in brain regions associated with EF, as well as the influence of hormones at different ages (e.g., pre-puberty, puberty, menstrual cycle phase) on the neural correlates of EF during childhood and adolescence is needed. Overall, gaining a better understanding of the neural underpinnings of EF, as well as between and within-sex differences, may suggest potential avenues for intervention that could result in improved cognitive, social, and psychological development, and physical and mental health outcomes in children and adolescents.

Genetic and Environmental Factors Associated with the Development of Executive Function

Genetics

In addition to neural mechanisms, genetic and environmental factors have also been associated with the development of EF. Twin studies have been used to estimate the extent to which interindividual variation in EF is influenced by genetic (i.e., heritability), shared environmental (e.g., family environment, maternal nutrition during pregnancy), and nonshared environmental influences (e.g., different educational experiences). Behavioural genetic studies that investigated EF in monozygotic twins (MZ), who share all their genes, compared to dizygotic twins (DZ), who share on average half their genes, who have shared familial environments suggest a strong genetic component. The findings of a twin study conducted with a sample of young adults revealed that individual differences in EFs were almost entirely genetic (99%) and were due to a general genetic EF factor that operated across all three components (i.e., updating (working memory), inhibiting (inhibitory control), shifting (cognitive flexibility)), although some genetic influences were specific to individual components (i.e., updating, shifting) (Friedman et al., 2008). Similar findings were reported by Engelhardt et al. (2015) in a sample of twins aged 7.89 to 15.25 years. These studies support the existence of a general EF factor that is highly heritable.

To date, genome-wide association studies have had little success in identifying the genetic correlates of EF. Very little variance in EF task performance has been accounted for with measured genotypes that reach genome-wide significance. In fact, the largest genome-wide association study of EF tasks (data were available for between 5,429 and 13,454 participants based on the task) yielded no genome-wide significant hits for any EF measure (Ibrahim-Verbaas et al., 2016). As genetic variation in behavioural traits such as EF likely reflects highly polygenic effects, with each effect accounting for only a small fraction of the overall variance (Davies et al., 2011), very large genome-wide association studies will be required to identify genetic variants associated with performance on EF tasks.

It has been suggested that childhood EF could be considered a developmental endophenotype (i.e., neurobiological phenotype that is conceptualized as an expression of genetic liability for a clinical disorder) for various outcomes that have a genetic basis, including cognitive, behavioural, and mental and physical health outcomes (Engelhardt et al., 2015). The consideration of EF as a developmental endophenotype may be particularly informative for children with certain clinical disorders, such as Attention-Deficit/Hyperactivity Disorder (ADHD) and Autism Spectrum Disorder (ASD), as this may present new opportunities to better understand heterogeneity in EF deficits (e.g., profile ASD subtypes) and for targeted assessments and interventions (Demetriou et al., 2019; Doyle et al., 2005). In a broader sense, it is also possible that performance on measures of EF could be used to identify children who are at risk for poorer psychological, social, and health outcomes. These "at-risk" children could be targeted to receive early intervention.

Environment

Although behavioural genetic studies support a strong link between a general EF factor and genetic variation, environmental factors (i.e., nonshared environment) could also play an important role in influencing EF development (Friedman et al., 2016). A significant body of work has examined associations between environmental factors and EF development, including socioeconomic status (SES), maternal mental health, maternal–child interactions, maternal and child nutrition, and exposure to environmental chemicals, to name just a few.

Socioeconomic Status

Socioeconomic status (SES) is one of the primary determinants of health (https://www.who.int/health-topics/social-determinants-of-health#tab=tab_1) and lower SES (e.g., lower maternal education, lower household income) has been associated with worse EF, even in the early preschool years (Hackman et al., 2015; Last et al., 2018; St. John et al., 2019; Ursache et al., 2012; Wiebe et al., 2011). Further, the effects of early SES on EF development have been found to remain consistent through middle childhood and into early adulthood (Friedman et al., 2016; Last et al., 2018; St. John et al., 2019), suggesting that the relationships between early indicators of SES and EF remain stable over time and display limited variability with age. These findings suggest that associated SES disparities in early childhood are not likely to resolve as the individual matures. However, later changes in family SES have been associated with changes in children's EFs. For example, Hackman et al. (2015) reported that later decreases in family income-to-needs, relative to early childhood, were associated with significant decreases in planning ability and trend-level effects for working memory. Such findings suggest that despite the high level of heritability and stability of EFs, they are not immutable to environmental factors such as SES.

Maternal Depression and Anxiety

Maternal depression and anxiety during the perinatal period and childhood have been associated with poorer EF outcomes in children; however, finding have been mixed (Buss et al., 2011; Gueron-Sela et al., 2018; Jensen et al., 2014; Park et al., 2018; Power et al., 2021; Ross et al., 2020). A recent menta-analysis reported a small, but significant, association between maternal depression during the perinatal period and child EF (effect size $r = 0.07$; 95% CI 0.03–0.10); equivalent to Cohen's $d = 0.14$. (Power et al., 2021). It is notable that no differences in EF outcomes in children were found between prenatal and postnatal exposure to maternal depression. The authors suggest that this absence of an effect could indicate either a "pervasive effect of maternal depression on offspring EF development or the importance of an unmeasured third factor (such as genetic substrates) that underlie pre- and postnatal depression" (Power et al., 2021, p. 231). It is important to note that women who experience perinatal depression are at higher risk of developing recurrent long-term mood disorders such as unipolar and bipolar depression (Dipietro et al., 2008; McMahon et al., 2005; Meltzer-Brody & Stuebe, 2014), so the effects of perinatal depression on children's EF development may be compounded by long-term maternal mood disruption.

Research that examined the influence of maternal anxiety on children's EF reported that maternal pregnancy-specific anxiety was associated with poorer EF in children 6–9 years of age, specifically lower inhibitory control in girls only, and lower visuospatial working memory performance in boys and girls (Buss et al., 2011). Further, maternal pregnancy-specific anxiety was a stronger predictor of EF in children than trait anxiety or depression. In contrast, Ross et al. (2020) did not find an association between prenatal or postnatal anxiety and children's EF at 2 years of age; however, this study measured general anxiety symptoms in mothers, not pregnancy-specific anxiety. Further, it is possible that an association between maternal anxiety and children's EF may not be evident by 2 years of age, and that this association may only become apparent later in childhood as EF processes emerge and develop.

It is also possible that the chronicity of exposure to maternal anxiety and/or depression both prenatally and postnatally may be a factor in EF development, with children who are exposed more frequently and to longer bouts displaying poorer EF. Finally, severe maternal anxiety and/or depression experienced proximal to the time a child assessed could affect EF performance and is something that needs to be considered in future research (Power et al., 2021).

Parent–Child Interactions

Parent–child interactions can be influenced by many factors, including maternal depression and anxiety, and the quality of these interactions could affect the development of EFs in children. Carlson (2003) proposed that three dimensions of parenting are involved in the development of EFs in children: maternal sensitivity, autonomy support or scaffolding, and mind-mindedness. Sensitivity refers to appropriate and consistent responses to infants' signals, whereas autonomy support/scaffolding involves actively supporting children's volition and offering them age-appropriate problem-solving strategies. Mind-mindedness refers to the parent's tendency to use mental terms while talking to the child. Bernier et al. (2010) investigated the associations between quality of parent-infant interactions, as assessed by these three dimensions of parenting, at 12–15 months of age and subsequent child working memory, impulse control, and cognitive flexibility at 18–26 months. All parenting dimensions were associated with EF outcomes, and parental autonomy support/scaffolding was the strongest predictor of children's EFs. These positive parenting behaviours were also associated with better EF performance at 3 years of age, with effects remaining even after controlling for 2-year EF (Bernier et al., 2012). Likewise, Kraybill and Bell (2013) found that maternal positive affect at 10 months of age was related to child EF at 4 and 6 years of age. Cuevas et al. (2014) reported that negative caregiving behaviours were associated with worse child EF as well as poorer maternal EF. Together, these studies provide strong support for the beneficial effects of positive caregiving behaviours on children's EF development.

Nutrition

Maternal nutrition during pregnancy and child nutrition in the early years are important contributors to children's EF development. The fetal brain is highly vulnerable to nutritional alterations in pregnancy, as specific nutrients (i.e., folate, choline, iron, vitamin D, and long chain fatty acids) and other food components (e.g., fibre, fat, and proteins) play a critical role in programming its development and in turn consequent cognitive processes (Kominiarek & Rajan, 2016). Numerous studies have reported a positive association between cognitive functions in children and maternal intake of micro- and macro-nutrients (e.g., vitamin A, vitamin B, folate, choline, iron, iodine, omega-3 fatty acids, protein) and associated foods (e.g., fish) (Arija & Canals, 2021; Bath et al., 2013; Campoy et al., 2020; Chen et al., 2021; Cusick & Georgieff, 2016; Derbyshire & Obeid, 2020; McCann et al., 2020; Nyaradi et al., 2013; Voltas et al., 2020; Wozniak et al., 2020). To date, no studies have specifically examined the association between combinations of maternal nutrients and child EF, and only two studies have investigated the associations between dietary patterns and EF (Mahmassani et al., 2022; Mortaji et al., 2021). Mahmassani et al. (2022) reported that a higher Mediterranean diet score, indicative of a healthier dietary pattern, during pregnancy, was associated with fewer metacognitive problems in middle childhood (i.e., 6.6–9.7 years), and a higher score on the Alternative Healthy Eating Index during pregnancy was associated with better overall EF in children. Mortaji et al. (2021) reported that maternal pregnancy diet quality moderated the association between the postnatal caregiving environment and children's EF at 3–4 years. To advance our understanding of the relationships between maternal nutrition and diet and children's EF development, research that investigates the combined effects of vitamins (e.g., B6, D), essential nutrients (e.g., folate, choline, DHA), minerals (e.g., iron, zinc), specific diets (e.g., Mediterranean diet), and other lifestyle factors (e.g., exercise, obesity) during pregnancy on children's health and neurodevelopment is needed (England-Mason & Dewey, 2021).

The effects of *child nutrition* on cognitive development are well established. Numerous studies have reported positive associations between intake or status of various nutrients, children's diet quality, and cognitive outcomes (Dror & Allen, 2008; Gordon et al., 2009; Grantham-McGregor & Ani, 2001; Haapala et al., 2015; Kvestad et al., 2017; Leventakou et al., 2016; Louwman et al., 2000;

Smithers et al., 2012). A recent systematic review highlighted the role of specific nutrients, including iron, polyunsaturated fatty acids, zinc, iodine, vitamin B12, and folate, in brain development and the development of EFs in children (Costello et al., 2021). It is notable that the majority of cross-sectional studies report positive associations between the status of various nutrients measured in blood and children's performance on EF tasks in both high- and low- and middle-income countries (Adjepong et al., 2018; Algarín et al., 2013; Jumbe et al., 2016; Louwman et al., 2000; Sheppard & Cheatham, 2017). Randomized controlled trails that have investigated the effects of multiple micronutrient supplementation/fortification interventions on EFs have demonstrated an overall positive effect on working memory (Petrova et al., 2019), attention and concentration (Vazir et al., 2006), and cognitive learning strategies (Wang et al., 2017). In contrast, other randomized controlled supplementation trials have not found significant effects (Aboud et al., 2017; Kennedy et al., 2009; Montgomery et al., 2018; Ryan & Nelson, 2008). Further, the evidence from single nutrient randomized controlled trials is mixed, with some reporting that improvements in EFs are associated with supplementation for iron (Scott et al., 2018), omega-3 fatty acids (Portillo-Reyes et al., 2014), iodine (Gordon et al., 2009; van den Briel et al., 2000; Zimmermann et al., 2006), and zinc (Sandstead et al., 1998; Tupe & Chiplonkar, 2009). These inconsistencies could be due to the populations investigated (e.g., deficient versus not deficient), the levels of supplementation provided, the complex interaction among nutrients, and the measures used to assess children's EF; therefore, future research is warranted.

Neurotoxicant

Neurotoxicant exposures *in utero* and in early childhood have been associated with poorer cognitive outcomes in children, including poorer EFs (Grandjean & Landrigan, 2014; Lanphear et al., 2005). Lead, mercury, and arsenic are neurotoxic metallic or metalloid elements that are ubiquitous in the environment (Agency for Toxic Substances and Disease Registry (ATSDR), 2022); and for lead, there is no known safe level of exposure (Centers for Disease Control (CDC), 2022). Studies that have investigated associations between childhood lead exposure and children's performance on EF tasks of working memory, inhibitory control, cognitive flexibility, and planning have reported adverse association at levels as low as 3 μg/dL (Chiodo, 2004; Froehlich et al., 2007; Kordas et al., 2006; Lanphear et al., 2005; Stewart et al., 2006; Surkan et al., 2007). Limited research has examined the associations between prenatal lead exposure and EF; however, a recent study reported that in a cohort with lead levels commonly experienced by U.S. women, there were few statistically significant associations with parent reports of child EF; trends were noted between higher prenatal exposure, and poorer planning/organization and shifting based on parent's responses on the Behaviour Rating Inventory of Executive Function (BRIEF) (Fruh et al., 2019).

Mercury can be found in the air, soil, and water and exists in three forms that have different properties, usage, and toxicity: elemental, inorganic, and organic (i.e., methylmercury, MeHg). The neurotoxic effects of acute and chronic exposure to high concentrations of mercury are well documented by Harada (1995). Little is known about the neurodevelopmental effects of prenatal exposure to inorganic and elemental mercury from workplace and environmental activities such as mining or smelting; however, a recent study suggests that they may be negative (Nyanza et al., 2021). The findings of studies that have investigated the neurodevelopmental effects of *prenatal* exposure to MeHg via maternal diet have been mixed (Barbone et al., 2019; Boucher et al., 2014; van Wijngaarden et al., 2017). Some have reported that prenatal MeHg exposure from fish consumption during pregnancy was not associated with EF outcomes (van Wijngaarden et al., 2017), whereas others conducted in the Faroe Islands, New Zealand, and the USA reported adverse associations between MeHg exposure levels and EF outcomes (Crump et al., 1998; Debes et al., 2016; Oken et al., 2005). Boucher et al. (2014) in a study of an Inuit population in Canada found that prenatal MeHg exposure was associated with poorer performance at 6.5–11 months of age on the A-not-B task, which is believed to be a precursor of EFs (e.g., working memory, inhibitory control) in infants. Research that has examined the effect of *child* exposure to MeHg has also reported inconsistent findings. In a recent study conducted in Brazil, higher childhood exposure levels, measured in hair, were associated with lower performance on measures of visual and verbal working memory and verbal fluency (Santos-Lima et al., 2020). In contrast, Cao et al. (2010) examined the associations between postnatal MeHg exposure, after adjusting for lead levels in toddlers enrolled in the Treatment of Lead (Pb)-exposed Children clinical trial (TLC) and found very few and largely inconsistent associations between blood MeHg concentrations and children's performance on tests of EF. The inconsistencies in the research literature could be due to variability in the measures used to assess EF and the ages at which EFs were assessed. In addition, exposure to mixtures of neurotoxicants and nutrients, and differences in the distributions of genes in different study populations that influence the metabolism of MeHg and nutrients could influence the associations between mercury exposure and EF outcomes (Julvez et al., 2013; Nyanza et al., 2021; Strain et al., 2015; Yeates et al., 2015).

Arsenic, a metalloid that can be found in rocks, air, water, and soil, can have adverse effects on physical and cognitive health. Prenatal and childhood exposure to arsenic from drinking water, even at low concentrations, has been associated with deficits in intelligence in children (Tolins et al., 2014); however, research examining the association between arsenic exposure and EF is limited. In a population birth cohort study from Catalonia, Spain, no association was noted between prenatal exposure to arsenic and child EF at 4 years of age (Forns et al., 2014). However, a study that examined childhood exposure reported negative associations. Specifically, childhood exposure to arsenic >5 μg/L compared to <5 μg/L from well water was associated with reductions of 6.09 points in Full Scale IQ and 4.88 point in working memory (Wasserman et al., 2014). Further, a recent study by Desai et al. (2020) found that in 7-year-old children from Montevideo, Uruguay, exposed to low levels of arsenic, higher exposure was associated with worse performance on measures of rule learning and reversal, visual attention, and working memory, but the effect sizes were small. Future longitudinal studies are needed to clarify the differential effects of prenatal and childhood exposure to arsenic on children's EF outcomes.

The influence of prenatal and childhood exposure to other chemicals including bisphenols, phthalates, perfluorinated compounds, polychlorinated biphenyls, and organophosphates on children's EF is an expanding area of research (Braun et al., 2011; Choi et al., 2021; England-Mason et al., 2021; Jacobson & Jacobson, 2003; Sagiv et al., 2021; Stein et al., 2014; Vuong et al., 2016). Although findings are mixed, studies to date suggest that prenatal and childhood exposure to these chemicals could be associated with poorer EF in children and that some of these associations are sex-specific (England-Mason et al., 2021). These adverse effects on EF could also contribute to additional neurodevelopmental, behaviour, and mental dysfunctions in children and adolescents.

Executive Function and Neurodevelopmental, Behavioural, and Mental Health Disorders in Children

Executive function is often impaired in children with neurodevelopmental, behavioural, and mental health disorders, including Autism Spectrum Disorder (ASD), Intellectual Disability, Attention-Deficit/Hyperactivity Disorder (ADHD), Specific Learning Disabilities (SLD) including reading and math disorder, Developmental Coordination Disorder (DCD), and Fetal Alcohol Spectrum Disorder (FASD), as well as pediatric depression and anxiety (Demetriou et al., 2018; Kingdon et al., 2016; Lifshitz et al., 2016; Lonergan et al., 2019; Murphy et al., 2018; van den Berg et al., 2021; Weber et al., 2018; Wilson et al., 2013; Yaniv et al., 2018). These complex conditions have been linked to disruptions in brain maturation and share an early onset (before puberty) of deficits in personal, social, and academic functioning (American Psychiatric Association, 2013) and have been associated with future mental health (Eyre et al., 2019).

Although children with these various disorders and mental health conditions display impairments in EF, the patterns of difficulties appear to vary by disorder. Among individuals with ASD, specific difficulties in working memory, cognitive flexibility, and planning have been reported (Margari et al., 2016; Otterman et al., 2019), although broader EF deficits across all domains have also been observed (Corbett et al., 2009; Demetriou et al., 2018; Hyseni et al., 2019). In contrast, in children with ADHD, EF difficulties have been noted in the areas of working memory, inhibitory control, vigilance, and planning (Corbett et al., 2009; Willcutt et al., 2005). A meta-analysis by Booth (2010) concluded that children with reading disability have difficulties in maintaining relevant information in working memory, inhibiting irrelevant information, and accessing material in long-term memory. More recent studies have reported that children with reading problems (i.e., developmental dyslexia) show deficits in several EF domains, including, verbal categorical and phonological fluency, visual-spatial and auditory attention, verbal and visual short-term memory, and verbal working memory (Barbosa et al., 2019; Varvara et al., 2014), suggesting that the EFs affected may be primarily in verbal domains. A large body of research has linked low mathematics performance (i.e., math disability, developmental dyscalculia) with impairments in inhibitory control (Szucs et al., 2013), verbal and visuospatial working memory (Bull & Lee, 2014; Szucs et al., 2013), set shifting (Willcutt et al., 2013), sustained visual attention (Anobile et al., 2013), and inattentive behaviours (Fias et al., 2013). There is also some evidence that the relationship between math disability and EF may be specific to measures of EF that demand numerically relevant information.(Ashkenazi et al., 2009; Siegel & Ryan, 1989; Wilkey et al., 2020). Developmental coordination disorder (DCD) has also been linked to EF deficits (Leonard & Hill, 2015). In a recent study, children with DCD were found to display persistent EF difficulties (i.e., working memory, inhibitory control, fluency) over a 2-year period mainly in nonverbal domains and in verbal fluency (Bernardi et al., 2018). In children with FASD, EF deficits have been documented in the areas of cognitive flexibility, planning, strategy use, verbal reasoning, some aspects of inhibitory control, set shifting, fluency, and working memory (Green et al., 2009; Jacobson et al., 2021; Rasmussen, 2005).

Difficulties in EFs are not only seem among individuals with a clinical diagnosis but also among children and adults with subclinical traits (Brocki et al., 2010; Christ et al., 2010; Otterman et al., 2019). This is important, as children with subclinical traits of disorders often remain undetected (Angold et al., 1999), and these sub-clinical symptoms may be associated with EF problems, which may result in impairments and could have a substantial impact on short-term and long-term life outcomes such as educational attainment (Blair & Razza, 2007; Corbett et al., 2009; Diamond, 2013).

Pediatric mental health disorders such as depression and anxiety have also been associated with deficits in EF (Wagner et al., 2015), although the findings of studies are not consistent. Wagner et al. (2015) reported that compared to healthy controls, the most pronounced EF deficits in children with major depressive disorder were in inhibitory control, sustained attention, verbal fluency, verbal memory, and planning. However, a recent meta-analysis concluded that there is little support for EF deficits in pediatric depression (Weber et al., 2018). Research that has investigated the association between pediatric anxiety disorders and EF is limited; however, a recent study reported that children and adolescents with anxiety disorder have poorer planning ability compared to a control group and that difficulties in planning were associated with problems in attention, working memory, and cognitive flexibility (Rodrigues et al., 2019).

Comorbidity among developmental disorders such as ASD, ADHD, DCD, and specific learning disorders such as reading disorder and math disorder, and mental health disorders such as depression and anxiety is common (Czamara et al., 2013; Dewey, 2018; Dewey et al., 2002; Kaplan et al., 2001; Ter-Stepanian et al., 2017). Children and adolescents with comorbid disorders tend to display poorer performance on measure of EF compared to children with a single disorder, and different comorbidities have been associated with different executive dysfunctions (Crisci et al., 2021; Ter-Stepanian et al., 2017). Further, a study by Dajani et al. (2016) found significant heterogeneity in EF performance within diagnostic groups (i.e., ADHD, ASD), with some children with ADHD (34%) and ASD (20%) displaying "average" performance on EF tasks and others displaying "impaired" EF skills (ADHD, 63%; ASD, 78%). Further, in children with comorbid ADHD and ASD, 92% were classified as displaying impaired EFs. These findings suggest that comorbidity should be carefully examined as it may play a significant role in EF performance and in the day-to-day functioning of children and adolescents with developmental, behavioural, and mental health disorders.

Assessments of Executive Function

Ratings of EF

The Behaviour Rating Inventory of Executive Function (BRIEF) (Gioia et al., 2000) is the most widely used rating scale for assessing EF and is considered the gold-standard. The BRIEF is a standardized 86-item inventory for parents and teachers of children aged 5–18, and it has recently been updated to a 63-item version, called the BRIEF-2 (Gioia et al., 2015). There is also a self-report version, the BRIEF-SR (Guy et al., 2000), for children aged 11–18, and a 63-item Preschool Version (BRIEF-P) (Gioia et al., 2003) for parents of children aged 2.0–5.11. The BRIEF inventories are valid and reliable tools for assessing real-world EF problems in children and adolescents (Gioia et al., 2000, 2003, 2015). The BRIEF inventories include individual subscales, which assess a wide variety of EFs (i.e., inhibit, shift, emotional control, working memory, plan/organize, initiate, monitor) and combine into broader indexes (i.e., inhibitory control, flexibility, metacognition, behavioural regulation, emotion regulation, cognitive regulation) and a Global Executive Composite (GEC). Notably, the BRIEF inventories demonstrate convergent and discriminant validity with other measures of common clinical difficulties, such as inattention, hyperactivity, impulsivity, depression, anxiety, and atypicality (Gioia et al., 2000, 2003, 2015). There are a few other rating scales of EF for children and adolescents (e.g., Ratings of Every Day Executive Functioning (REEF) (Nilsen et al., 2017) or related screeners (e.g., Behavioural Screener for the Assessment of EFs, Behaviour Assessment System for Children (BASC-EF)) (Karr & Garcia-Barrera, 2017), but the BRIEF questionnaires are the most frequently used measures.

Performance-Based Tasks of Executive Function

There are a multitude of task-based measures of EF. For young children, these are generally adaptations of neurocognitive tasks, which have been devised into simple games. For example, Hughes (1998) adapted Luria's Tapping Test (Luria, 1966) into a Hand Game, which asks preschool children to imitate or make the opposite gesture of the experimenter. Other notable examples include Zelazo's (2006) adaptation of the traditional inhibitory control task, the WCST (Heaton et al., 1981), into a card sorting game for preschool children, and Kerr and Zelazo's (2004) adaptation of a classical affective-decision making test, the Iowa Gambling Task (Bechara et al., 1994), into the Children's Gambling Game. Many of the performance-based measures of EF developed for young children demonstrate developmental sensitivity, such as tasks of working memory (e.g., Motor Sequencing, Backward Digit Span, Count and Label), inhibitory control (e.g., Shape Stroop, Day/Night, Bear/Dragon, Gift Delay), cognitive flexibility (e.g., Reverse Categorization, Multilocation Search), and emotional control (e.g., Disappointing Gift) (for task details see Carlson, 2005). For older children and adolescents, traditional neurocognitive assessments, sometimes with slight variations, can be administered. This includes tests such as the WCST, Verbal Fluency Test, Design Fluency Test, Digit Span Forward/Backward, Stroop, Tower of London/Tower of Hanoi, Trail Making Test, and N-back (Chan et al., 2008). Many of these tests are individual measures of EF (e.g., WCST); however, some are included in standardized assessment batteries of intellectual or neuropsychological functions such as the Wechsler Scales of Intelligence (e.g., WISC-V) (Wechsler, 2014), NEPSY-II (Korkman et al., 2007), Delis-Kaplan Executive Function System (D-KEFs) (Delis et al., 2001), and National Institutes of Health Tool Box (NIH-TB) (Weintraub et al., 2013). These standardized batteries have strong psychometric properties; however, it is important to note that although many unstandardized performance-based measures of EF can have low test-retest reliability, they often demonstrate convergent validity and clinical utility (Anderson et al., 2008; Chan et al., 2008).

Neuroimaging and Physiological Indicators of Executive Function

Studies of brain structure, function, and connectivity provide information on the underlying neural structures associated with EFs (see section "Neural basis of executive function"). The number of studies investigating the neural basis of EF within healthy and clinical populations has risen dramatically over the past two decades. Functional neuroimaging techniques such as functional magnetic resonance imaging (fMRI), position emission tomography (PET), electroencephalogram (EEG), and near-infrared spectroscopy (NIRS) have illuminated the brain regions that become physiologically and metabolically activated during EF tasks, while structural neuroimaging methods such as magnetic resonance imaging (MRI) and diffusion tensor imaging (DTI) have characterized the volume differences and white matter alterations in individuals with EF deficits. Recently, the insights gained from functional and structural neuroimaging research have been supplemented by additional physical and physiological indicators of EF. This includes monitoring physical movements such as eye tracking, metrics of physiological arousal such as galvanic skin response (GSR) and heart rate, and physiological regulation measures such as respiratory sinus arrhythmia (RSA).

Problems in the Assessment of Executive Function

Executive function is challenging to study and measure from a developmental perspective, largely due to the conceptual inconsistencies previously discussed (see sections "Theoretical considerations" and "Models of executive function") and the issue of task-impurity (i.e., that tasks designed to measure EF typically implicate other cognitive processes) (Hughes & Graham, 2002; Miller et al., 2012). Task impurity is problematic as it introduces systematic variance attributable to non-EF processes associated with a specific task and measurement error. For example, performance on the Stroop (i.e., an inhibitory control task) is also related to colour processing and articulation speed. Another problem in the assessment of EF is that a single task may tap into multiple components or processes of EF. This is often the case for even "simple" tasks, such as the backward Digit Span (i.e., a working memory task), which presumably requires inhibitory control to meet the task demands of inhibiting the natural tendency to repeat items in the same order in which they were heard. Although many experimental psychology tasks have been developed in the hopes of isolating the different components of EF (i.e., fractionation of EF), this is likely at the cost of losing the very "essence" of EF and affects ecological validity (Miller et al., 2012). Latent variable approaches, such as confirmatory factor analysis (CFA), are suggested as a "purer" method of assessing EF as they extract common variance that is shared across observed variables and thereby reduce measurement error (Miyake et al., 2000; Miyake & Friedman, 2012). However, even these statistical approaches demonstrate that EF measures purported to assess the same construct often correlate weakly, calling into question the reliability and validity of assessments of EF using existing tasks (Gärtner & Strobel, 2021). Advancements in technology, such as virtual reality (VR), may enable the real-time evaluation of EF in more “real life” scenarios and offer improved ecological validity (Borgnis et al., 2021).

There are methodological concerns that are specific to the assessment of EF in children. The first is the concordance between the two common methods of measuring EF – parent ratings and performance-based tasks. It is well acknowledged that EFs measured using these different methods are often weakly correlated at best, and that performance-based measures assess a specific aspect of EF (e.g., peeking behaviour on the Gift-Delay) and parent-report instruments assess more global aspects of “everyday” functioning (Bodnar et al., 2007; Ten Eycke & Dewey, 2016; Toplak et al., 2013). It has been proposed that these discrepancies may be due to the engagement of different levels of cognitive processing, as performance-based measures are often concerned with the efficiency of information processing (i.e., algorithmic level), while global rating scales typically assess the goals and beliefs of an individual during decision-making processes (i.e., reflective level) (Toplak et al., 2013). Thus, these different measures likely assess different constructs of EFs, and different neurodevelopmental processes are associated with the algorithmic level (e.g., motor functioning) compared to the reflective level (e.g., attentive ability) (Ten Eycke & Dewey, 2016). A second methodological concern is related to language development in young children. Although EF tasks can be designed to require no or limited verbal ability, the development of EF likely depends on improvements in language abilities; therefore, it is probably misguided to separate them (Hughes & Graham, 2002). Further, as systematic evidence indicates that individual tasks engage different EFs at different ages (i.e., measurement invariance), more research is needed that examines the test-retest reliability and validity of existing and novel measures of EF, particularly as they pertain to everyday contexts (Miller et al., 2012).

Interventions for Executive Function

So why is it important to develop early interventions for EF? First and foremost, EF develops and changes from infancy through childhood and adolescence and into adulthood and old age, and across the lifespan interventions have been associated with improvements in EF (Diamond, 2016; Ferguson et al., 2021; Kinsella et al., 2020). Second, the early gap between those with better and worse EF often does not disappear and can grow larger over time (Fitzpatrick et al., 2014; Hackman et al., 2015; Johnson et al., 2016; Mulder et al., 2017), and problems in inhibitory control and working memory identified in early childhood are associated with later problems in EF and social relationships (Ahmed et al., 2019; Brocki et al., 2010; Jacobson et al., 2011; Moffitt et al., 2011; Rinsky & Hinshaw, 2011; Wåhlstedt et al., 2008). Third, children’s early EF skills predict academic performance from elementary school to college and university (Ahmed et al., 2019; Cortés Pascual et al., 2019; Fitzpatrick et al., 2014; McClelland et al., 2013; Ramos-Galarza et al., 2019). Therefore, interventions that improve EF early in life may significantly affect children’s trajectories of academic achievement and ultimately their social and economic outcomes over their lifespan.

In children aged 2–6, it has been suggested that intervention efforts focus on supporting the three core components of EF (i.e., working memory, inhibitory control, and cognitive flexibility), as these are foundational for all other EF and self-regulatory skills. In middle and late childhood, it has been suggested that interventions target planning/organization and emotion regulation, while interventions for adolescents should focus on the multi-dimensional and context-specific aspects of EF and self-regulation (Bailey & Jones, 2019). Evidence from studies that have included typically developing children, children at risk for EF problems, and children with neurodevelopmental disorders suggest that various interventions are associated with improved EF skills. Diamond et al. (2007) reported that children trained with "Tools of the Mind", a research-based preschool curriculum that focuses on the development of cognitive, social-emotional, self-regulatory, and foundational academic skills, performed better than their untrained peers on measures of EF. Similarly, research with preschool children participating in The Chicago School Readiness Project (CSRP), an intervention designed to support low-income children's self-regulation, found that compared to comparison children, children enrolled in preschool classes where Head Start teachers had been trained in CSRP displayed significantly higher attention skills, greater impulse control, and improved vocabulary, letter-naming, and math skills (Raver et al., 2011). In a recent study that focused on working memory training, Blakey and Carroll (2015) showed that in 4-year-old children, working memory training improved performance on non-trained working memory tasks, but did not affect performance on inhibitory control or cognitive flexibility tasks. In another study that focused on training specific EFs, Thorell et al. (2009) found that preschool children trained for 5 weeks on a visual-spatial working memory task showed improvements in non-trained visual-spatial and verbal working memory and transfer to attention tasks. In contrast, children trained on inhibitory control showed no improvement on non-trained inhibition tasks and no transfer to tasks of working memory or attention. Overall, early intervention efforts focused on the three core components have been shown to improve specific EFs, but there is limited support that these improvements transfer to other EFs or tasks.

Several studies that have examined that the success of play interventions for the development of EFs in preschoolers have also reported promising results. For example, Traverso et al. (2015) conducted an intervention focused on the development of working memory, inhibitory control, and cognitive flexibility with children aged 5. Twelve play sessions lasting 30 min each were conducted over 1 month at the educational centre the children attended. The children who took part in the intervention performed better on tasks that targeted these three areas of EF. A play-based intervention study by Hermida et al. (2015) with kindergarten children found few differences between the intervention group and controls in EF skills; however, the intervention group showed significantly higher language and math grades one year after the intervention. Rosas et al. (2019) reported that a longer play-based intervention (i.e., 60 45-minute sessions held over a 3-month period), similar to Hermida et al. (2015) and Traverso et al. (2015) resulted in improved EFs in preschool children at 8 months post intervention.

Computerized training programs such as CogMed, which progressively increases working-memory demands, have also been associated with improved working memory; however, these improvements did not generalize to other EFs such as cognitive flexibility or inhibitory control (Bergman Nutley et al., 2011; Holmes et al., 2009; Thorell et al., 2009). In a study that investigated the effects of CogMed working memory training compared to math training in adolescents with severe learning disability and comorbid ADHD, those in the working memory training group showed greater improvements in a subset of working memory measures compared with those in the math training group. However, there was no transfer of training to measures of cognitive and behavioural attention and academic achievement (Gray et al., 2012). Finally, in a randomized control trial that used a computer game to train multiple EFs, including visuospatial working memory, inhibitory control, and cognitive-flexibility, in school-aged children with ADHD, improvements in working memory and inhibitory control were specifically related to the type of treatment received; no improvements were noted for cognitive flexibility (Dovis et al., 2015). The results of these studies suggest that computerized training programs may improve the EF that is being trained, but there is little generalization to other EFs.

The EF intervention literature is beginning to investigate whether mindfulness training is associated with improved performance on measures of EF and emotion regulation and could be a promising intervention for improving EF skills in children as young as 4 years of age (Schonert-Reichl et al., 2015; Zelazo et al., 2018). However, the research to date is limited and no specific conclusions can be drawn regarding the efficacy of mindfulness in improving EF in children and adolescents.

A recent review (Diamond & Ling, 2016) and a meta-analysis (Takacs & Kassai, 2019) both support the contention that interventions can improve some EFs in children and adolescents, but there is limited transfer of training from the trained EF (e.g., working memory) to other EFs (e.g., inhibitory control, cognitive flexibility). Further, based on the research to date "we do not know how much they can be improved … or how long benefits last and what determines how much EFs improve or whether benefits last" (Diamond & Ling, 2016, p. 43), which supports the need for prospective longitudinal intervention studies investigating the long-term effects of EF interventions.

Directions for Future Research

Executive function has become an important cross-disciplinary construct that has been the focus of over a half-century of dedicated research. Although the field of EF suffers from terminological inconsistencies, the conception and evaluation of the three core processes (i.e., the tri-component view) – working memory (updating), inhibitory control (inhibition), cognitive flexibility (shifting) – is predominant in the field. However, questions have been raised regarding the suitability of reducing EF to these three core components, and more foundational work is needed to consistently conceptualize this construct.

In addition to clarifying these conceptual issues, research is needed in multiple areas to promote the healthy development of EF from the prenatal period through to early adulthood. First, more studies are needed that investigate if sex and/or gender differences and hormones are associated with the structure and function of the brain regions (e.g., DL-PFC, ACC) that have been linked to the development of EF. Second, although individual differences in EFs are almost entirely genetic, which is an arguably immutable factor, there are multiple protective factors, which support the healthy development of EF, and risk factors that confer risk for difficulties with EF, which pinpoint key targets for intervention. This includes environmental factors such as socioeconomic status, parental depression, parent-child interactions, maternal nutrition during pregnancy and childhood nutrition, and prenatal and early childhood exposure to environmental neurotoxicants. Third, policy changes are necessary to help ameliorate underlying racial and economic inequalities and more targeted intervention research is needed in children at different developmental stages (e.g., targeting the core components of EF in preschool children and planning/organizing skills and emotion regulation in school-age children). Related to these concerns is a final important avenue for future research, the operationalization of EF. Given the acknowledged conceptual inconsistencies in the field of EF, it is not surprising that existing measures of EF demonstrate varied developmental sensitivity, psychometric properties, and limited concordance. This is of the utmost concern, as ecologically valid and reliable measures of EF are needed to consistently identify the genetic basis and neural correlates of EF, the environmental factors that shape the development of EF, and the targets for intervention to support the healthy development of EF in all children and adolescents including those with neurodevelopmental, behavioural, and mental disorders. This issue relates back to the conceptualization of EF and suggests that some of the field's longstanding views warrant reconsideration. The field of EF also should consider the bidirectional influences between EF and self-regulation (Blair & Ursache, 2011). Interventions could target both abilities, which in turn could promote long-term neurocognitive health and positive outcomes (e.g., academic success) (Howard et al., 2021). Further by embracing the etiological complexity associated with the development of executive functions and utilizing advanced statistics, we may better understand both typical and atypical development of EF across multiple levels of analysis spanning genes to behaviour and could foster a transdiagnostic paradigm shift in our conception, assessment, and treatment of impairments in EF in children and adolescents (Beauchaine & Thayer, 2015; Beauchaine & Zisner, 2017).

Theory of Mind

14

Derek E. Montgomery, Virginia Tompkins, and Joann P. Benigno

Introduction

Theory of mind is widely studied in neurotypical and child clinical populations (Cotter et al., 2018; Wellman, 2014). Premack and Woodruff (1978) coined the term "theory of mind" to characterize the prediction and explanation of behavior by attributing unobservable psychological states. The importance of ToM in child development rests upon the assumption that what people say and do is incompletely understood, if not altogether incomprehensible, without some grasp of how thoughts and feelings frame and give meaning to those behaviors.

Meta-analyses report delays or impairment in ToM development in children diagnosed with autism spectrum disorder (ASD), language disorders, attention deficit hyperactivity disorder (ADHD), and intellectual disabilities (Cotter et al., 2018). However, differences in ToM performance in children with ASD and neurotypical children have narrowed over time which may reflect increasing heterogeneity within the ASD population (Rødgaard et al., 2019).

ToM in ASD[1] is by far the most extensively studied among neurodevelopmental disorders. Consequently, research in that area is a focal point throughout the chapter, although we integrate findings from other populations when doing so illuminates points and themes under discussion. According to the DSM-V (American Psychiatric Association, 2013), one of the two core diagnostic criteria of ASD is social communication and social interaction differences which may manifest themselves in

---

[1] In this chapter, we use person-first language (e.g., children with ASD). However, we recognize that the use of identity first language is preferred (e.g., autistic children) by some members of the autistic community.

difficulties with initiating and maintaining bouts of social engagement, conversation, and establishing and navigating personal relationships with others (e.g., peers). These deficits are accompanied by behavior patterns characterized as restricted and repetitive that may present as strong interests or participation in a limited range of activities.

Though impaired ToM is one possible explanation for the observable behavioral challenges those with autism experience in the realm of social engagement, it does not fully account for variations in social competence (Roselló et al., 2020). However, as discussed throughout the chapter, there is considerable debate and continued need for research on the nature and extent of its impact.

Cognitive accounts of children's ToM are dominant in the literature and they are our focus in this chapter. The chapter begins by characterizing the nature of the construct and examining how it is measured in childhood. Our focus is on explicit ToM reasoning measured by behavioral studies rather than on tacit, nonverbal forms of ToM that are perhaps better characterized as "submentalizing" (see Heyes, 2014). The third section addresses how ToM relates to executive function, language, and social behavior. The fourth section of the chapter examines ToM-based behavioral interventions for children with autism. The chapter concludes with a discussion of future directions, with focus on the measurement, assessment, and treatment of ToM. In essence, readers of this chapter will learn about the developmental landscape of ToM in neurotypical and neurodiverse populations, why it matters, how other skills relate to it, and what to do when working with children who require support to advance their ToM skills.

Theory of Mind: Construct and Assessment

Cognitive processes, such as reasoning and drawing inferences about thoughts and feelings, distinguish ToM from constructs like empathy that involve predominantly affective processes (Happé et al., 2017; Schurz et al., 2021). Beyond that distinction, precise definitions of ToM remain elusive (Warnell & Redcay, 2019). One challenge is the multiplicity of mental state concepts (e.g., belief, knowledge, pretense, intention, and desire) and the wide ranging ways in which they relate to behavior and inform social interactions. Reflecting the breadth of its scope, ToM is, arguably, a multidimensional construct (Warnell & Redcay, 2019). For instance, evidence from social cognitive neuroscience suggests that reasoning about cognitive states is separable from reasoning about affective states (e.g., Shamay-Tsoory & Aharon-Peretz, 2007).

Heterogeneity in measurement follows from the breadth of the theory of mind construct. A recent survey identified more than 200 different early childhood "theory of mind" measurements in the research literature (Beaudoin et al., 2020). The variability, as we discuss below, complicates attempts to identify a single instrument as a definitive measure of ToM. Instead, it may be that "theory of mind" is an umbrella term under which separable processes are tied to different behavioral measurements (e.g., Schurz et al., 2021). As Table 14.1 illustrates, there is a wide variety of most ToM behavioral measures. Research on the psychometric properties of ToM measurements is relatively limited (Beaudoin et al., 2020; Brewer et al., 2017). Despite this caveat, ToM behavioral measurements may serve a useful role in clinical settings as informal criterion-referenced measurements (Westby & Robinson, 2014). This section concludes by highlighting considerations for their use in applied settings.

Theory of Mind: The False Belief Task

Research on theory of mind in childhood began with a focus on false belief understanding (Wimmer & Perner, 1983). In a typical false belief task, a scenario plays out in which (a) a protagonist witnesses

Table 14.1 Representative ToM measures for children

Early Childhood: 5-step ToM Scale	Advanced Theory of Mind
1. **Diverse Desires** – The child and someone else have different desires about different snack options; the child must infer the other person's snack preference based upon that person's different desire 2. **Diverse Beliefs** – The child and someone else express different beliefs about an object's location. The child does not know the actual location. The child predicts where the person with the different belief will look for the object 3. **Knowledge Access** – The child knows the contents of a container and judges whether someone without informational access would also know the identity of the hidden contents 4. **Contents False Belief** – A distinctive container (e.g., band-aids) holds unexpected contents (e.g., pencils). The child must infer what a naive observer will think is inside the container 5. **Hidden Emotion** – The child must distinguish between a character's actual feelings (sad) and emotional display (happy)	**False Belief: Second-order False Belief task** – One of the characters in a vignette, A, forms a false belief about what B believes. Children must judge that A will draw an incorrect inference about B because of the false belief about B's belief. (e.g., Perner & Wimmer, 1985) **Inferences from Perceptual Stimuli: Reading-the-mind-in-the-eyes test (RMET)** – Thirty-six photographs of the eye region depict various expressions of emotion and thought. Participants choose from among four options the mental state descriptor (e.g., "serious" "reflective") that best describes what the person is thinking or feeling (Baron-Cohen et al., 2001) **Story-based Inferences: Strange Stories** – Brief vignettes of social interactions that feature a non-literal verbal utterance (e.g., a joke or an ironic statement). Participants infer the speaker's intended meaning when asked to interpret the utterance (Happe, 1994; White et al., 2009)
Informant-Reported Theory of Mind in Childhood	**Assessment Battery of Theory of Mind in Childhood**
Theory of Mind Behavior Checklist – Parents respond to questions assessing the frequency over the last week of eight ToM- related behaviors (e.g., understood a joke, comforted somebody, asked about someone's feelings) observed in their children. Ratings are from never to very often (Begeer et al., 2015)	**The ToM Subtest from Developmental Neuropsychological Assessment (NEPSY)** – In the verbal portion, 15 items assess 1st and 2nd order false belief, recognition of mental states, and comprehension of figurative language. The contextual portion includes social perspective taking tasks in which the child must select the picture that matches the feelings of a character in six different situations (Korkman et al., 2007)

Note. The 5-step ToM Scale descriptions are adapted from Wellman and Liu (2004). Tasks are listed in the order they are typically passed, from least to most difficult

an object placed in a location but (b) does not witness its transfer to a new location (Wimmer & Perner, 1983). Children are asked to predict where the protagonist, upon returning, will look for the object. They must reason from the actor's subjective perspective rather than from an objective perspective. In neurotypical development, children's explicit understanding of false beliefs generally emerges between ages 4 and 5 (Wellman et al., 2001).

False belief tasks are by far the most widely administered ToM measurement (Beaudoin et al., 2020). They offer a variety of practical advantages in basic and applied settings. They can be administered quickly and are relatively easy for children to follow, especially when vignettes are accompanied with pictures and comprehension prompts. The test-retest reliability for false belief measures is generally acceptable, especially when scores are aggregated, for children with varying intellectual abilities (Hughes et al., 2000). Also, there is a degree of clarity on what false belief tasks are measuring. They are relatively circumscribed in their focus on children's capacity to infer and reason about a belief in conflict with their own. Task variations load onto a single latent factor (Hughes et al., 2018). Finally, false belief tasks are generally good at differentiating between neurotypical and neurodiverse populations. For instance, a meta-analysis conducted on the first wave of ToM research in the 1980s and 1990s found that (a) children with intellectual disabilities outperformed children with ASD, but (b) both groups were significantly outperformed by neurotypical controls (Yirmiya et al., 1998). By far, the most common task in those studies was the false belief task.

Despite the advantages, reliance on false belief tasks alone is limiting and assessment efforts have benefited from two advances in the field. First, new tasks allow for measuring precursors to false belief understanding. Second, findings that false belief mastery in childhood *is* attainable for individuals with autism mean that further more nuanced understanding might also be possible (Happé, 1994). Many Advanced ToM tasks were initially developed to investigate reasoning after false belief understanding for children and adolescents with ASD (Miller, 2012). We discuss each of these developments in turn.

Theory of Mind: The 5-Step Scale

A 5-step ToM Scale (see Table 14.1) tests the assumption that false belief understanding is built upon conceptual precursors that develop in early childhood (Wellman & Liu, 2004). For instance, a basic conceptual awareness that people can have different mental experiences (Diverse Desires, see Table 14.1) would seem to be a prerequisite for understanding that those different perspectives include true and false beliefs. Each task in the 5-step scale is verbally administered and requires children to identify and reason about a perspective different from their own. The scale exhibits internal consistency and convergent validity (Hiller et al., 2014). Both cross-sectional and longitudinal studies find that neurotypical children (roughly ages 2–6) usually progress through the scale in a stepwise manner (Wellman, 2014; see Table 14.1 for the sequence). Occasional cultural variations in which two tasks are passed in reverse order implicate a role for socio-cultural processes in ToM development (Slaughter & Perez-Zapata, 2014).

Children with ASD and children diagnosed with mild intellectual disability are delayed in passing each step in the scale but, for the most part, the sequence for both groups resembles the sequence for neurotypical children (Peterson et al., 2012; Smogorzewska et al., 2018). An exception is that false belief understanding is particularly difficult for children with ASD and often comes after mastery of the Hidden Emotions task (Peterson et al., 2012). Over a 1½ year period, the majority of children with ASD (ages 3–11 at initial testing) who were not at ceiling made gains on the ToM scale (Peterson & Wellman, 2019). However, there was no evidence of children with ASD "catching up" with TD controls.

One clue for the particular difficulty of false belief understanding for children with autism comes from findings that passing the task appears to substantially rely on verbal abilities. Fisher et al. (2005) found that grammatical knowledge and receptive vocabulary, combined, predicted false belief understanding in almost 90% of the ASD sample (middle childhood) in their study. The magnitude of the predictive relation was much less pronounced for a comparison group of children with moderate learning difficulties. We discuss more fully why language and false belief understanding are related later in this chapter (Section "Language and theory of mind development").

Advanced Theory of Mind

The Advanced tasks in Table 14.1 represent common approaches to measuring ToM in children who have mastered false belief understanding. They are generally administered in middle childhood (ages 7–12) and adolescence (ages 12–18). Advanced ToM measurements tend to have multiple items that allow for a greater range of performances than the pass-fail tasks used in early childhood. Another common task feature involves asking children to infer what characters think and feel in the context of narrative structures (e.g., sequence, goal, and interaction) that are verbally conveyed or inferred from the patterned movements of geometric figures. For instance, in the Strange Stories task, an item asks children to explain why someone would say a ‘white lie’ to spare someone’s feelings (Happé, 1994). Children must coordinate the perspective of two characters to infer why someone would say something that is not true.

The variety of task features and content among the Advanced ToM tasks naturally raises concerns over whether the instruments are all measuring the same construct. Some have found that various Advanced ToM tasks form distinct factors in neurotypical children (Osterhaus et al., 2016) and in children with ASD (Altschuler et al., 2018). However, others have not found relations among various Advanced tasks (e.g., Warnell & Redcay, 2019). Evidence from neurotypical children finds improvement on Advanced ToM measurements through adolescence (Meinhardt-Injac et al., 2020). However, the rate of development and the impact of covariates such as language on development may vary across different tasks which further supports the notion that ToM is not a unitary construct (Meinhardt-Injac et al., 2020).

Clinical Implications

If different ToM measurements are capturing different dimensions of ToM, then developing a profile from a battery of measurements would be more informative than simply distilling performance into a single score (Westby & Robinson, 2014, see Table 14.1 for a representative example of ToM batteries). A battery of measurements could prove useful in providing an objective assessment with sufficient breadth to cover a range of ToM outcomes in intervention studies (see Section “Intervention”). A profile could, in addition, specify a targeted intervention approach (Westby & Robinson, 2014). A profile could also distinguish between children’s understanding of cognitive and affective states. Although more research is needed, the distinction may carry clinical relevance as only ToM tasks about affective states predicted social symptoms in children with ASD ages 7–11 years (Altschuler et al., 2018) and social adjustment in similarly aged children with intellectual disabilities (Nader-Grosbois et al., 2013).

A battery of tasks that vary in difficulty can also provide information about the developmental level of children’s ToM understanding. In a study of 62 children with ASD (8- to 16-years-old), a cluster analysis resulted in three groups: (a) Children who passed tasks like those found in Table 14.1 that measure precursors to false belief understanding, (b) children who exhibited false belief understanding, and (c) those who performed well on Advanced ToM tasks (Hoogenhout & Malcolm-Smith, 2017). The groups were comparable in age but differed in severity level. All of the children in the first cluster needed additional support and were placed in autism-specific schools, whereas only one child in the highest cluster was placed in an autism-specific school.

Because ToM assessments differ in the demands they impose on verbal skills and the executive functions, the assessment of those skills can inform task choices in clinical settings (see Hamilton et al., 2016). For instance, the use of multiple-choice options to replace open-ended questions is an option for children with severe language impairments (e.g., Burger-Caplan et al., 2016). Caregiver reports (see Table 14.1) are another alternative for children whose verbal skills limit their ability to complete behavioral tasks. Caregiver reports also complement behavioral measurements by providing information about ToM skills as they are applied in everyday settings. Those observations could be helpful in identifying instances when ToM performance is discrepant from social skills (Livingston et al., 2019). Direct observations of children’s social interactive behaviors are possible with assessments that utilize emerging methodologies such as virtual reality or dynamic, interactive procedures (Beaudoin et al., 2020).

Theory of Mind: Individual Differences and Social Behavior

Children vary in the rate at which they succeed on ToM tasks. A meta-analysis of 58 longitudinal studies of over 7000 children ranging from early childhood to adolescence found that rank-order differences in ToM were moderately stable over time (Devine, 2021). The degree of stability was comparable in both early and middle childhood. The correlates and antecedents of individual differences are heavily researched. The next section looks at three constructs with particular prominence in the literature: the executive functions, language, and social behavior.

Executive Function in Theory of Mind Development

The components of the executive functions are the interrelated but distinct processes that include planning, inhibition, working memory, and cognitive flexibility. They develop throughout childhood and adolescence and promote the deliberate, conscious control of goal-directed behavior (Zelazo & Carlson, 2012). ToM task performance is correlated with executive functioning for neurotypical children (e.g., Devine & Hughes, 2014). ToM tasks impose executive demands because they involve suppressing one's own perspective and taking another, less salient, perspective. Many tasks also feature vignettes that require cognitive switching between perspectives and keeping track of narrative details.

A meta-analysis found that differences in executive functioning predicted false belief understanding rather than the other way around in early childhood (Devine & Hughes, 2014). The relation was evident across different executive function tasks. More than playing a role in overcoming various task demands, early executive capacities may also support the development of ToM (see Devine & Hughes, 2014, for a discussion). However, the research literature for children after age 5 is inconclusive, with evidence suggesting that executive functioning predicts ToM development and also that the relation is bidirectional (see Weimer et al., 2021). Given the wide range of Advanced ToM task demands, further research is needed to clarify how different components of executive functioning might impact ToM performance (Weimer et al., 2021).

The executive function-ToM relation is also evident in neurodivergent populations such as ADHD (Pineda-Alhucema et al., 2018) and autism (e.g., Pellicano, 2007). Interpretations of group differences in ToM should take into account how the executive functions impact performance on behavioral ToM tasks. For instance, in a study of children with ADHD (ages 8–12), attentional and inhibitory processes mediated ToM deficits (Mary et al., 2016). Studies on children with ASD during early childhood (e.g., Pellicano, 2007) and those including participants into adolescence (e.g., Joseph & Tager-Flusberg, 2004) confirm the relation between executive function skills such as planning and ToM. Similar to studies on neurotypical populations, more research is needed to clarify the changing nature of the connections between executive function and ToM across development beyond the preschool years in children with ASD.

Language and Theory of Mind Development

Similar to the executive functions, the connections between language and ToM have been widely investigated and clear links have been established between language and ToM in the preschool years and beyond (see Tompkins et al., 2019). Milligan et al. (2007) found that all measures of language including both specific linguistic structures (i.e., understanding of sentential complements) and general language skills (e.g., syntax and semantics) accounted for performance on measures of ToM. de Villiers and de Villiers (2014) posit that mastery of sentential complements with embedded communicative or mental state verbs (e.g., Noelle *said* that Kaylee was dancing; Noelle *thought* that Kaylee was dancing) is prerequisite to children's false belief understanding. Recognizing that such sentences are true even if the complement clause is false reflects false belief understanding. The relation between false belief understanding and complementation structures involving communication verbs is particularly robust for children with ASD (Tager-Flusberg, 2000). In contrast, others (e.g., Slade & Ruffman, 2005) assert that general language skills, such as vocabulary and syntax, are critical for ToM understanding, whereas understanding of sentential complements is not required.

Farrar et al. (2017) conducted a meta-analysis accompanied by qualitative analysis to explore these two competing views. Based on the data sourced, Farrar et al. explored the possibility of different "linguistic pathways" to ToM understanding and how the nature of language-ToM relations might depend on the population(s) under investigation. To this end, they were limited to analyzing studies that included measures of ToM, complementation, and general skills. Though results yielded greater support for the general language hypothesis for TD children, findings suggested that the complementation hypothesis may hold true for children with ASD. Farrar et al. note that these findings should be interpreted with caution given the limited number of studies and heterogeneity of the populations in the studies analyzed. See Farrar et al. (2017) for qualitative analyses of the studies included and possible explanations (both methodological and conceptual) that may account for variations in the ToM performance across populations of children with and without language impairments.

Theoretical debates aside, it is evident that language (general language skills or specific syntactic structures) is an influential factor in all children's ToM development. Thus, the role of language in ToM should be considered when working with children with ASD (Whyte et al., 2014) and language impairments (Miller, 2004; Westby & Robinson, 2014). Earlier work on the ToM-language connection in children with Developmental Language Disorder (DLD; formerly known as Specific Language Impairment) suggested that reducing the language demands associated with the ToM tasks yields similar ToM performance for children with DLD and their same age peers (Miller, 2004). According to the Nilsson and López (2016) meta-analysis, greater clarity is needed to discern if language is the primary factor responsible for ToM challenges in children with DLD or if variations in skills (e.g., executive functions) or environmental or genetic differences underlie ToM outcomes.

Theory of Mind and Social Behavior

ToM reasoning also involves social cognitive processes like perspective-taking that, in theory, should impact children's social behavior and relationships. This prediction has received extensive attention in neurotypical children and many studies offer some support for it. A meta-analysis conducted on studies of children between ages 2 and 12 found a modest but statistically significant relationship between ToM and prosocial behavior (Imuta et al., 2016). A relationship of similar magnitude between ToM and popularity with peers was found in a meta-analysis of studies with children ages 2–10 (Slaughter et al., 2015).

There is less research on possible ToM-social behavior links in child clinical populations. Nevertheless, there is some evidence that ToM and peer relations are associated in children with language impairments (Andrés-Roqueta et al., 2016) and intellectual disabilities (Nader-Grosbois et al., 2013). There is considerably more research examining children with ASD. Studies report a relation between ToM and social behaviors, although null findings in some studies indicate that further research is needed in this area (Brunsdon & Happé, 2014). One methodological area that warrants further attention is researchers' choice of social behavior measurement. For instance, general social skill instruments may be overly broad and include items more closely associated with conformity to social conventions (e.g., following instructions) than with specific interpersonal perspective-taking skills like joining into a peer group that are theoretically aligned with the ToM construct (Peterson et al., 2016).

The heterogeneity of verbal skills in children with ASD poses a challenge for conceptualizing possible ToM-social behavior links. Because verbal ability is so strongly predictive of false belief performance in children with autism, it is possible that the tasks are solved in a linguistically mediated fashion. Perhaps children verbally work out the solution through step-by-step reasoning that is mostly devoid of direct inferences about beliefs (Happé, 1995). If so, success on ToM tasks does not clearly reflect the factors like perspective-taking and social reasoning that purportedly impact social skills. Evidence in support of this possibility comes from a study in which language mediated the relation between ToM and peer competence for ASD children ages 5- to 13-years (Peterson et al., 2016).

Another challenge for the ToM-social behavior link is that some individuals with ASD exhibit good social skills despite difficulty in ToM understanding. In a study of adolescents (ages 10- to 15-years) with ASD, scores on an Advanced ToM task were used to classify participants as having relatively good or impaired theory of mind based on whether they were above or below the median of TD peers (Livingston et al., 2019). Those who exhibited fewer social symptoms despite low ToM scores were classified as high compensators. High compensators had significantly better executive functioning skills and verbal IQ scores than those with comparable ToM but more severe social symptoms. General cognitive features could be used to work around ToM impairments. For instance, top-down executive processes may be recruited by high compensators for socially adaptive purposes like planning for social interactions or inhibiting behaviors that might be unwelcome in some contexts (Livingston & Happé, 2017).

Intervention

The majority of ToM interventions targeting children with developmental disabilities focus on children with ASD (Southall & Campbell, 2015), though a few have focused on children with language impairment or intellectual disability (e.g., Durrleman & Delage, 2020; Hutchins & Prelock, 2014). Because the social-communicative impairments that are core symptoms of ASD are so closely associated in theory to the ToM construct, our primary focus is on children and adolescents with ASD. Interventions aimed at improving ToM skills in children and adolescents with ASD either target mentalizing skills directly (e.g., Wellman et al., 2002) or the developmental processes underlying ToM skills, such as joint attention, emotion identification, or executive function skills (e.g., Rice et al., 2015; Solomon et al., 2004). Interventions also aim to improve ToM skills as a mechanism to improve social behavior and to generalize those skills to everyday social contexts (e.g., Szumski et al., 2019).

This section focuses on interventions in which ToM is either the skill targeted for improvement or the outcome of interventions. It is beyond the scope of this chapter to provide an exhaustive review of these interventions (but see meta-analytic work; Fletcher-Watson et al., 2014; Hofmann et al., 2016). Rather, our aim is to provide representative examples of the interventions with the most rigorous methodology (e.g., group comparisons) and replicability as these provide the strongest evidence for the efficacy of particular approaches; see Southall and Campbell (2015) for a review of other types of ToM intervention (e.g., small N, multiple baselines). We also review more recent findings and include interventions that examine ToM as an outcome of intervention, not only the target of intervention. These interventions can be generally categorized as those that target ToM skills directly, one-on-one and group interventions focused on social skills more broadly, computerized interventions (Southall & Campbell, 2015), and interventions targeting language. In this section, we review these approaches and conclude with some limitations and practical considerations.

Types of Interventions

Targeted ToM Interventions

In one of the earliest ToM interventions, Hadwin et al. (1996) aimed at improving emotion understanding (situations that elicit particular emotions), false belief (e.g., seeing leads to knowing), or play (e.g., teaching pretend play) over eight 30-min sessions ($N = 30$; Mage = 9 years). Based on pretest to posttest scores, they found that children improved on the specific tasks that were trained for emotion understanding and false belief, but not play. However, performance did not generalize to other highly similar tasks (e.g., different protagonists, scenarios) and there were no crossover effects (e.g., teaching false belief understanding did not lead to better emotion understanding). Performance also did not generalize to children's spontaneous use of mental state terms while narrating a story (Hadwin et al., 1997).

Other interventions target ToM skills by teaching children to visualize beliefs. *Photos in the Head* uses mannequin or doll heads (Fisher & Happé, 2005; McGregor et al., 1998; Swettenham, 1996) to teach children concepts about thought (e.g., a thought is like a picture in one's head). Intervention proceeds until concepts are understood, up to ten 20–25 min sessions. Building on the work of Swettenham (1996), who found little generalization to untrained tasks, McGregor et al. (1998) found that children with ASD (8–16 years) performed significantly better on false belief tasks after training relative to ASD control and TD control groups, though their progress was less advanced with less generalization to other false belief tasks than the TD intervention group ($N = 48$). Fisher and Happé (2005) replicated the *Photos in the Head* Intervention in a sample of 27 6- to 15-year-olds with ASD; they found that improvements extended to a 12-week follow-up and generalized to other ToM tasks (e.g., a deception task). Similarly, *Thought-Bubble Training* uses pictures of people with a thought bubble to encourage children with ASD to visualize what someone is thinking (Paynter & Peterson, 2013; Wellman et al., 2002). Training progresses through six stages (Paynter & Peterson, 2013). Paynter and Peterson (2013) found that this approach led to significantly better false belief task performance and generalization to non-trained ToM tasks, including at a delayed posttest 23 days after training relative to a control group ($N = 24$; 4–12 years).

Group Social Skills-Theory of Mind Interventions

Although there is evidence of efficacy of targeted interventions, the benefit of group-based intervention, particularly for ToM and social skills, is that these skills can be practiced in the context of interaction with peers and models. Group interventions focus on social interactions in context and often include a comprehensive set of targeted skills, such as identifying emotions, nonverbal communication, perspective taking, and conversational and problem-solving skills (e.g., Bauminger, 2007; Begeer et al., 2011; Solomon et al., 2004). This more holistic approach is important because for older children and adolescents with ASD, the core symptoms of the disorder (i.e., impairment in communication, social interaction, and reciprocity) translate into difficulties with establishing and maintaining relationships, which in turn can lead to other mental health difficulties, such as rejection, anxiety, loneliness, and depression (Cheung et al., 2021; Waugh & Peskin, 2015).

Many early group interventions with older children with ASD were limited by small sample sizes, a lack of randomized control groups, and lack of generalization to other skills, such as teacher-rated social skills (e.g., Ozonoff & Miller, 1995). More recently, researchers have utilized randomized controlled trial (RCT) designs. Begeer et al. (2011) examined the *Theory of Mind Training*; training occurs in groups of 5–6 children during 16 weekly 1½ h sessions, which include a progression of 53 ToM lessons. In an RCT with children with ASD ($N = 40$; 8–13 years), they found that the intervention group improved on several ToM tasks relative to the control group as well as on their understanding of mixed and complex emotions. However, there was no significant effect of intervention on generalized social skills (empathy or parent-reported social skills). Begeer et al. (2015) also examined a shortened version of this training (the *Mini ToM Intervention*) in an RCT with a waitlist control group ($N = 97$) with children with ASD aged 7–14 years. They also found intervention effects on intermediate false belief tasks and parents' reports of ToM behavior (e.g., child understood a joke), and a reduction in autistic features, but not easier or more complex false beliefs (e.g., second-order), emotion understanding, and parent- or teacher-rated social skills.

Similarly, Waugh and Peskin (2015) developed the *Social Skills and Theory of Mind Training (S.S.ToM)* Intervention to integrate the internal processes of ToM with the external demands of maintaining friendships. In an RCT with 49 children with ASD (aged 6–13 years), children met weekly in small groups of four to seven for 10 weeks. Training sessions concurrently focused on mental state concepts and social skills (with visual scaffolding) and parents received their own training in supporting these concepts in children. They found that the S.S.ToM group showed significant growth in most areas of social responsiveness and ToM (Strange Stories and parent-reported ToM), whereas a Children's Friendship Training group and waitlist control group did not experience the same gains across most measures. These findings were largely replicated in a recent study in Hong Kong schools with children with ASD in the intervention group improving in parent-reported social competence (particularly empathy, such as concern for others), ToM, and qualitative parent-reported functioning at home, school, and in the community (Cheung et al., 2021; $N = 74$; aged 6–14 years).

In the *Social Competence Intervention for Adolescents (SCI-A) program*, core social deficits are targeted (e.g., perspective taking) within the educational setting by trained school personnel (Stichter et al., 2016). The intervention involves five units (e.g., feelings and emotions) with five to seven 45-min lessons each. Stichter et al. (2016) found significantly improved ToM (i.e., understanding of faux pas) from pretest to posttest, but not performance on the Reading the Mind in the Eyes test ($N = 34$). Students' parents and teachers also reported improvements on social awareness in the areas of social cognition, social communication, and social motivation. This intervention is also efficacious in younger children at improving ToM and parent-reported social skills (Stichter et al., 2012).

Peer modeling programs have also been efficacious for increasing ToM and other social skills of children with ASD. For example, in the *SENSE Theater* program, age-matched peers and children with ASD engage in a 10-session summer camp program with 10 objectives focused on social interaction and communication through play and performance (Corbett et al., 2016). In a study of children with ASD ranging in age from 8 to 14 ($N = 33$), Corbett et al. (2016) found a significant increase in communication, play, social skills, and ToM with a particularly large effect on ToM (i.e., social perspective taking) for those in the intervention group relative to a waitlist control group of children with ASD. Interestingly, however, they found that the effect of treatment on autistic features (i.e., Social Responsiveness Scale) depended on children's initial level of social interaction style (e.g., amount of time engaged in group play).

There are also more intensive ToM interventions; for example, in the 50-lesson *Social Skills Training* intervention, children with ASD participate in one-on-one training during the first year and in group training with TD peers during the second year (Bauminger, 2007). Training focuses on several social skills, including group behavior, conversation, emotion understanding, cooperation, and double messages (e.g., irony). Bauminger (2007) found evidence of improvements in some aspects of emotion recognition, emotion understanding, and justification answers in the Strange Stories task, as well as other social skills ($N = 26$; school-aged children with ASD). Although most of these group interventions have been conducted with older school-aged children, there is also some evidence that social skills interventions are efficacious at improving ToM skills in younger children when the intervention is focused on resolving social conflict through conversation ($N = 52$; Szumski et al., 2019).

Though there are far fewer interventions with children with intellectual disability, group ToM intervention also shows promise for improving ToM in this population. In the *ToM Program for*

Children, groups of 3 children with intellectual disability meet twice a week for 45 min aimed at teaching nine mental states through games, pictures, videos, and group activities (Jacobs & Nader-Grosbois, 2020). These researchers found that compared to a control group, children in the intervention group had improved ToM, particularly cognitive rather than affective aspects of ToM performance; intervention effects were stronger for children with initially lower cognitive abilities (*N* = 30; 4–12 years). There was also some evidence for improvement in some aspects of parent-rated ToM skills and teacher-rated social skills for children in the intervention group.

Computer-Based Theory of Mind Interventions

Researchers note several benefits of using computer-assisted interventions for children with ASD (Parsons & Mitchell, 2002; Rice et al., 2015; Silver & Oakes, 2001); computers are repetitive and predictable, present only the necessary information, do not require social interaction, are interactive and multimodal, can be completed at one's own pace, can provide customized feedback and intensive one-on-one training, and are cost-effective. Features such as sound effects, actions, and animations can draw children's attention to relevant stimuli and are intrinsically rewarding.

Silver and Oakes (2001) examined a computer intervention, the *Emotion Trainer,* with children with ASD in an RCT (*N* = 22; 10–18 years). Participants completed 10 computer sessions over 2–3 weeks. Trials started with simple emotion labelling and progressed to more advanced concepts (e.g., emotions triggered by particular situations). Participants responded and were given immediate feedback and reinforcement. Children in the intervention group improved on some, but not all, of the Emotion Trainer tasks from the beginning to ending of the intervention period. Compared to the control group, children receiving the Emotion Trainer program also had greater emotion recognition and Strange Stories scores.

Similarly, the *FaceSay*™ computer program involves games aimed at teaching the facial processing skills needed for social cognition, such as eye gaze and joint attention; the intervention occurs in 25-min sessions each week for 10 weeks (Rice et al., 2015). In an RCT with children with ASD (*N* = 31; 5–11 years), Rice et al. (2015) found that children in the intervention group improved in affect recognition, ToM skills, and teacher-rated social skills.

However, there was no effect of intervention on direct observations of positive and negative play behavior on the playground. These results do suggest generalization as the *FaceSay*™ program focuses on facial processing skills, not ToM skills directly. Bauminger-Zviely et al. (2013) also found that a computerized social skills program led to improved performance on the Strange Stories task from pretest to posttest (*N* = 22; *M*age = 9 years).

Language-Theory of Mind Interventions

The language interventions focus on training complement syntax in children with lower language skills, which puts them at risk for lower performance on ToM tasks (Durrleman & Delage, 2020). In the *Differentiating Ideas from Reality with Exercises* (DIRE) intervention, children are trained to understand complements of communication, e.g., "X said that Y". Children progress through 100 trials in 8 to 12 30-min sessions (Durrleman & Delage, 2020). They found that both children with DLD and TD children significantly improved in comprehension of complements after the training (*N* = 50; 3–9 years). These two groups also improved significantly in the (untrained) verbal and low-verbal ToM tasks. Some effects were maintained at a delayed posttest 6–8 weeks later. Similarly, Durrleman et al. (2019) contrasted DIRE training and a word-learning control condition in a sample of ASD, DLD, and TD children (*N* = 60; 2–11 years). They found significant improvement in the syntax training group (but not the control group) on understanding of false complements, verbal ToM, and nonverbal ToM. Though sample sizes were small, the intervention appeared to affect each of the groups similarly.

Generalizability and Other Difficulties

Numerous researchers have noted the difficulty of generalizing skills trained in ToM intervention with children with ASD to non-trained abilities (Begeer et al., 2015; Fletcher-Watson et al., 2014; Paynter & Peterson, 2013; Silver & Oakes, 2001; Southall & Campbell, 2015; Stichter et al., 2012). Most treatment gains are assessed in the short term and generalization to non-trained tasks is elusive. Whereas numerous studies found gains in ToM understanding, generalization to other domains, real-world behaviors, or skills or tasks not directly taught was often absent (Begeer et al., 2011; Fisher & Happé, 2005; Hadwin et al., 1996; Paynter & Peterson, 2013).

It is also important to note that the interventions reviewed here may not generalize to children with ASD and co-occurring intellectual disability. Nearly all of the ToM interventions have excluded children with below-average verbal IQ or general IQ scores, often because comparison groups include children matched on IQ (e.g., Begeer et al., 2011, 2015; Rice et al., 2015; Szumski et al., 2019; Waugh & Peskin, 2015). Yet, 1/3 of individuals with ASD have intellectual disability (Centers for Disease Control, 2020). Children with below-average verbal intelligence do not appear to benefit from ToM intervention as well as children with ASD, but average language skills (Bowler & Strom, 1998).

A related concern is whether treatment gains diminish over time. Most studies only include an immediate posttest (e.g., Bauminger-Zviely et al., 2013; Corbett et al., 2016; Ozonoff & Miller, 1995; Stichter et al., 2012, 2016; Szumski et al., 2019); however, there is some evidence that treatment effects on ToM outcomes are maintained 3 weeks to 3 months later (Paynter & Peterson, 2013; Waugh & Peskin, 2015). Still, others find no lasting effects at delayed posttests; however, participation rates at delayed posttests tend to be small (e.g., Begeer et al., 2015; 31%; Soorya et al., 2015; 49%).

Many of these interventions are pretest to posttest designs (e.g., Hadwin et al., 1996) or assignment to treatment or control groups is not randomized (e.g., Ozonoff & Miller, 1995; Swettenham, 1996), which is needed to sufficiently judge whether interventions are efficacious. This is problematic as it is possible that children in the experimental group receiving no intervention improve in false belief performance over time (e.g., Fisher & Happé, 2005). It is also possible that children in the experimental group show significant gains from pretest to posttest, whereas Time × Group interactions are not statistically significant (i.e., the experimental group improved over time, but not more so than the control group; e.g., Jacobs & Nader-Grosbois, 2020). Small samples have also limited the conclusions that can be drawn from many of the ToM intervention studies with many studies finding no effect of intervention on ToM skills (e.g., Solomon et al., 2004). However, RCTs with larger samples are becoming more common in ToM intervention work, improving our ability to draw cause and effect conclusions from these studies (e.g., Begeer et al., 2015).

Other difficulties are that well-designed interventions involve verification of diagnosis and recruitment of targeted samples, matching children on cognitive ability (e.g., IQ test scores), training staff to implement intensive interventions, and maintaining relationships with families over this duration, including those in the control group (Solomon et al., 2004). Additionally, few studies report on procedural fidelity to the intervention (Southall & Campbell, 2015).

Future Directions

Interventions aimed at improving ToM have yielded varying outcomes. Moving forward, there are important considerations for researchers to keep in mind pertaining to methodology and assessment as well as designing interventions for children with ASD. Progress is tied to refinement of the ToM construct and its measurement. The goal of this section is to provide an overview of these considerations; recommendations for future research are threaded throughout.

Measurement and Construct

ToM behavioral measurements are often brief vignettes presented verbally or pictorially. The development of dynamic, interactive assessments might offer improved ecological validity and provide a picture of ToM strengths and difficulties that are simply missed by more passive assessments. For instance, videotaped adaptations of the Strange Stories vignettes are a step closer to actual social interactions because they provide multiple social cues such as intonation and facial expression that convey what others think or feel (Murray et al., 2017). Interactive tasks that require reciprocity and collaboration with the tester can provide direct evidence of children's capacity to perspective-take (e.g., Backer van Ommeren et al., 2017).

Research is also needed for identifying the underlying component processes of theory of mind (e.g., gaze following or perspective-switching) and validating behavioral measurements of those respective processes (Schurz et al., 2021; Warnell & Redcay, 2019). Agreed-upon terminology about theory of mind and its taxonomic organization could, in turn, lead to an assessment protocol. An established protocol would allow for consistency across studies and would allow for refinement in assessment and interventions (Happé et al., 2017). Related, a developmental perspective might track the impact of component processes such as gaze following that, when impaired, have downstream effects on language acquisition and then ToM (Brooks & Meltzoff, 2015). Longitudinal research that establishes developmental precursors would, of course, have implications for training and intervention.

Increased empirical attention on the social and cultural context for ToM development in child clinical populations would inform the refinement and utility of caregiver reports. Research and assessment on the family environment often focus on the impact of the child with ASD on the parent rather than on possible bidirectional relations (see Hickey et al., 2020). This stands in contrast to the wealth of research addressing the impact of parenting on theory of mind development in neurotypical children (Miller, 2016). To illustrate, parental talk about the mind is a well-documented correlate of ToM development in neurotypical young children (e.g., Tompkins et al., 2018). Much of that research takes place in the context of shared reading. Increased empirical attention on linguistic input during shared practices like storytelling could inform the types of parent-child information clinicians gather and resultant intervention strategies (Channell & Bosley, 2021).

Interventions and Methods

Given the inherent limitations of improving a skill that is a core difficulty of the ASD diagnosis, researchers have summarized suggestions for the design of intervention in this population, including repetition of tasks and multiple examples, highly structured intervention, breaking the intervention into small steps sequenced from easier to more difficult concepts, practicing skills in real settings and in different contexts, role play, and others (Parsons & Mitchell, 2002; Silver & Oakes, 2001).

Many interventions are conducted by researchers and trained clinicians (e.g., Waugh & Peskin, 2015). For these interventions to be effective in the real world, another consideration is how easy they are to implement by parents or teachers. Thus, researchers argue that it is important to utilize manualized programs (i.e., manual and formal curriculum) to increase confidence in implementation and the ability to address the needs of clinical populations (Szumski et al., 2019). Some of the manualized ToM interventions discussed here include the *Mini ToM intervention* (Begeer et al., 2015), the *Social Competence Intervention for Adolescents (SCI-A)* curriculum (Stichter et al., 2016), the *S.S.ToM* (Waugh & Peskin, 2015), and the *SENSE Theater Intervention* (Corbett et al., 2016). Interventions also need to be accessible and affordable for use in home and at school (Parsons & Mitchell, 2002).

Golan et al. (2010) also note that individuals with ASD may not be intrinsically motivated to learn from others' eyes or faces as TD children; thus, interventions designed for children with ASD need to involve stimuli that are engaging. Similarly, researchers argue that interventions should capitalize on the strengths of children with ASD, particularly their proclivity to visualize information (*S.S.ToM.*; Waugh & Peskin, 2015), understand pictures (*Thought Bubble Training*; Wellman et al., 2002), and systematize their environment (e.g., *The Transporters Intervention*, Golan et al., 2010). According to the double empathy problem (Mitchell et al., 2021), individuals with ASD are better able to understand and empathize with the minds of others with ASD than neurotypical minds. Thus, it is possible that group interventions for children with ASD may be less challenging and more effective when other children with ASD are the social communication partners rather than neurotypical peers.

Another consideration and area of growing interest concerns moderators of intervention. Regarding participant characteristics, interventions may be more or less efficacious depending on the severity of diagnosis, interaction style, or level of co-occurring maladaptive behavior (Begeer et al., 2015). For example, group interventions are often used with individuals who are higher functioning (Begeer et al., 2011; Solomon et al., 2004) and children with less severe diagnoses tend to respond better to ToM intervention (Begeer et al., 2011). For children with ASD, the impact of co-occurring diagnoses such as intellectual disability (Roselló et al., 2020) or ADHD (Berenguer et al., 2018) also need to be taken into account when determining inclusionary and exclusionary criteria for participants. Additionally, social difficulties are heterogeneous. Some children with ASD may be uninterested in initiating social contact, whereas others may be overbearing in their engagement with others (Begeer et al., 2015; Waugh & Peskin, 2015). Thus, the impact of intervention may interact with baseline individual differences or even family characteristics. For example, de Veld et al. (2021) found greater treatment effects on some ToM skills when children with autism had either more or older siblings.

Intervention studies do not typically systematically compare dosage—either of session length or total duration of the program. Though most sessions are kept brief (10–20 min; Szumski et al., 2019), the total length of intervention varies from 1 to 2 weeks (e.g., Hadwin et al., 1996; Swettenham, 1996) to several months or even 2 years (e.g., Bauminger, 2007; Szumski et al., 2019). It is not clear if longer interventions would result in better gains in ToM performance though Silver and Oakes (2001) found that the number of times children used the *Emotion Trainer* program correlated with their improvement in emotion recognition and Strange Stories performance. Dosage effects may explain why some ToM interventions with children with ASD have not improved ToM performance, perhaps because only a few sessions were focused on ToM within a broader social skills training (Soorya et al., 2015).

More work is also needed on the efficacy of these intervention approaches in culturally and linguistically diverse populations as most work has focused on Western cultures (Cheung et al., 2021). However, there may be cultural differences in language, resources, family support, or expectations around service (Cheung et al., 2021) that should be considered when implementing these interventions in non-Western cultural settings. For example, Cheung et al. (2021) noted that the high volume of homework for Hong Kong children made it impractical to complete the *S.S.ToM* intervention homework.

Finally, there remains theoretical debate about the nature of improvement in ToM skills in children with ASD. Some researchers view training not as teaching conceptual understanding to children with ASD, but with providing them with a compensatory mechanism to mentally represent others' beliefs (Wellman et al., 2002) or "hacking" strategies (Happé, 1995). However, given their success at training ToM performance that generalized beyond the tasks trained, others have concluded that ToM intervention has the potential to improve children's fundamental understanding of their social world (Paynter & Peterson, 2013).

Conclusions

In this chapter, we have provided an overview of the key developments and common tasks used to assess ToM from early childhood through adolescence. There is a wide range of possibilities to further develop, refine, and implement ToM interventions for children with ASD and other neurodiverse populations. Partnerships with other healthcare professionals including speech-language pathologists are important given the relation between individual differences in language and ToM. Interventions tailored to the individual child's goals will not only support advances in ToM understanding, but also how they use those skills to support their social interactions with others. From an empirical and clinical standpoint, there is more work to be done to better understand how ToM translates to social communication and social interactions in real-world contexts.

Acknowledgments We would like to thank Bridget Wright for her comments on an earlier version of this chapter.

Theories of Intelligence

Matthew J. Euler, Julia V. Vehar,
and Jasmin E. Guevara

Introduction

The goal of this chapter is to provide an overview of theories of intelligence, spanning from historical to contemporary models, with an eye toward highlighting the ways in which theoretical developments have shaped practical aspects of clinical assessment. A common working definition of intelligence, initially provided by Gottfredson, and since widely adopted in the field (e.g., Nisbett et al., 2012; Protzko, 2017; Warne, 2020), describes the construct as:

> [A] very general mental capacity that, among other things, involves the ability to reason, plan, solve problems, think abstractly, comprehend complex ideas, learn quickly and learn from experience. It is not merely book learning, a narrow academic skill, or test-taking smarts. Rather, it reflects a broader and deeper capability for comprehending our surroundings—"catching on," "making sense" of things, or "figuring out" what to do. (Gottfredson, 1997a, p. 13)

Unpacking this definition some, at least three things, stand out. First, intelligence is fundamentally held to be a cognitive construct, defined primarily in terms of thinking skills or capabilities, with no immediate emphasis on motivational, personality, or other constructs. Second, intelligence is somehow both a unitary construct (i.e., described in the singular) and a process that manifests in numerous different ways. Third, intelligence is held to be a highly *general* capacity that is expressed in varied contexts, outside of academic settings alone, and which does not merely reflect school-based learning.

While all three features of the definition above align with the current scientific consensus on intelligence, a number of important issues remain obscured. The most prominent of these is the tension between the notion of intelligence as a unitary capacity versus some sort of composite made up of many lower-order abilities. As will be seen, this has been the central point of dispute in debates about the nature of intelligence for over 100 years and continues to be so today. Related to this is the fact that intelligence is notoriously difficult to define precisely. Scholars have taken a number of approaches in attempting to define it, with each balancing the tensions inherent to the construct with varying degrees of success. At one end of the continuum, Gottfredson's (1997a) definition above provides a partial list of some of the things that intelligent individuals *do* and excludes some common objections.

As such, it is really more of a description of how to recognize intelligent behavior than a definition per se. At the other end of the continuum, Arthur Jensen, another prominent author in the field, avoided the term entirely in his seminal book on the closely related topic of psychometric *g* (described below). Indeed, Jensen described the results of two scientific symposia on the topic of defining intelligence—respectively held in 1921 and 1986, both without success—and concluded that the term "should be discarded altogether in scientific psychology" (Jensen, 1998, Chapter 3). Between these two extremes, numerous authors have offered their own definitions of intelligence, variously ranging from concise yet vague, elaborate and list-like, or (like Jensen) simply admitting futility (see: Wasserman, 2012, pp. 39–40).

This difficulty in defining intelligence reflects what appears to be a fundamental tension in the concept itself. On the one hand, *tests* of intelligence must be capturing some meaningful property of individuals, in the sense that differences in performance between people are highly stable across the lifespan (Deary et al., 2004) and strongly relate to real world outcomes measured later in life. Those include not only occupational and educational status (Ceci & Williams, 1997; Gottfredson, 1997b; O'Connell & Marks, 2021; Strenze, 2007), and creative and scientific accomplishments (Park et al., 2007), but surprisingly, even health and longevity (and even when controlling for childhood SES: Calvin et al., 2011). Likewise, the core phenomenon in the field of intelligence research—the finding that performances on diverse types of tasks essentially always positively correlate (see below)—has been consistently replicated for over 100 years (Spearman, 1904), across hundreds of datasets (Carroll, 1993), and recently, across much of the globe (Warne & Burningham, 2019). Taken together, these facts indicate that whatever is being measured by intelligence tests clearly manifests at the level of individuals, differentiates people in important respects, and is highly replicable across time, cohorts, and even cultures. As such, theories of intelligence and the tests on which they are based are not only measuring something "real," but they arguably capture some of the most robust phenomena in all of behavioral science (and compare to the replication crisis facing some areas of psychology; Aarts et al., 2015; Stanley et al., 2018).

Conceptual and Practical Issues Yet, on the other hand, many issues remain. For example, how is it that intelligence is somehow a single, general process that nevertheless manifests in numerous and highly diverse situations? To wit, tasks of spatial reasoning, general cultural knowledge, verbal rehearsal of number or letter sequences, and speeded visuomotor tasks are all considered to be important indicators of intelligence (Wechsler, 2008a). Yet each involves manifestly different content and likely recruits fairly diverse neural networks. In turn, is intelligence truly a unitary entity, or is it composed of subprocesses, and if so, in what fashion? This generality also complicates the search for neural correlates of intelligence, which might otherwise help ground and refine the construct. This is because of the fact that, as behavior becomes more complex, the neural networks involved are likely to become more variable from one person to the next (Euler, 2018).[1]

These persistent questions about the nature of intelligence also complicate the resolution of related debates, including questions about how intelligence develops (Demetriou et al., 2018; Savi et al., 2019), the extent to which genetic and environmental factors interact during development (Dickens & Flynn, 2001; Tucker-Drob et al., 2011), the degree to which intelligence overlaps with or depends on

---

[1] It is worth noting that these challenges are not necessarily true of psychological constructs in general. Research on memory provides a clear counterexample where, like intelligence, formal scientific investigations also began near the end of the nineteenth century (Ebbinghaus, 2013), but has since succeeded in moving from a broad and vaguely defined construct to a situation where numerous sub-types of memory have been distinguished and linked to specific neural processes (Squire & Schacter, 2003). The difference likely reflects the fact that memory can be studied experimentally via within-subject procedures that ignore individual differences, whereas intelligence has been studied almost entirely as a between-subjects phenomenon.

other processes like motivation or certain personality constructs (Colom et al., 2019; DeYoung et al., 2005; Duckworth et al., 2011), and how the processes that make an individual person intelligent relate to the between-subject effects that form the bulk of the literature (Kovacs & Conway, 2016; Weinberger, 2015).

It is perhaps because of these tensions that the much derided definition offered by E.G. Boring (1923) actually turns out to be fairly apt. Famously, Boring asserted that "…intelligence as a measurable capacity must at the start be defined as the capacity to do well in an intelligence test. Intelligence is what the tests test." However, in the subsequent (and typically omitted) portion of the quote, he went on to write:

> This is a narrow definition, but it is only the point of departure for a rigorous discussion of the tests… An observational method for extending knowledge of intelligence as the tests test it is the method of statistical correlation. The relation to intelligence of any measurable capacity at all can be determined by comparing the relative performances of a large number of persons in an intelligence test with their achievement in the measure of capacity in question. (p. 35)

Thus, while Boring's initial definition is clearly circular and seemingly arbitrary, it is only "the point of departure" for a more serious discussion that acknowledges that construct validation is *always* an iterative process (Cronbach & Meehl, 1955). That is, research on psychological traits necessarily begins from a colloquial understanding of a term, from which scientists rationally develop measures designed to assess the trait in question. From there, they assess the ability of the measures to *predict real world outcomes* thought to relate to the construct and proceed to further refine their theories and instruments. In the case of intelligence, Boring's definition not only foreshadows the nearly unmatched predictive validity of intelligence testing, but also the ongoing difficulty in refining the construct.

For clinicians, it is of course the accuracy of those real-world predictions that determine whether intelligence testing is useful, and it is our aim in this chapter to show how theoretical debates about intelligence are relevant to practitioners. In our view, these debates matter because the most successful theories get translated into tests directly. From there, they go on to influence the ways that psychologists interpret and present test data to clients and their families, which in turn shape the perceptions that clients and those around them go on to form about their needs and capabilities. As such, seemingly esoteric debates about whether intelligence is wholly unitary or at least multifaceted, and whether it is a static and "intrinsic" property of people or something that develops over time ultimately bear on people's lives in important ways.

In this respect, we want to close this section by noting a final tension surrounding intelligence, intelligence research, and its assessment in individual people. On the one hand, well-validated intelligence tests, like those discussed later in this chapter, clearly do measure something important about individuals, in a reliable fashion, and in a way that provides information about their possible or probable (but not foreordained) outcomes. As such, it is clearly a mistake to interpret the ongoing theoretical controversies about intelligence as cause to entirely dismiss the construct or the enterprise of intelligence testing. Moreover, all areas of science face ongoing debates, and the debates we highlight below, should also not be taken as justification for dismissing the considerable amount that is known about human intelligence, or for adopting alternative theories that persist in the popular media (and even some textbooks) but have failed to withstand serious scrutiny (see: Warne et al., 2018).

Yet, the fact that the theoretical consensus does develop and change should give both theorists and clinicians appropriate humility in their statements about what test scores mean for individual people. Yes, the empirical record of intelligence testing is strong, but conceptions about its nature, malleability, and its influence via social and cultural factors continue to mature. This casts the assertions of some figures in this area that intelligence is an immutable characteristic of people or even specific groups in an especially poor light, particularly given the impossibility of ever isolating and quantifying the many factors that influence intellectual development (Turkheimer, 2000). Indeed, it is regrettable that many figures in the history of intelligence research held views that are now (rightly) considered highly objectionable for the ways in which they disparaged various groups on the basis of race, sex, and disability and for advocating eugenics as a means to "improve" future generations (e.g., see: Allen, 2001; Schumacher, 2019; Wasserman, 2012). Although such views were unfortunately common at the time, and have been long rejected (Warne, 2019), they cast a shadow that intelligence research is still working to overcome (Wai, 2020). As such, two of our aims in this chapter are to demonstrate how continued study has helped to distinguish the empirical facts of intelligence from unjustified assumptions that were sometimes inferred on their basis and to highlight the importance of conceptualizing intelligence in a way that recognizes the dignity and supports the success of all individuals.

The rest of the chapter is structured as follows: section "Early theories of human intelligence" reviews the historical development of theories of intelligence, beginning from the earliest scientific research at the end of the nineteenth century. The section "Twentieth-century perspectives" covers contemporary models that are instantiated in some of the assessment batteries in current wide use. In section "Recent developments in theories of intelligence", we review the newest group of theories, which are noteworthy in that each is either explicitly developmentally or process-focused in its orientation. Thus, readers will note the general arc of theoretical development from a relatively static (and at times essentialist) view of human intelligence, toward an increasing emphasis on the different facets of intelligence and how they interact over the course of cognitive development. The section "Practical applications and implications" concludes the chapter by reviewing the connections between specific theories of intelligence and some of the intellectual assessment batteries in common use clinically and presents a brief (hypothetical) case example to illustrate how theoretical debates influence battery structure, and ultimately clinical interpretations. Finally, we note that because we have aimed to provide an accessible overview of theories of intelligence for practicing clinicians, we have necessarily emphasized the critical features of various theories, at the expense of a more nuanced presentation of some views. Thus, we point interested readers to the source material cited below, as well as more detailed reviews available elsewhere (Deary, 2000; Jensen, 1998; McFarland, 2019).

Early Theories of Human Intelligence

Francis Galton and Reductionism in Intelligence Research The earliest writings on individual differences in intelligence date back to ancient times. However, it is generally agreed that, like much of the rest of psychology, the formal study of cognitive ability did not begin until the late nineteenth and early twentieth centuries with the work of Francis Galton, Alfred Binet, and Charles Spearman (Jensen, 1998). Galton provides a useful starting point, as the figure generally associated with the first attempt to measure individual differences in mental abilities.

Discussions of Galton appropriately situate him within the intellectual milieu of the late nineteenth century and especially in relation to Darwin's account of natural selection which was gaining acceptance at the time. The preface of the second edition of his book *Hereditary Genius* (1891) gives an indication of his basic views and scientific goals, where he wrote:

> At the time when the book was written, the human mind was popularly thought to act independently of natural laws, and to be capable of almost any achievement, if compelled to exert itself by a will that had a power of initiation. Even those who had more philosophical habits of thought were far from looking upon the mental faculties of each individual as being limited with as much strictness as those of his body, still less was the idea of the hereditary transmission of ability clearly apprehended. (vii)

From this, we can immediately see the connection between Darwin's theory of natural selection and Galton's project. Explicitly, natural selection provided a scientific explanation for how different species came to possess their traits, and in particular, it emphasized that it was the degree to which a trait proves adaptive for a given environment that determines whether it would ultimately be passed on to an organism's offspring. Galton's aim was to apply this same logic to human beings. Specifically, he aimed to show that, like other species, (1) the characteristics of human beings had also been selected for on the basis of their adaptive benefits, (2) they are subject to physical and biological constraints, and (3) they could be passed down by heredity (Galton, 1883, 1891).[2] In the quote above, we can also see that Galton was in part reacting to what he perceived as a tendency to view human beings as falling outside the reach of physical laws. Thus, a main goal of his work, and one of his primary intellectual contributions, was to *naturalize* the study of human traits, by showing that they could be measured in the first place and by trying to understand them through the lens of natural selection.

The remainder of Galton's research efforts can be seen in this light, which informs his scientific contributions as well as his failures. In terms of the former, Galton's interest in understanding even basic aspects of variation among people led him to make foundational contributions to the fields of biometrics (the measurement of human bodily characteristics, such as fingerprinting) as well as statistics. Most notably, these interests led him to establish what he termed the "Anthropometric Laboratory," where, with the help of several assistants, he was able to record information on the basic demographics and physical features (height, weight, eye color) of nearly ten thousand individuals, as well as their performances on a battery of simple perceptual and motor tasks (e.g., pitch discrimination, reaction time; Galton, 1882; Sattler, 2002). From his studies there and elsewhere he established that many human characteristics vary along distributions and demonstrate reliable statistical associations (e.g., the association between height and limb length, or between the heights of parents and their children). From this work, he developed the precursor to the correlation coefficient, regression analysis, and the concept of regression to the mean (Fancher, 2009).

Galton's emphasis on natural selection and heredity also provides the through-line that connects his work in the Anthropometric lab to his views on intelligence. Namely, although he did not think that simple tasks measured intelligence directly, he did view them as indicators of basic physical efficiency, which in turn would influence intellectual ability by way of sensory constraints (Wasserman, 2012). In particular, he held that since we gain our knowledge of the world solely through the senses, a greater ability to discriminate basic stimulus features should result in a "larger…field upon which our judgment and intelligence can act" (Galton, 1891, p. 19). From this, one can see how Galton became the namesake for reductive approaches in intelligence research. That is, approaches that emphasize the role of what are ostensibly "lower-order," more basic physiological processes in supporting or constraining intelligence, and the related idea that it should be possible to understand intelligence by "decomposing" it into simpler constituent parts. Likewise, although Galton never provided his own positive definition of intelligence (Jensen, 1998), his hereditary view of the construct is evident in his assumption that it was an inborn aspect of individuals, which was subject to relatively little influence by training or education (Galton, 1883, 1891).

Despite the positive aspects of Galton's program to naturalize the study of individual differences, his emphasis on natural selection, and specifically the reductive way with which he applied it to intelligence, also provides a guide to understanding his failures. Most prominently, subsequent attempts at

---

[2] The controversy surrounding the heritability of intelligence—the degree to which variability in intelligence is "due to" genetic versus environmental factors—is not our focus here and requires a much longer treatment. Suffice it to say that the topic is exceedingly complex, and insofar as "*all* human behavioral traits are heritable" (Turkheimer, 2000; emphasis added), any fruitful discussion starts from the premise that genetic and environmental factors inevitably interact in producing complex traits, rather than trying to resolve the question in favor of one explanation or the other (Turkheimer, 2019).

measuring intelligence via anthropometric procedures near the turn of the twentieth century quickly confirmed the limitations of the approach (Wasserman, 2012). Likewise, while there is now clear support for Galton's contention that seemingly simple tasks of reaction time or sensory discrimination should relate to intelligence (Deary et al., 2001; Sheppard & Vernon, 2008), in practice, the effect sizes are modest. A fair interpretation of these results might be that, while Galton was vindicated in principle, the fact that these processes are only moderately related to actual intelligence makes their theoretical significance somewhat unclear. Finally, Galton can also be critiqued for the way in which he continually conflated the notion of "natural" processes with those that are hereditary per se, which fails to recognize that even environmental influences on traits can of course be entirely natural (e.g., the effortless way in which most children learn their native language). This conflation also fails to recognize that all behavioral traits are ultimately physiologically mediated. In summary then, whereas Galton played an important role in setting the study of individual differences on a scientific footing, in the end, his work also illustrates the limitations of an overly reductive approach to understanding intelligence.

Alfred Binet and the First Practical Test of Intelligence In historical reviews, it is sometimes common to contrast Galton and Binet as exemplifying opposite extremes in their approach to studying intelligence. Galton is generally presented at one end of the continuum, as a figure who worked in many fields, but was primarily concerned with theoretical issues in intellectual assessment, whereas Binet is typically portrayed as solely concerned with the applied goal of developing a working test of intelligence. In actuality, Binet was a prolific author whose interests also ranged fairly widely and was concerned with theoretical issues (Siegler, 1992), while Galton's work on the basic measurement of individual differences, and especially in statistics, should be equally recognized for its impact on applied aspects of assessment. Nevertheless, it remains useful to contrast the two figures, at least heuristically, due to the much more direct impact of Binet's work on conceptions of intelligence as it is actually measured. Indeed, it is not an overstatement to say that most of the crucial features of contemporary intelligence test batteries, and many of the insights underlying them, were developed in Binet's work.

As detailed by Wasserman (2012), Binet's research to develop a working test of intelligence spanned a period of 21 years, beginning with the 1890 publication of a series of studies he had conducted with his then school-age daughters and culminating in the publication of the third revision of the Binet-Simon Intelligence scale in 1911. Throughout the intervening period, Binet worked with several colleagues to develop a working scale of intelligence, which included testing and revising items, planning scale development, and publishing their ideas. In an 1895 paper with Victor Henri, Binet explicitly contrasted their approach with that of Galton, critiquing the latter's overemphasis on "sensations and simple processes" and presciently arguing that "we must not deduce…that it is sufficient to study elementary processes to know the nature of complex processes" (Nicolas et al., 2014).

The most immediate impetus to develop a working scale came in 1904, when the French government commissioned a study of how to extend public education to children with auditory or visual impairments or developmental disabilities (Wasserman, 2012). Together with Theodore Simon, Binet then developed and normed 30 tasks on a group of 50 children ages 3–11, publishing the test in 1905 as the Binet-Simon scale (Sattler, 2016; Wasserman, 2012). Although the scale was unfortunately ignored in its time by the French establishment (Siegler, 1992), its publication was a singular event in the history of intelligence assessment.

There are a number of features that made the Binet-Simon scale so innovative. First, he gave considerable thought to how the scale would actually function in practice. As a result, it featured standardized instructions for administration and scoring (thereby helping to maximize the reliability of the scale) and involved no specialized equipment for its administration. Second, it was the first norm-referenced scale, meaning that rather than taking absolute measures of performance (as one could do for sensorimotor variables such as visual acuity or grip strength), performance was rated relative to the average performance of children at the same age. This innovation reflected his insight to incorporate developmental considerations into the test, recognizing that what is an appropriate level of difficulty at a given age would not be appropriate for another, and which also justified the decision to order the tasks by increasing difficulty and complexity. This age-normed approach was further codified in the 1908 revision via the mental age score, which formed the basis for what became the IQ score (Wasserman, 2012).

Most crucially, because Binet was focused on the issue of differentiating individuals, this led him to recognize that complex rather than simple tasks were much better suited to this purpose. He recognized that it was not necessary to completely characterize mental functioning, or to determine all the mental variables on which individuals differ, but merely to identify the "strongest and most important" (Binet & Henri, 1895; translated by Nicolas et al., 2014). In contrasting his approach with that of Galton's, he wrote:

> The objection will be made that the elementary processes can be determined with much more precision than the superior processes. This is certain, but people differ in these elementary processes much more feebly than in the complex ones; there is no need, therefore, for as precise a method for determining the latter as for the former. (Binet & Henri, 1895; translated by Siegler, 1992, p. 181)

This quote concisely communicates a fundamental principle that distinguishes the "general" (i.e., experimental) approach to psychology with the effort to measure individual differences (Cronbach, 1957). On the one hand, simple processes are, by their very nature, much more amenable to precise measurement. And, because they are simple, it is much easier to discern their connection to particular nervous system functions (consider visual acuity or pitch discrimination), which also makes them compelling for researchers who are interested in physiological or genetic correlates of traits. Yet on the other hand, because simple tasks do reflect the action of comparatively discrete neural processes, the processes they tap are likely to be highly *conserved* across individuals. Thus, the very quality that makes simple tasks appealing for reductionist research also undermines their usefulness as measures of individual differences (Euler, 2018). Binet's key insight, which is still evident in contemporary intelligence measures, is that even though complex mental processes cannot be measured as precisely, because they admit of greater variation across people, that alone makes them sufficient as indicators of individual differences.

The last important innovation of the Binet-Simon scale was the fact that it sampled a diverse range of abilities. This reflected both Binet's skepticism about the value of single tasks used in isolation as measures of intelligence (Boake, 2002) and his substantive view that "intelligence is not a single function, indivisible and of a particular essence" (Binet, 1909/1984; cited in Siegler, 1992). Binet was clearly correct about one of these and less so about the other. Although history has clearly vindicated his choice to use to diverse tasks to derive a composite measure of intellectual ability, the question of whether intelligence reflects a single essence is not at all settled and remains a defining issue in the field.

Spearman, Psychometric** g**, and the First Factor Models of Intelligence In 1904, Charles Spearman made what is probably the definitive contribution in the history of intelligence research, with his discovery of psychometric g. In his article, Spearman identified and set out to correct what he saw as the major problems with prior efforts to scientifically characterize human intelligence. These included failures to control for confounds (e.g., age differences between subjects, practice effects), failures to minimize and statistically account for measurement error, and most crucially, failures to describe the results in a precise, quantitative fashion (Spearman, 1904).

Spearman attempted to address these issues in a series of studies conducted with children and adolescents, whom he assessed on measures of basic sensory discrimination (following Galton and the thinking of the time) and then related to estimates of intelligence, in the form of grades in various academic subjects, and instructors' and others' rankings of the students' intellectual ability. Although Spearman's samples were very small by contemporary standards (only 33 boys participated in the most important study), he nevertheless observed positive correlations among the perceptual measures and the intelligence estimates, as well as between the two. Most importantly, however, because of his goal to produce more rigorous estimates of the true relationships, he took two additional steps that proved decisive.

First, he devised a method to statistically control for measurement error in the correlation between two variables, which allowed him to estimate the *true* correlation between them (and thereby laying the groundwork for classical test theory; Jensen, 1998). He then devised a way to extend this procedure, such that it could be used to indicate the amount of shared variance between two *series* of measurements. For example, if one calculates the average correlation among the sensory measures, the average correlation among the ability estimates, and the average correlation between the two, one can then apply the formula to these three variables and identify the amount of true score variance (the variability that is free from measurement error) that the two series share in common. Note that this also applies to the correlations between variables within a single domain, such that tests of auditory and visual discrimination and judgments of weights can all be subjected to this procedure to determine how much variance they share in common. Spearman found, for the first time, that performances in seemingly very different subjects (e.g., English, Classics, French, Mathematics, Music, and Pitch discrimination) were all positively related.

Second, Spearman identified that by arranging the resulting correlation table hierarchically, he could use an additional procedure to examine the patterns of shared variance among the different variables (Jensen, 1998). Specifically, he showed that, as a matter of mathematical necessity, when the relative sizes of the correlations are consistent throughout the entire table, it is then possible to separate the variance contributing to them into only two parts: a first part, that is common to all the variables in the table, and a second part, that is unique to each individual task (Spearman, 1927). That is, he showed that, for any set of variables showing this pattern, *a single statistical factor* accounts for a large portion of their shared variance. In the time since, it is been shown that this single factor emerges from cognitive batteries in a highly reliable way and accounts for a much greater share of variance than any additional factors (Deary, 2012). The practical importance of this is that, although one might intuitively expect that a host of highly different cognitive processes would account for differences between people in Mathematics versus English, in actuality, just a single process (or a set of integrated processes) may be most relevant. Based on these findings, Spearman developed his "two-factor" theory, where he argued that individual differences in any tests of cognitive ability draw upon differences in just one general factor and a test-specific factor, where the former reflects just a single, universal intellectual ability. He provisionally termed this factor "general intelligence" and later revised this to the more theoretically neutral, lowercase letter *g* (see additional details in Beaujean, 2019).

A few additional points should be made about psychometric *g* and the statistical method of factor analysis that Spearman pioneered with his discovery of it. First, it is important to note that although *g* is almost inevitably found in factor analyses of cognitive test batteries, this fact is an empirical regularity rather than a logical necessity. For instance, in personality research, the most well-established model involves not one, but five separate dimensions (Costa & McCrae, 1992), with its major competitor being a six-factor model (Ashton & Lee, 2007). This indicates that there is nothing inherent to exploratory factor analysis that dictates the number of factors that will be obtained. In the case of personality, where several different dimensions are needed to represent individual differences, the practical result is that there is no fixed relationship between the way a person scores on one dimension and another (e.g., someone can be high on Agreeableness and high, low, or average on Neuroticism or any other dimension). Critically, this is not the case for cognitive ability, where individuals who score highly on one task tend to score highly on another. This latter pattern is termed the *positive manifold phenomenon* (simply meaning that the correlations among the tests are all positive) and is the underlying reason why *g* emerges from cognitive test batteries.

Second, an important corollary to Spearman's finding that *g* is a universal feature of any sufficiently broad sampling of cognitive tasks is his observation that any two tasks that relate to *g* equally well (i.e., that have the same "*g*-loadings") should be equivalent as measures of overall intellectual ability. Spearman termed this principle the "indifference of the indicator" and offered it as the reason why Binet's method of aggregating performance across many types of tasks was successful for measuring intelligence (Spearman, 1927). That is, insofar as the variance in any cognitive test largely reflects *g,* in any broad sampling of tasks, *g* will dominate over their more idiosyncratic variance, making the aggregate across them little more than a measure of *g* itself (Spearman, 1927). Importantly, this phenomenon can be readily observed in actual test data where, for example, tasks of vocabulary knowledge and visual-analogical reasoning have been shown to have nearly identical *g*-loadings despite their highly dissimilar content (Wechsler, 2008b).

Finally, while the empirical record of *g* is undeniably strong, it is important to clarify some additional issues pertaining to what does and does not follow from the basic empirical facts about it. For example, while the existence of *g* does *seem* to indicate that just a single process "explains" individual differences in cognitive task performance, the validity of this interpretation hinges entirely on what one means by an explanation. To be explicit, *g* is, at its core, a *statistical* entity that reflects patterns of variation in performance on cognitive tasks. As such, it does seem valid to say that it "explains" variation among individuals, in the sense of the amount of variance it might account for in a social science context (e.g., correlating with occupational outcomes in population-based studies), or in terms of its predictive validity for informing clinical or educational decisions about an individual based on their obtained IQ score (e.g., about the appropriateness of a particular placement or intervention). However, this does not mean that *g* reflects a unitary *physical* entity in the nervous system or anywhere else, in the sense of resulting from just a single cognitive or physiological process. This last issue—the degree to which *g* as a statistical phenomenon corresponds to real phenomena in the brain—is of course an empirical question and has been the starting point for debates in the field ever since.

Initial Alternatives to Two-Factor Theory Following the publication of Spearman's (1904) paper, and throughout the rest of the twentieth century, psychologists put considerable effort into trying to develop the most accurate theory of human intelligence. Like Spearman, many of these authors used factor analytic techniques to test structural models. In these models, each factor reflects a statistical grouping of tests that form a set by virtue of correlating relatively highly with one another and being relatively uncorrelated with the others in a given battery. In turn, the "structure" of the model refers to the number of statistical factors that are needed to represent the variance among the test scores and the patterns of interrelations between the different factors that make up the model. Recalling the examples above, response patterns on personality questionnaires can often be represented well with structural models containing five or six factors, while Spearman of course argued that just a single factor, *g*, was common to all cognitive tasks. The psychological meaning or interpretation of a given factor depends on the degree to which the underlying items contributing to it clearly involve the same type of content (e.g., verbal or visual material) or processes (mental speed, long-term memory, etc.). Finally, competing models can be compared to one another in terms of how well they "fit" the data in terms of the amount of variance each explains and other statistics. Thus, many debates in intelligence research in the twentieth century (and still today) concern competing models that aim to describe the structure of human intelligence in terms of how various cognitive processes might interrelate to ultimately explain the variance among test scores.

The clearest challenge to Spearman's two-factor theory, or any theory that posits a *g* factor, initially came from what have been termed "multifactor" theories, which were promoted by authors like Thorndike, Thurstone, and Guilford (Sattler, 2016). The critical feature of these theories is that they all argued that intelligence was made up of multiple, *uncorrelated* psychological factors, represented by distinct, narrower abilities, such as memory and speed of processing. Because these abilities were held to be uncorrelated, multifactor theories directly opposed the idea that variation in intelligence could be subsumed by a single general factor as in two-factor theory. A major appeal of these models is the fact that, unlike *g*, which seems to resist a clear psychological interpretation, it is fairly intuitive to imagine that individual differences might be split up among many different faculties and that these might roughly correspond to different aspects of brain functioning, educational experience, or practice. A number of these models were proposed, including Thorndike's multifactor theory, which was conceptual rather than quantitative, and Guilford's Structure of the Intellect model which contained over 100 factors that intersected across three dimensions (Sattler, 2016). For present purposes, it is most useful to focus on the canonical multifactor theory, Thurstone's "Primary Mental Abilities" model.

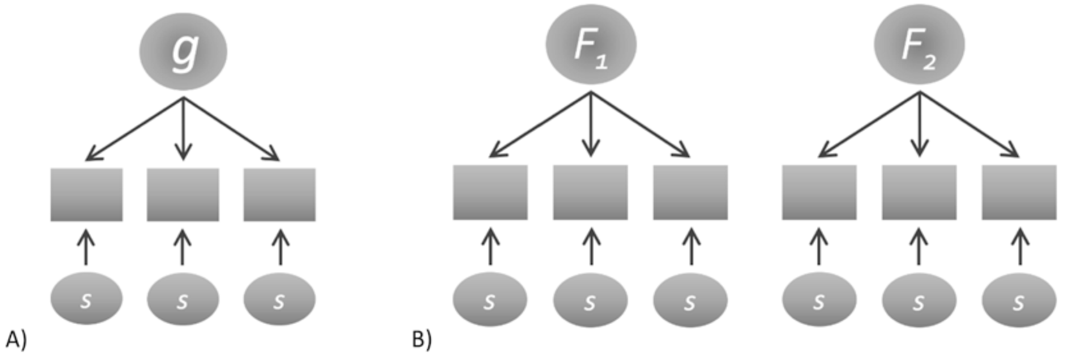
Like other multifactor theorists, Thurstone held that cognitive ability was comprised of multiple, uncorrelated abilities. To support this view, he developed tests that were designed to function as pure measures of the primary abilities and employed a method of factor analysis which allowed one to identify multiple, maximally independent factors (Jensen, 1998). Through a series of studies, Thurstone was able to identify what he argued were eight primary mental abilities (e.g., verbal comprehension, perceptual speed, and memory; Wasserman, 2012). Over time, however, it became clear that rather than enabling one to identify factors that are truly uncorrelated, Thurstone's method essentially forces this result and precludes the identification of a single general factor which could otherwise emerge. In fact, it was eventually established that although Thurstone's measures were somewhat successful in measuring only a single primary mental ability, they all also measured *g*, with the latter sometimes accounting for more variance in the score than the primary ability of interest (Jensen, 1998). Ultimately, Thurstone was forced to acknowledge that what he hoped were independent mental factors were actually intercorrelated and could themselves be accounted for by a second-order *g* factor. Figure 15.1 depicts schematic versions of Spearman's two-factor theory and Thurstone's Primary Mental Abilities model.

This same result has proved true of other theories that have aimed to identify sets of uncorrelated processes that might account for individual differences in cognitive performance. In short, although it is the case that individuals do vary along different cognitive dimensions (e.g., one person might have strong verbal skills and weak spatial skills, and vice versa for someone else), and that these do somewhat correspond to different aspects of brain functioning, it is simultaneously true that most of the variance in cognitive ability is shared across cognitive domains, as reflected by the positive manifold.[3] Thus, the debate as to whether human cognitive abilities might actually be uncorrelated has now been decisively settled. Human cognitive abilities are positively intercorrelated, full stop.

Notwithstanding their empirical defeat, the early multifactor models nevertheless left two important legacies. First, Thurstone's work on primary mental abilities eventually culminated in a consensus around what are now called "broad" ability factors. These are abilities that are common to tests involving similar cognitive processes (much like Thurstone's primary abilities), but which are identified at an intermediate level of abstraction, between narrow abilities that are measured by individual tests and a higher-order *g* that accounts for the variance among the broad factors themselves (e.g.,

---

[3] This is a subtle point. The reason why these can be simultaneously true has to do with the fact that the processes that cause variation within individuals are not necessarily the same as those that cause variation between them. Psychometric *g* reflects that fact that an individual's strengths or weaknesses in various sub-domains are independent of their overall intellectual level.



Note. Two schematic factor models. Manifest variables are depicted as rectangles and latent variables are depicted as ovals. A) Example version of two-factor theory involving the three tests, whose common variance loads onto a single *g* factor and plus a unique test-specific factor. B) Example Primary Abilities model involving six tests, two abilities, and no general factor.

Fig. 15.1 Example factor models of intelligence
Note. Two schematic factor models. Manifest variables are depicted as rectangles and latent variables are depicted as ovals. (**a**) Example version of two-factor theory involving three tests, whose common variance loads onto a single *g* factor plus a unique test-specific factor. (**b**) Example Primary Abilities model involving six tests, two abilities, and no general factor

verbal comprehension would be considered a subdomain of the broad factor of verbal skills, both below *g*). Thus, the ultimate outcome of the debate between Spearman and Thurstone was essentially an integration of their two views, such that Spearman came to acknowledge the existence of broad factors in batteries that sufficiently sample from similar types of tests, and Thurstone accepted the emergence of a general factor from the intercorrelations among the broad abilities. These so-called hierarchical models are endorsed by many researchers in the field today (see Fig. 15.2, and section "Twentieth-century perspectives"). Second, although the statistical case for *g* has been long settled, its physiological basis remains very much under debate. In fact, a model first developed in Spearman's own time—the "bonds" model (also called sampling theory), advanced by Godfrey Thomson—has reemerged as an important alternative for conceptually explaining *g*. In brief, Thomson argued that while *g* was an adequate quantitative description of the positive manifold, it did not follow that its emergence from a battery of tests indicates the presence of just a single underlying process (Bartholomew et al., 2009). Instead, Thomson argued that *g* could also emerge for the reason that tests require overlapping sets of mental processes to complete them. The more processes that are shared by a set of tests, the higher the correlation between them (Bartholomew, 2004). Because Thomson's model was somewhat overlooked in the scholarly literature until recently, the next Section addresses other important developments in conventional factor modeling that occupied the second half of the twentieth century, before returning sampling theory and other more innovative models in section "Recent developments in theories of intelligence".

Twentieth-Century Perspectives

Cattell's Theory of Fluid and Crystallized Intelligence In 1943, in the context of mass testing for military conscription during World War II, Raymond B. Cattell reviewed the state of adult intelligence testing in the United States and described his surprise at the many problems he saw in the field.

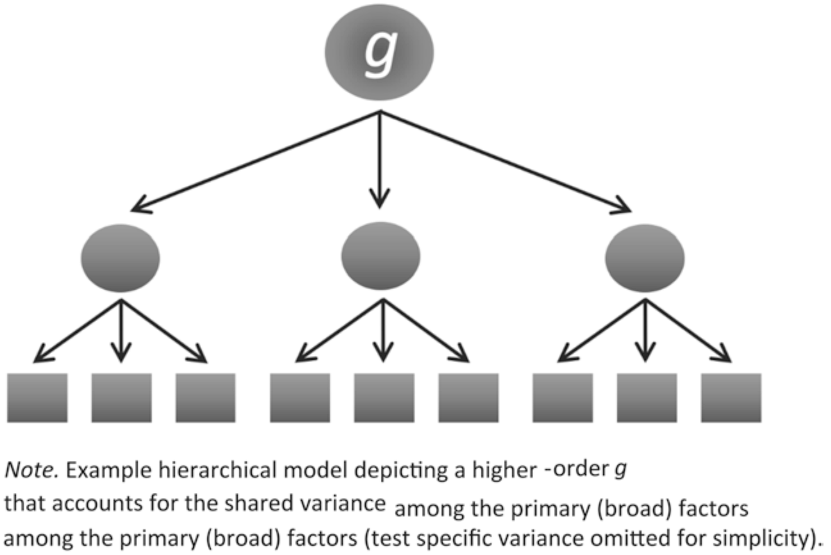


Fig. 15.2 Example hierarchical model
Note. Example hierarchical model depicting a higher-order *g* that accounts for the shared variance among the primary (broad) factors (test-specific variance omitted for simplicity)

Overall, he noted a disconnect between the large number of tests available and their general inadequacy for use in the population at large. This was typically due to the tests having been normed for college students, and thus being insufficient for assessing intelligence in individuals with more limited educational experience, people who lacked English fluency, or older individuals who performed more slowly on timed tests but nevertheless demonstrated high intelligence when assessed by other means (Cattell, 1943). Cattell saw all of these weaknesses as ultimately resulting from the lack of adequate theory as to the nature of intelligence, which in turn had provided insufficient guidance for test development. He then offered his own view—based on both factor analytic results and a synthesis of broader findings in psychology—that adult intelligence primarily consists of not one, but two, broad cognitive abilities. These abilities, now termed fluid (Gf) and crystallized intelligence (Gc), still represent two of the most important concepts in theoretical and applied work on intelligence.

Fluid intelligence reflects the ability to solve novel problems, and especially emphasizes efficiently responding to unfamiliar stimuli under momentary conditions, whereas crystallized intelligence reflects learned skills and knowledge. Critically, Cattell held that the two abilities are developmentally connected, such that someone's crystallized intelligence explicitly reflects the solidification, through learning, of what was once fluid ability. Thus, it is through the application of one's momentary cognitive resources (perception, attention, reasoning) that an individual comes to develop various skills and habits that they can then call upon to solve knowledge-based problems. In turn, any cognitive test can be grouped according to whether it involves more fluid versus crystallized abilities, or some combination of the two. The most famous measure of fluid intelligence is likely the Ravens Progressive Matrices, in which the examinee is presented with an array of figures that vary in their visual characteristics (image color, shape, texture, and combinations therein) and must identify the item that correctly completes the array from a set of figures that vary on the same features. The items become progressively more difficult as the test progresses, moving from essentially simple visual matching problems to those that require multipart logical operations, with typical administrations requiring examinees to complete approximately 40 items in 30 min (Raven & Court, 1998). Thus, the Ravens matrices test exemplifies many characteristics of typical fluid intelligence tasks, and most notably, the use of visual and especially figural content, and the need for attention and "on-the-spot" reasoning under timed conditions. In contrast, canonical measures of crystallized intelligence include vocabulary tasks or tests of general knowledge, which depend heavily on prior learning.

In developing the theory of fluid and crystallized intelligence, Cattell sought to address a number of issues in the broader field. These included (1) changes in the *g*-loadings of various tasks from child to adult samples, (2) the dissociation of mental speed from overall ability in adults as they age, and (3) the tendency for brain injury to most adversely affect tasks requiring mental speed and novel or abstract problem solving, while generally sparing language measures like vocabulary and verbal comprehension (Cattell, 1943). The persistence of Gf-Gc theory reflects how well it accommodates the phenomena responsible for these effects. For example, because Gf and Gc differ in the degree to which they depend on momentary cognitive processes, they exhibit distinct developmental trajectories over the lifespan. Gf, through its reliance on mental speed in particular, increases through childhood into early adulthood, after which it begins to decline, likely reflecting patterns of white matter maturation and change in the brain (Bendlin et al., 2010; Penke et al., 2010; Ferrer et al., 2013). Conversely, because the acquired skills and semantic knowledge that support crystallized intelligence are more related to cortical networks (particularly in the left hemisphere; Palmer et al., 2021), its developmental trajectory shows a similar increase through childhood into early adulthood, but remains stable or actually increases through the sixth decade of life and is relatively preserved even into old age (Salthouse & Davis, 2006; Spreng & Turner, 2019). These associations are also consistent with decades of neuropsychological research, which has demonstrated impairments in tasks that require fluid abilities in conditions affecting white matter connectivity and diffuse neural networks, such as in severe traumatic brain injury or subcortical dementias, with relative preservation of language functions and other crystallized skills (Lezak et al., 2012). Finally, because Gf seems to be best tapped by tasks involving abstract, figural content, rather than verbal and factual information that is more explicitly emphasized in formal education, it was also argued that Gf-Gc theory provided a basis for developing "culture-fair" intelligence tests (Cattell, 1963).

In the following years, Cattell worked with his student, John Horn, to expand the theory of fluid and crystallized intelligence to include other broad abilities. Like the original theory, the authors were motivated by evidence that the original Gf-Gc model could not account for developmental and neurological processes that seemed to affect domains beyond just fluid and crystallized skills. Ultimately, their follow-up studies culminated in the extended Gf-Gc theory, which includes the following eight domains: Acculturation Knowledge (Gc), Fluid Reasoning (Gf), Short-Term Memory (Gsm), Long-Term Memory (Glm), Processing Speed (Gs), Visual Processing (Gv), Auditory Processing (Ga), and Quantitative Knowledge (Gq) (Sattler, 2016). As detailed by Horn and Blankson (2012), in the extended model, Gf and Gc reflect their original interpretations—the capacity for focusing attention, understanding the elements of problems, and reasoning about them efficiently (Gf), and the "acquisition of knowledge about the language, concepts, and information of the dominant culture" (Gc). Gsm reflects the ability to maintain and manipulate information held in mind over brief intervals (often called working memory), while Glm reflects the capacity to maintain and retrieve information over spans ranging from minutes to longer. Gv and Ga reflect abilities mediated in their respective sensory domains, such as spatial orientation, visualization, and length estimation (Gv), and auditory comprehension and judgments of rhythm (Ga). Gq entails mathematical abilities like number facility and algebraic manipulation, while Gs is tapped by tasks like perceptual and decision speed. Last, it is also worthwhile to note that the factors that make up extended Gf-Gc theory can be conceptually grouped according to their broad developmental and neurological correlates—those that are vulnerable to diffuse neurological injury or age-related decline (Gf, Gs, Gsm), those that relate to the development of expertise (Gc, Gq, Glm), and those that reflect particular sensory functions (Gv, Ga) (Horn & Blankson, 2012).

There are a few other things to note about the extended Gf-Gc theory before moving on. First, as is true of the factors in any structural model, in actual practice, performance on tasks designed to tap any of the domains will rely on Gf, Gc, and other domains to varying degrees. Second, both the original and the extended Gf-Gc theories explicitly do not include a *g* factor (Jensen, 1998). This actually relates to an important criticism of the theory, which is that, in models with broad factors that do allow for a higher-order general factor, it is frequently not possible to statistically distinguish Gf from *g* itself (e.g., see Kvist & Gustafsson, 2008). This undermines the claim the Gf is a meaningful statistical entity apart from *g,* and particularly in light of the common finding that tasks designed to measure Gf are often the most highly *g*-loaded in any battery (e.g., Wechsler, 2008a). The final point, although somewhat complex, is important and relates to more recent developments regarding the cultural dependence of tasks of Gf and Gc.

In particular, although it is certainly the case that tests of Gc are heavily dependent on cultural knowledge, it has now become clear that measures of Gf are also not (and probably can never be) "culture fair" or "culture-free." Compelling evidence for this comes from studies on the Flynn effect, which is the finding that scores on intelligence tests tend to increase in populations over time (i.e., later generations score higher on the same version of a test than their parents or grandparents did; Williams, 2013). Interestingly, it has been repeatedly shown that the Flynn effect is actually *largest* for tasks of Gf and systematically decreases as tests rely more on Gc (Pietschnig & Voracek, 2015). Though initially counterintuitive, the best explanation for these findings appears to be that the effect results from increasing capacity for abstract reasoning in individuals across generations, perhaps due to increasing societal demands on information processing (Armstrong et al., 2016; Fox & Mitchum, 2012). That is, it is considered relatively unlikely that factors like genetics or nutrition would have changed dramatically and fast enough in populations where the Flynn effect has been studied to account for these differences in test performance between children and their parents or grandparents. Conversely, the average person's familiarity with certain forms of technology and more abstract concepts has clearly increased over successive generations (Flynn, 2007). Thus, insofar as the observed increases in abstract reasoning are much more likely to reflect changes in cultural demands rather than other effects, it suggests that tasks of Gf must also be culture-loaded to an important degree. In summary then, although tasks of Gc are very obviously culture-loaded, it does not follow that tasks of Gf are "culture-fair," simply because they do not explicitly involve linguistic stimuli or information gained through formal education. To the contrary, it seems likely that familiarity with figural material and certain types of cognitive operations can be culturally transmitted as well, such that tasks of Gf are probably best understood as merely "culture-reduced," relative to typical tasks of Gc. In the end, such developments highlight the need to consider how these factors could be at play in any test, and especially for examinees with unique or more limited cultural and educational experience.

Vernon, Carroll, and Hierarchical Models of Intelligence The final set of twentieth-century models to consider are the hierarchical models, which consist of three levels or "strata" of cognitive constructs that vary in their generality. An example of hierarchical model depicting a higher order *g* is shown in Fig. 15.2. The general form of any hierarchical model consists of three or four levels, with narrow abilities (those tapped by a single test; e.g., reading speed, numerical fluency) at the lowest level, broad factors at the next level (akin to Gc, Gf, etc.), and a *g* factor at the highest level of the model. One important hierarchical model was developed by Phillip E. Vernon, who argued that the structure of intelligence had *g* at the apex, followed by the two broad abilities of verbal-educational skills versus spatial-mechanical skills at level two, and a set of three narrower abilities below these (these are: verbal fluency, divergent thinking, and scholastic and numerical abilities below verbal-educational; and perceptual speed, psychomotor and physical skills, and spatial and mechanical abilities below spatial-mechanical; Vernon, 1951, 1965). Although Vernon's model seems to resemble the original Gf-Gc model at first glance (with its two broad factors anchored by verbal versus spatial skills), as described by Johnson and Bouchard (2005b), the two models actually differ in important ways.

First, in direct contrast to Gf-Gc theory, Vernon explicitly incorporated *g* in his model of intelligence, for the reason noted above that it is often not possible to truly separate Gf from *g* (Johnson & Bouchard, 2005b). Second, whereas the core of the Gf-Gc model is the conceptual separation of those two capacities based on their relative dependence on prior learning (prominent for Gc, much less so for Gf), Vernon's model instead contrasts the two broad factors in terms of their primary information processing modalities. Thus, although tasks of fluid abilities often emphasize visual stimulus presentation or spatial reasoning, and tasks of crystallized abilities tend to emphasize language, Gf should not be equated with visuospatial skills, and Gc should not be equated with language. Vernon's mode, in contrast, explicitly emphasizes distinct content dimensions and acknowledges the influence of learning to performance on both (Johnson & Bouchard, 2005b). Thus, Vernon's broad factors can be better understood distinguishing between abilities that are emphasized in educational (e.g., mathematics) versus noneducational contexts (e.g., mechanical skills), where both are understood to be influenced by experience.

As a result of these differences, the two theories make different predictions for how particular tasks should relate to their respective broad factors. To take a hypothetical example, in the Arithmetic subtest of the Wechsler scales, the examinee is asked to solve verbal arithmetic problems that are spoken aloud (Wechsler, 2008a). When viewed through the lens of the original Gf-Gc model, this task would likely rely substantially on both factors, via its demands on attention and working memory processes related to Gf as well as mathematical knowledge related to Gc. Conversely, under Vernon's model, the task might be better represented by just the verbal-education factor alone, for the reason that word problems are routinely taught and practiced in school, and less commonly encountered in noneducational contexts. Notably, although Vernon's model is much less familiar to broader psychology than Cattell's ideas about fluid and crystallized intelligence, the former has consistently outperformed Gf-Gc theory in studies that have explicitly compared the two (Johnson & Bouchard, 2005a, b). As such, it represents an important contrasting perspective that users of intelligence tests should also keep in mind.

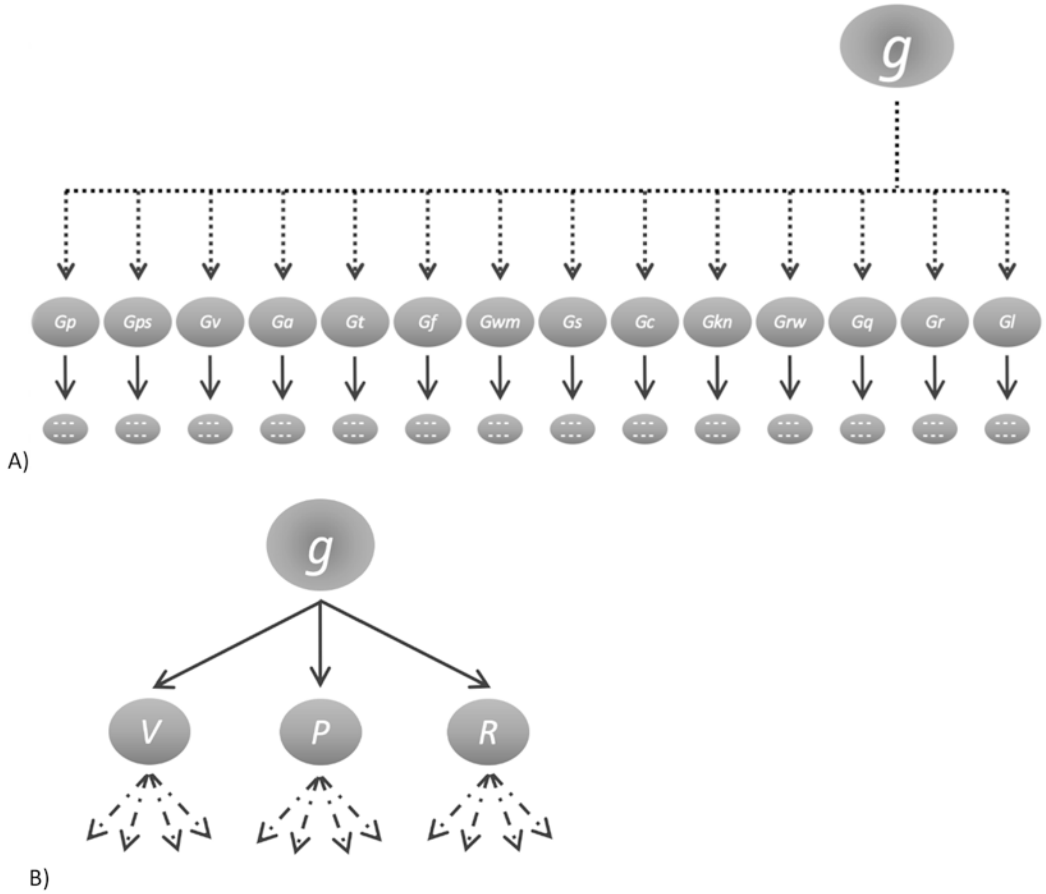
The final twentieth-century model to be familiar with is Carroll's three-stratum theory. Carroll's model is widely regarded as one of the most important achievements in research on cognitive ability (Beaujean, 2015, p. 132; McGrew, 2009; Wasserman, 2012, p. 44), for the way that it comprehensively synthesized and consolidated much of the prior work in the field. In his book *Human Cognitive Abilities* (1993), Carroll presents his reanalysis (via factor analytic methods) of over 460 cognitive ability datasets drawn from 19 countries and over 131,000 individuals. In this process, he derived factors at various hierarchical levels, which he tentatively grouped according to features such as task descriptions, patterns of similar factor loadings, test instructions, and details of items and scoring procedures, which he then progressively refined. In these initial steps, he arrived at 19 groups of factors ranging from general and broad cognitive factors (e.g., *g*, Gc, memory factors) to those reflecting things like academic achievement, sensory acuity, and interpersonal and motivational skills. Below these, he identified numerous narrow ability factors (that varied as a function of the tests in a given battery), and which reflect things like communication ability, length estimation, figural fluency, reading comprehension, tonal memory, and simple and choice reaction time, among many others (Carroll, 1993).

Near the conclusion of this monumental work, Carroll described his view of the structure of human cognitive ability, which is noteworthy in at least three respects. First, as noted above, he argued for a three-level hierarchy, with a general factor (*g*) at the apex, followed by broad and narrow ability factors. Regarding *g,* he stated simply that "[t]here is abundant evidence for a factor of general intelligence…found at the highest order of analysis for a given dataset" (Carroll, 1993, p. 624). Carroll's comprehensive survey was thus essentially the final word among scientists on whether *g* is in fact an inevitable consequence of cognitive ability batteries (insofar as scientific questions are ever definitively closed). He then listed eight broad factors, which, in his words, "differ in the relative emphases they give to process, content, and manner of response" (Carroll, 1993, p. 634). In this respect, the three-stratum model highly resembles the extended Gf-Gc theory. The second important feature of the three-stratum model is that Carroll explicitly ordered the broad factors according to their statistical proximity to *g*, with Gf being closest, followed by Gc, learning and memory, visual and auditory perception factors, broad retrieval ability (e.g., verbal fluency skills), and two speed-based factors at the far end. Third, he also acknowledged several tentative aspects of the model and explicitly cautioned that "it is not intended that the three strata be rigidly defined" (Carroll, 1993, p. 635). Among these, he noted that narrow abilities often load on multiple different factors as opposed to just one, he felt that there could be intermediate levels of generality between the strata he identified, and perhaps most importantly, he did not consider the eight broad factors he listed to have exhausted all possibilities (Carroll, 1993). Thus, although Carroll's work was important for how it consolidated prior insights and set an authoritative standard against which to compare future models, it also left the door open for future developments.

Contemporary Psychometric Models of Intelligence: CHC, VPR, Bifactor, and Formative Models Readers who have followed to this point should have a strong grasp of the ideas needed to understand the most prominent contemporary models of intelligence under discussion in the scholarly literature and applied test development. This is because these final two models are largely extensions of earlier work. They are: the Cattell-Horn-Carroll theory (CHC), which (naturally) integrates the extended Gf-Gc model with the three-stratum model, and the Verbal-Perceptual-Image Rotation model (VPR), which is an outgrowth of Vernon's hierarchical model (see Fig. 15.3). Both models might be considered "conventional" in the sense that they were developed using the factor-analytic techniques that were, until recently, used for all the models discussed in this literature. At the conclusion of this subsection we also introduce readers to two additional considerations about structural models (the bi-factor model and the distinction between reflective and formative models) that are commonly encountered in this literature.

CHC theory is arguably the closest one could come to what might be considered a consensus view about the structure of intelligence. As noted above, it represents a synthesis of the views of Cattell and Horn on the one hand and Carroll on the other. Overall, it acknowledges the considerable overlap between their accounts (and, indeed, Carroll himself saw his findings as confirming aspects of Gf-Gc theory; Carroll, 1993, p. 624) and attempts to reconcile differences between and develop refinements based on subsequent findings. Most of the following information on CHC theory was taken from Schneider and McGrew's (2018) recent chapter reviewing and updating the theory, which provides a detailed exposition of the broad and narrow factors (along with assessment recommendations and other considerations) and to which we refer interested readers.

As Schneider and McGrew outline in their chapter, CHC consists of a hierarchical model that emphasizes broad abilities grouped across several dimensions. Although the model is hierarchical, it focuses primarily on the existence and relations between broad and narrow abilities and offers a fairly nuanced account of the status of *g*. In an important earlier paper on CHC, *g* is depicted as part of the theory, but none of the loadings between *g* and any of the broad abilities are shown, in an effort to reconcile the original authors' disagreement on the status of the general factor (McGrew, 2009). A subsequent chapter aligns somewhat with Carroll's view in including *g*, but encourages users of the theory to reach their own conclusions about applying it or not, depending on their theoretical view and the assessment context in which they are working (Schneider & McGrew, 2012, p. 111). In the most recent account, the authors acknowledge *g* as a statistical factor, as well as its predictive validity as an index of someone's overall cognitive ability, but they express reservations that it reflects any unified



Note. Schematic versions of the CHC and VPR models. A) CHC model with 14 broad factors, with dashed lines for *g* indicating the nuanced account of *g* in CHC.B) VPR model shown with three broad factors. Dashed lines to narrow abilities indicate that these are always contingent on battery content.

Fig. 15.3 CHC and VPR models

Note. Schematic versions of the CHC and VPR models. (**a**) CHC model with 14 broad factors, with dashed lines for *g* indicating the nuanced account of *g* in CHC. (**b**) VPR model shown with three broad factors. Dashed lines to narrow abilities indicate that these are always contingent on battery content

cause that underlies those manifest effects. Later in the same chapter, the authors also point out that, when examined closely, Cattell's version of fluid intelligence functions in much the same way as Spearman's *g*, making the point somewhat moot (Schneider & McGrew, 2018).

The crux of CHC theory is the broad factors, their conceptual groupings, and the narrow factors that comprise them. Each broad factor can be conceptualized along one of two orthogonal dimensions. The first dimension divides the broad abilities into those that are expressed via tasks of speed versus level (i.e., emphasizing speed or accuracy). The second dimension separates the abilities into the following four conceptual groups: *Motor Abilities* (Psychomotor abilities (Gp), and Psychomotor speed (Gps)); *Perceptual Processing* (Visual-Spatial (Gv) Auditory (Ga), and Decision Speed (Gt)); *Controlled Attention* (Fluid Reasoning (Gf), Working Memory (Gwm), and Attentional Fluency/Processing Speed (Gs)); and *Acquired Knowledge* (Comprehension-Knowledge (Gc), Domain-

Specific Knowledge (Gkn), Reading and Writing (Grw), Quantitative Knowledge (Gq), plus the two speed/efficiency-based factors of Retrieval Fluency (Gr) and Learning Efficiency (Gl)). Four other tentative, non-speeded abilities are also suggested to exist under Perceptual Processing (Kinesthetic (Gk), Tactile (Gh), Gustatory (Gg), and Olfactory processing (Go)), though the authors acknowledge that more research would be needed to definitively establish these (Schneider & McGrew, 2018).

Similar to the theories from which CHC was derived, its broad factors can also be grouped under an alternative conceptual framework. Under the latter scheme, the groupings are the Domain-Free Capacities (Gf, Gwm, Gl, Gr, Gs, Gt), which are independent of particular sensory modalities; those that pertain to Acquired Knowledge Systems (Gc, Gkn, Grw, Gq), which are less-readily modeled as distinct factors, and which are also linked to personality dimensions and interests (e.g., one's interests influence the areas in which they develop domain-specific knowledge); and the Sensory- and Motor-Linked Abilities, which though somewhat broad, are not nearly as general as those that operate across modalities (Schneider & McGrew, 2018). Interestingly, in the latest update to CHC theory, Schneider and McGrew also make a case for eventually including emotional intelligence (Gei) as a broad ability within CHC. They cite long-standing scholarly interest in social and interpersonal functioning as a subdomain of intelligence as well as more recent factor-analytic evidence in support of including emotional intelligence, but also note that additional research is needed to confirm its status as a unique ability and clarify the narrow domains that comprise it (Schneider & McGrew, 2018).

The final contemporary structural model is the Verbal-Perceptual-Image Rotation (VPR) model, which has been developed in a series of papers by Wendy Johnson and colleagues (Johnson et al., 2007; Johnson & Bouchard, 2005a, b; Major et al., 2012). As noted above, the VPR model represents a refinement of Vernon's hierarchical model, which involves *g* at the highest level and two broad factors of verbal-educational and spatial-mechanical-practical abilities. In their first article on the topic, Johnson and colleagues compared the statistical adequacy of three models, which were respectively based on the original Gf-Gc theory, Carroll's three-stratum model, and Vernon's model in the same large dataset (Johnson & Bouchard, 2005b). Results indicated that Vernon's model demonstrated better overall model fit than either Gf-Gc or the three-stratum theory, and the narrow stratum factors it contained were more clearly differentiated from the broad factors than in the other models. For example, fluid intelligence was not distinguishable from *g* in the three-stratum model, and neither lower-order fluid nor crystallized factors could be distinguished from their broad factor counterparts in the Gf-Gc model. Nevertheless, although Vernon's model was statistically superior, it still did not meet the authors' a priori criteria for a "well-fitting" model. Thus, in an exploratory fashion, they assessed a refined model which included a memory factor at an intermediate level and added a broad visualization factor to the two other factors representing verbal/academic and perceptual skills. The resulting VPR model demonstrated the best fit of any of the models assessed (Johnson & Bouchard, 2005b). Shortly thereafter, the authors replicated their findings in two additional large datasets (both containing over 500 participants and more than 40 tests), demonstrating that Vernon's model consistently outperformed the original Gf-Gc model, and further, that the VPR model provided an additional improvement (Johnson et al., 2007; Johnson & Bouchard, 2005a).

Finally, in a 2012 article, Johnson and colleagues compared the VPR model against the newer models of extended Gf-Gc theory and CHC theory. The study took advantage of the large project TALENT dataset, which contains test results from over 300,000 high school students tested in the United States in 1960. The authors first ran exploratory models to characterize the dataset and develop representative factor structures, from which they compared the three models using the same set of input variables. This resulted in an extended Gf-Gc model that contained additional broad factors of quantitative and visualization ability, and a six-factor version of CHC was implemented. Importantly, because the VPR model recognizes the fact that model structure and fit are always contingent on the tests from which the model is estimated, this enabled some domains to be modeled under a single factor in VPR (e.g., English and Mathematics, which both plausibly fall under a verbal-educational factor), whereas no such hybrid factor is possible in the other two models (Major et al., 2012). As in the earlier studies, the VPR model consistently outperformed the other models across all fit indices.

In contrasting CHC and VPR, a few points stand-out. Most notably, CHC was developed with the needs of intelligence test users in mind and aims to continue in that vein. Its authors explicitly cite validity considerations in determining which broad and narrow factors should be included in the model, and in their criteria for removing or adding factors (Schneider & McGrew, 2018). Accordingly, CHC has been explicitly integrated into several current intelligence test batteries (most notably, the Woodcock-Johnson), and even if not directly incorporated, its influence is still clear in recent revisions of others (e.g., the factor structure of the WISC-V; Schneider & McGrew, 2018, p. 80). This contrasts with the VPR model, which emphasizes theoretical considerations around parsimony to a greater degree. For example, VPR includes *g*, and thus avoids the difficulty of including both it and Gf in a single model where the two might be statistically and conceptually indistinguishable (Major et al., 2012). Further, following Vernon, VPR includes many fewer broad factors than CHC (3 versus 14+), and the presence and interpretation of any narrow factors is always understood to be contingent on the composition of the underlying battery. This is a critical point that is easy to overlook in psychometric research on intelligence. In practice, factor models (as opposed to conceptual theories) are fundamentally a function of the data from which they were derived. In addition, while CHC has largely embraced the fluid-crystallized distinction, which differentiates between tests based on their dependence on acquired knowledge, VPR instead maps onto what may be a more natural distinction between verbal and spatial processes, as mediated by the left and right hemispheres of the brain (Major et al., 2012). This relates to the final point, that while the fluid-crystallized distinction may align with how intelligence develops within individuals, such processes are unfortunately not captured in traditional factor-analytic studies on individual differences (Johnson et al., 2007). In summary then, while readers can expect further studies aiming to determine which model is superior to the other in various respects, the “correct” answer will likely depend on one’s reason for applying a structural model of intelligence in the first place. The goal of the CHC model is to provide a comprehensive “taxonomy” of human cognitive abilities (McGrew, 2009), which, though deeply informed by theory, has a decidedly applied bent. The VPR model is perhaps better understood as a broader conceptual framework for thinking about the major dimensions of human cognitive variability (and its manifestation in factor models) in a parsimonious way.

Before closing this section and moving on to discuss the “up-and-coming” models of intelligence, we wish to highlight two additional considerations that readers may encounter when approaching this literature on their own. The first of these is the bi-factor model as an alternative to the hierarchical model, where the two differ in how they account for *g* and the broad factors. In brief, in the hierarchical model, *g* forms the top of a conceptual hierarchy and is derived from the correlations among the broad ability factors (Jensen, 1998, p. 98). In essence, this means that the broad factors (also sometimes called “group” factors in this context) are estimated first, and *g* is derived secondarily from the correlations between the broad factors. In contrast, in the bi-factor model, *g* is estimated directly as the shared variance common to the manifest variables (the test themselves), and the broad factors are estimated secondarily from any remaining variance that is shared among tests that assess similar constructs (Beaujean, 2015; Rodriguez et al., 2016). The result of this latter procedure is that variance in the broad factors is truly independent from *g,* unlike the hierarchical model. Although there are technical reasons why psychometricians may prefer one approach over the other, the reason for raising the distinction here has to do with its implications for substantive ideas about the nature of intelligence. Namely, whether one conceives of *g* as reflecting processes that are somehow independent of those captured by the broad factors (in the case of the bi-factor model), versus whether one sees the influence of *g* as mediated through the broad factors alone.

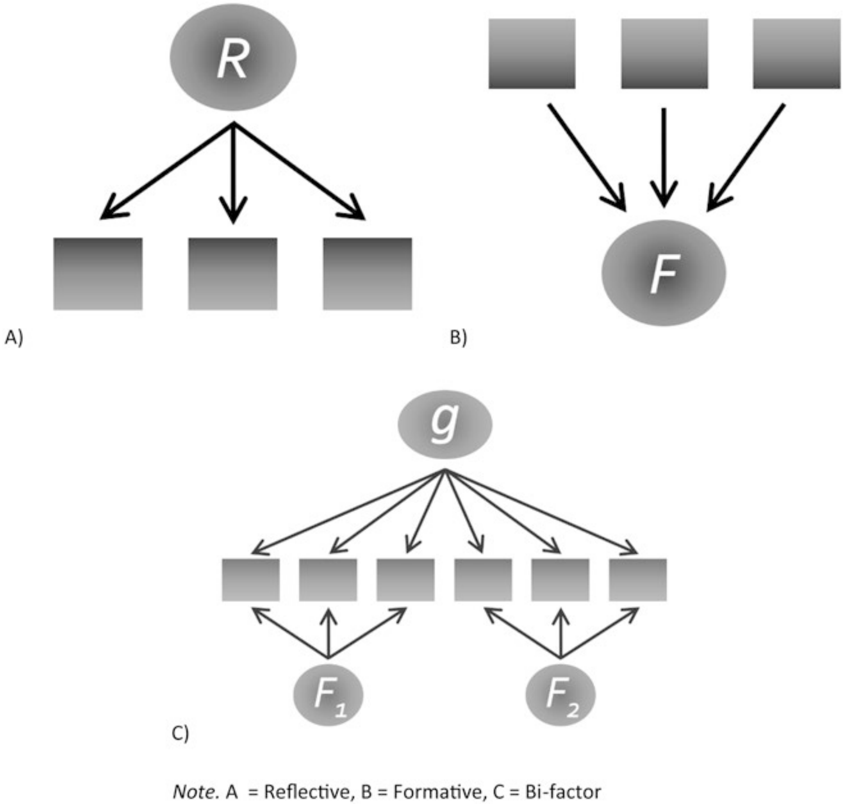


Fig. 15.4 Example reflective, formative, and bi-factor models
Note. (**a**) Reflective, (**b**) Formative, (**c**) Bi-factor

A final point to make in this section concerns the distinction between so-called reflective and formative latent variable models (see Fig. 15.4). All of the models discussed up to this point (with the possible exception of VPR; Major et al., 2012, p. 544) represent reflective models, which are interpreted as expressing the idea that variation in the latent variable is the *cause* of the variation in the variables that load onto it (Borsboom et al., 2003). This is indicated by the direction that the arrows travel (in the case of the three-stratum model, for example) from *g*, to the broad and narrow factors, and ultimately to the tests themselves. Strictly speaking then, such a model would be interpreted as asserting that variability in *g*, whatever its true neurological basis, is somehow the ultimate cause of the variability in the broad factors and the indicators. In contrast, in a formative model, the arrows travel from the manifest variables (the tests or items) to the latent variable, such that the variance in the latter is understood as reflecting variance in the indicators rather than the reverse (Conway & Kovacs, 2015). Common examples of formative variables include concepts like overall health or socioeconomic status (SES). Taking the case of SES, it is intuitive that there is no such thing as a single underlying cause that explains one's level of income or education. Instead, the very notion reflects the combined variance among those and other indicators, which of course can vary independently in any given person (e.g., a highly educated professor with a middle-class salary, and a wealthy celebrity who did not complete high school). As the next section will illustrate, the most recent theoretical models of intelligence have begun to take seriously the idea that, although *g* can be represented *statistically* as a reflective variable, it may be better understood as a formative variable in terms of its relation to brain functioning and development (Deary et al., 2016).

Recent Developments in Theories of Intelligence

In the last two decades, the dominance of traditional factor models of intelligence has given way somewhat to make space for alternative approaches. These alternatives belong to two classes of models, respectively, known as sampling theory (also called the "bonds" model) and network models. Although the two types of models and their variants differ in important ways, they are united by the fact that they all incorporate the advances made during the factor-analytic era, but expand beyond them to offer a more process-oriented view of intelligence. Specifically, although they all acknowledge the positive manifold, and take it as their starting point, each one is also designed to account for it without invoking a unitary, reflective *g*. This means that these models are not only somewhat more plausible from a neurological standpoint, but for some models, it also enables them to address other effects for which traditional factor theories cannot account.

Thomson's Bonds Model and Process Overlap Theory A 2009 paper by Bartholomew et al. (2009) almost single-handedly reignited interest in Godfrey Thomson's bonds model. As outlined by those authors, Thomson was a contemporary of Spearman, who developed the bonds model as an alternative to two-factor theory. Critically, Thomson did not argue that two-factor theory was necessarily incorrect, but only that it is not the *sole* possible explanation for the emergence of the positive manifold (Bartholomew et al., 2009). That is, whereas two-factor theory argues that positive correlations between tests arise from a unitary cognitive or neural source (e.g., "mental energy"; Spearman, 1927), Thomson argued that they could also come about as the result of overlapping cognitive or neural processes that are required by different types of tests. This overlap could be instantiated by the number of "bonds" that the tests share or sample from, and hence the alternative name, sampling theory. From a contemporary perspective, these overlapping bonds might literally be considered synaptic connections, and indeed, Thomson appears to have contemplated ideas along these lines (Thomson, 1951; cited in Bartholomew et al., 2009).

Although Thomson's model was largely forgotten throughout the twentieth century and deemed inadequate as an explanation for the positive manifold by some theorists (Jensen, 1998, pp. 120–121), two papers from the group led by Bartholomew and Deary suggest that scholars were wrong to dismiss it. In brief, by taking advantage of statistical developments that were not available to Thomson (who came to his initial idea by simulating data using dice throws) they were able to show that Thomson's model, which assumes that test scores are a combined function of the specific bonds sampled in the course of the completing the items, gives rise to the identical covariance matrix as Spearman's model that assumes the presence of a latent general factor (i.e., *g*). Further, they show that, like two-factor theory, Thomson's model can also be generalized to datasets containing more than one factor (Bartholomew et al., 2009). Crucially then, because the two models give rise to identical patterns of correlations, it is not possible to statistically distinguish between them. Instead, the choice should be made based on other considerations, like biological plausibility, where sampling theory has a clear advantage. In a second paper, the authors expand the support for the bonds model via simulation studies, show its capability to fit real datasets, and describe how individual differences in the type and number of bonds that people possess could in fact account for differences in patterns of intellectual ability (Bartholomew et al., 2013).

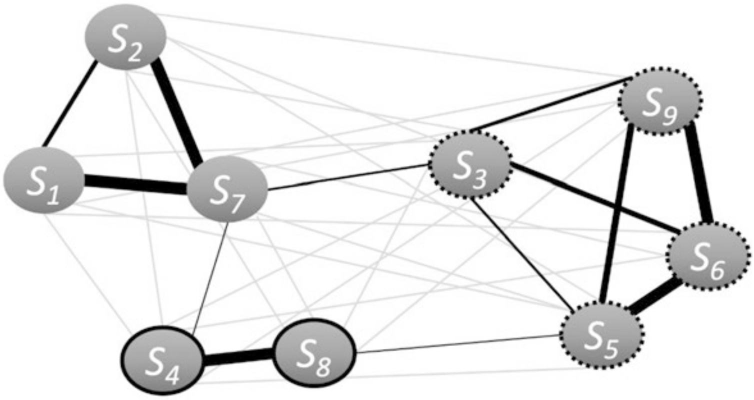
In recent years, a novel model heavily inspired by sampling theory has been proposed in the form of Process Overlap Theory (Kovacs, 2019; Kovacs & Conway, 2016). Like all of the most recent theories, Process Overlap Theory takes the positive manifold phenomenon as its starting point and aims to describe how it could arise without appealing to a latent, unitary *g*. Simultaneously, the theory aims to explain other important phenomena in the intelligence literature, such as the high correlation between *g* and Gf in factor models, and the fact that as tasks become more complex, they also become more *g*-loaded. After reviewing a number of key findings from differential and cognitive psychology, Kovacs and Conway (2016) conclude that the positive manifold arises, not from a unitary cause of mental ability that influences all tasks, but rather because, in practice, all cognitive tasks rely on a subset of independent, domain-general processes that act as limiting factors during cognitive performance. Thus, the positive manifold does not reflect a *single* underlying cause, but the tendency for tasks to draw upon an overlapping set of domain-general processes.

The processes in question are subsumed under the umbrella of executive functions and include things like working memory capacity (itself a multicomponent function), attentional control, goal maintenance, and related abilities (Kovacs, 2019). Drawing on the strong connection between Gf and these executive abilities, and the near unity of *g* and Gf, the authors argue that any cognitive task relies on these domain-general functions as well as domain-specific abilities, with this distinction driving the patterns of relations within and among the broad factors. Hence, tests of verbal reasoning versus mental rotation tasks would be distinguished by their reliance on their respective broad factors, but they might also require working memory and/or attentional control. From here, one can see the similarity to sampling theory, in that both task domains sample from the same set of executive processes, but from a distinct set of domain-specific skills. Importantly, however, unlike two-factor theory, not all tests in a battery need to sample the exact same set of domain-general processes for the positive manifold to arise. It is enough for each test to share one such process with any other (Troche et al., 2021). As a result, a general factor would emerge from a factor analysis of those data, but its underlying cause would be a set of independent (though overlapping) abilities, thereby making it a formative rather than reflective latent variable (Kovacs & Conway, 2016).

Overall, Process Overlap Theory provides a number of innovations over prior models and faces a few limitations. In terms of the former, it has the important virtue of not only providing a new conceptual account of the positive manifold, but it also links this to a formal statistical model of item responding. This means that unlike the prior generation of factor models, Process Overlap Theory explicitly connects patterns of between-subjects variation to the hypothesized cognitive processes that govern responding within individuals. Thus, it takes the important step of trying to ground individual differences research on a foundation of cognitive process models that describe how those differences actually arise. Along these lines, it also stands apart from conventional factor models in connecting relatively well with neuroimaging findings. In particular, it aligns with evidence suggesting that frontoparietal networks in the brain are the most reliable neural correlates of intelligence (Basten et al., 2015; Duncan, 2010; Jung & Haier, 2007; Santarnecchi et al., 2017) and strongly overlap with the networks that govern executive functioning (Barbey et al., 2012). Thus, it is plausible that these networks could operate as a domain-general bottleneck on cognitive ability (Euler, 2018), in the same manner as that predicted by the theory. In terms of limitations, although Process Overlap Theory has elicited considerable interest since its publication, studies evaluating it have thus far provided only mixed support (Frischkorn & von Bastian, 2021; McFarland, 2020; Troche et al., 2021). Some authors have also criticized conceptual aspects of the theory, such as the evidence for attentional control as a viable psychometric construct (Schubert & Rey-Mermet, 2019) and its distinctiveness from two-factor theory and other prior accounts (Deary et al., 2016; Gottfredson, 2016). Notwithstanding these criticisms, Process Overlap Theory still has much to recommend it as an additional formative model of the positive manifold, and as an attempt to link intelligence research to cognitive process models of within-subject effects.

The Mutualism Model and Network Approaches Network models of intelligence represent the biggest departure from traditional factor models and are the focus of most of the innovation currently going on in psychometric work on intelligence. These models are unique in that, instead of positing a hierarchy of latent variables, they represent intelligence as a system of interacting abilities that relate

Fig. 15.5 Network model
Note. Hypothetical network model of intelligence depicting clusters of related tests rather than latent variables



Note. Hypothetical network model of intelligence depicting clusters of related tests rather than latent variables.

directly to one another, where the different tests in a battery are graphically represented as distinct nodes connected by links, which are derived from the partial correlations between them (Kan et al., 2019; Savi et al., 2019; see Fig. 15.5). In a network model, the conceptual role of group factors based on related abilities is replaced by patterns of correlations between the tests, as reflected in the number and strengths of the different links connecting the nodes in the network, such that strongly related nodes can form clusters (Borsboom et al., 2021; Kan et al., 2019). Such models are rapidly gaining interest not only in intelligence research, but throughout differential psychology (e.g., personality and psychopathology research), for the way in which they can reveal the connections between measured variables without reifying specific constructs as the underlying "causes" of the observed correlations.

The first network model of intelligence was the mutualism model developed by van der Maas et al. (2006), which represented the first modern attempt to mathematically account for the positive manifold without invoking a latent *g* factor. Rather than focusing on the correlations between particular types of tests (as in traditional factor models), the authors began by reconceiving cognitive ability as a complex system of interacting parts. Specifically, they invoked the metaphor of an ecosystem where initially independent parts (i.e., distinct, uncorrelated abilities) might come to be related through reciprocal interactions that occur during development (van der Maas et al., 2006). Breaking from the psychometric tradition, the authors employed a modeling framework from ecology that allowed them to represent the growth in cognitive abilities during development, as well as their interactions. They imposed several realistic constraints on their model (e.g., that growth cannot be unrestricted) and used simulations to evaluate the intercorrelations and factor structures that would result under different scenarios in a large population of subjects with a given number of initially uncorrelated abilities (van der Maas et al., 2006, 2019). Critically, they were able to show that when there is no correlation among the limiting factors during development (i.e., in the absence of a *g*-like scenario), the positive manifold will still arise merely from the existence of small, positive correlations between the abilities in the model. Importantly, additional analyses showed that the interactions between abilities need not all be positive for this to unfold (and in fact, under this condition, the model produces a hierarchical factor model) and that the mutualism model could also account for other effects in the intelligence literature, such as the increasing heritability of intelligence over time (van der Maas et al., 2006, 2019). Thus, following sampling theory, the mutualism model represented the second mathematical demonstration that the positive manifold (among other effects) could arise in the absence of an underlying *g* factor.

In the years since the publication of the first mutualism model, the theory has received both positive and negative support from empirical studies. On the one hand, research on predicted developmental effects (Gignac, 2014) and patterns of correlations among group factors (Gignac, 2016) has been taken as evidence against the mutualism model. On the other hand, the original authors have responded to these (and other) claims (van Der Maas et al., 2019; van der Maas & Kan, 2016), and the theory has been supported in other data showing, for example, positive interactions between vocabulary and reasoning skills across periods of development (Kievit et al., 2017, 2019). Most recently, the theory has been updated to incorporate other expected effects from the literature, such as reciprocal positive influences from the environment (e.g., natural talent leads to training opportunities, which further enhance talent), as well as the stronger influence of fluid skills on overall functioning (van der Maas et al., 2017, 2019). In just the last several years, interest in network models of intelligence has gained additional momentum, with several studies showing that network models can statistically compete with and even outperform traditional factor models in published intelligence batteries (van Dijk et al., 2017; Schmank et al., 2019, 2021), and with the publication of an entirely new model that aims to address single-subject learning effects via a network account of intelligence (Savi et al., 2019, 2021).

In summary then, these alternative approaches all show that it is entirely possible to explain the emergence of the positive manifold without appealing to *g* as a real, casual entity. Moreover, they have the advantage over traditional approaches of being more physiologically plausible and demonstrate greater capacity to incorporate cognitive process models of how intelligence develops and manifests within individuals. As such, they hold promise for finally integrating the between-subjects effects that have dominated research on intelligence with experimental and developmental models of cognition as it is actually expressed.

Practical Applications and Implications

In this section, we will provide a brief hypothetical case study to illustrate how theoretical models ultimately influence clinical assessment. Commonly used tests may differ in their theoretical foundations and emphasize certain aspects of information. Therefore, it is important to consider how an individual's performance is dependent upon the structure of the tests used.

Demographic and Referral Information Gabriel, aged 16 years and 6 months, is a left-handed, white male who was adopted at the age of 3 by his current guardians. His adoptive mother completed a Master's degree and works full time for a software engineering company. His adoptive father completed a Bachelor's degree and works full time as a landscape architect. Gabriel's medical history prior to adoption is unknown. Gabriel was referred for assessment due to concerns over academic performance and difficulties completing coursework.

Assessment of Intelligence As part of a larger battery, Gabriel will be given an assessment of intelligence. The Wechsler scales of intelligence are some of the most widely used measures of intelligence (Rabin et al., 2005). Due to his age, selecting the appropriate measure is a vital consideration as he is within the age range for both the Wechsler Intelligence Scale for Children–fifth edition (WISC-V) and Wechsler Adult Intelligence Scale–fourth edition (WAIS-IV). An overarching summary of Gabriel's hypothetical profile for each measure and resulting interpretations based on theoretical considerations are presented below. For more detailed profile analyses of these measures, please reference their respective manuals. While no singular test or test score should ever be interpreted out of context or be the sole basis for a case formulation, the focus of this section is on the implications of results from tests of intelligence rather than across a full battery of tests.

Wechsler Intelligence Scale for Children–Fifth Edition (WISC-V) The Wechsler Intelligence Scale for Children–Fifth Edition (WISC-V; Wechsler, 2014) is designed for children ages 6:0–16:11 and provides a Full-Scale Intelligence Quotient (FSIQ) from 5 primary index scores: Verbal Comprehension Index (VCI), Visual Spatial Index (VSI), Fluid Reasoning Index (FRI), Working Memory Index (WMI), and Processing Speed Index (PSI; Wechsler, 2014). A General Ability Index (GAI) may be computed from the VCI, VSI, and FRI to provide an estimate of intelligence that is independent of working memory and processing speed. This assessment is well-represented, based on confirmatory factor analysis, by a five-factor structure consistent with the Cattell-Horn-Carroll (CHC) model, including a fluid reasoning factor (*Gf*), visual processing factor (*Gv*), crystallized knowledge factor (*Gc*), short-term memory factor (*Gsm*), and processing speed (*Gs*), in which *Gf* is equivalent to *g* (Flanagan & Kaufman, 2009). Thus, the WISC-V is generally interpreted through this theoretical lens (Wechsler, 2014).

A hypothetical WISC-V profile for Gabriel is outlined below (see Table 15.1). All score labels and their respective standard score ranges are based on the American Academy of Clinical Neuropsychology consensus statement on score labels (see Guilmette et al., 2020).

Based on Gabriel's WISC-V profile, neither estimate of intellectual ability (FSIQ, GAI) is interpretable due to the discrepancy between the Visual Spatial domain and the Verbal Comprehension domain (Flanagan & Kaufman, 2009). However, his lower GAI score, in comparison to his FSIQ, can be accounted for by the former's greater reliance on tests of visuospatial abilities, an apparent weakness

Table 15.1 WISC-V profile

WISC-V indexes	Qualitative description
Full Scale IQ (FSIQ)	Low average (80–89)
General Ability (GAI)	Below average (70–79)
Verbal Comprehension (VCI)	Average (90–109)
Vocabulary	Average

Digit span	Average
Picture span	Low average
(Letter number sequencing)	Average
Processing Speed (PSI)	Low average (80–89)
Coding	Low average
Symbol search	Low average
(Cancellation)	Low average

Note. Hypothetical WISC-V profile for Gabriel. Composite scores are in bold and Primary Index Scales are underlined. The subtests that comprise each Primary Index Scale are listed beneath the Index. The **FSIQ** composite score is generated from scores on the subtests of Vocabulary, Similarities, Block Design, Matrix Reasoning, Figure Weights, Digit Span, and Coding. The **GAI** composite is generated from scores on the subtests of Vocabulary, Similarities, Block Design, Matrix Reasoning, and Figure Weights. The subtests in parentheses () are considered Secondary subtests which are not included in the calculation of Primary Index Scales for Gabriel, as tests of WMI and PSI are not included. A closer examination of his index level scores is required to understand Gabriel's intellectual functioning as these scores are all unitary (i.e., the discrepancy between subtests in a domain is not greater than 1.5 standard deviations; Flanagan & Kaufman, 2009). Notably, his profile suggests a significant weakness in visual spatial functioning. Additionally, his performance on tests of processing speed and fluid reasoning are in the low average range. With regard to pairwise comparisons of the index scores, Gabriel's significantly better performance within the WMI compared to the VSI supports the idea that his ability to mentally manipulate information is not driving the poorer performance seen on tests of VSI (Wechsler, 2014). His greater performance on VCI measures in comparison to both the VSI and FRI suggests a consistent weakness in the ability to use visual information for problem solving or a strength in verbal reasoning (Wechsler, 2014). Finally, at the subtest level, the poorer performance on Picture Span vs. Digit Span and Figure Weights vs. Arithmetic again supports the conceptualization that Gabriel has a more difficult time with visually presented information (Wechsler, 2014).

Using the five-factor model to aid in clinical interpretation, Gabriel appears to have a significant weakness in the visual processing factor (*Gv*). This is an important consideration for interpretation of the entire profile as subtests that either directly or indirectly tap into *Gv* will be associated with poorer performance. Particularly, this conceptualization explains the weaknesses seen for tests of fluid reasoning (*Gf*) and processing speed (*Gs*) as a result of the visual processing demands of these subtests; an idea further supported at the subtest level. Thus, the performances observed for the FRI and PSI are likely underestimations of his true ability for these factors. However, the subtests assessing Short-Term Memory (*Gsm*) and Crystallized Knowledge (*Gc*) factors are significantly less influenced by *Gv* requirements on the WISC-V, besides the Picture Span subtest, and thus his average performance on both may be accurate representations of his abilities. Ultimately, due to significant variability between domains of the WISC-V, a single score is derived from these indices that cannot be meaningfully interpreted as an accurate representation of Gabriel's level of intellectual functioning.

Wechsler Adult Intelligence Scale–Fourth Edition (WAIS-IV) The Wechsler Adult Intelligence Scale–Fourth Edition (WAIS-IV; Wechsler, 2008b) is an instrument for assessing intelligence in older adolescents and adults ages 16:0 through 90:11. The WAIS-IV computes a Full-Scale Intelligence Quotient (FSIQ) from four primary index scores: Verbal Comprehension Index (VCI), Perceptual Reasoning Index (PRI), Working Memory Index (WMI), and Processing Speed Index (PSI; Wechsler, 2008a). A General Ability Index (GAI) may be computed from the VCI and PRI to provide an estimate of intelligence that is independent from working memory and processing speed. Unlike the WISC-V, the WAIS-IV is based on a four-factor structure, with the four factor indices (i.e., VCI, PRI, WMI, and PSI) represented on the second tier of the three-tier hierarchy. Thus, it somewhat resembles Carroll's three-stratum model, which predated CHC. A hypothetical WAIS-IV profile for Gabriel is outlined below (see Table 15.2).

Again, due to the discrepancies between tests of perceptual reasoning and those of verbal comprehension, neither the FSIQ nor the GAI is meaningful representation of Gabriel's overall intellectual ability (Lichtenberger & Kaufman, 2013). Consistent with the WISC-V profile, the WAIS-IV GAI score is lower than the FSIQ as it does not include tests of working memory or processing speed. Therefore, we must again focus our interpretation of Gabriel's intellectual abilities based on his performance at the index score level. His scores indicate a significant weakness in the perceptual reasoning domain as well as difficulties in the processing speed domain. Conversely, Gabriel's VCI and WMI performances are, like in the WISC-V, within the Average range. Notably, he exhibited a strength in verbal associative and learned knowledge (VCI) compared to tests of nonverbal reasoning and problem solving (PRI), a weakness that cannot be accounted for by difficulties with working memory abilities (WMI). At the subtest level, Gabriel performed better on a test of verbal associative reasoning abilities than on tests of learned knowledge.

Table 15.2 WAIS-IV profile

WAIS-IV indexes	Qualitative description
Full Scale IQ (FSIQ)	Low average (80–89)

Note. Hypothetical WAIS-IV profile for Gabriel. Composite scores are in bold and Primary Index Scales are underlined. The subtests that comprise each Primary Index Scale are listed beneath the Index. The **FSIQ** composite score is generated from scores on the subtests of Vocabulary, Similarities, Information, Block Design, Matrix Reasoning, Visual Puzzles, Digit Span, Arithmetic, Coding, and Symbol Search. The **GAI** composite is generated from scores on the subtests of Vocabulary, Similarities, Information, Block Design, Matrix Reasoning, and Visual Puzzles. The subtests in parentheses () are considered Supplemental subtests which are not included in the calculation of Primary Index Scales

Interpreting the observed WAIS-IV profile from a Wechsler Theoretical Model approach (Lichtenberger & Kaufman, 2013), we will compare Gabriel's abilities of Visual-Motor Speed (Block Design, Symbol Search, Coding), Problem Solving without Visual-Motor Speed (Matrix Reasoning, Visual Puzzles, Figure Weights, Picture Completion), and Mental Manipulation (Digit Span, Letter Number Sequencing). While a small difference, Gabriel exhibits greater Problem Solving without Visual-Motor Speed abilities in comparison to those of Visual-Motor Speed, suggesting difficulty quickly encoding and responding to visually presented information by responding motorically and that he may use verbal mediation strategies (Lichtenberger & Kaufman, 2013). His significantly better performance on measures of Mental Manipulation than Visual-Motor Speed, and to a lesser extent Problem Solving without Visual-Motor Speed, indicates a better ability to attend to auditory than visual stimuli (Lichtenberger & Kaufman, 2013).

Network-Based Interpretation of WAIS-IV As discussed in the previous section, a newer approach to WAIS interpretation is based on network structures derived from the correlations between tests representing different abilities (van Dijk et al., 2017). One such model, based on all 15 subtests of the WAIS-IV, found the verbal comprehension and processing speed indices as currently organized in the WAIS-IV to be unique and consistent factors of the overall FSIQ (van Dijk et al., 2017). However, subtests of the PRI appeared to cluster into a visual processing factor, consisting of Block Design, Visual Puzzles, and Picture Completion, and a fluid reasoning factor of Arithmetic and Figure Weights (van Dijk et al., 2017). Notably, the Matrix Reasoning subtest was not correlated with any subtests (van Dijk et al., 2017). Additionally, according to this analysis, there were no correlations between the core WMI subtests (van Dijk et al., 2017). The authors theorize that this is largely driven by Arithmetic tapping into multiple factors, while Digit Span is a consistent test of working memory (van Dijk et al., 2017). These findings mirror the organization of the WISC-V in both factor distinction (Visual Processing, Fluid Reasoning) and subtest reorganization and inclusion of subtests with greater factor relevance (Wechsler, 2014).

An edited version of Gabriel's same WAIS-IV profile, but now incorporating the network structure (with hypothesized network clusters in italics), is outlined below (see Table 15.3). Note that the subtests are grouped by network clusters that do not always align with the WAIS-IV factor structure. Thus, the cluster qualitative descriptions are based on average performance across all subtests included in the cluster and are not a true standardized score.

As can be seen from this network model profile, the interpretation of Gabriel's verbal comprehension and processing speed abilities remain the same: average and low average, respectively, as these clusters are consistent with the current WAIS-IV structure. His performance on measures assessing the working memory domain is still in the average range; however, it must be noted that using this network model, Arithmetic is no longer in this domain. Additionally, his performance on measures comprising the visual processing cluster suggests a significant weakness in this domain compared to the others. His fluid reasoning abilities appear to fall within the low average range. Despite the similarities between this profile interpretation and the first WAIS-IV interpretation, the differences provide

Table 15.3 Network model WAIS-IV profile

Note. Hypothetical WAIS-IV profile for Gabriel incorporating the structure identified by analysis of the network structure of the WAIS-IV. Composite scores are removed from this profile as the networks are based on cluster abilities and not used for calculations of composite scores. The clusters identified in the network are presented in italics. The subtests that comprise each cluster are listed beneath each. The subtests in parentheses () are considered Supplemental subtests by the WAIS-IV, but are included in estimation of cluster performance for the network model. Because the Matrix Reasoning subtest was not correlated with other subtests, and thus not in a cluster, it stands alone on the table key insights into potential underlying causes of Gabriel's variable performance. Of note, the separation of the PRI into two domains (i.e., visual processing and fluid reasoning) clarifies the nature of Gabriel's weaknesses as being largely restricted to visual-spatial difficulties. Further, the inclusion of Arithmetic into the fluid reasoning cluster, instead of the working memory cluster, provides additional evidence to suggest that visual presentation of information is impacting Gabriel's performance rather than a significant weakness in fluid reasoning abilities. As Matrix Reasoning was not found to correlate with any cluster of tests, it cannot be interpreted within the existing domains. Taken together, based on a network approach to WAIS-IV profiles, Gabriel's intellectual ability is in the average to low average range; although as noted previously, when considering his score discrepancies, a single score is likely not a valid estimation of his true ability.

Conclusion Ultimately, the decision of which intelligence test to use for a client like Gabriel carries significant interpretive implications. In this case, to better illuminate Gabriel's visual spatial (*Gv)* weakness, the inherent structure of the WISC-V was more successful. Likewise, although not validated for clinical use, it appears that similar conclusions about the profile would follow from the network model approach to the WAIS-IV. Although just a hypothetical example, one potential explanation for Gabriel's profile could be the phenomenon of right-hemisphere "crowding." The crowding hypothesis suggests that, due to an early abnormality in the left hemisphere (e.g., tumor, stroke, traumatic brain injury), the right hemisphere takes over language dominance at the expense of visuospatial processes that are typically housed on the right (Danguecan & Smith, 2019; Lidzba et al., 2006). Because Gabriel's parents do not have a comprehensive history of the first 3 years of his life, a brain insult in the left hemisphere resulting in the crowding effect cannot be eliminated. Regardless, based on the two batteries of intellectual functioning, Gabriel has the capacity to perform well in school compared to his peers but may need modifications to reduce visuo-spatial demands. Understanding an individual's strengths and weaknesses for the constructs that comprise intelligence is vital; however, this cannot be done without an understanding of the theoretical underpinnings of the assessment and what that tells you about your client.

Conclusion

An examination of the history and development of intelligence models illustrates its existence as a real, measurable construct. Intelligence has been defined through numerous theoretical and practical approaches. This chapter provided outlines of historical models (Spearman's two-factor theory, multifactor theories, Gf-Gc model, hierarchical models) to contemporary models (CHC, VPR, bi-factor, formative) with a final review of the newest approaches to understanding intelligence (bonds model, Process Overlap Theory, network models). Several principles from intelligence theories relate to practical implications in clinical practice (see Table 15.4 for a guide to the main connections made in this chapter). Intelligence instruments are built upon structural and theoretical findings. As such, it is important to understand how structural models used for interpretation have emerged and how statistical techniques can influence how cognitive abilities are represented. By understanding the development of theories of intelligence, one not only gains knowledge of how theories came to be, but also an awareness of the impacts it has on conceptualization of clinical measurements of the construct.

Table 15.4 Key principles from intelligence theories for practitioners

Principle	Practical implication
In large samples of individuals and cognitive tests, human cognitive abilities are intercorrelated	Individuals who perform well on one type of cognitive test, regardless of content, tend to perform well on others, and vice versa
Cognitive strengths and weaknesses in individuals are statistically independent of their overall intellectual level	It is important to consider overall functioning alongside strengths and weaknesses in interpreting intelligence batteries
Novel reasoning (*Gf*) and application of learned knowledge (*Gc*) represent partially dissociable skills with different trajectories within individuals over the lifespan	Mental speed and novel problem-solving skills typically decline with older age; learned skills and knowledge are largely preserved into later life
Tests of crystallized knowledge (*Gc*) are inherently culture-loaded due to their measurement of learned information. While measures of fluid reasoning are comparatively culture-reduced, performance on these measures is not entirely independent of cultural exposure	It is not possible to devise an entirely culture-free test. Thus, the impact of a client's background must be accounted for in all interpretations of test scores
The most common structural models supported by factor analysis show a hierarchical, three-stratum structure in which *g* is on the highest tier, followed by a variable number of broad and narrow abilities on the second and third tiers, respectively	Individual subtests on a cognitive instrument may represent narrow abilities, while groups of subtests contributing to an index may represent broad abilities. Each individual subtest may load differently on *g*
The factors present in models of intelligence always reflect the battery administered, and different models may provide different frameworks for representing the structure of human cognitive abilities	The "correct" model of intelligence somewhat depends upon one's goal for representing cognitive abilities
Contemporary models explain the positive manifold phenomenon through the lens of interacting cognitive and neural processes	Performance on intelligence tests represents complex cognitive and neural processes. Contemporary models may clarify how these processes differ within individuals
The theoretical foundation of intelligence measures often differs and may lead to differences in interpretation	Appropriate selection of an intelligence measure is an important consideration for accurately representing a client's cognitive abilities. An individual's cognitive abilities, strengths, and weaknesses may be differently represented using different structural or theoretical models

Part III

Testing Methods in Clinical Child Psychology

16

Intelligence Tests

Jacqueline M. Caemmerer,
Stephanie Ruth Young, Eunice Blemahdoo,
and Emily Louise Winter

Introduction

Assessment plays an essential role in child psychology. Broadly, assessment allows practitioners to better understand the spectrum of individual differences and establishes a common terminology for research, clinical practice, and policy applications. At the individual level, assessment informs clinical decision-making, including diagnosis and intervention planning, and serves to support eligibility criteria for many educational and public services (e.g., special education, Medicaid; Dowdy et al., 2009). Intelligence tests are commonly used to assess individuals with various developmental and neurological disorders, brain injuries, or intellectual gifts in a variety of contexts including schools, clinics, hospitals, military, and personnel selection (Dowdy et al., 2009; Jewsbury et al., 2017). Performance on intelligence tests is linked to important life outcomes such as academic achievement, years of education completed, occupational performance, income, and even health behaviors and mortality (Gottfredson & Deary, 2004; Neisser et al., 1996). Given the strong influence and predictive power of measures of intelligence, intelligence tests (often referred to as IQ tests) continue to play an important role in the field of psychology.

This chapter begins with an overview of popular individually administered IQ tests for children. The common purposes and settings in which IQ tests are used are described, as well as examples of how children's performance on IQ tests informs diagnostic and intervention decisions. Finally, we conclude with a discussion of the similarities and differences between IQ tests and other related tests that practitioners often include in assessments of children.

A discussion of IQ tests must acknowledge their history of biased and oppressive applications (Valencia, 2010). For example, IQ tests are implicated in segregation within schools and the disproportionate identification of children who are racially, ethnically, and linguistically diverse in special education (e.g., Skiba et al., 2016; Sullivan & Bal, 2013). This issue was raised in *Larry P. v. Riles* (1977). This court case influences the use of IQ tests in California schools today. The plaintiffs argued

that Black students in the San Francisco Unified School District were overrepresented in special education classes for the "educable mentally retarded" (the current preferred term is intellectual disability) based on their performance on intelligence tests. The court ruled the tests were biased as they assumed knowledge linked to White middle-class culture, intrinsically disadvantaging Black students (Wade, 1980). Also the norming sample of the IQ test at that time included only White children, which is described in more detail below. This ruling, which still stands today, prohibits California school districts from using IQ tests to evaluate Black children for special education services. While special education determination serves as just one example, the full extent to which the measurement of intelligence has been applied in oppressive ways is outside the scope of this chapter. Still, it is important to bear in mind the historical context of intelligence tests to avoid the missteps of the past.

Overview of Popular IQ Tests

The focus of this chapter is individually administered IQ tests, in which a qualified practitioner and child meet one-on-one for a testing session. IQ tests often consist of multiple subtests, or tasks, that involve different types of questions, stimuli, and response formats which measure different cognitive abilities. There are dozens of IQ tests available today, a comprehensive review of which is beyond the scope of this chapter. Rather, this section highlights a handful of tests frequently used by practitioners (e.g., Benson et al., 2019; Rabin et al., 2016; Wright et al., 2017). A historical overview of IQ test development is presented to provide the context of frequently used IQ tests, and the most recent editions of each test are described. Additionally, nonverbal and abbreviated/brief IQ tests are briefly described. This section concludes with factors practitioners should consider when selecting the most appropriate tests for the children they test.

First Practical IQ Test and the Stanford-Binet

Alfred Binet is often viewed as the creator of the modern IQ test. Binet was a French psychologist who was tasked with developing a test to distinguish between children who were typically developing and children who were developmentally delayed. In 1905, Binet and psychiatrist Theodore Simon created the Binet-Simon Intelligence Scale for children. Their test was intended to be an objective measure to identify children who needed special school services rather than subjective and potentially biased family and teacher reports (Siegler, 1992). The Binet-Simon Intelligence scale included tasks that measured children's language, memory, judgment, reasoning, and social comprehension. The test was revised in 1908 and performance on all the subtests formed a single composite score, or a combined summary score of multiple data points, of the child's estimated intellectual level or mental age. The *mental age score* created a meaningful metric and indicated the highest age level at which the child answered most subtest items correctly. For example, the mental age score for a 10-year-old who scored equal to the average 13-year-old is 13, which is 3 years higher than the child's chronological age (Boake, 2002).

Henry Herbert Goddard, the research director at the Training School at Vineland for children with cognitive disabilities, was the first to bring the Binet-Simon scale to America. He translated the test into English and in 1908 he published "The Binet and Simon Tests of Intellectual Capacity" (Benjamin, 2009). Goddard encouraged the use of the test by a wide range of practitioners in a variety of settings, including American physicians, professionals within public schools, and professionals at Ellis Island who tested individuals who immigrated to America (Benjamin, 2009). Other versions of the Binet-

Simon Intelligence Scale closely followed. In 1916, Lewis Terman, a psychology professor at Stanford University, translated the French Binet-Simon scale and adapted the test to align with American culture, naming it the Stanford-Binet. The Stanford-Binet included new subtests, extended the age range into adulthood, and Terman replaced the mental age composite score with the *intelligence quotient*, or IQ. Historically, the intelligence quotient was calculated by dividing a person's mental age by their chronological age and multiplying by 100. Notably, the creator of the intelligence quotient William Stern cautioned against equating this single score with a person's worth (Kaufman et al., 2019).

Terman's Stanford-Binet test and subsequent revisions became the dominant IQ tests in America for several decades (Boake, 2002; Kaufman, 2009). The Stanford-Binet was first revised in 1937, and Terman collected *norm or standardized samples* that were described as more representative of the general population. Norms or standardized samples are large samples of individuals who complete a test and serve as the basis of comparison for the test scores of people who take the test. These normative comparisons are the basis of IQ tests and allow practitioners to determine whether the individuals they test perform similarly to their same-aged peers, that is within the average range for their age, or significantly below or above average. Terman used parents' occupations to select children to include in his norm sample. He matched the proportions of various occupations documented in the US census data to his sample, and thus included children from a variety of socioeconomic backgrounds (Boakes, 2002). Yet this focus on representativeness did not extend to race and ethnicity; only White children were included in the norming samples of the Stanford-Binet editions until 1972 (Graves & Aston, 2016). Now the norm samples of IQ tests are designed to match the diversity of the current US population. Modern IQ tests include the child's race, ethnicity, sex, and geographic region and their parents' educational level, often as a proxy of socioeconomic status, to design their norm samples. Proportions of individuals from each demographic category are matched to the percentages documented in the recent US Census data. The representativeness of test norm samples continues to be an important criterion for practitioners when they select tests (AERA, APA, NCME, 2014).

Early on, the Binet-Simon scale and Stanford-Binet were criticized for a heavy reliance on language-based measures which were not appropriate for individuals with limited English proficiency, such as individuals who were immigrants, were deaf or hard of hearing, or had little or no formal schooling. In response, physicians, psychiatrists, and psychologists (many of whom worked at Ellis Island) developed "*performance tests*" intended to remove the language demands and measure visual rather than verbal reasoning with the manipulation of picture boards, puzzles, or blocks (Boake, 2002). The early focus on language-reduced performance tests shaped the development of subsequent IQ tests and continues to be of strong interest today.

The most recent, fifth edition of the Stanford-Binet (SB-5) includes an equal balance of verbal and nonverbal content. The SB-5 measures children's general intelligence, verbal, fluid reasoning, quantitative reasoning, visual-spatial, and working memory abilities (see Table 16.1 for definitions of these cognitive abilities). The SB-5 covers a wide age range from 2 to 85 and above and continues the test's tradition of including toys and manipulatives to engage young children (Becker, 2003). The SB-5 norm samples were collected in 2001–2002 (Roid, 2003). Best practice suggests practitioners should use IQ tests whose norms were collected within the past 10 years (Kranzler & Floyd, 2020) due to a phenomenon known as the *Flynn Effect* (Flynn, 1987). James Flynn documented a tendency for IQ test scores to increase over time when old norms were used, approximately 3 points per decade. This means outdated test norms are problematic as they can result in inflated IQ scores (e.g., Kanaya et al., 2003). For example, if a child earned an IQ score of 70 on a test with norms collected 20 years prior, it is likely the child's adjusted IQ score is six points lower, 64. While the Flynn Effect is a well-documented phenomenon, some evidence suggests the Flynn Effect is declining or may be ending over time (Pietschnig & Voracek, 2015; Dutton et al., 2016).

Table 16.1 Definitions of cognitive abilities in the Cattell-Horn-Carroll (CHC) theory of intelligence and descriptions of typical subtests

Cattell-Horn-Carroll abilities	Description
General intelligence (*g*)	"General mental ability for reasoning, problem solving, learning." (Colom et al., 2010, p. 489) On IQ tests *g* is measured by a total or overall composite score measured by subtests measuring several cognitive abilities
Fluid reasoning (Gf)	The ability to problem-solve with unfamiliar information or novel procedures that cannot be performed automatically. In some studies, Gf and *g* significantly overlap and are statistically indistinguishable (Caemmerer et al., 2020). Quantitative abilities are subsumed within fluid reasoning Gf subtests often involve detecting and completing patterns using visual or numerical information and analyzing such information to complete puzzles
Verbal comprehension-knowledge (Gc)	The breadth and depth of cultural knowledge including language and information learned inside and outside of school. Sometimes referred to as crystallized intelligence Gc subtests often include vocabulary tasks, describing similarities and differences between words, and general information questions
Visual-spatial processing (Gv)	The ability to perceive, transform, discriminate visual information and identify patterns and mentally rotate images Gv subtests often involve mental rotations of visual stimuli, reproducing images using manipulatives or by copying images with pencil and paper, and identifying similar images from distractors
Auditory processing (Ga)	The ability to perceive, discriminate, and manipulate meaningful sounds, which includes phonological coding Ga subtests are not included on most IQ tests, but they typically involve segmenting, blending, and manipulating small units of sound (phonemes)
Working memory (Gwm/Gsm)	The ability to apprehend and maintain awareness of a limited amount of information and manipulate it Gwm subtests often involve retaining and manipulating series of numbers, words, or both, which increase in length and are presented verbally or visually
Long-term storage and retrieval (Glr)	The ability to store and consolidate new information in long-term memory (Gl) and fluently retrieve the information later (Gr) Schneider and McGrew (2018) recently argued Glr may be better represented as two separate abilities (Gl and Gr). Glr subtests often involve teaching the child associations between images and words and requiring them to recall those associations, sometimes after a delay
Processing speed (Gs)	The ability to automatically and fluently perform simple or overlearned cognitive tasks, especially when a high degree of focused attention is required Gs subtests often involve simple scanning, matching, copying, or naming tasks which are timed and require both speed and accuracy

Note. Broad ability definitions are adapted from Schneider and McGrew (2018)

Wechsler Tests

Starting in the 1960s, Stanford-Binet's dominance was replaced by the Wechsler IQ tests, which continue to be the most popular IQ tests today (Rabin et al., 2016; Benson et al., 2019; Wright et al., 2017). David Wechsler's perspective on IQ tests was informed by his experience testing Army recruits during World War I to determine if they were fit for service (Boakes, 2002; Kaufman, 2009). The United States' Army testing program played an important role in the growth of IQ testing; more than 1.7 million recruits completed IQ tests between 1917 and 1919 (Yerkes, 1921). The Army used different tests to assess groups of literate English speakers (Alpha test) and recruits who were illiterate or non-English speakers (Beta test). Wechsler valued both verbal and performance tests, and the two Army tests and the Stanford-Binet inspired many of the subtests on his first test, the Wechsler-Bellevue Intelligence Scale. Wechsler self-published his first test in 1939 while he was the chief psychologist at Bellevue Psychiatric Hospital. He collected the test norms himself and gathered data on White children, adolescents, and adults between the ages of 10 and 59 in Brooklyn, NY (Boakes, 2002; Kaufman, 2009). Norming samples continued to include White children exclusively until the 1970s, when they began to better reflect the racial and ethnic diversity of the United States (Graves & Aston, 2016). In addition to more representative norms, IQ test publishers now routinely statistically test items for bias and publishers and researchers test whether IQ tests measure similar cognitive constructs across various demographic groups.

Wechsler was an innovator in his development of IQ tests. He replaced the intelligence quotient score approach with a *standard score that has a mean of 100 and standard deviation of 15* (Kaufman, 2009). These same standard scores continue to be used in IQ tests today. Another of Wechsler's major contributions to the field of IQ testing was to create a single test which produced separate verbal, performance, and overall composite scores (also known as the full-scale IQ score) derived from an individual's performance on 10–12 subtests. Multiple composite scores were appealing to clinicians who wanted to gather a richer breadth of information from testing when most other prevailing tests, including the Stanford-Binet, continued to only offer one overall IQ score (Kaufman, 2009). Practitioners interpreted the strengths and weaknesses across the individual's multiple composite and subtest scores to inform diagnostic and treatment decisions. This approach, known as profile analysis, continues to be used today, but has its critics, which note reliability concerns (McGill et al., 2018).

The Wechsler-Bellevue was a test designed for assessing children and adults, but in the decade following the test's publication, Wechsler created three separate tests targeted at narrower age ranges. The Wechsler Intelligence Scale for Children (WISC; Wechsler, 1949) was appropriate for 6- to 16-year-olds, the Wechsler Adult Intelligence Scale (WAIS; Wechsler, 1955) was appropriate for 16-year-olds through adulthood, and the Wechsler Preschool and Primary Scale of Intelligence (WPPSI; Wechsler, 1967) introduced some new tasks appropriate for young children aged 2.5–6 years old. Later editions of the Wechsler tests primarily consisted of the original Wechsler-Bellevue subtests, but in the 1990s novel tasks were also added (Kaufman, 2009).

The most recent editions of the child-focused tests are the Wechsler Intelligence Scale for Children, Fifth Edition (WISC-V), and the Wechsler Preschool and Primary Scale of Intelligence, Fourth Edition (WPPSI-IV). The WISC-V is appropriate for children ages 6–16 years old and measures overall intelligence, verbal, fluid reasoning, visual-spatial, working memory, and processing speed abilities (Wechsler, 2014). A Spanish version of the WISC-V is available for Spanish-speaking children and includes a separate norming sample of children whose primary language is Spanish (Wechsler, 2017). The WPPSI-IV measures slightly different abilities depending on the age of the child. Overall intelligence, verbal, working memory, and visual-spatial abilities can be measured for children aged 2.5–3 years old. In addition to these cognitive abilities, processing speed and fluid reasoning can be measured in children from ages 4 to 7 years and 7 months (see Table 16.1; Wechsler, 2012). The most recent fourth edition of the Wechsler Adult Intelligence Scale (WAIS-IV; Wechsler, 2008) is designed for adolescents and adults ages 16–90 and measures similar cognitive abilities. Although Wechsler died in 1981, he continues to be listed as the sole author of the revisions of his widely popular tests (Kaufman, 2009).

Woodcock-Johnson Tests

In 1977, Richard Woodcock published the Woodcock-Johnson Psycho-Educational Battery (WJ). Woodcock's goal was to create a practical test that included many novel subtests which addressed psychologist's, special educator's, and teachers' concerns about students' learning (Shinn et al., 1977). The WJ consisted of 27 subtests which measured cognitive abilities, academic achievement, and students' interests. The WJ was the first IQ test to be co-normed with an achievement test, which included reading, mathematics, writing, and other academic subtests. Part one of the WJ, the Cognitive battery, included 12 subtests which measured verbal knowledge, visual-spatial, fluid reasoning, memory, auditory processing, and quantitative abilities (Shinn et al., 1977). The 1989 Woodcock-Johnson-Revised (WJ-R) test was divided into the Tests of Cognitive Ability (WJ-R Cog) and Tests of Achievement (WJ-R ACH; Woodcock, 1990). Unlike its predecessor, the WJ-R Cog was guided by theory, specifically Cattell and Horn's Gf-Gc theory (fluid and crystallized intelligence, see theories of intelligence chapter). In addition to fluid and crystallized intelligence, the WJ-R also measured short-term/working memory, long-term retrieval, processing speed, auditory processing, and visual processing abilities. The test provided composite scores for seven broad cognitive abilities plus an overall IQ composite score (Woodcock, 1990). The breadth of cognitive abilities measured by the Woodcock-Johnson test distinguishes the test from others (Reynolds & Niileksela, 2015).

The most recent WJ fourth edition, the WJ IV Tests of Cognitive Abilities (WJ IV Cog), is based on the Cattell-Horn-Carroll (CHC) theory, which now guides the development of most popular IQ tests currently in use (Keith & Reynolds, 2010). The WJ IV Cog is appropriate for a broad age range from ages 2 to 90 and older and measures more CHC-based broad cognitive abilities than any other IQ test. The WJ IV Cog measures overall intelligence and the seven broad cognitive abilities listed above. A parallel Spanish form of the test, the Batería IV Woodcock-Muñoz, is also available for a broad age range of Spanish speakers (Woodcock et al., 2019).

Kaufman Assessment Battery for Children

Alan Kaufman's experiences with IQ test development began in the 1970s when he assisted David Wechsler with the revision of the WISC (WISC-R; Kaufman, 2009). Approximately a decade later, Alan and his wife Nadeen Kaufman developed the Kaufman Assessment Battery for Children (K-ABC, 1983). The Kaufmans' goals included the development of a test based on neuropsychological and cognitive psychology theories, the introduction of new IQ tasks/subtests, the reduction of IQ score mean differences between White and Black children, and the introduction of unscored teaching items at the beginning of subtests to ensure children understood the task directions prior to the completion of scored items (Kaufman, 2009). The Kaufman Assessment Battery for Children is now in its second edition, with a recent normative update in 2018 (KABC-II NU). The KABC-II NU measures overall intelligence, verbal, fluid reasoning, visual-spatial, working memory, and long-term retrieval abilities. The KABC-II includes test directions and scoring guidelines in Spanish (Kaufman & Kaufman, 2018). The KABC-II can produce two global or overall IQ scores, one that includes the influence of subtests that measure verbal abilities (Gc) such as vocabulary and verbal reasoning and one that excludes verbal subtests.

Differential Ability Scales

Colin Elliot, a British school psychologist, published the Differential Ability Scales in 1990 with the intention of measuring children's "ability" which the authors deemed to be a "specific and narrower domain of human cognition" than intelligence (Gordon & Elliott, 2001, p. 66). Other distinguishing goals of the Differential Ability Scales were to create a more engaging test for young children and to allow test users to administer subtests that better matched the child's ability level regardless of their age. This flexible subtest administration approach is useful when assessing young children and those with lower abilities (Elliott, 2007). The most recent second edition, DAS-II, was published in 2007 (the norming sample was collected in 2005) and assesses children 2.5–17 years of age. The DAS-II assesses general intelligence, verbal, visual-spatial, fluid reasoning (for 2.5–3.5-year-olds visual-spatial and fluid reasoning are combined), and optional working memory and processing speed composite scores are available. Additionally, there are Spanish and American Sign Language instructions for nonverbal subtests.

Reynolds Intellectual Assessment Scales

Two of Alan Kaufman's former doctoral students, Cecil Reynolds and Randy Kamphaus, developed the Reynolds Intellectual Assessment Scales in 2003 (RIAS). The Reynolds Intellectual Assessment Scales was intended to minimize test administration time by requiring only four subtests to produce three composite scores, the overall general intelligence (*g*), verbal abilities (Gc), and fluid reasoning (Gf) scores subtests (Reynolds & Kamphaus, 2015). The typical administration time is 25 minutes for the four subtests that compose the general intelligence score. The RIAS was intended to reduce dependence on motor coordination, visual motor speed, and reading ability in the measurement of intelligence. The most recent second edition (RIAS-2), published in 2015, is designed for ages 3–94 and includes optional memory and processing speed composite scores. The RIAS-2 allows the child to provide Spanish responses on the verbal subtests (Reynolds & Kamphaus, 2015).

Brief or Abbreviated IQ Tests

IQ tests require substantial time to administer and score and are often time intensive for both the examiner and examinee. The typical administration time for comprehensive IQ tests often exceeds one hour. Brief or abbreviated IQ tests were created to reduce administration time as they consist of fewer subtests and/or items and are thus brief in coverage of skills and in administration time (Homack & Reynolds, 2007). Typical administration time for abbreviated IQ tests ranges from approximately 20 to 30 minutes, which reduces the burden on examiners and examinees.

Two of the most popular abbreviated IQ tests are derived from their well-established full-length counterparts: the Wechsler Abbreviated Scale of Intelligence, Second Edition (WASI-II; ages 6–90; Wechsler, 2011), and the Kaufman Brief Intelligence Test, Second Edition (KBIT-2; ages 4–90; Kaufman & Kaufman, 2004). In addition, the WJ IV Tests of Cognitive Abilities (WJ IV Cog; ages 2 to 90+; Schrank et al., 2014) have an option to compute a total IQ score based on three subtests instead of seven, the Brief Intellectual Ability Composite. The subtests in these abbreviated measures are primarily measures of fluid reasoning (Gf) and crystallized intelligence (or verbal comprehension-knowledge, Gc) and were chosen because the subtests have the strongest relation with general intelligence (*g*). The ultimate goal of an abbreviated or brief IQ test is to offer a similar estimate of general intelligence as a full-length test (Pierson et al., 2012).

Brief or abbreviated tests tend to be less sensitive and specific than longer forms. They are not as accurate at identifying those who do or do not meet specific diagnostic criteria (Homack & Reynolds, 2007). As such, abbreviated or brief tests cannot serve as a substitute for comprehensive tests and should not be used as a diagnostic tool or in high-stakes decision making (McCrimmon & Smith, 2013). Abbreviated IQ tests may be most useful when intelligence is not the primary concern or reason for the evaluation (Bain & Jaspers, 2004), or to screen for, or rule out, intelligence as a contributing factor to a child's presenting concerns. Examples include cases primarily focused on behavioral and emotional concerns or in settings such as hospitals, residential treatment centers, juvenile detention centers, or research labs where the primary focus is not cognitive or education-focused. In such cases, a global or overall estimate of intelligence may suffice to select developmentally and cognitively appropriate interventions and placements.

Nonverbal IQ Tests

Since the development of the first IQ test, test users have been concerned about the high language demands of the tests. Tests which rely heavily on the use of language may underestimate the abilities of individuals who are not proficient in the dominant language, either because they are primarily speakers of another language or their exposure to the language was inadequate due to environmental circumstances. In response, performance tests were created and used in assessments at Ellis Island and in the military during World War I. The first nonverbal IQ test was created by John C. Raven in 1936, the Raven's Progressive Matrices (Mun et al., 2020). Children do not use language to respond to nonverbal IQ tests, instead they point, manipulate objects, or gesture. Most nonverbal IQ tests are considered language-reduced because simplified language is used to provide test directions. Those that are administered completely without language require examiners to use gestures and facial expressions instead. Thus, expressive language is not required for all nonverbal IQ tests, and receptive language demands are diminished for language-reduced nonverbal IQ tests or not required for nonverbal IQ tests without verbal instructions (Drevon et al., 2017). Even when language is completely removed from the directions and responses of the test, the child likely uses internal verbal problem solving to respond to the items. This may mean the child's nonverbal scores are influenced by language, which could influence whether the scores are an accurate representation of their abilities (Braden, 2000).

In addition to minimizing the influence of language, practitioners also use nonverbal IQ tests to reduce the influence of cultural knowledge on individuals' test scores. Thus, nonverbal IQ tests are appropriate for any individuals whose test scores may be influenced by constructs that are irrelevant to the measurement of their intelligence or cognitive ability (this concept is referred to as *construct irrelevant variance*). Practitioners may select nonverbal IQ tests for a child who has not yet developed English proficiency or whose first language is not English, immigrated to the United States from another country, is deaf or hard-of-hearing, has a speech and language disorder, has selective mutism, experienced neurological damage, or is culturally and linguistically diverse (Bracken & McCallum, 2016). Two popular nonverbal IQ tests are the third edition of the Leiter (Leiter-3; ages 3 to 75+; Roid et al., 2013) and the Universal Nonverbal Intelligence Test Second Edition (UNIT-2; ages 3–21; Bracken & McCallum, 2016). Both tests remove language completely from the test administration and are considered multidimensional nonverbal tests because they measure other cognitive abilities in addition to general intelligence such as fluid reasoning, visual spatial, memory, and processing speed (Kranzler & Floyd, 2020).

A popular language-reduced, unidimensional nonverbal intelligence test is the Raven's 2 Progressive Matrices (Raven et al., 2018). The Raven's 2 includes simple oral directions, but the examinee responds nonverbally. The Raven's 2 includes a single subtest of geometric patterns, is primarily considered a measure of fluid reasoning, and produces one general intelligence composite score. The Raven's 2 can be used with a broad age range, ages 4–90 years old, and is used in practice as well as research studies. Practitioners can administer the Raven's 2 one-on-one or with groups, and a digital administration option can be completed via an online platform.

Technological Advances

Practitioners have traditionally administered IQ tests in a paper-and-pencil format, but technological advances are beginning to shift the testing experience for examiners and the children they test. In the traditional assessment formats, practitioners record and score children's responses on a paper record form, and children are required to respond to paper stimuli books or other tangible objects. Technology-based testing options are increasing in popularity, however, and some of the tests described earlier are available in both traditional and computer-assisted formats. Technology-based testing is often facilitated by tablets or computers which display stimuli and record and score responses automatically (e.g., Q-Interactive by Pearson Assessments, https://qiactive.com/; NIH Toolbox, http://www.nihtoolbox.org/). Potential advantages of these computer-assisted tests are efficiency, increased administration and scoring accuracy, and reduced administration times (Young et al., 2021). Researchers are currently exploring equivalency and validity issues related to traditional and computer-assisted assessments. A particularly innovative IQ test, the International Cognitive Ability Resource (iCAR), is publicly available, untimed, and self-proctored, and examinees aged 14 and older can complete the iCAR online in their own homes (Condon & Revelle, 2014; see https://icar-project.com/ for more details). However, in its current form, the ICAR is only suitable as a research tool and is not to be used in clinical settings or decision-making contexts.

Conclusion

Across different IQ tests, similar, but not identical, tasks are used to measure different cognitive abilities (see Table 16.1). Often subtest items are arranged hierarchically with the easiest items presented first and the most difficult items presented last. Some IQ tests incorporate manipulatives into subtests such as blocks, cards, or other familiar objects, which are often believed to be more engaging for young children, whereas other IQ tests do not use such materials (i.e., the Woodcock-Johnson Tests of Cognitive Abilities and the Reynolds Intellectual Assessment Scales). Despite differences in subtest demands, stimuli, and response formats, research studies suggest that the underlying cognitive abilities measured by several different IQ tests are similar (Caemmerer et al., 2020). However, if a child is given two or more IQ tests, the child's scores will not be identical across tests due to measurement error (Floyd et al., 2005).

The IQ test overview section described many of the IQ tests practitioners most frequently used with children (Benson et al., 2019; Rabin et al., 2016; Wright et al., 2017), but this overview is not exhaustive and many other IQ tests are available. When determining which IQ test is appropriate for a child, practitioners must consider multiple factors. Test selection involves psychometric, theoretical, practical, and clinical preference considerations. Test users are responsible for carefully reviewing evidence of reliability and validity of test scores, standardization/norming sample characteristics, and the alignment of each with the characteristics of the populations the practitioner tests (AERA, APA, NCME, 2014). Often test publishers report this detailed psychometric information in technical manuals which test users must carefully review to facilitate test selection. Practitioners may also consider theories of intelligence and how they align with the IQ tests, the typical administration time required for the test, the match between the language of the test and the child, and the cost of test materials. The inventory of tests at the assessment setting may influence test selection as many practitioners are limited to a small number of choices as IQ tests are expensive. Typical assessment settings in which IQ tests are used with children will be discussed further in the next section.

Current Uses of IQ Tests with Children

Qualified Test Users

Most IQ tests are standardized and individually administered, or one-on-one, tests. Standardized tests are administered according to strict instructions such that, to the extent possible, every examinee experiences the test in the same way. "Standardized tests present the same or very similar test materials to all test takers, maintain close adherence to stipulated procedures for test administration, and employ prescribed scoring rules that can be applied with a high degree of consistency" (AERA, APA, NCME, 2014, p. 35). Because IQ tests are norm-referenced, careful adherence to the standardized administration conditions allows a child's performance on the test to be compared to a norm group of same-aged peers. This comparison provides information about the child's relative standing in comparison to peers, whether the child's performance is similar to peers (and considered within the average range) or higher or lower than others their age. Deviations from standardized administration conditions potentially introduce variability into the child's performance and can invalidate test scores.

Given the importance of accurate administration and scoring, IQ tests must be administered, scored, and interpreted by highly trained qualified examiners. Definitions of qualified examiners vary across IQ test publishers, professional associations, and state psychological boards. Some states further differentiate between those eligible to administer a test from those who can interpret the results. Across definitions, qualifications consistently include an examiner whose training included supervised experiential learning and education in psychometric principles, and the examiner must thoroughly review the examiner manual. Three professional organizations—the American Educational Research Association (AERA), American Psychological Association (APA), and the National Council on Measurement in Education (NCME)—jointly released *The Standards for Educational and Psychological Testing* (2014) to promote sound psychological testing standards. The fourth edition describes the ideal examiner as a professional with graduate-level training and supervised experience in measurement and assessment. In addition, the examiner is responsible for selecting the most appropriate test based on test taker characteristics, possessing the knowledge and skills necessary to accurately interpret results, and aligning the intended use of the test with the abilities measured.

Diagnostic Use

Qualified practitioners who serve children frequently administer IQ tests in schools, community clinics, private practices, medical settings, residential treatment centers, juvenile justice settings, and any other child-focused setting. Across settings, IQ test results may be used to inform diagnostic decision making and determine eligibility for services and specific placements. It is important to note that in most cases IQ tests are intended to be used as just one source of information and not the sole criteria for important decision-making processes. Across psychological assessment applications, comprehensive multimethod, multi-setting, multisources evaluations are deemed best practice, and thus IQ tests should be just one tool used to inform clinical decisions (Sattler, 2018; De Los Reyes et al., 2015).

Educational Purposes

Today, intelligence tests are used by practitioners inside and outside schools to determine a child's eligibility for specialized services, accommodations, and placements. Their use is related to decades of federal special education legislation, now known as the Individuals with Disabilities Education Improvement Act (IDEA, 2004). Within special education programming, IQ tests are primarily used to identify children with specific learning disabilities and intellectual disabilities. Beyond special education, IQ test results are often used to identify children who are considered gifted and talented. IQ tests may also be used to provide accommodations and support services in schools through a section 504 plan; such plans improve children's access to the general education environment (Russo et al., 1998). Medical or psychological diagnoses, such as Attention Deficit Hyperactivity Disorder, may warrant a section 504 plan.

Within schools, children with specific learning disabilities constitute the largest group of students receiving special education services, approximately one-third (Hussar et al., 2020). Definitions of learning disabilities or disorders vary but are often described as important in a learning domain such as reading, writing, speaking, and performing mathematical calculations that is due to a neurodevelopmental disorder which persists despite adequate academic instruction (IDEA, 2004; American Psychiatric Association (APA), 2013). Traditionally, IQ tests were an integral component of evaluations for specific learning disabilities. The oldest learning disability identification model required a significant discrepancy between a child's IQ test scores and their standardized academic achievement test scores (known as the ability-achievement discrepancy model). Some contemporary models continue to incorporate IQ test performance and examine students' performance on IQ, academic achievement, and neuropsychological tests for patterns of intraindividual strengths and weaknesses that may explain students' learning difficulties. Another contemporary model, response to intervention model, does not use IQ tests and instead emphasizes progress data based on a child's response to scientific, research-based instruction (Maki et al., 2015). While IQ tests' current role in the identification of learning disabilities remains controversial and there is no single accepted approach to the identification of learning disabilities (Grigorenko et al., 2019), IQ tests are currently a required tool to determine if a child meets criteria for an intellectual disability.

Intellectual disability diagnostic criteria require significantly below average intellectual functioning and adaptive behavior (everyday behaviors expected by society across living settings; Schalock et al., 2010) when compared to age-, gender-, and socioculturally similar peers (American Psychiatric Association (APA), 2013; 34 CFR §300.8(c)(6)). IQ test scores two or more standard deviations below the mean score of 100 are generally considered significantly below average and consistent with intellectual disability criteria (McNicholas et al., 2017). This translates to a standard IQ score of 70 or below, which is located in the left tail of the normal distribution and is lower than more than 97% of the population (see Fig. 16.1 for a visual representation of the IQ test score distribution). Similarly, children who are identified as gifted often have IQ scores in the other tail of the normal distribution. Giftedness describes students who excel in intellectual, creative, artistic, or other specific learning domains (20 U.S.C. Section 7801(22)). IQ tests have consistently informed giftedness definitions and access to advanced educational programming. Most often, the criterion for giftedness involves an IQ score 1.5–2 standard deviations above the mean score (i.e., IQ score ≥120 and above) and higher than nearly 95% of their peers. Although IQ scores in this range are as infrequent as those in the intellectual disability criterion range, gifted educational services are not legally protected (McClain & Pfeiffer, 2012). Some experts recommend practitioners specifically use nonverbal IQ tests to increase the representation of culturally and linguistically diverse students in gifted and talented programs, but current research evidence is mixed (Mun et al., 2020). Children who are gifted are more likely to have areas of weakness overlooked in the school setting such as learning, attention, and social behaviors. These students are often labeled *twice-exceptional* (2E; Foley Nicpon et al., 2011; Reis et al., 2014).

It is important to note that IQ test scores are imperfect measures of a person's true cognitive ability and include measurement error, just as all test scores do (AERA, APA, NCME, 2014). Therefore, some experts encourage practitioners to consider the confidence interval of a test score when making high-stakes decisions that rely on strict cut-off scores, such as those used for giftedness and intellectual disabilities (Kranzler & Floyd, 2020). A confidence interval is a range of scores that contain the individual's hypothetical true score with a specific degree of confidence. For example, let's assume a child's IQ score is 73 and the 95% confidence interval is 68–76. When interpreting the confidence interval, a practitioner would indicate there is a 95% chance that the child's true score is somewhere between 68 and 76. Thus, the child may meet one criterion for an intellectual disability, and their level of adaptive functioning would also be examined.

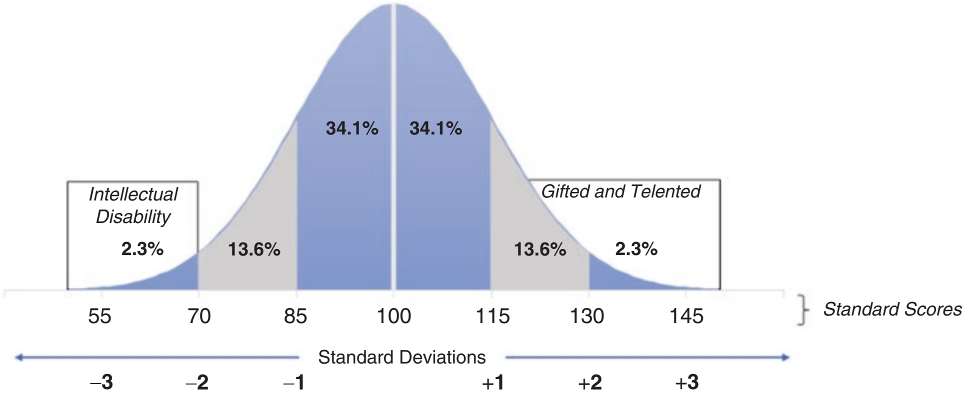

Fig. 16.1 Normal distribution of IQ test standard scores

This figure displays the ranges of IQ test standard scores and the accompanying proportions of people in the population whose scores are within those ranges. Approximately 68% of people will earn scores between 85 and 115 (one standard deviation below (−1) and above (+1) the mean of 100). Approximately 95% of people will earn scores between 70 and 130 (two standard deviations below (−2) and above (+2) the mean score). And approximately 99% of people will earn scores between 55 and 145 (three standard deviations below (−3) and above (+3) the mean score). The further a person's score is from the mean of 100, the less often the score is observed in the population. When practitioners communicate IQ test scores to others, they often use qualitative labels to describe whether a score is considered average, below, or above average, or very high or low. Often scores between 90 and 109 or 85 and 115 are considered within the average range. There is no universal set of qualitative labels, however, and practitioners and test publishers apply these labels inconsistently (Lichtenstein, 2020).

Case Study: Example of IQ Test Results Used for Educational Purposes

Abby is a 9-year-old girl in the fourth grade. Abby's parents described her as precocious, strong-willed, and sometimes difficult when she was young. They remember being surprised at how quickly she acquired language when she first started speaking. She was easily naming colors, numbers, and shapes around 2 years old and started reading when she was four. However, Abby was known to tantrum and pout when she did not get her way. As she got older, she continued to have difficulty moving on when she felt things were unfair. Abby liked school and did well academically, though teachers noted she often raced through her work and began to distract other children when she finished. There were also concerns for "talking back" to teachers. Abby was interested in playing with other children her age, but sometimes had difficulty maintaining friendships, and often seemed more comfortable talking to adults.

Abby's parents were concerned about her socially and behaviorally at school and worried she may have attention or social/emotional problems. They brought her to a psychologist for an assessment who administered a psychoeducational battery of several assessments. Abby's IQ score was two standard deviations above other children her age (i.e., IQ test score was 130), and her scores on other tests were similarly high. The results of this evaluation were used to help place Abby in a gifted and talented program. When Abby was appropriately challenged, her distracting behaviors in the classroom decreased. She also had the opportunity to meet other children with similar interests and was able to make several new friends.

IQ Tests and Intervention Design Children's IQ test results are widely used for educational diagnostic and placement decisions. Critics of the use of IQ tests in education argue, however, that IQ test results are not useful for classroom instructional planning or the design of interventions (Hilliard, 1994). Aptitude-treatment interactions test whether the effectiveness of instruction depends on, or is moderated by, a child's cognitive abilities, which are often measured by IQ tests (Kearns & Fuchs, 2013). For example, if a child has weak working memory abilities (i.e., the ability to hold information in one's mind and manipulate it) implementation of a working memory intervention may be expected to enhance the child's academic performance. Current research findings suggest the effects of working memory training programs do not often generalize to real-world skills and studies do not support consistent aptitude-treatment interactions (Kearns & Fuchs, 2013; Melby-Lervåg & Hulme, 2013). Thus, IQ test results may not be useful for intervention design and current evidence does not support this purpose.

Healthcare Purposes

IQ tests are often used within healthcare settings for individuals with neurodevelopmental disorders as well as acquired neurological deficits. IQ tests are generally used within the context of a larger neuropsychological battery which aims to measure a comprehensive range of aspects of brain functioning, such as cognitive, motor, language, visual-perceptual, memory, attention, and executive functions.

Intelligence tests are often administered as part of a neurodevelopmental battery for children with neuropathology identified prenatally, at birth, or in early development. Neurodevelopmental concerns may result from a range of perinatal complications (e.g., prematurity, low birth weight, hypoxia, perinatal strokes), congenital problems (e.g., spina bifida, cerebral palsy), or genetic conditions (e.g., Down or Fragile X syndromes). For these children, intelligence estimates can provide a useful "snapshot" of their global cognitive functioning that is influenced by multiple genetic, biological, cognitive, and experiential factors (Dennis et al., 2009). Intelligence tests are important in these populations due to the frequency of comorbid intellectual disabilities (Lee et al., 2019). Early neurodevelopmental screening and monitoring is recommended for all children, especially those at an increased risk due to a medical condition (Centers for Disease Control and Prevention [CDC], 2021).

Generally, early childhood screenings consist of developmental tests that evaluate broad foundational abilities such as cognitive, gross and fine motor, social-emotional, adaptive, and emerging receptive and expressive language skills. Experts debate whether fewer cognitive abilities are measured by IQ tests in toddlers and preschoolers, referred to as less differentiation of cognitive abilities (Tideman & Gustafsson, 2004; Potvin et al., 2015). IQ is thought to become more stable at approximately age six (Deary, 2014), but some evidence suggests IQ scores in infants can moderately predict later measures of general intelligence and academic outcomes (Fagan et al., 2007; Yu et al., 2018). In applied practice, early IQ scores can identify children at risk for cognitive weaknesses and facilitate early intervention services for children classified with a developmental delay.

IQ tests are also used to assess and monitor individuals with acquired brain dysfunction, which are injuries and insults to the brain, like traumatic brain injuries (TBI) or toxicities, or neuropathologies like epilepsy or cancer. For example, for children with pediatric brain cancer, tumor growth and the associated treatments can impact cognitive functioning over time. Radiation therapy and chemotherapy have repeatedly been shown to cause declines in IQ scores for years after the completion of treatment (Baade et al., 2010). As such, regular monitoring of neurocognitive functioning of patients over time is recommended to help inform intervention and treatment.

At a broad healthcare level, IQ tests contributed to public health policy changes which have improved health indicators for society (Kaufman 2009). IQ tests helped to expose the harmful effects of environmental toxins, such as lead, on child development. High levels of lead exposure have been linked to low high school academic achievement (Fergusson et al., 1997) and comorbidity with ADHD (Braun et al., 2006). The inverse relationship between lead exposure and IQ has consistently informed the Center for Disease Control's acceptable exposure thresholds (Canfield et al. 2004; Surkan et al. 2007).

Case Study: Example of IQ Test Results Used for Healthcare Purposes

Michael is a 5-year-old boy with a history of epilepsy. He began to have seizures in infancy, which were determined to be arising from his left temporal-parietal networks. Michael trialed several antiepileptic medications before finding one that worked about 2 years ago, and his seizures are now well controlled. Michael was slow to meet his developmental milestones and was not speaking in phrases until he was 3 years old. Michael's teachers noted he was struggling when he started kindergarten. He was not learning his numbers and letters as quickly as the other children and needed to be retaught many times. He also had much more difficulty staying in his seat and following instructions compared to other children. His parents also noticed some of these difficulties at home; Michael was always on the go and constantly moving from one task to another. They expressed concerns to Michael's neurologist who referred him for a comprehensive neuropsychological evaluation.

Michael's neuropsychologists administered a comprehensive battery of tests including IQ, language, visual-spatial, motor, memory, attention, executive functioning, and academic measures. His parents also completed rating scales of his social-emotional and adaptive skills. Michael's overall IQ score was in the low average range. There was a significant weakness in his language skills across multiple tests, which was consistent with his history of left-sided seizure activity and early language delays. He was also noted to have difficulties with attention, processing speed, and executive functioning which are common in children with epilepsy. The results of this evaluation helped Michael get an Individualized Education Program that included speech/language therapy services at school as well as accommodations for difficulties with attention and behavioral regulation in the classroom. Results also helped Michael's teachers and parents better understand Michael's personal strengths in nonverbal and visual-spatial skills, which was helpful in planning learning activities and opportunities for success.

Other Purposes

Individuals with significant disabilities often have needs that require intensive support into and throughout adulthood (Luecking & Wittenburg, 2009; Schalock et al., 2010). IQ tests may be used to determine eligibility for intensive services, such as placement in a residential care facility, employment supports, community-based supports, Medicaid, and social security disability and supplemental security income benefits. IQ tests, along with other assessment data, can document an individual's level of impairment and provide supporting evidence to the government and other agencies about the level of care needed.

In addition, IQ tests are often used in the juvenile justice system to screen youth for intellectual disabilities. Individuals with intellectual disabilities have protections under the law, for example, they cannot be executed in states with the death penalty (Everington & Olley, 2008). Documentation of cognitive impairments during one's early life could mean the difference between life and death for some individuals. In addition, IQ tests are frequently used in the court system for juvenile competency to stand trial evaluations (Ryba et al., 2003).

IQ and Other Related Tests

Spearman's discovery in 1904 that the variation across many different types of IQ subtests can be explained by one overarching factor, general intelligence (*g*), is one of the cornerstones of intelligence testing today (Savi et al., 2019). However, the particular types of tests subsumed under general intelligence are not always clearly delineated. There has been extensive research and debate on which types of tests can be considered measures of "intelligence," and which tests measure something else, such as neuropsychological functioning or academic achievement. Neuropsychological tests are thought to measure specific functions of the brain and tend to be indicators of aspects of brain dysfunction (Boyle et al., 2012), while academic tests measure the amount of knowledge and/or level of academic skills an individual acquired or mastered through planned instruction in educational settings (Chang & Davis, 2011). Given that most scholars agree that intelligence involves both biological and experiential factors (Savi et al., 2019), it is not surprising that both neuropsychological and academic measures are frequently involved in IQ tests to some degree.

Neuropsychological and intelligence tests have been found to assess similar abilities. In fact, within a neuropsychological framework, intelligence has been conceptualized as a composite of neurocognitive abilities measured within a comprehensive neuropsychological evaluation (Larrabee, 2000). Intelligence tests and neuropsychological tests have similar diagnostic accuracy in detecting brain dysfunction (Kane et al., 1985; Sherer et al., 1994); both are frequently used as part of a comprehensive neuropsychological assessment as a measure of "premorbid functioning," a baseline estimate of ability prior to the event causing dysfunction (Gansler et al., 2017). Furthermore, evidence suggests neuropsychological measures may be better conceptualized as measures of intelligence, particularly within a Cattell-Horn-Carroll intelligence theory framework, rather than as unique constructs (Buczyłowska et al., 2020; Jewsbury et al., 2017; Salthouse 2005). Despite the notion that neuropsychological measures may not always be statistically distinguishable from IQ tests, some authors argue against interchanging the two, as neuropsychological tests fundamentally aim to reveal impairments in specific cognitive functions while IQ tests take a broader approach at understanding cognitive abilities overall (Gansler et al., 2017).

Historically, inferences based on children's performance on IQ tests were used to predict their educational performance. Therefore, it is not surprising that IQ test developers often estimate relations between scores on their IQ tests and standardized academic achievement tests as evidence of predictive validity. This source of validity evidence is also referred to as evidence based on relations with other variables, which involves relations between the test and related external variables (AERA, APA, NCME, 2014). Correlations between children's general intelligence (*g*) score, or the overall comprehensive score produced by intelligence tests, and scores on tests of standardized general academic achievement are high, with estimates approximating 0.80. This means that approximately 50–70% of the variation in children's standardized general achievement is explained by general intelligence (Deary et al., 2007; Kaufman et al., 2012). Despite these strong correlations, standardized intelligence and achievement tests appear to measure distinct nonequivalent constructs (Kaufman et al., 2012). Children's overall intelligence (*g*) is the strongest predictor of their academic skills, but other cognitive abilities subsumed under *g* (i.e., fluid reasoning, verbal comprehension, working memory) differentially predict children's reading, writing, and math skills (Caemmerer et al., 2018; McGrew & Wendling, 2010). Researchers do not agree whether the focus of these cognitive-achievement relations should be on overall intelligence only or both overall intelligence and other broad cognitive abilities (Zaboski et al., 2018). Additionally, these predictive relations are not only limited to children's standardized achievement performance. Children's IQ test scores are statistically significant, albeit relatively weaker, predictors of their classroom grades, approximately 40% of the variance in their grades is explained by IQ tests (Gustafsson & Balke, 1993; Rindermann & Neubauer, 2004).

Conclusion

Intelligence tests are widely used with children for a variety of purposes. The first IQ test was created more than a century ago to test children for educational purposes. Since then, the use of IQ tests has spread to many settings and many other IQ tests have been published. Different IQ tests include a variety of tasks and stimuli, but despite these differences, IQ tests appear to measure similar cognitive abilities. Children's performance on IQ tests may inform diagnostic and eligibility decisions for supports and placements in schools, healthcare settings, intensive treatment settings, or courts. The results of IQ tests should not be used as the sole criteria for any clinical decision, instead IQ tests should be just one of many tools in a practitioner's assessment repertoire.

Francesco Scibelli, and Stefano Vicari

History of Adaptive Behavior

Defining refers to describing the meaning and the exact limits of something. Before the development of the definition of intellectual disability (ID) by the American Association on Intellectual and Developmental Disabilities (AAIDD), the inclusion of adaptive behavior in the diagnosis of ID and the understanding of the limits in one person's functioning have a long history.

Going far back in time, Ancient Greeks left the first documented scripts on adaptive behavior and its relationship with ID. They introduced the word "idiot" to define someone who does not interact with other people and does not participate in community settings.

Both Greek and Roman societies used to think that a person who cares for his or her health and who is able to attend social activities could be defined as "normal." "Idiots" were despised and often killed, because they were considered a burden to the society (Barr, 1905).

During the Middle Ages, the social stereotype did not change; in fact, people with intellectual disorders were often used as jesters with the purpose to entertain aristocrats (History of Intellectual Disability, 2016). The condition was usually attributed to witchcraft.

Only in the Enlightenment period, the first changes of direction were observed. For instance, both Christian humanitarian and scientific studies helped to make the lives of people with ID more worthy to be lived. In the seventeenth century, Thomas Willis provided the first description of ID as a disease. Some European societies started to build up interventions and individualized instructions for people with such disorders.

Another step for the definition of ID was made by Locke (1689), who first distinguished between "idiots" and "madmen."

J. L. Matson (ed.), *Handbook of Clinical Child Psychology*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-24926-6_17

In 1838, Itard published the first report of a 10–12 years old child with mental retardation. A hunter and his wife that afterwards decided to adopt him found this child, named the “Wild boy of Aveyron,” in the woods; he was not able to understand and to express language. Every attempt to give him teachings seemed to be unsuccessful. For this reason, the psychiatrist Itard decided to take the wild boy with him in order to study his condition and try to improve his adaptive functioning. At the beginning, the child was unable to meet social norms, to be empathetic, and to learn rules, but thanks to the effort of Itard, the wild boy developed a simplified language and rudimental behaviors that allowed him to interact with other people. Itard taught him to use cutlery, to be politely seated, and to dress himself, demonstrating that adaptive behavior can be modified by environment and rehabilitation (Oakland & Harrison, 2008).

In the same year, Esquirol published a revolutionary book on mental retardation. He noted that different levels of severity can be observed in ID and that language skills may be a key to distinguish between pathological and normal cognitive levels. Furthermore, he pointed out the importance of using objective methods to measure cognitive functioning. In 1838, Seguin, Esquirol’s student, opened a school for children with special needs. This initiated the establishments of more than 80 residential institutions around Europe and America.

In 1859, with the publication of “On the Origin of Species,” Darwin opened the debate about the relative contribution of nature – biological inborn characteristics and nurture – environmental impact on the development of man’s behavior (Darwin, 1859). What is important to remember about this controversy is the idea that species such as ours could change over time. Darwinians believed that ID was inherited.

Influenced by Charles Darwin’s theory, his cousin the psychologist, Francis Galton, proposed selective breeding of humans to reduce ID. He was interested in mental testing and conducted many of the first surveys to measure cognitive functioning. He was also the one who coined the terminology “mental test”.

In 1905, Alfred Binet produced the first standardized test to measure intelligence in children. Binet and his colleagues tried to differentiate between children who could and could not benefit from education (Binet & Simon, 1948). According to Binet, intelligence could be defined as a skill to cope with all the daily life demands. Even though still implicitly, adaptive behavior continued to be considered an important ingredient in intelligence’s definition. During these years, the psychologists Binet and Simon produced the first standardized intelligence scale, known as “Binet-Simon Scale.” In 1916, Lewis Terman revised this test, renaming it “Stanford-Binet Intelligence Scale” and introducing the concept of IQ (intelligence quotient), which was the ratio between mental and chronological age (Cianciolo & Sternberg, 2004). However, his conceptualization of IQ had different limits, such as it didn’t allow clinicians to compare people of different ages.

Only with David Wechsler (1939), who introduced the Deviation Intelligence Quotient, those methodological problems will be solved, as the latter notion allows to evaluate the performance of a subject in comparison to individuals of the same and different chronological ages and to compare the results provided by different tools (Picone et al., 2006).

In parallel with the development of mental testing, the first supported associations began to be founded. In 1879, the United States formed the “Association of Medical Officers of American Institution for the Idiotic and Feebleminded,” renamed “American Association on Mental Deficiency” in 1933 and later “American Association on Mental Retardation” (AAMR). In 2007, as the term “mental retardation” was increasingly been replaced by the less offending definition “intellectual disability,” AAMR changed its name to AAIDD (Schalock et al., 2007). The latest name is used throughout this chapter.

Although adaptive behavior did not play a central role in the diagnosis of ID during the first half of the twentieth century, the importance of social competency, adaptability to environment, and ability to cope with daily life was never completely abandoned. Alternative measures to mental testing began to appear as early as 1916.

Doll (1927), Kuhlman (1920), and Porteus (1921) started to develop psychometric measures of adaptive behavior. Doll, for example, underlined that social inadequacy due to low intelligence was one of the main points of mental retardation. Doll claimed that since IQ tests were normed on the general population, they were unable to really predict how much a person deviated from others. For this reason, he introduced the Vineland Social Maturity Scale (VSMS) (Doll, 1936), a tool of 117 items measuring practical skills and social competence. VSMS was a caregiver-report instrument and was administrable only to children. However, it had different limitations, such as the assumption that a person who has acquired a skill will display that skill.

In 1939, the first edition of the Wechsler Scales (WAIS), named the Wechsler–Bellevue Intelligence Scale, was published by David Wechsler (1939). This test is currently on its fourth edition (WAIS-IV) released in 2008 by Pearson and represents the most used and reliable intelligence test in the world. What is interesting to notice is the definition that D. Wechsler gave to intelligence: *"Intelligence is the aggregate or global capacity of an individual to think rationally, to act purposefully and to deal effectively with his environment"* (1939). Wechsler himself underlined that it would be unreasonable to thinking that intelligence tests may be the only measure of intelligent behavior and other factors should be taken into account. Indeed, dissatisfaction with the IQ scores as the sole index in people with ID raised over the time.

The assessment of adaptive behavior was formally included in the diagnostic nomenclature of ID in 1959, when Heber claimed that performance on mental tests does not always correspond to the real one person's daily life functioning (Heber, 1959). He conceptualized adaptive behavior as a construct consistent of three main factors: practical, social, and conceptual skills.

This new acknowledgment created the need to develop standardized measures of adaptive behavior. In 1969, Nihira and colleagues published the "Adaptive Behavior Checklist," the first psychometric assessment instrument of adaptive functioning to be used together with standard intelligence tests (Nihira et al., 1993). This scale had two forms: one for people older than 12 and one for people younger than 12. Nowadays, its revised nomenclature is the AAMR Adaptive Behavior Scale.

Heber's classification was reaffirmed in 1983 by Grossman, who underlined the importance of adaptive behavior in the diagnosis of ID (for a better definition provided by Grossman, see section "Adaptive Behavior: Assessment"). Both Heber and Grossman recognized the multidimensionality of adaptive behavior and underlined the influence of sociocultural factors on one person's cognitive and adaptive functioning.

Nowadays, it is clear that adaptive skills are essential to survival. Two people can perform at the same level on standardized cognitive tasks, but can exhibit completely different adaptive behaviors to their environments; for this reason, adaptive skills should be always evaluated during ID assessment.

Adaptive behavior deficits have been included in the current official definition of intellectual disability provided by AAIDD (Luckasson et al., 2002, p.1):

Intellectual disability is a disability characterized by significant limitations in both intellectual functioning and in adaptive behavior, which covers many everyday social and practical skills. This disability originates before the age of 18. The following five assumptions are essential to de application of this definition:

1. Limitations in present functioning must be considered within the context of community environments typical of the individual's age peers and culture.
2. Valid assessment considers cultural and linguistic diversity as well as differences in communication, sensory, motor and behavioral factors.

3. Within an individual, limitations often coexist with strengths.
4. An important purpose of describing limitations is to develop a profile of needed supports.
5. With appropriate personalized supports over a sustained period, the life functioning of the person with intellectual disability generally will improve.

In addition to AAIDD, another system for classifying ID is the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), which is published by the American Psychiatric Association (APA, 2013) and which criteria for the diagnosis of ID are as follows:

1. Deficits in intellectual functioning. This includes various mental abilities, such as reasoning; problem solving; planning; abstract thinking; judgment; academic learning; experiential learning. These mental abilities are measured by IQ tests.
2. Deficits or impairments in adaptive functioning. This includes skills needed to live in an independent and responsible manner. Limited abilities in these life skills make it difficult to achieve age appropriate standards of behavior. Without these skills, a person needs additional supports to succeed at school, work, or independent life. Deficits in adaptive functioning are measured using standardized, culturally appropriate tests.
3. These limitations occur during the developmental period. This means problems with intellectual or adaptive functioning were evident during childhood or adolescence. If these problems began after this developmental period, the correct diagnosis would be neurocognitive disorder. For instance, a traumatic brain injury from a car accident could cause similar symptoms.

It is important to underline that, with the publication of DSM-5, IQ scores have been replaced by level of adaptive behavior deficits as the criterion to establish the severity levels of ID. Actually, adaptive behavior is more salient than IQ in predicting the support needs of a person.

Comparing the DSM-5 definition of ID with the ones of the previous editions, it emerges how the last version encourages a more comprehensive view of the individual and emphasizes the importance of adaptive behavior. For instance, in contrast to DSM-IV, which needs impairments in two or more skill areas, the DSM-5 criteria require an impairment in one or more superordinate skill domains (e.g., conceptual, social, practical) (Papazoglou et al., 2014).

Throughout the past 50 years of definitions provided by AAIDD and APA (see APA, 2013; Luckasson et al., 2002; Papazoglou et al., 2014), the relevance of adaptive behavior raised edition after edition. A valid diagnosis of ID requires the clinician to integrate assessment of cognitive functioning and adaptive behavior. In fact, the definition of ID, going back more than 100 years to the present, confirms that both are essential in the classification of ID.

In conclusion, the definition of adaptive behavior has a long history. Today it can be conceptualized as the collection of conceptual, social, and practical skills that have been learned and are performed during daily life. This definition is a continuation of the attention given to adaptive functioning and social adequacy in the diagnosis of ID (Shogren et al., 2017).

At this moment, there are at least 200 adaptive functioning scales that have been used for diagnosis, research, and individualized programming purposes; however, very few have adequate norms and reliability to diagnose ID in people with low IQ. For this reason, in the next paragraph only the principal standardized adaptive behavior instruments will be described.

Adaptive Behavior: Assessment

Assessment of adaptive behavior plays a key role in the diagnosis of ID. Furthermore, it provides important information about planning of treatments not only in individuals with ID, but also in individuals with neurodevelopmental disorders.

Back in the 1970s, investigating adaptive behavior was meant to understand "*the effectiveness and degrees to which the individual meets the standards of personal independence and social responsibilities expected for his age and cultural group*" (Grossman, 1973, p.11). Personal autonomies (moving around, using money) and the ability to take care of themselves (cleaning oneself, getting dressed) and to manage home-life (cooking, cleaning the house, washing clothes) are some features of the dimension of personal independence. The ability to follow the rules, to manage the time, to attend social events, and to respect different social norms represents some features of the dimension of social responsibilities.

Considering all the activities and the skills referable to adaptive behavior, both in the DSM-5 (APA, 2013) and in the last three editions of AAIDD manuals (Luckasson et al., 2002; Schalock et al., 2010; Schalock & Luckasson, 2021), three domains have been identified.

1. *Conceptual domain*: it includes communication and academic skills. Referring to communication, both comprehension and language production should be considered.
2. *Social domain*: it includes relational, social skills, and socio-emotional self-regulation abilities.
3. *Practical domain*: it includes compliance with safety rules and daily life skills. In regard to the latter, personal care, health care, legal decision, and housework tasks should be considered.

Moreover, when we refer to adaptive behavior, we must consider some crucial features (Harrison, 1990; Barclay et al., 1996, Sparrow et al., 1984). The adaptive behavior has the following characteristics:

(a) *Age-specific*: it develops in the first years of life, becomes more complex in adulthood, and then may face a decline in geriatric age. Furthermore, some behaviors can manifest and be adaptive at one age and not be it in other age ranges. For example, for a child, asking the mother to be accompanied to the bathroom is an adaptive behavior in the first years of life while it is no longer so when he/she is older.

(b) *Context-specific*: it is closely dependent on the demands of the environment in which the individual lives. Expectations about adaptive behavior are influenced by:
  - The different cultural/geographical group to which one person belongs.
  - The different contexts: conceptual, social, and practical abilities are not only expressed at home with caregivers but also with teachers, friends, and unknown people to relate to for various reasons (e.g., call a doctor's office to make an appointment). An evaluation of adaptive behavior in different contexts like home and school is recommended.

(c) *Concrete manifestation*: adaptive behavior must reflect the typical performance of the individual, not its best performance nor the performance he could hypothetically put in place if there was the opportunity.

(d) *Modifiability:* adaptive behavior can worsen or improve based on several factors including environmental changes or habilitation/rehabilitation programs.

Only through an accurate evaluation, that considers the different domains (conceptual, social, and practical) and different features of adaptive behavior, the clinician understands the exact functioning of the individual.

How is it possible to accurately assess adaptive behavior? Over the years, the scientific scene has tried to answer some questions concerning the methodological aspects of the evaluation of adaptive functioning:

1. *How should the evaluation be carried out? Directly or through third parties?*

Currently, the scales for measuring adaptive functioning involve interviewing the caregiver. Some exceptions provide a self-assessment by the individual (see ABAS-2 16–89 years "self-rating," Harrison & Oakland, 2003), but especially in cases of ID, it cannot be considered for diagnosis purposes. For the same reasons, the advantage of an indirect assessment also consists in measuring adaptive behavior even in cases of severe or profound ID, in which direct assessment is very difficult.

2. *Is it preferable to use one or more sources of information?*

As seen above, one feature of adaptive behavior is that it is context-specific. For this reason, having multiple sources of information (home, school, work) allows you to delve deeper into the functioning of the individual (Tassè et al., 2012, 2016).

3. *Is it necessary to have a global adaptive functioning score or different domains' scores?*

A profile that considers the different domains allows you to have a more specific picture of the functioning of the individual, of his strengths and weaknesses. This is important both for an accurate diagnosis of ID (criterion B of Diagnostic and Statistical Manual fifth edition, DSM-5 Manual; APA, 2013) and for planning targeted interventions.

These characteristics discussed above should be present in the main tools for assessing adaptive functioning.

Another crucial aspect highlighted by the AAIDD is to refer to tools that "should provide robust standard scores across the three domains of adaptive behavior" (Schalock et al., 2010; p.49): the use of well-standardized instruments yields quite unbiased results. Moreover, being the adaptive behavior context-specific, it will be necessary to use tools that are standardized for the cultural/geographical group to which the individual belongs. In fact, in the evaluation of adaptive functioning, changes are usually made to the tools used to make them applicable in the different cultural contexts (e.g., some items of Receptive or Expressive Subscales in Italian version of Vineland II Survey Interview Form are modified with respect to American version).

Although only in the fifth edition of the DSM, the assessment of adaptive functioning has been included as a criterion for the definition of severity levels of ID, over 200 rating scales have been produced since the 1970s. However, in 2012, Tassé and colleagues established that only four standardized adaptive behavior instruments had characteristics and psychometric adequate properties to be used in the clinical determination of ID. These four instruments are: Adaptive Behavior Assessment System, second edition (ABAS-2; Harrison & Oakland, 2003); Adaptive Behavior Scale – School, second edition (ABS-S: 2; Lambert et al., 1993); Scales of Independent Behavior-Revised (SIB-R; Bruininks et al., 1996); and Vineland Adaptive Behavior Scale, second edition (VABS-2; Sparrow et al., 2005).

Over the years some tools have been updated; furthermore, new tools have been devised to assess adaptive functioning. To date, among the most popular and updated instruments on the international scene, it is possible to include:

- Adaptive Behavior Assessment System, third edition (ABAS-3, Harrison and Oakland, 2015).
- Vineland Adaptive Behavior Scale, third edition (Vineland-3, Sparrow et al., 2016).
- Diagnostic Adaptive Behavior Scale (DABS, Tassé et al., 2017).

The adaptive scales mentioned in these bullet points are better described below.

Adaptive Behavior Assessment System or ABAS

Originally published by Harrison and Oakland (2000), this instrument has been revised with the publication of second (Harrison & Oakland, 2003) and third editions (Harrison & Oakland, 2015). Nevertheless, the third edition has not yet been adapted and standardized in all countries and for all age groups considered in the American version (from 0 to 89 years): for example, Italy adopts the second edition in children and adolescents from 1 to 18 years old (Italian edition Ferri et al., 2014). In the introduction of the latest American version of ABAS, the authors underlined that the ABAS-3 maintains "*all the essential features of ABAS-II and has numerous improvements*" (Harrison and Oakland, 2015; p. 1).

The *ABAS-3* consists of five distinct questionnaire forms:

- *Parent or Primary Caregiver Form 0–5 (from 0 years to 5 years and 11 months*): it examines the adaptive behavior of newborns, toddlers, and preschoolers at home and in other familiar contexts. Parents or caregivers who know the child can complete the ABAS-3 0–5 form.
- *Teacher or Day Care Provider Form 2–5 (from 2 years to 5 years and 11 months):* it assesses the adaptive behavior of toddlers and preschoolers in kindergarten or day care centers. The respondents are generally the teachers, support teachers, or other persons providing care for children.
- *Parent Form 5–21 (from 5 years to 21 years and 11 months):* it examines the adaptive behavior of children and young adults at home or in other familiar settings. Parents or other primary caregivers complete the ABAS 5–21 form.
- *Teacher Form 5–21 (from 5 years to 21 years and 11 months):* it is usually filled in by the teacher or teacher's aide and is used to assess children and young adults who still go to school.
- *Adult Form 16–89 (from 16 years to 89 years and 11 months):* it assesses the adaptive behavior of adolescents and adults at home or in other community settings. Parents or other people who know the examined person can fill it in. The person may also complete it himself/herself, but the scores must be interpreted with caution by the clinician, especially in the case of people with ID.

The respondent of the questionnaire evaluates if the assessed person is capable of a given adaptive behavior, and how often it can be observed through a Likert scale ("never," "sometimes", "almost always"). Furthermore, if the respondent doesn't have enough information about a specific adaptive behavior, he/she must note that his/her answer is only a supposition. Before delivering the questionnaire, the clinician needs to be sure that the respondent has understood all the instructions. It is important to point out that the respondent must answer taking into account the routine and not the potential performance of the exanimated person. Indeed, potential negative issues regarding parent completion of questionnaire include problems with comprehension of items and underestimation/overestimation (deliberate or unintentional) of the person evaluated.

The ABAS-3 investigates the adaptive skills areas, which may slightly differ in different forms (for more details see the User's Manual; Harrison and Oakland, 2015).

For example in *ABAS-3 5–21 Parent Form,* there are:

- *Communication:* the listening, comprehension, and linguistic production skills necessary to communicate with other people are investigated.
- *Community Use*: moving independently outside the home, making purchases, and calling technicians for home repairs are some of the abilities investigated.
- *Functional Academics*: basic pre-academic skills for reading, writing, and math or other skills like calculating the change after a purchase are investigated.

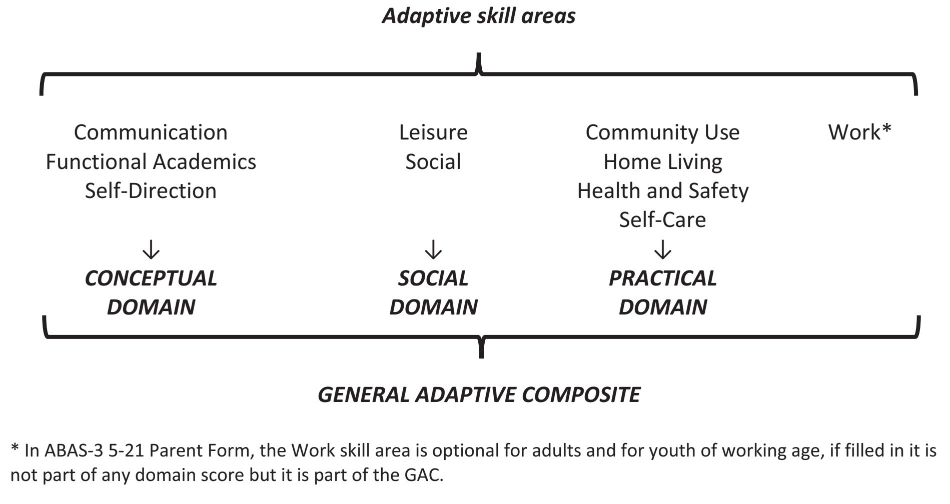

Fig. 17.1 Example of adaptive skill areas, domains, and GAC in ABAS-3 5–21 Parent Form

- *Home Living:* skills needed for cleaning, tidying the house, preparing simple food, and using household appliances such as microwave are looked into.
- *Health and Safety*: this area evaluates the skills necessary for health protection such as following safety rules, keeping out of danger, and using medicines.
- *Leisure:* this area evaluates the skills needed to organize recreational activities or games and follow the games' rules.
- *Self-Care*: skills related to personal care like eating, dressing, bathing, and hygiene are investigated.
- *Self-Direction*: this area investigates the skills necessary for autonomy, responsibility, and self-control such as starting and finishing tasks, respecting time limits, and making choices.
- *Social*: this area investigates the skills necessary to socialize/maintain friendships. The person's abilities to express emotions and use good manners are also investigated.
- *Work*: the skills necessary for a good functioning and good management of both part-time and full-time work are investigated.

The results of each area are converted into scores with mean of 10 and standard deviation of 3. The ABAS-3 also generates three domains (Conceptual, Social, and Practical) and a General Adaptive Composite (GAC) (see Fig. 17.1). Both the domains and the GAC are expressed in standard scores (mean (M) = 100, standard deviation (SD) = ±15) and percentile rank. A qualitative description of the scores ("extremely low," "low," "below average," "average," "above average," "high") is also available to facilitate the interpretation of the results in both of the domains – including the GAC – and adaptive skill areas.

The standard scores of each domain and GAC help clinicians in making appropriate clinical decisions in ID according to DSM-5 criteria. No less important are the scores of the adaptive skill areas: they may provide further important implications for clinical practice to better plan intervention programs with specific goals.

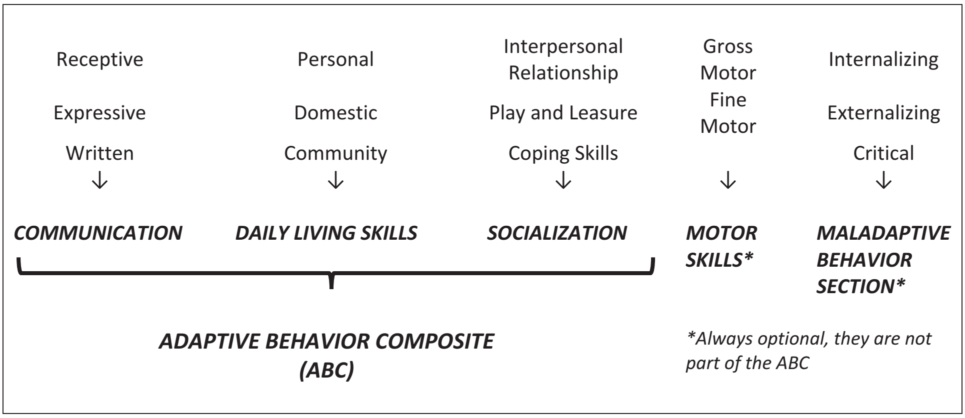

Fig. 17.2 Example of adaptive domains, subdomains, and ABC in VABS-3 Interview Form or Parent/Caregiver Form

The Vineland Adaptive Behavior Scales or VABS

The Vineland Adaptive Behavior Scales (VABS) represent the most used measure of adaptive behavior skills from birth to geriatric age. Since its first publication, the instrument allows to assess one person's development of independence and social responsibility, by using a semi-structured interview carried out with a person closed to the patient.

The Vineland Adaptive Behavior Scales have been recently released in its third edition (VABS-3) (Sparrow et al., 2016). The last edition consists of three forms:

- Interview Form: from 0 to 90+ years old.
- Parent/Caregiver Form: from 0 to 90+ years old.
- Teacher Form: from 3 to 21 years.

In the Interview Form, the interviewer does not read the items to the respondent, but uses open-ended questioning to help the caregiver to better describe specific behaviors. In the Parent/Caregiver Form and Teacher Form, the items are read and scored by the respondent who fills in the questionnaire.

As the previous edition, the investigated domains are: Communication, Daily Living Skills, Socialization, Motor Skills, and Maladaptive Behavior. However, in VABS-3, Motor Skills and Maladaptive Behavior are always optional. In fact, while Vineland Adaptive Behavior Scales 3 (VABS-2) included the Motor Skills domain in the computation of the Adaptive Behavior Composite (ABC) for children younger than 7 years, this is not true for any age on the VABS-3. This is one of the biggest changes of this new version which aligns with the adaptive domains (Communication, Social, Practical) encoded by DSM-5 (APA, 2013) and by AAIDD (Luckasson et al., 2002; Schalock et al., 2010, Schalock & Luckasson, 2021) (for a better definition, see section "History of Adaptive Behavior").

For each domain and ABC, raw scores are normalized in standard scores (M = 100, SD = ± 15) with lower scores indicating greater functional impairment.

Each domain is made up of subdomains which differ slightly depending on the Form (Interview or Parent/Caregiver versus Teacher) (see Fig. 17.2). Raw score of each subdomain is converted into normative data (M = 15, SD 3).

For example, Interview Form and Parent/Caregiver Form consist in:

- *Receptive subdomain*: it investigates how the individual listens and pays attention and what he/she understands.
- *Expressive subdomain*: it investigates how the individual uses words and phrases to provide information.
- *Written subdomain*: it investigates writing and reading skills from 3 years old.
- *Personal subdomain*: it explores how the individual eats, dresses, and takes care of personal hygiene.
- *Domestic subdomain*: it investigates how the individual takes care of the house from 3 years old.
- *Community subdomain*: it investigates how the individual orients him/herself, uses money and computer, and carries out work activities from 3 years old.
- *Interpersonal Relations subdomain:* it explores how the individual interacts with others.
- *Play and Leisure subdomain:* it investigates how the individual plays and manages free time.
- *Coping Skills subdomain:* it investigates how the individual manifests a sense of responsibility and care for others from 2 years old.
- *Gross-Motor subdomain*: it investigates how the individual uses arms and legs for movement and coordination.
- *Fine-Motor subdomain*: it explores how the individual uses hands and fingers when manipulating objects and drawing.

Each subdomain is composed of items that investigate the adaptive behaviors of the individual in a very detailed way. The clinician, in case of the Interview Form or the respondent, in case of Parent/Caregiver Form of Teacher Form, determines/evaluates if the assessed person is capable of a given adaptive behavior.

Assignment criteria are slightly different from the ones in VABS-2. In both versions, each item can be scored from 0 to 2; however, for example, in VABS-2, a score of 1 was assigned when a behavior was “sometimes” or “partially” observed, while in VABS-3, a score of 1 is assigned when behavior is observed “sometimes.” A VABS-2 rating of “partially” allowed for the possibility that prompting of the behavior may have occurred; in the VABS-3, the behavior must occur spontaneously. Furthermore, there are also other more minor changes such as relocation of items between domains and updates to the language or the calculation of starting point (basal) or stop point (ceiling) (for more details see the User’s Manual; Sparrow et al., 2016).

In conclusion, VABS-3 are the leading instrument for supporting the diagnosis of ID, specified by AAIDD and DSM-5. The tool can be used to take track of possible changes due to growth or intervention and to understand if a person needs specific support. In all their version, VABS represent the most used measure of adaptive functioning both in clinical practice and research, because of their high internal consistency, test-retest reliability, inter-interviewer reliability, and inter-raters reliability.

Scales of Independent Behavior – Revised

As well as Vineland Scales, another test with an adequate standardization sample is the *Scales of Independent Behavior (SIB)* that has been introduced by Bruininks and colleagues (Bruininks et al., 1996).

In 2012, Tassé and his colleagues (2012) have revised the instrument, publishing the *Scales of Independent Behavior – Revised (SIB-R)* that represent one of the main standardized adaptive behavior instruments with characteristics and psychometric properties sufficient to be used in the clinical determination of intellectual disability. It contains norms for individuals from 3 months to over 80 years old and investigates cognitive abilities, social skills, physical disabilities, and needs of support. The SIB-R may be administered in a structured interview or by a checklist procedure in which the respondent completes the questionnaire. The SIB-R contains 14 subscales that fall into four main clusters: social interaction/communication skills, personal living skills, community living skills, and motor skills. It investigates the presence of eight areas of problem behavior, too. Scores range from 0 (never does) to 3 (does very well-almost always). SIB-R provides a Broad Independence Standard Score a 4 Domain Standard Scores (M = 100, SD = ±15).

Diagnostic Adaptive Behavior Scale

The Diagnostic Adaptive Behavior Scale (DABS, Tassè et al., 2017) assesses adaptive behavior in people from 4 to 21 years old. It is a standardized test based on the tripartite model of adaptive behavior that includes conceptual, social, and practical domains (see section "Adaptive Behavior: Assessment"). Compared to other adaptive behavior scales, the DABS was specifically constructed to provide information around the decision point for identifying the presence or absence of significant impairment in adaptive behavior for the diagnosis of ID.

The DABS is a semi-structured interview that is conducted with a respondent who well knows the person assessed. The scale includes 500 items that are rated with a score range from 0 to 3: 0 = No-rarely or never does it; 1 = Yes-does it with reminders or assistance but rarely or never independently; 2 = Yes-does it sometimes independently – but sometimes needs reminders or assistance; 3 = Yes-does it always or almost always independently – never or rarely needs reminders. Also available as an exceptional rating is the "No Score." The "No Score" should be used only if the assessed person has a lack of opportunity due to cultural, gender, and/or geographic/regional factors, a lack of opportunity due to environmental constraints, or if the respondent has no direct knowledge of individual's typical performance.

The scale provides standard scores (M = 100, SD = ±15) for conceptual, social, and practical adaptive skills and an overall adaptive behavior score that measures the global adaptive functioning.

Other Measurements for Assessing Adaptive Functioning as Part of Scales of Evaluation of Psychomotor Development

Adaptive Behavior in the Denver Developmental Screening Test and the Denver II

The Denver Developmental Screening Test (DDST) (Frankenburg et al., 1967) is one of the most popular measures of developmental problems in young children. Since its first publication in 1967, it has been standardized in over 12 countries. In 1992, a revised version, named Denver II (DDST II), has been published and nowadays it is used in public health clinics, private practice, and clinical research (Frankenburg et al., 1992). Furthermore, the American Academy of Pediatrics Council on Children with Disabilities has Denver II on its approved screening tools list.

The DDST II consists of 125 tasks and is a quick screening in the examination of the pediatric patients to determine whether infants and preschool children are achieving developmental milestones. It can be administered to children from birth to 6 years of age. The scale is both an observational assessment and an assessment based on parental report. It is important to underline that DDST II is not a QI Test or a diagnostic tool. Furthermore, it does not allow to predict later development; then, if a child fails the DDST screening, a more formalized assessment (i.e., with the Bayley Scales of Infant Development; Bayley, 2006, 2019) is recommended.

DDST II provides an organized clinical impression in four main domains:

1. *Social and Emotional:* getting along with people, smiling at people, caring for personal and other people emotions, etc.
2. *Language/Communication:* hearing, understanding, using words, etc.
3. *Cognitive:* learning, thinking, problem-solving, etc.
4. *Movement/Physical Development:* sitting without support, putting block in cup for fine motor and jumping for gross motor, etc.

Scoring depends on age and ability of child and each item is scored as pass, fail, or refused.

Even though DDST II represents an overall evaluation of developmental delay, it can give information also about adaptive behavior in children. For instance, the Movement/Physical Development Domain may be used as an indicator of practical skills during daily life (i.e., in the "4 years range," the item "pours, cuts with supervision, and mashes own food" reminds the subscale "Home" in the VABS-2; see section "Vineland Adaptive Behavior Scales - VABS").

To conclude, even if not diagnostic by itself, this test is useful for detecting children (such as those with HIV, hypoxic-ischemic encephalopathy, or ID) who have global problems or who fail in a specific domain, extrapolating information also about adaptive functioning. The instrument can also be used to track childrens' development over time.

Adaptive Behavior in Bayley-III and the Bayley-4

The Bayley Scales of Infant and Toddler Development (BSID) is an individually administered instrument originally developed by psychologist Nancy Bayley to assess the development of children aged 1–42 months (Bayley, 2006). Since its first publication, the scale has been revised different times and is nowadays on its fourth edition (Aylward, 2020). The third and the fourth edition are the most used versions during both clinical practice and research activity.

The *Bayley-III* (BSID-III) assesses infant and toddler development across five main domains: Cognitive, Language (Receptive and Expressive), Motor (Gross and Fine), Social-Emotional, and Adaptive. Assessment of the first three scales is conducted using items administered directly to the child. Assessment of the latter two scales relies on primary caregiver interview. Each subscale can be administered independently, then the instrument is very useful also in multidisciplinary evaluations. The instrument allows to identify children's strengths and weaknesses, to establish if a deeper assessment is required, and to take track of development changes and progresses of an eventual intervention.

The Bayley-III employs the Parent/Primary Caregiver Form of the ABAS-2 (Harrison & Oakland, 2003) as its Adaptive Behavior Scale. Thus, the items included on the Parent/Primary Caregiver Form of the ABAS-2 are the same as those included on the Adaptive Behavior Scale of the Bayley-III. The Bayley-III manual underlines that the scale is based on (1) the conceptualization of adaptive behavior promoted by AAIDD (see section "History of Adaptive Behavior") and (2) the legal and professional standards applicable to disability classifications, provided by the DSM IV-TR (APA, 2000).

The Bayley-4 (BSID-4) has been introduced to conduct developmental assessments in order to identify children with developmental delay so that early intervention services could be provided. As the previous version, it contains five core domains (see above) that are administered to infants and toddlers from 16 days to 42 months of age. Compared to BSID-III, the new version includes questions for the caregiver. For instance, adaptive behaviors on the Bayley-4 are measured solely via caregiver report because self- or teacher-report obviously cannot be obtained for children in this age range. Moreover, BSID-4 takes approximately 30% less time to complete the assessment than the previous editions. In addition, while scoring on BSID-III is dichotomous (1, 0), in BSID scoring is polytomous

(2, 1, 0), where 1 means that the skill or behavior is emerging. Another main difference is that in BSID-4 *the adaptive behavior scale utilizes Vineland Behavior Assessment System* rather than ABAS-2 one. More specifically, the Bayley-4 Adaptive Behavior Scale consists of 120 items selected from the Vineland-3 (Sparrow et al., 2016).

It is interesting to notice that the three domains of the Bayley-4 Adaptive Behavior Scale, namely Communication, Daily Living Skills, and Socialization, are compatible with the adaptive behavior areas specified as necessary for the diagnosis of ID by the AAIDD (Schalock et al., 2010) and the DSM-5 (APA, 2013). In fact, the terms conceptual, practical, and social used by AAIDD and DSM-5 correspond to the domains of Communication, Daily Living Skills, and Socialization of the Vineland-3 (and the Bayley-4). Deficits in these areas reflect the impact that the adaptive skill deficit has on the individual's day-to-day function. On the Bayley-4, severity is reflected by standardized scores.

To conclude, the Bayley Scales is an useful tool to early identify ID, to assess the principle domains of development, such as adaptive behavior, and to investigate changes over the growth.

When Standardized Scales Cannot Be Used

In some cases, adaptive behavior standardized assessments cannot be used, for example, when there are not reliable or closed people who can answer for the patient's adaptive functioning. In these situations, other information regarding adaptive functioning can be adopted:

1. *Direct observation*: What does the person really do? How does the person interact with other people? How much is the person able to take care of him/herself?
2. *External sources of information*: School records, medical information, previous cognitive, and psychological evaluations.
3. *Interviews* with closed respondents who are not able to complete a standardized assessment, but can give qualitatively important data.

When structured evaluations cannot be performed, the examiner should use multiple types and sources of information combined with clinical judgment. It is important to remember that adaptive behavior is different from problem behavior. More specifically, behaviors that interfere with one person's daily life (i.e., a child throwing objects to seek adults' attention) are defined as maladaptive behaviors and not as the absence of adaptive behavior (i.e., the same child could be able to more maturely interact with meaningful others, but could not exhibit this skill in certain situations). The clinician, when using direct observation, should be cautious in order not to overestimate or overlook individual's disability. To this purpose, clinical expertise and specific trainings are essential when working in the field of ID.

Adaptive Behavior in Some Neurodevelopmental Disorders

Adaptive Functioning in Individuals with Autism Spectrum Disorder (ASD)

Autism Spectrum Disorder (ASD) is a group of neurodevelopmental disorders characterized by deficits in social-communication skills and the presence of repetitive or restricted patterns of behaviors and/or interests. The estimate prevalence of ASD in the American population is 1:54 (Maenner et al., 2020). As the word "spectrum" suggests, individuals with ASD show a wide heterogeneity in core symptoms severity, in cognitive and language level as well as in adaptive functioning.

Researchers have shown that this heterogeneity is also reflected in clinical outcomes. Early diagnosis and early treatment based on ABA (such as Early Intensive Behavioral Intervention (EIBI), Pivotal Response Training (PRT), or Naturalistic Developmental Behavioral Intervention (NDBI) such as Early Start Denver Model (ESDM), Cooperative Parent Mediated Therapy (C-PMT); Lovaas and Smith, 2003; Koegel et al., 1999; Dawson et al., 2010, Valeri et al., 2020) has increased the percentage of individuals with ASD with a good level of functional and adaptive independence in adulthood. However, there is still a great number of individuals with ASD (at least a half) who fail to reach good outcomes in terms of independence showing vulnerabilities during their entire life (Billstedt et al., 2005; Eaves & Ho, 2008; Howlin et al., 2004; Tsatsanis, 2005).

It is well-known that IQ and language level are consistently correlated to positive outcomes in ASD (Billstedt et al., 2005; Howlin et al., 2004). However, the role of adaptive functioning is less clear. Findings from a longitudinal study that lasted 20 years have shown that the correlation between IQ and adult success in individual without cognitive impairment is weaker than thought. On the contrary, these authors found that the adaptive skills are more associated with good outcomes compared to IQ and language level in this portion of population. In fact, some individuals with ASD could have a high IQ, but limited adaptive skills, while others with borderline cognitive and good level of independent life-skills could reach good outcome rating.

However, the role of adaptive level in predicting adult outcomes has been still not fully explored. In a relatively recent review, Magiati and her colleagues (2014) examined the relation between several variables measured in childhood and adult outcomes of individuals with ASD. None of the 25 studies included in this review has examined the presence of relationships between adaptive level in childhood and adult outcomes. These results showed a tremendous lack of research on the relation between adaptive functioning and adult outcomes, thus showing a great importance to further explore this relation in future research. Nonetheless, we are aware of the important role of IQ and language level in predicting adult outcomes; a better knowledge of the role of adaptive functioning will allow researchers to predict the role of patterns of IQ, language level, and adaptive functioning more precisely.

For example, having a good level of daily living adaptive skills in childhood could be crucial for a child with ASD and severe cognitive impairment. Those skills could be related to his functional independence in adulthood, to parental burden (by easing parents in daily assistance), and therefore to personal and familiar quality of life. Furthermore, those abilities could contribute to other related abilities such as those involved in a job. Being able to organize daily routine in childhood could be related to the ability to organize work routines and demands in adulthood. On the contrary, the same adaptive daily living skills could be less important for a child with ASD without cognitive impairment where higher-level abilities are expected. Other skills, such as “fine-grained” communication and socialization skills, could play a major role in reaching a satisfactory life for adult people without cognitive impairment when compared to people with cognitive impairment.

The future exploration of the role of adaptive functioning in predicting adult outcomes could bring to a better definition of intervention plan in childhood, thus improving the quality of life of individual with ASD and their families. However, this kind of information is actually limited.

In the following sections, we will shortly review adaptive profile of individuals with ASD in cross-section and longitudinal studies and his predictors. The review of literature is not intended to be exhausting, given the limited space. We will just describe main studies to depict a picture of autism adaptive profile.

Adaptive Profile of Individuals with ASD

The greatest part of the studies on adaptive functioning in ASD has been conducted with Vineland Scales (i.e., Paul et al., 2004; Tomanik et al., 2007). Most studies have shown that people on the spectrum show deficits in adaptive functioning independent from cognitive level. These studies agree to define a typical “autism profile” characterized by a marked impairment in socialization, weakened delay in adaptive communication, and a relative strength in daily living skills (Bolte & Poustka, 2002; Carter et al., 1998). However, all the scores are usually under the average.

Some authors have found that the impairment in adaptive functioning may vary according to the level of cognitive ability. An adaptive level below the average has been found in individuals with ASD with higher functioning (i.e., Perry et al., 2009; Saulnier & Klin, 2007), while individuals with lower functioning and cognitive impairment showed an adaptive behavior on par with cognitive level or, sometimes, above (i.e., Perry et al., 2009). Furthermore, the gap between IQ and adaptive skills in individuals with higher functioning could be enlarged with the growth; some studies have shown that this discrepancy between IQ and adaptive level increases with the age (Szatmari et al., 2003).

Concerning change in adaptive functioning over the time, the heterogeneity of ASD has complicated the possibility to depict trajectories of adaptive functioning. While a static picture of autism profile has been defined over the time in several studies, there is still dearth of longitudinal studies on adaptive functioning in ASD. However, two major studies provide important information that help to predict the adaptive functioning over the time.

A relatively recent study from Szatmari and his colleagues (2015) has allowed to partially fill this gap in knowledge. In a large sample (416 children with autism) followed from approximately 3–6 years old, they found three different groups based on baseline Adaptive Composite Score on VABS-2 and the trajectory over the time: Group 1 with lower functioning and worsening trajectory (around 30% of the sample), Group 2 with moderate functioning and stable trajectory (around 50%), and Group 3 with higher functioning and improving trajectory (around 20%). However, these results are limited to a global measure of adaptive level (Adaptive Composite Score) and do not provide any information on specific scales (Communication, Socialization, and Daily-living skills). Furthermore, this study is limited to a preschool sample, while the trajectory of adaptive behaviors could further modify over the years.

A wider and deeper investigation comes from Baghdadli and her colleagues (2018), who followed a group of 106 individuals with ASD for 15 years approximately from 4 years to 20. Considering results as a whole, the authors found that adaptive functioning was below the average all over the time. However, they found that adaptive functioning showed significant improvement over the time in socialization, communication, and daily-living skills in approximately 20% of the population, confirming results from Szatmari's study. Interestingly, improvement in this portion of population was significant as predicted by lower autism symptoms and higher language/intellectual levels at time of inclusion. Surprisingly, adaptive level at baseline did not predict adaptive level in the last timepoint, thus making hard a prediction of the trajectory based on the first adaptive assessment. However, the results from this study must be considered carefully, given that 80% of the population included had a coexistent intellectual disability.

Taken together, the research here shortly summarized the need to focus on adaptive functioning in all the spectrum independently from age, cognitive level, and autism symptoms. The most consistent finding is that all people on the spectrum experience some trouble in keeping pace with typical social/cultural standards of personal independence. This is well-known by families of individuals with ASD. Research suggests that adaptive functioning (in particular daily living skills) is a significant predictor of family quality of life (Gardiner & Iarocci, 2018) in adolescence. This stage of life is crucial in individuals with ASD. While a great number of services and intervention are now available for children with ASD, services for adolescents and adults are somehow limited and/or available only for people with high socioeconomic level. Furthermore, while some social routines (such as group participation) could be mediated by the presence of a caregiver (teacher, therapist, parent) during childhood, adult-mediation, it is not socially accepted during adolescence and adulthood. These factors could further increase the gap on reaching independence between individual on the spectrum and individuals with typical development.

Summing up, there are a large number of studies that cast light on the critical role of adaptive functioning. Focusing on adaptive functioning during treatment in earlier stage of treatment would help to increase all abilities that could be important for the people we are working on. However, given that intervention resources could be limited, it is important to choose adaptive skills that could be relevant for that specific person in order to live as much as independent in his social group.

Factors That Could Affect Adaptive Behavior in ASD

The knowledge of factors that could affect adaptive behavior in ASD could help in designing effective intervention plan to improve adaptive level of individuals with ASD.

The most consistent predictors of a good adaptive functioning are cognitive and language level (Szatmari et al., 2015), while the role of ASD symptoms is less clear with studies finding mixed results (Perry et al., 2009). Despite their importance, IQ and language level seems to have small effects on adaptive functioning in individuals without ID, while other research suggests that executive functioning could have greater effects (Pugliese et al., 2015). Recent studies (12 years follow-up) showed that executive functioning when assessed in preschoolers could predict adaptive level in Communication, Daily Living Skills, and Socialization skills (Pugliese et al., 2015). Deficit in executive functioning, such as ability to self-monitoring, problems in inhibition or shifting, are frequently reported in people on the spectrum (Christ et al., 2007; Hill, 2004; Luna et al., 2007; Kenworthy et al., 2008). Self-monitoring refers to the skills to monitor one's own behavior to reach a predefined goal and modify one's behavior accordingly. Deficit in this area has been related to some ASD symptoms such as repetitive behaviors, perseverative responding, and joint attention deficit (Hill, 2004). Inhibition is the ability to suppress an automatic response voluntarily and deliberately. Difficulty in inhibition is often connected with some deficit in ASD such as ability to turn-taking during conversations with others. "Shifting" is the skill to intentionally move thoughts and actions in response to changes in environment. Also, this ability has been linked with some deficits in individuals with ASD (Granader et al., 2014; Rosenthal et al., 2013) such as lack of flexible thinking, difficult to cope with new social situations, or difficulty with change in environment resulting in "meltdowns." These abilities may significantly impact relationships of individuals with ASD throughout the lifespan. Focusing intervention on these abilities could lead to higher adaptive level, especially in individuals without ID.

Interestingly, an ultimate factor that could affect the adaptive functioning is the presence of siblings in the family. Individuals with siblings experienced increasing adaptive growth trajectories in longitudinal studies when compared to individuals without siblings (Rosen et al., 2021). The result from this study emphasizes the role of siblings in increasing adaptive skill in most individuals consistently with literature describing positive effect of siblings on development (see work on theory of mind, social communication, and nonverbal communication (i.e., Matthews & Goldberg, 2018; Ben-Itzchak et al., 2019)).

Adaptive Functioning in Individuals with Williams-Beuren Syndrome

Williams-Beuren Syndrome (WBS) is a rare disorder (1:7500) related to a de novo hemizygous microdeletion on chromosome 7q11.23. The deletion usually ranges from 1.55 Mb in 95% of cases to 1.84 Mb in 5% of cases (Osborne et al., 2001; Bayés et al., 2003; Schubert, 2009). A common feature in most of the individuals with WBS is the presence of hyper-sociability. A global developmental delay, with relative spared language skills and deficit in visuospatial skills, is usually found (Alfieri et al., 2017; Vivanti et al., 2018).

Despite less renowned, also individuals with WBS share several problems in reaching an independent life. By following Elison and her colleagues (Stinton et al., 2010) in one of the widest studies on outcomes, only 8% of 92 adults with WBS included in the study lived completely independently. The remaining participants were living in residential accommodation for people with intellectual disabilities (39%) or with their parents (53%). Furthermore, only 7% of participants had a regular employment with a regular payment, while the remainder were employed in “special job,” in voluntary unpaid job, or unemployed. Interestingly, despite their hyper-sociability, about a third of the individuals included in the study have poor abilities to create and maintain friendship relationships and a half of them were described as having a poor comprehension of the concept of friendship.

Similarly to what happens in ASD, also in WBS IQ is one of the major predictors of good outcomes in independent life, particularly concerning self-care, social impairment, and occupational functioning. Individuals with higher IQ tend to reach higher satisfaction in described areas. Furthermore, this study has also found that Vineland Adaptive Behavior Composite (ABC) plays a major role in self-care, social impairment, and occupational functioning, as well as in behavioral impairment and physical health problems.

Taken together, these data highlight the difficulties of individuals with WBS in reaching a satisfying independent life. However, research on this topic is still scarce and further investigation would help describing adaptive profile associated to good outcome in this syndrome.

In the next sections, we will review the research on adaptive profile of individuals with WBS in cross-section and longitudinal studies, which are the predictors of adaptive level. Again, we will just describe main studies to depict a picture of WBS adaptive profile, without any intention to be fully exhaustive.

Adaptive Profile in Individuals with WBS

In a recent review, most of the individuals with WBS shared a global adaptive profile below the normal range both in preschoolers and in schoolers, with a wide range of functioning for all ages considered in this study. While some individuals showed functioning profoundly or severely impaired, others have an adequate or moderately low adaptive level (Hahn et al., 2014; Howlin et al., 2010; Mervis & John, 2010; Mervis et al., 2001).

The analysis of adaptive profile in preschoolers with WBS has shown mixed results. Differently from what happens in ASD, pattern of strengths and weaknesses differs from one study to another and tends to modify over the years. These differences could be due in part to the different assessments used in investigation, and in part to modification in adaptation to evolutionary tasks.

The main studies on adaptive functioning in preschoolers have used both old and new version of Vineland as well as ABAS-2. While some authors (Kirchner et al., 2016) did not find any relevant differences between scales in adaptive levels (16 preschoolers, with mean age of 28.7 months) by means of ABAS-2, others found uneven pattern of strengths and weaknesses. For example, Hahn and her colleagues (2014) have highlighted a profile characterized by strengths in communication and socialization (18 prescholeers, with mean age of 47 months), using Vineland Adaptive Behavior Scales – Interview Edition, Survey Form. Furthermore, other authors (Hamner et al., 2019) showed a relative point of strength in socialization (but not communication) by means of the parent report form of VABS-2, in a sample of 18 children with mean age of 47 months, while others (Alfieri et al., 2021b) found only strength in communication (but not in socialization) by means of the Vineland Adaptive Behavior Scales – Interview Edition, Survey Form. Beyond heterogeneity of tools used, the main limitation of these studies is the limited sample presumably due to the rareness of the disorder.

However, the results of the studies become more consistent by moving from preschoolers to scholars. Most of the research show that socialization and communication domains are usually found above other domains (Mervis et al., 2001; Mervis & Klein-Tasman, 2000). Interestingly, all the studies in scholars’ sample have used the same tool (Vineland Adaptive Behavior Scales – Interview Edition, Survey Form), accounting for the unevenness of results in research on early stage of life. Moving to studies on adulthood, a different profile emerged, with socialization that remained a strength, while Daily Living Skills and Communication fall in the lowest areas of functioning (Cherniske et al., 2004; Howlin et al., 2010).

As per ASD, longitudinal studies on adaptive functioning are limited also in WBS. As far as we know, only three longitudinal studies have been conducted. Fisch et al. (2010) found a relative stability in functioning after 2 years in children and adolescents. Differently, Mervis and Pitts (2015) found a significant decrease of adaptive functioning after 3 years follow-up (in particular, in Motor Skills and Community Living skills, while Communication and Socialization were more stable). Howlin and colleagues (2010) found a significant improvement in Socialization and Daily Living adaptive skills in the longer study available (12-year follow-up), suggesting that some adaptive skills could improve over time. Concerning group trajectories, Mervis and Pitts (2015) found that many children (around 42%) showed a significant decline, while only a smaller proportion (7%) of their participants had a significant improvement.

One of the most known characteristics of individuals with WBS is the hyper-sociability and the interest in people. For that reason, WBS has been considered a disorder on the "polar opposite" of autism for a long time (Schultz et al., 2001). However, recent investigation has revealed that WSB and ASD show more similarities than differences (Alfieri et al., 2022). In fact, children with ASD and those with WBS show some kind of deficit in socio-communicative abilities: problems in shared attention, showing or giving objects in preschool age; troubles in social relationships, pragmatic language, and emotional awareness in school age (Vivanti et al., 2018). Furthermore, despite relative preserved language abilities, only expressive skills in adaptive profile were higher mental age, while receptive skills were found significantly lower, thus indicating difficulties in comprehension including pragmatic skills (Alfieri et al., 2017).

For that reason, cross syndrome studies have been conducted in order to assess similarities and differences between adaptive profile of individuals with ASD and WBS (Hamner et al., 2019, Alfieri et al., 2021a; Alfieri et al., 2022). Interestingly, results from these studies showed that, when matched for age and cognitive level, individuals with ASD and WBS were globally similar on adaptive level. Some differences emerge only in preschoolers in communication (Alfieri et al., 2021b) and socialization (Hamner et al., 2019), but these differences were not found in scholars. These results further emphasize the difficulties in social-communicational skills of individuals with WBS. While the hypersociable personality should persuade that individuals with WBS would have poor problem with socialization, this characteristic seems to have a good impact on their social relationships only in early stages of life. However, when friendship and other relationships become more complex and demanding, difficulties emerge also in this population so much that no significant difference between individuals with ASD and WBS emerges in this research (Alfieri et al., 2021a). This is confirmed from data on outcomes of adult individuals with WBS where around 30% fail to have stable relationship with other people. Interestingly, a similar proportion of individuals with WBS show social-communication problems during childhood (Klein-Tasman et al., 2007, 2009, 2018) in structured assessment conducted with gold standard tools for autism diagnosis.

Factors That Could Affect Adaptive Behavior in WBS

The most consistent predictor of adaptive behavior in individuals with WBS is IQ (Mervis et al., 2001; Alfieri et al., 2021a). However, also other features have been considered for their relationship with adaptive functioning WBS such as the ability to request help when completing tasks and low persistence in completing tasks for preschoolers. Considering "hot executive functioning," Phillips (2008) reported that difficulties in emotion regulation are related to lower adaptive functioning in preschoolers (especially in Motor Skills and Personal Living Skills) beyond and above intellectual level. Finally, other useful information is derived from Mervis & John, (2010), who showed that difficulties in sensory regulation are related to poorer adaptive functioning both in children and adolescents.

Adaptive Functioning in Individuals with Fragile X Syndrome

Fragile X Syndrome (FXS) is a genetic disease inherited through X chromosome, included since 2001 among Rare Genetic Syndromes as it occurs in only 1/4000 males and 1/8000 females (Salcedo-Arellano et al., 2019). It was first described in 1943 by Martin and Bell, from which the condition takes its second name (it is also called "Martin-Bell Syndrome"). However, the molecular basis of FXS was discovered only in 1991, when the FMR1 gene (Fragile X Mental Retardation 1) located on the long arm of the X chromosome and whose mutation gives rise to the Syndrome, was isolated for the first time (Corona & De Giuseppe, 2018).

FXS is actually considered the most common inherited cause of ID, the second most prevalent cause after Down syndrome, and the most common monogenic cause of ASD.

The condition is caused by an abnormal expansion in the number of trinucleotide CGG (cytosine-guanine-guanine) located in the 5' UTR in *FMR1* at Xq27.3. More specifically, it is the result of the expansion of the CGG repeat in each generation moving from the permutation range of 55–200 repeats and expanding to a full mutation when passed by a mother to her children (Nolin et al., 2003). FXS patients have more than 200 repeats of this codon. Interestingly, people with permutation (55–200 repeats), although not affected by XFS phenotype, may exhibit other medical, psychiatric, and cognitive symptoms that can interfere with their daily life but also with their children's adaptive functioning (Moser et al., 2021). Very common medical problems in premutated people are Fragile X Associated Tremor/Ataxia Syndrome (FXTAS) and fragile X-associated primary ovarian insufficiency (FXPOI).

FMR1 gene encodes the Fragile X Mental Retardation Protein (FMRP), which binds several mRNAs, mainly in the brain and testicles, which are the most affected areas. Indeed, people with FXS exhibit language delay, hyperactivity, anxiety and mood disorders, cognitive deficits, learning disabilities, and macroorchidism in males. Girls are usually less affected than boys and only 25% of FXS women have ID.

Much of what has been published about the link between the genotype of people with FXS and the degree of neurobehavioral functioning is based on the measure of the CGG trinucleotide levels and the consequent quantity of FMRP produced (Garber et al., 2008). However, adaptive behavior is one of the most reliable indicators for assessing outcome in children with developmental disorders, such as Fragile X Syndrome, because it represents a more significant estimation of real-life skills.

In the following paragraphs, we will shortly review adaptive profile of people with FXS in longitudinal and cross-section studies. Factors that may influence adaptive behavior in FXS will be analyzed too.

Adaptive Profile in Individuals with FXS

Research on adaptive behavior, overall and within behavior domains (i.e., communication, socialization, daily living, and motor skills), has identified three main possible development trajectories in people with FXS: (1) declines over time (i.e., Klaiman et al., 2014), (2) normal development until the age of 10 and then decline or stabilization (i.e., Fisch et al., 1999), and (3) steady increase from early childhood until adolescence (i.e., Hatton et al., 2003). Those different outcomes may be influenced by the different ages of people included in the various research samples, types of standardized scales and scores used (i.e., standard vs. raw scores), and by the presence/absence of comorbidities in the FXS individuals who have been studied.

However, results from the most recent longitudinal studies (i.e., Hahn et al., 2015) agree that middle childhood is a critical age period for adaptive behavior in FXS. A considerable number of children with FXS lose the adaptive behavioral skills previously learned both in relation to their peers and in absolute terms. The biggest decline can be observed in the socialization and communications domains, in line with the pragmatic, receptive, and expressive language difficulties observed in people with FXS (Abbeduto et al., 2016).

In contrast, daily living abilities (i.e., housekeeping, using public transportation, using community services, using mobile-phones, etc.) seem to be a relative strength also with growth (Hatton et al., 2003).

Factors That Could Affect Adaptive Behavior in FXS

The first research on behavioral functioning in FXS focused on the correlation between FMRP expression and phenotypes outcomes. For instance, Cohen et al. (1996) in a study comparing people with full mutation versus *FMR1* mosaicism showed that individuals with complete FXS had lower adaptive functioning, a result that was interpreted to be due to the amount of FMRP produced. However, biological factors cannot explain alone the adaptive behavior patterns observed in people with FXS. Then, other contributors to adaptive behavior should be taken into account, such as cognitive abilities. Several studies showed that IQ scores tend to decline over the time and a positive correlation between performance on intelligence tests and adaptive behavior scores has been observed, especially in women (Glaser et al., 2003). The biggest interrelationship has been underlined between IQ scores and the Adaptive Behavior Composite measured with VABS.

Furthermore, in confirmation of the importance of context factors explained in section "Adaptive Behavior: Assessment", it has been observed how home environment is one of the most significant predictors for long-term adaptive functioning. Parental expectations, parenting skills, home facilities, and emotional climate influence adaptive functioning more than anything else. Then, the finding of a positive correlation between lack of adaptive skills in FXS children and severity of premutation in their mothers is not surprising (Mooser et al., 2021).

In addition to cognitive abilities, the co-occurrent presence of ASD influences adaptive functioning. For instance, Smith and colleagues (2012) in a cross-syndromes study showed that individuals dually diagnosed with FXS and ASD displayed a more severe impairment in social and communication domains than people with FXS only.

Summing up, people with FXS exhibit adaptive behavior deficits that can be due to biological factors, IQ level, comorbidity with other diseases, and environmental factors. Home environment is the most significant predictor of adaptive behavior in people with FXS.

Conclusion

Adaptive behavior refers to the skills requested to function in everyday life and to cope with different life demands. It comprehends social interaction, communication, practical, and motor skills, which are all important to living a life worth living.

The current definition of ID includes deficits in both intellectual and adaptive functioning with degree of disability assigned according to adaptive behavior impairment. For this reason, adaptive behaviors should be always evaluated during ID assessment. Standardized and reliable tools should always be used. Identifying weaknesses and strengths in one person's adaptive functioning is essential to better understanding specific disorders and for the development of novel interventions. In fact, it has been observed that in different neurodevelopmental disorders, there is a regression in adaptive behavior skills that inevitably interferes with the possibility to gain independence in adulthood. This acknowledgment rises an important question: is the decline in adaptive behavior possible to prevent?

Researchers and clinicians have the important responsibility to answer this question and implement new and early intervention strategies.

Applied Behavior Analysis: Conceptual Foundations, Defining Characteristics, and Behavior-Change Elements

Skylar C. DeWitt, Andrea M. Stephens,
and Adam M. Briggs

The discipline of behavior analysis is made up of three branches, including (a) behaviorism (the philosophical worldview of behavior analysis), (b) the experimental analysis of behavior (the study of fundamental principles and processes of behavior), and (c) applied behavior analysis (ABA; the application of a behavioral worldview and basic principles toward solving problems of societal importance; Morris et al., 2013). Individuals who maintain this worldview, study the science of behavior analysis, and apply these concepts and principles are known as behavior analysts. Behavior analysts acknowledge that anything a person says or does is behavior, regardless of whether it occurs publicly (i.e., is observable) or privately (i.e., is not observable). Further, behavior analysts recognize that most behavior serves a particular purpose and is primarily influenced by the environmental variables that occur prior to and following the behavior. Behavior analysts conduct research in pursuit of developing and evaluating evidence-based practices for improving our field's approach toward promoting socially significant behavior change. Although ABA-based procedures are an empirically supported treatment that has the potential to mitigate core and associated features of autism spectrum disorder (Reichow, 2012; Roane et al., 2016; Smith & Iadarola, 2015), it is important to note that the principles underlying this therapeutic approach are similarly effective when applied to other populations, settings, and behaviors.

The purpose of this chapter is to introduce the reader to the (a) origins and conceptual basis of ABA, (b) defining characteristics of a behavior-analytic approach, and (c) fundamental behavior-change elements used by applied behavior analysts. Our overview includes demonstrations of how the science of behavior analysis has been applied to address various behavioral concerns.

Origins and Conceptual Basis of Applied Behavior Analysis

It could be said that the field of ABA formally began in 1968 with the founding of its flagship publication, the *Journal of Applied Behavior Analysis* (*JABA*); however, its origin and conceptual foundations are the culmination of events initiated many years before the founding of the journal. To be fully understood, ABA must be considered in the context of the philosophy and basic research traditions from which it evolved and remains connected today.

B. F. Skinner is widely regarded as one of the founders of the science of human behavior, contributing to some of the first publications on the philosophy of the science of behavior (i.e., behaviorism) and its basic science (i.e., the experimental analysis of behavior; Morris et al., 2013). Skinner's theoretical work and basic research were primarily influenced by ideas and empirical findings proposed by several pioneers, including Charles Darwin, Edward Thorndike, Ivan Pavlov, and John B. Watson. For instance, Thorndike's "Law of Effect" (Thorndike, 1911) played a significant role in Skinner's behaviorism by explaining how consequences are critical variables that influence the future occurrence of behavior. Further, Skinner used components of Watson's "Behaviorist Manifesto" to inform the philosophy of behaviorism, which emphasizes the environment's influence on shaping and maintaining behavior (Rakos, 2013). Skinner's *radical* behaviorism differs from traditional behaviorism in that it includes all human behavior, including behavior that cannot be overtly observed (i.e., covert behaviors and private events such as thoughts, feelings, and emotions). Skinner posited that all human behavior, including covert behavior, is subject to the same laws and principles of behavior as observable, overt behaviors (Heward & Cooper, 1992).

Beyond his contributions to the philosophy of behavior analysis, Skinner's approach toward conducting research was characterized by careful observation of the dependent variable (i.e., behavior) and systematic manipulation of the independent variable (e.g., reinforcement). In particular, his research aimed to demonstrate basic concepts and principles of behavior through a data-driven examination of functional relations (e.g., schedules of reinforcement; Ferster & Skinner, 1957). Much of the research conducted in the experimental analysis of behavior by Skinner and his contemporaries elucidated many of the basic concepts and principles of operant learning.

Researchers who applied basic principles and processes to modify human behavior were vital to the founding of ABA. Morris and colleagues (2013) conducted a systematic literature review and identified 36 articles published between 1959 and 1967 that formed the methodological and applied foundation that contributed to the emergence of ABA. The results indicated that although several case studies applied operant conditioning strategies to modify human behavior (e.g., Azrin & Lindsley, 1956; Bijou, 1955; Fuller, 1949; Gewirtz & Baer, 1958; Lindsley, 1956), it is likely that "The psychiatric nurse as a behavioral engineer" (Ayllon & Michael, 1959) formally marks the beginning of ABA as it reported data of individuals that were based on objective, direct observations of behavior. Much of the early research in ABA focused on the reduction of problem behavior; however, by the 1980s, ABA research shifted beyond simply modifying problem behavior with powerful (but arbitrary) consequences (i.e., behavior modification) and shifted to a model that aimed to determine why behaviors are occurring (i.e., understanding the functions of behavior) in order to replace problem behavior with appropriate behavior (Dietz, 1978). With this shift, a more individualized approach toward intervention was popularized, in which clinicians implemented function-based interventions to address behavior change. Additionally, clinicians reduced their reliance on punishment-based procedures and instead focused on identifying reinforcement-based interventions to increase appropriate, functionally equivalent replacement behaviors (Mace, 1994).

As a discipline today, ABA clinicians use the principles of behavior to inform behavior change in a meaningful and socially valid way for their clients (Furman & Lepper, 2018; Slocum et al., 2014; for more discussion on social validity in ABA, refer to the Dimensions of ABA section below).

Defining Characteristics of a Behavior-Analytic Approach

The field of ABA is distinctively different from other areas of clinical practice. In an attempt to explicitly describe these differences, we provide an overview of the dimensions of ABA within the framework provided by Baer et al. (1968) and discuss several other characteristics unique to a behavior-analytic approach.

Dimensions of Applied Behavior Analysis

Baer et al. (1968) described ABA as a self-examining, self-evaluating, discovery-oriented research procedure for studying behavior. Specifically, the authors noted that seven defining dimensions must be present to ensure that effective practices are developed, implemented, and evaluated. In particular, ABA must be *applied, behavioral, analytic, conceptually systematic, technological, effective,* and *generalizable*. This values-based approach fosters a unique sense of accountability among clinicians practicing ABA, as it provides a set of expectations to be met in practice. When reviewing each dimension below, we describe how they translate into practice.

Applied

Behavior-change goals must be practical and important to the society in which they are implemented (i.e., socially relevant). Skills learned via ABA are expected to translate to positive behavioral change in client settings encountered throughout their lived experience (e.g., in the home, at school, during play). Before a behavior-change goal is set, the clinician should ask themselves, how important is this behavioral change for the client and their daily life? For example, a client with language difficulties should receive an intervention that targets this skill deficit by teaching functional communication such that it will occur across people (e.g., teacher, parent, relative) and situations (e.g., school, home community).

Behavioral

Behavior is the subject matter and the target of any ABA intervention; the goal of any intervention is to produce meaningful behavior change. A target behavior (e.g., a tantrum episode) must be observable and measurable to ensure that progress can be monitored and tracked in a meaningful and evidence-based way (e.g., a graph detailing a clear decrease in the behavior). In the previous example of tantrums, specific behaviors such as hitting and kicking or destruction of work materials are easily measured due to their distinct occurrences. This level of specificity serves as a benchmark in ABA interventions, as it allows the clinician to more accurately track trends in client behavior, monitor treatment progress, and know when they ought to make changes to treatment plans.

Analytic

An ABA intervention strives to demonstrate a causal relationship (i.e., functional control) between an independent variable (IV; e.g., behavioral intervention) and a dependent variable (DV; e.g., behavior of interest), where the implementation of, or a change in, the behavioral intervention results in a desirable change in the behavior of interest. The effects of an intervention are commonly evaluated using a single-subject or "within-subject" design methodology in which an individual serves as their own control (i.e., the occurrence of behavior before intervention serves as the control and the clinician compares this period of responding to the level of behavior after experiencing the intervention). This methodology favors repeated measures of individual behavior and more easily allows for replicating treatment effects. This is a valuable approach for evaluating clinical recommendations and monitoring the influence of prescribed interventions, as it sets the occasion for ongoing clinical decision-making. For example, imagine a clinician implementing a behavior reduction procedure for a client who throws their toys to gain attention from their caregiver. In this situation, the clinician should record data on the child's toy-throwing behavior both prior to and after the intervention is implemented. In order to understand whether the intervention is effective, the clinician should evaluate the change in toy-throwing behavior from the baseline phase to the post-intervention phase. If the clinician really wants to be certain the intervention is responsible for the behavior change, they might even consider briefly removing the intervention to see if behavior returns to baseline levels (so long as this is safe and the environment can tolerate a brief increase in the target behavior). If this reversal produces baseline levels of responding, then the clinician can reverse back to the intervention, recapture treatment effects, and be confident that their prescribed intervention is, in fact, responsible for the observed treatment effects.

Conceptually Systematic

Behavior-change procedures should be consistent with the field's concepts and principles. For example, a clinician looking to promote appropriate classroom behavior in a client might look to the extant literature on implementing the Good Behavior Game (Barrish et al., 1969), a procedure that reinforces a child's on-task behavior during instructional time. This procedure is based on principles of operant conditioning, such that the client will learn to engage in appropriate on-task behavior and abstain from inappropriate behavior during classroom time altogether. Alternatively, an intervention developed independent of an existing conceptual system is not expected to translate to meaningful behavior change over time. Even if the procedure does result in behavior change, it would be difficult to understand why. Thus, it is crucial for ABA clinicians to maintain contact with the professional literature to ensure they are developing interventions in a way that aligns with our field's current conceptual systems and are considered best-practice and evidence-based procedures.

Technological

Behavior-change procedures (i.e., treatment plans) are operationally defined and described in such a way that they can be implemented consistently and replicated by others. This is particularly important for cases in which multiple clinicians and technicians are involved in implementing the intervention prescribed to an individual, as it ensures that therapeutic practice is consistent across all forms of implementation. ABA clinicians are ethically obligated to ensure this expectation is met in the development of any treatment plan or procedure. For example, a clinician may be tasked with writing a procedure designed to fade instructional prompts with a client. In this procedure, the clinician would detail each individual step in the fading procedure, including steps to take when the client responds incorrectly.

Effective

Behavioral interventions should produce meaningful and socially valid behavior change. In other words, the resulting behavior change must be sufficient and relevant enough to be of practical value. *Social validity* is measured by assessing the significance of treatment goals (i.e., considering whether a behavioral goal is desired by the society in which the client lives), the acceptability of treatment procedures (i.e., does the client and their caregiver consider the intervention procedures to be acceptable), and the importance of treatment effects (i.e., is the client and their caregiver satisfied with the results of the treatment; Kazdin, 1977; Wolf, 1978). For example, a behavioral intervention designed to teach a client who attends school in a large and sprawling facility to navigate hallways efficiently would likely be of high social validity for that client. Alternatively, this same intervention may have low social validity for a home-schooled client. ABA clinicians are expected to consider the social validity of behavior -change procedures prior to designing such programming.

Generalizable

Generalized behavior change occurs across different contexts (e.g., in a variety of settings, across multiple caregivers), is durable, and persists over time (i.e., maintenance). While skills are often taught in a clinical environment and with a small number of clinicians, skills are considered to be truly "learned" when they appear in a generalized manner. For example, consider a client who has been taught to request bathroom breaks. If this skill was taught in a clinical setting, but has consistently translated to the client successfully requesting bathroom breaks from their teachers at school, then it has generalized. As such, ABA clinicians are expected to consider the potential for skills taught in a clinical context to translate to the natural environment and provide steps to facilitate this process as a critical feature of the behavioral intervention plan.

Characteristics of Applied Behavior Analysis

In addition to the dimensions of ABA defined above, there are unique characteristics of ABA that offer a framework for effectively designing and individualizing behavior-change programs to meet the specific needs of each case (Behavior Analyst Certification Board, 2014). First, the focus on the four-term operant contingency allows for a precise understanding of the constellation of variables involved in the behavior-change program. Second, methods for selecting a target response and unit of measurement are based on the unique features of the behavior. Third, identifying and delivering consequences are done in a careful and systematic manner. Finally, the intervention's influence over the target response is evaluated in a manner that allows for the isolation of causal variables and a clear understanding of the intervention's impact. We provide further details on each of these characteristics and their importance within an ABA approach below.

Understanding the Operant Contingency

As previously described, *operant behavior* is behavior that is selected and maintained by environmental consequences. Operant behavior is different from a reflex in that it has been learned and shaped as the result of consequences in an individual's environment that have made the behavior more likely to occur in the future (Skinner, 1965). It is important to examine what may be motivating an individual to emit a behavior (*motivating operations*), what setting events occur directly before the behavior (*antecedents*), and what occurs directly after the behavior (*consequences*). Together with the behavior of interest, the prior elements (motivating operations, antecedents, behavior, and consequences) comprise the *four-term operant contingency* used by clinicians to predict, analyze, and establish new behaviors. The elements of the four-term contingency will be described below as it pertains to response acquisition.

Motivating Operations Motivating operations are environmental variables that alter the effectiveness of stimuli, events, or objects as *reinforcers* (a change in an individual's environment that occurs directly after a behavior that increases the future frequency of that behavior) or *punishers* (a change in an individual's environment that occurs directly after a behavior that decreases the future frequency of that behavior). Pertaining to response acquisition, clinicians aim to analyze and set up *establishing operations* (environmental variables that increase the effectiveness of stimuli, events, or objects as reinforcers); in other words, establishing operations influence what is motivating an individual to emit a behavior in that moment (Laraway et al., 2003). For example, if an individual is hungry and deprived of food because they did not eat breakfast (the establishing operation), they may be more likely to emit a behavior to obtain food (such as ordering food at a restaurant), as obtaining food is likely valuable to them in that moment to relieve the hunger.

Antecedents Antecedents are stimuli, events, or circumstances that immediately precede a behavior. Antecedents are essential to analyze as it is likely that the behavior of interest occurred under those antecedent conditions previously and will likely occur again in similar setting conditions in the future if reinforcement is available (Miltenberger, 2004). Using the previous example of an individual who is experiencing food deprivation (establishing operation), antecedents to ordering food may include a server approaching the table the individual is seated at and asking what the individual would like to order.

Consequences Consequences are stimuli, events, or circumstances that immediately follow a behavior. Consequences that are directly related to the establishing operations and antecedents are likely to have a significant influence on the frequency at which the behavior will occur in the future (Vargas & Vargas, 1991). In the context of response acquisition, consequences that immediately follow the response may act as a reinforcer if the consequence increases the likelihood of the response occurring again in the future. In the example of the food-deprived individual, if the server responds by saying they are out of food (e.g., "sorry, our kitchen is closed") and does not bring a grilled cheese, the individual is not as likely to emit the response in the future than if the server responds to the individual by saying they will get them the grilled cheese (e.g., "sure thing") and brings the grilled cheese minutes later. Affirming access to the sandwich and delivering it to the individual may act as reinforcers of the behavior, increasing the frequency of asking for the sandwich at this restaurant in the future.

Selection of a Target Response

Several important factors are considered by ABA clinicians in determining what behaviors to target for intervention. When starting services (and continuing throughout the duration of services), behavioral assessments consisting of interviews, direct observations of behavior, and other tests are administered to clients and their caregivers. These behavioral assessments aim to gather important information regarding not only behaviors to target for intervention, but also the relevant environmental variables that may be influencing the behaviors so that an effective intervention can be introduced to address them (Matson & Minshawi, 2007).

After completing the behavioral assessment, clinicians assess several variables to ensure a response is appropriate to target, including the behavior's social significance and relevance. Concerning the former, behaviors targeted for intervention must reflect the needs of the client and receive approval from relevant stakeholders (e.g., caregivers, teachers, bosses, etc.). Concerning the latter, behaviors targeted for intervention must be relevant to the client and positively impact their quality of life. For a behavior to be considered relevant, it must allow the individual to access reinforcement in their environment outside of services (i.e., their natural environment). For instance, it would be inappropriate and irrelevant to teach an adult client to complete an academic task if their overall goal of therapeutic services is to promote independence in a workplace setting where that academic task is not needed. Further, clinicians often aim to teach behaviors to clients that will allow them to access new environments and reinforcement (e.g., crawling, driving, navigating, reading) or to teach behaviors that will lead to new, untrained behaviors occurring in untrained settings (e.g., training choice, self-management strategies; Bosch & Fuqua, 2001; Mahoney et al., 2007; Rosales-Ruiz & Baer, 1997).

Once a behavior is identified in assessment, determined to be socially significant, and recognized as relevant, clinicians operationally define the behavior. The description of the behavior must include observable and measurable features to be considered an operational definition. Once defined, any person looking at the definition should be able to observe others and definitively say if the behavior occurred or did not occur. To help with this, ABA clinicians provide examples and non-examples of the behavior in their operational definitions. An example operational definition for requesting a break is as follows: any instance in which the individual vocally states a phrase asking for a break or time out from activities during classroom instruction time. Examples of requesting a break include instances in which the individual raises his hand and vocally asks for a break (e.g., "may I have a break please?") and instances in which the individual approaches the classroom instructor and vocally asks for a short break, time out, recess, or time to breathe. Non-examples of asking for a break include instances in which the individual does not vocally request a need for a break and walks out of the classroom or requests to go home.

Measurement

To ensure beyond a subjective doubt that behavior change is occurring, clinicians in ABA take objective data (i.e., measurements) on the target response. Measurement of behavior is a crucial aspect of evaluating the treatment characteristics' control over the nature of the response. Behavior can be measured in several ways, and the selection of measurement criteria is largely dependent on the topography and function of the target response and the goal of the overall program. For instance, if a clinician taught a new response to a student consisting of raising their hand to obtain a teacher's attention, the clinician would likely initially choose to take data on how often this new response occurs (i.e., measuring frequency or rate). In other instances, it may be more appropriate to measure how long a behavior occurs (i.e., *duration*), how long it takes for the response to occur after the presentation of an instruction (i.e., *latency*), or the amount of time between occurrences of the target response (i.e., *interresponse time*). Lastly, clinicians may use permanent products, such as homework assignments, quizzes, or other changes to the environment that can be directly observed after the occurrence of the response, to measure performance (LeBlanc et al., 2016). For instance, if a clinician teaches a child how to write their name, they may measure performance by examining the sheets of paper the child wrote on for accuracy in spelling (e.g., percent of letters written accurately). For a skill to be considered acquired, clinicians teach, measure, and monitor the target responses until a predetermined mastery criterion is met (e.g., Billy will use a pencil to correctly write his name within two lines of a wide-ruled notebook page with 100% accuracy across three consecutive trials).

Establishing, Selecting, and Delivering Consequences

During response acquisition training, the target response is reinforced to increase the future frequency of its occurrence. To reinforce a behavior, clinicians deliver reinforcers immediately following the target response. Preferences for reinforcers differ across clients and may even fluctuate on an individual basis. Reinforcers can take various forms and can include tangible items (e.g., favorite toys, food), activities (e.g., playing a game, swinging), and social interaction (e.g., praise, conversations). Reinforcers can also be established through continuous pairing of an unconditioned or conditioned reinforcer (e.g., food, favorite toy) with a previously neutral item (e.g., tokens, praise) until the neutral item begins to function as a conditioned reinforcer (Longano & Greer, 2006; Peterson et al., in press). To select which stimulus is most preferred by the client, clinicians conduct stimulus preference assessments to identify items that are likely to function as reinforcers (Heinicke et al., 2019). At the beginning of response acquisition training, reinforcers are often contrived and delivered immediately after the target response. As the response is acquired, clinicians systematically transition from reliance on contrived, arbitrary reinforcers to the use of naturally occurring reinforcers, (i.e., vocal praise or completion of the activity itself) to promote maintenance and generalization of the responsein the everyday environment (Briggs et al., in press; Stokes & Baer, 1977).

Performance Evaluation

As noted previously, evaluation of behavior change is typically done via a within-subject design where the subject serves as their own control. Within-subject designs are generally preferred over other methods (e.g., between-group designs), given their purpose is to evaluate the effects of the intervention with a particular individual (Cox, 2016). In a within-subject design, repeated measurements of the target behavior (i.e., dependent variable) are collected and compared across a pre-treatment phase (i.e., baseline phase) and treatment phase (i.e., independent variable) to determine if the intervention produces desirable behavior change.

Throughout the assessment and treatment process, data are graphed on a regular basis (e.g., during every treatment session) in order to monitor client progress and evaluate treatment effects. The graphed data are analyzed using visual inspection methods, which allows the clinician to assess trends and variations within the data (e.g., increasing, decreasing, stable). Continuously monitoring the data provides the clinician with ongoing information regarding the effectiveness of the intervention. Based on the patterns of responding, clinicians determine whether treatment should continue as is (i.e., is effective) or whether it needs to be modified (i.e., because it may be ineffective). Clinicians use the data to inform their clinical decision-making and increase the likelihood of producing desirable behavior change and achieving the behavior-change goals of the client.

Fundamental Behavior-Change Elements

As mentioned above, ABA involves the application of well-established concepts and principles serving as fundamental components within behavior-change programming. In particular, applied behavior analysts have developed a technology for teaching behavior, improving features of existing behavior, determining maintaining variables of maladaptive behavior, and designing function-based treatments to reduce problematic behavior. Although much of the response acquisition and behavior reduction technology has been discovered with individuals diagnosed with developmental disabilities, it has also been extended to and demonstrated to be effective in early childhood, regular education, and college classrooms and in workplaces, homes, and other various settings. In the following sections, we provide an overview of commonly used response acquisition and behavior reduction procedures.

Response Acquisition

A significant focus in ABA services is building individuals' skill repertoires. Socially important skills vary on a case-by-case basis according to the needs and goals of the client and their caregivers. For instance, a young child may be taught to appropriately request an item or activity from caregivers, whereas an adult may be taught to complete work tasks so they can obtain integrated, competitive employment. Regardless of the behavior being taught, ABA clinicians use the principles of behavior to reinforce new responses and refine aspects of existing behavior (e.g., teaching a verbal request for items if an individual is already requesting items via pointing). The following section will provide an overview of essential elements ABA clinicians use when training new responses.

Teaching Strategies

The strategies used to teach responses typically differ depending on multiple factors, including the topography of behavior, goals of teaching, and client preferences. Despite their differences, many teaching strategies incorporate basic components based on the principles of behavior, including establishing stimulus control and using prompting, shaping, and chaining. The basic tenets of these strategies are described below.

Establishing Stimulus Control When teaching or refining behavior, clinicians aim for behavior to occur in the presence of some antecedent stimuli, but not in the presence of other antecedent stimuli. In a classroom setting with a teacher present, clinicians may teach students to raise their hands and wait to be called on before speaking. If a student were to be in a situation where it would not be appropriate to gain their teacher's attention (e.g., when the teacher is busy with another student), this hand-raising behavior would not be productive in getting the teacher's attention (Torelli et al., 2017). As such, clinicians aim to arrange relevant antecedent stimuli that signal when behavior should or can occur and result in reinforcement (when at school with a teacher present, raising one's hand allows for access to the teacher's attention). The ultimate goal of this programming strategy is to gain *stimulus control*, which occurs when aspects of behavior are changed by the presence of antecedent stimuli. When a behavior is likely to result in reinforcement, the antecedent stimulus present is referred to as discriminative stimulus (e.g., the teacher in a classroom setting is a discriminative stimulus for hand-raising behavior); however, when a behavior is not likely to result in reinforcement, the antecedent stimulus is referred to as stimulus delta (e.g., absence of the teacher in a classroom setting or when a student is alone at home is a stimulus delta for hand-raising behavior). When a behavior occurs in the presence of a discriminative stimulus, but not in the presence of a stimulus delta, a behavior is said to be under stimulus control (Sidman, 2008).

Using Prompts and Prompt Fading When teaching behaviors, *prompts* are often used to help clients perform a targeted skill correctly. These prompts can occur in many forms (e.g., verbal, physical, models, visual aids, and gestures) and are often presented according to their intrusiveness. For example, a gestural prompt (e.g., pointing at an object needed to complete a behavior, such as a pencil for writing) is considered less intrusive than a physical prompt in which a clinician would physically assist the client to complete a behavior (e.g., holding a client's hand and helping guide the pencil). However, the goal of using a prompt is to increase the likelihood that the client will engage in the correct response, so the least intrusive but most effective prompt is necessary to accomplish this. Prompts are often not presented as the sole (or long-term) intervention when teaching skills; rather they are meant as short-term aids that are to be faded out in order to promote independence (Quigley et al., 2018).

Shaping Complex Behavior Shaping involves reinforcement of successive approximations of behavior and is another strategy for teaching behavior. Clinicians often begin by reinforcing some behavior already in a client's repertoire that is similar to the behavior goal. For instance, a clinician might first reinforce touching a sock if the behavior goal is for the child to put on a sock. Next, the clinician would reinforce picking up the sock. After this, the clinician would reinforce each instance of behavior that got closer and closer in the form to the behavior goal (e.g., grasping sock with two hands, bringing sock to foot, placing the foot in the sock, and pulling the sock over the foot), while not reinforcing instances of behavior that are not closer in the form to the behavior goal (e.g., throwing sock, putting a sock on hand, etc.). Further, shaping can be used to modify aspects of the behavior once learned, such as how often it occurs and for how long it occurs. Shaping has been used to teach or modify several behaviors, including feeding (Hodges et al., 2017) and academic task engagement (Athens et al., 2007).

Chaining Sequences of Behavior Together Like shaping, chaining also involves the breakdown of behavior into simple steps. Unlike shaping, chaining explicitly involves a *behavior chain*, or sequence of responses in which one response follows the other, serveing both as reinforcement for the previous response in the chain and setting the occasion for the next step of the chain. Using the same putting-on-a-sock example as above, the behavior chain consists of the following steps: pick up the sock, grasp sock with two hands, bring the sock to the foot, place foot in the open end of the sock, and pull the open end of the sock over foot until the closed end of the sock reaches the toes and the open end of the sock is above the ankle. Instead of reinforcing successive approximations (as in shaping), clinicians use *task analyses* (consisting of the breakdown of steps for the behavior goal) to help identify what responses make up the behavior chain. Then, chaining strategies are then used to teach the goal behavior.

Three main variations of chaining strategies are used by clinicians, including forward chaining, backward chaining, and total task chaining. In forward chaining, clinicians first teach the client to perform the first step of the task analysis (e.g., pick up sock) and complete the rest of the steps for them. Once the first step is mastered by the client, the clinician then allows the client to perform the first step and teaches the second step in the chain (e.g., grasp sock with two hands). This continues until the entire behavior chain is performed independently by the client. In backward chaining, the clinician performs all steps of the chain until the last step (e.g., pull the open end of the sock over the foot until the closed end of the sock reaches the toes), in which the clinician teaches it to the client. Once the last step is successfully performed by the client independently, the clinician performs each step until the second to last step and teaches this step (e.g., place the foot in the open end of the sock) and allows the client to perform the last step independently. This process is again repeated until the client performs the entire behavior chain independently. Lastly, in total task chaining, the clinician teaches the client the entire behavior chain until the client is able to perform each step with independence (Bancroft et al., 2011; Slocum & Tiger, 2011).

Behavior Reduction

Treating problem behavior has been a major concern of applied behavior analysts since the field's inception (e.g., Wolf et al., 1964). The advent of functional analysis (FA) methodology (Iwata et al., 1982/1994) resulted in an important shift in intervention development and treatment philosophy. Most importantly, the determination of the conditions that maintain problem behavior during an experimental FA allows clinicians to develop effective function-based interventions to replace the problem behavior with a functional, more appropriate alternative behavior.

Development of a Function-Based Intervention

A function-based intervention is developed in phases, generally beginning with an indirect assessment of problem behavior (e.g., caregiver interviews designed to capture first-hand accounts of client problem behavior). Next, a clinician will often conduct a descriptive assessment in which they observe the client’s problem behavior and generate hypotheses about the function. Following this data collection, an FA is often conducted. While an in-depth explanation of FAs is beyond the scope of this chapter (see Dozier et al., 2022, for coverage of the topic), it is important to understand that once the variable(s) responsible for the maintenance of problem behavior is discovered, interventions can be derived to (a) decrease the motivation to engage in the problem behavior, (b) eliminate the reinforcer for the problem behavior, or (c) provide the reinforcer for an alternative response. In fact, previous research has shown that interventions based on the outcome of FAs are more effective than those that are not (Didden et al., 1997; Iwata et al., 1994) and have resulted in a decrease in the reliance on punishment contingencies for reducing problem behavior (Pelios et al., 1999). Next, we will review some common function-based intervention approaches that may use the outcomes of an FA to inform antecedent- and consequent-based intervention approaches.

Antecedent-Based Interventions

In antecedent-based behavioral interventions, events or conditions that occur prior to a specific behavior are manipulated with the intention of eliminating or reducing the specific behavior (Smith, 2011). This style of intervention is generally used after conducting an FA to identify the function of the behavior, as this allows the clinician to design the intervention in a way that will reliably affect the behavior of concern through the manipulation of variables like motivating operations (Michael, 2004). Motivating operationss are generally broken down into two categories: establishing operations, which increase the effectiveness of a reinforcer, and abolishing operations, which decrease the effectiveness of a reinforcer (Laraway et al., 2003). For example, a clinician might use this approach to create an intervention for a child who disrupts a classroom in order to receive attention by instructing the teacher to regularly provide attention to the child before any disruptive behavior occurs to decrease the value of attention following disruptive behavior (thereby serving as an abolishing operation). As a result, the child’s disruptive behavior is likely to decrease given that they are already receiving the attention and there is little to no motivation to engage in other behavior to get it. In the previous example, the teacher’s attention would be provided "freely" or not based on the child’s behavior (i.e., noncontingently). Noncontingent reinforcement is an antecedent-based intervention that consists of the presentation of a reinforcer regardless of the occurrence of a specific behavior (in this case, providing attention regardless of disruptive behavior), that generally occurs on a set schedule.

Consequent-Based Interventions

Consequent-based interventions often utilize procedures based on concepts of reinforcement, extinction, and punishment with the intention of reducing the targeted problem behavior. Differential reinforcement is a common procedure in ABA that includes several variations distinguished by the relationship between the newly taught behavior and the problem behavior. A clinician’s decision regarding which variation of the DR procedure to use often depends on the main goal for the problem behavior; for example, if the goal is to eliminate the behavior by introducing a functionally equivalent alternative behavior, then a DR procedure may best suit the intervention (Hanley & Tiger, 2011).

Extinction involves withholding reinforcement for a given response (e.g., problem behavior). Like with antecedent-based interventions, the function of the target behavior must be identified before implementing an extinction procedure (Vollmer et al., 2021). Once the function is identified (e.g., social-positive, social-negative, and automatic reinforcement; Iwata et al., 1994), extinction procedures can be designed to precisely address the problem behavior.

Finally, another approach to consequent-based interventions is the use of punishment procedures. Punishment involves the contingent presentation of an aversive stimulus or removal of a reinforcing stimulus (i.e., positive and negative punishment, respectively) to decrease the likelihood that a specific behavior will occur again in the future (Lerman & Toole, 2011). Although clinicians in our field adhere to The Principle of Least Restrictiveness (Vollmer et al., 2011) when selecting and prescribing interventions, if it is determined that a punishment procedure is required, it is best practice for the procedure to first receive formal approval from a Human Rights Committee before implementation is deemed appropriate and ethical. Punishment procedures are generally designed to mirror contingencies that occur throughout one's natural environment. Negative punishment-based procedures such as a time-out or point loss in a token system are often prescribed for this reason. In sum, punishment is rarely relied on as an intervention strategy now that the field embraces a function-based intervention approach when treating problem behavior.

Maintenance and Generalization

As stated previously, a key goal of behavioral intervention is to produce changes in client behavior that persist over time (i.e., maintained) and occur across different contexts (i.e., generalized). Oftentimes, a goal is for the performance to transfer across relevant (non-training) environments and perhaps even to other (untrained) ways of behaving, as a behavioral technology would have limited clinical value if it failed to produce durable and useful changes in responding.

To increase the likelihood that a behavior will maintain over time and generalize across contexts, it is important to create an environment that supports behavior change at the onset of treatment. A clinician may use schedule thinning, a procedure in which a clinician programs for generalization and maintenance by systematically reducing reinforcement (e.g., gradually increasing the number of appropriate responses required for reinforcement) in order to expose the client to conditions that more closely resemble those which they are likely to encounter in their natural environment (Briggs et al., in press; Hagopian et al., 2011). In addition, a clinician may plan strategically for the desired behavioral outcome by selecting target behaviors that will arise under naturally occurring reinforcement contingencies in the environment. In other words, a clinician may design treatment in such a way that the client will encounter similar situations in their everyday life, and the natural consequence for correct responding resembles the contrived consequence encountered in treatment. For example, if a client is taught via behavioral intervention to request help when frustrated as a pathway to receiving assistance, it is likely that this behavior will be met with a similar consequence when used in their natural environment following treatment.

Concluding Remarks

In this chapter, we provide a general overview of the historical and conceptual foundations of ABA, cover characteristics that are unique to this discipline, and review some commonly used behavior-change elements while demonstrating the range of ABA's application to various issues of social importance. We hope this information serves as a useful resource for those interested in learning more about ABA and its areas of application.

Our reason for providing general coverage of ABA is that our field's science is robust and clinical approaches and best-practice recommendations are ever-changing (Briggs & Mitteer, 2021). Therefore, it is worth noting that our field's approach toward program development and procedural implementation is far more complex and intricate than the general description of program components described here. As a result, our field requires highly skilled case managers (i.e., Board Certified Behavior Analysts; BCBAs) and advanced support staff (i.e., Board Certified Assistant Behavior Analysts; BCaBAs) to provide close oversight of the case and ongoing supervision and training of front-line staff (i.e., Registered Behavioral Technicians; RBTs) in order to promote timely clinical decision-making and ensure the integrity of program implementation.

Another reason for this close oversight is because, more often than not, behavioral interventions are relatively intensive and occur over an extended period of time (Virués-Ortega et al., 2010). As a result, it is typically critical for caregivers (e.g., parents, school personnel) to be very involved with the planning and implementation of the behavioral intervention outside of the clinical setting (e.g., at home, in school). To address this, there have been recent advancements to the caregiver training literature (e.g., Matson et al., 2009), which include suggestions for improving access to and practicality of this support and training (e.g., via telehealth; Yi & Dixon, 2020).

In closing, if this introductory chapter on ABA piqued your interest and you are considering whether you might pursue a career path in this field, it is worth noting that a recently released jobs report has indicated that demand for behavioral services far outweighs the professionals available to offer behavioral services, suggesting that applied behavior analysts are in high demand across the country (BACB, 2021). Therefore, this career field is promising given the upward mobility (e.g., RBT to BCaBA to BCBA to BCBA-D), transferability (BACB certification/licensure recognized within nearly every state), and job satisfaction it provides (Plantiveau et al., 2018).

Functional Assessment

Joshua Jessel and Catherine Jessel

Problem behavior is a common concern among clinicians who work with children diagnosed with intellectual and developmental disabilities or psychiatric disorders. Problem behavior encroaches on the safety of the child and those in their immediate surrounding and chronic problem behavior can have a substantial impact on a child's quality of life (Chiang & Wineman, 2014; Kamio et al., 2013). The topography of problem behavior can vary on an individual basis including more common variants such as aggression, self-injurious behavior, or property destruction to idiosyncratic variants such as elopement, pica, and fecal smearing. That is to say, there are not necessarily any topographical identifiers for defining the occurrence of problem behavior and behavioral interventions have been designed to address operant mechanisms regardless of how the problem behavior is formally expressed.

One of the biggest developments in the assessment and treatment of psychologically based problems in children is functional assessment. Functional assessment is a general term that encompasses any pretreatment evaluations of problem behavior that are intended to improve a clinician's understanding of the influence of any possible environmental determinants for said problem behavior. The assumptions being that primary causes for problem behavior can be found in the proximal environmental events and an appeal to these operant mechanisms as an explanation for the problem behavior is sufficient to develop treatment. If a child is exhibiting problem behavior, a clinician can use a functional assessment to investigate potential causes in antecedents that have historically evoked and consequences that have strengthened problem behavior to individualize subsequent treatment procedures. Appreciation for the clinical utility of functional assessment for informing treatment has grown to the point of a nationwide mandate for its use in severe cases (Individuals with Disabilities Education Act, 1997, 2004).

Clinical utility broadly refers to the importance of a set of procedures for improving the socially relevant treatment outcomes of a client. When applied to functional assessment, it means that clinicians should select the assessment methods that best inform the design of the most effective and

acceptable set of treatment procedures (Hayes et al., 1987). In that regard, a functional assessment can only be validated as having clinical utility by evaluating the subsequent treatment it has informed. Therefore, a functional assessment is more than just an analytic tool for identifying relations between environmental events and problem behavior (i.e., contingencies). There are a seemingly infinite number of contingencies that can be assessed if clinicians were so inclined: from general classes that are believed to impact the average child to the everyday events specifically experienced by a particular child. The purpose of the functional assessment is not to determine what *can* influence problem behavior. If that were the case, clinicians would spend an absurd amount of time exposing the child to an endless catalog of potential contingencies. The purpose of a functional assessment in clinical practice, and indeed its usefulness, is determined by its ability to (a) identify the ecologically relevant contingency in a reasonable amount of time and (b) influence the clinician's decision-making process when developing a treatment package (Kratochwill & Shapiro, 2000).

The arduous task begins for the clinician when determining under what circumstances a functional assessment is necessary and has clinical utility. That is because there is no decisive set of rules that inform decisions of when to use a functional assessment and the clinician is typically left to rely on their professional judgment. Concluding that a functional assessment should be conducted to improve treatment outcomes is not an inconsequential decision to make considering the time and resources that must be diverted toward individualized supports. Furthermore, many functional assessment methods require specialized training with supervision from a Board Certified Behavior Analyst (BCBA) or licensed psychologist. A concrete decision-making process may, therefore, hold particular value for clinicians and help guide evidence-based practice.

Guiding Evidence-Based Practice of Functional Assessment

Evidence-based practice requires a multifaceted approach that is informed not only by the external scientific literature but by the clinician's expertise and client-specific values (Smith, 2013). Determining the need and level of services for a particular client is a highly specialized and individualized process, which integrates the experiences of the clinician and client in each case with the extant evidence for particular behavioral procedures. Whenever a clinician is presented with a child who exhibits problem behavior, they should be asking themselves five main questions to determine whether or not a functional assessment is necessary and appropriate given the situation:

1. Have universal strategies failed?
2. Is the topography of problem behavior dangerous?
3. Is the occurrence of problem behavior socially impactful?
4. Will the functional assessment result in a unique and more effective intervention?
5. Is the functional assessment feasible given the current staff and resources?

These five questions are designed to inspire critical interpretations of potential treatment paths and improve a clinician's confidence that the appropriate procedures were considered. However, the questions are by no means meant to be a staunch set of rules, as if answering a certain number in the affirmative necessitates the use of a functional assessment. Evidence-based practice is meant to be flexible, allowing the clinician to make informed decisions on a case-by-case basis. Because there are no objective criteria for informing the decision to conduct a functional assessment, the questions are intended to guide the decision-making process and ensure that the clinician reviews all relevant information before implementing any subsequent procedures.

Have Universal Strategies Failed?

All children are likely to experience difficult situations in their lifetime and may resort to problem behavior in an attempt to return to a historically reinforcing environment. In fact, problem behavior is highly prevalent when children first transition away from the home to the classroom setting (Powell et al., 2007). These transitions in early childhood can create challenging moments that depend on healthy coping strategies; however, even if these strategies are lacking, problem behavior for most children is still likely to return to characteristic levels once sufficient experience with the novel context and contingencies has occurred. That is because universal strategies for reducing problem behavior in groups tend to work (Reinke et al., 2014) and if they didn't, each child would require costly individualized services. Therefore, a child may simply require exposure to contingencies that favor appropriate behavior, and general strategies such as differential reinforcement with praise and classroom rewards usually suffice.

A functional assessment becomes a viable consideration when universal classroom and general behavioral strategies have been used unsuccessfully. Consistent and sustained problem behavior is potentially indicative of a far more chronic issue and may not be so easily addressed with an improvement in classroom milieu. Therefore, a clinician who is presented with a child who has been known to exhibit problem behavior across multiple contexts with professionals trained in behavioral management over long periods of time may come to the conclusion that traditional reinforcement-based strategies have failed and further individualized supports informed by a functional assessment will be necessary to achieve intended goals.

Is the Topography of Problem Behavior Dangerous?

Some problem behavior is manageable and to be expected. A child may cry when a toy is removed and others may get into fights with classmates at school, to some limited extent. However, severe problem behavior can interfere with a child's ability to create lasting friendships or even attend a classroom with other students. The topography of problem behavior can become so dangerous that it necessitates the use of mechanical, physical, or pharmacological restraints (Trader et al., 2017). Severe SIB often falls into this category of dangerous topographies because any response, regardless of how often it occurs, could result in irreparable physical harm (Schroeder et al., 2002). For example, even a single instance of eye gauging could result in permanent blindness.

Dangerous problem behavior has also been found to be sensitive to a variety of environmental variables, making functional assessment an important consideration. That is because the topography of problem behavior is not associated with a particular function in most cases. Hanley et al. (2003) reviewed the functional assessment literature, delineating between five general classes of reinforcement that dangerous behavior was found to be sensitive to (i.e., escape, attention, tangible, automatic, and multiply controlled). The authors found that in most cases dangerous behavior was unlikely to have clear indicators of function determined by the topography. In fact, problem behavior has been known to be sensitive to far more idiosyncratic variables and individualized contingencies (Jessel et al., 2016; Schlichenmeyer et al., 2013). This diversity in functions of dangerous problem behavior creates a unique barrier for clinicians attempting to develop an intervention. In these situations, functional assessments may be an indelible tool for sifting through the convoluted variables that could influence dangerous problem behavior.

In some cases, the topography of problem behavior may not be directly harmful to the child, but places them in a dangerous situation. For example, a child may exhibit the problem behavior of eloping from certain contexts without consent of the adult. Although elopement could be as innocent as leaving a workstation to play with preferred toys in a classroom setting, it is not difficult to envision the danger of elopement from a caregiver's home at night, near a busy intersection, or a public area with many strangers. Aside from the potential to place a child into a dangerous position without adult supervision, elopement shares the same aforementioned concern regarding functional heterogeneity (Falcomata et al., 2010; Piazza et al., 1997; Traub & Vollmer, 2019). That is, a treatment's efficacy is directly related to behavioral function and not behavioral topography.

Is the Occurrence of Problem Behavior Socially Impactful?

This is not to say that the topography needs to be dangerous to be considered a concern. The frequency with which problem behavior occurs could also influence the necessity of a functional assessment. For example, screaming may not result in any physical injury, but if it occurs frequently throughout the day, the child may have to receive services isolating them from others because of the potential for disrupting classroom activities. Furthermore, the constant screaming in the home could create a stressful environment for other family members, thereby influencing the quality of caregiver relationships. Determining the level of social impact is not limited to, and can be influenced by, multiple factors beyond the risk of severe injury.

The intensity of problem behavior could also be initially low, but remains a concern considering the potential for harm if the intensity were to increase to unsafe levels. A child may chronically hit a caregiver at a young age without causing any significant bodily harm. Although caregivers may find this behavior to be a nuisance for the time being, without proper intervention the problem behavior is likely to shape up and become more difficult to manage as the child grows up. The common misconception being that problem behavior is something that a child will "grow out of," when in fact early problem behavior is far more indicative of increased risk of isolation from peers and exclusion from community activities (Horner et al., 2002).

There may be other dimensions beyond frequency, intensity, and severity of problem behavior that could be socially impactful. The clinician needs only to become informed of the restrictiveness of the environment and intensity of services that are or will be required to manage problem behavior in determining whether or not a functional assessment seems appropriate. In addition, this question is highly influenced by the subjective experiences of those involved to ensure that the behavioral services provided will directly result in meaningful improvements in the child's life. The totality of determining what behavior change would be considered *meaningful*, and how the change is achieved, exists on three main levels regarding the intended goals, appropriateness of the procedures, and satisfaction with potential outcomes (Wolf, 1978). The question of social impact is intended to provide the clinician with the mindset of providing relevant services that others will find acceptable for improving their current circumstances.

Will the Functional Assessment Result in a Unique and More Effective Intervention?

The functional assessment is designed to reduce assumptions regarding environmental influence over problem behavior. Therefore, its purpose is to identify relevant variables that are not readily known by the clinician to be included in any subsequent intervention. By its very nature, the term *function-based* intervention refers to the value of conducting a functional assessment for informing treatment procedures. This infers that in many cases a functional assessment will result in a unique and more effective intervention for problem behavior. Without a functional assessment, the clinician is left to speculate on relevant environmental variables contributing to problem behavior and may have to wait to happen on a set of effective intervention procedures through the highly inefficient process of trial and error. Beyond the process being inefficient, the treatment designed without a functional assessment is often less effective (Heyvaert et al., 2014; Campbell, 2003) and could even worsen problem behavior if the procedures used are contraindicative of the function (Iwata et al., 1994d). Therefore, it is highly important for a clinician to understand the conditions under which a functional assessment will be truly informative of a given set of environmental circumstances.

Of course not all problem behavior may be influenced by enigmatic environmental variables in need of further investigation. Furthermore, interventions for problem behavior may be quite homogenous in some contexts that the results of functional assessment would have nothing to contribute to the specific circumstances. For example, Saini et al. (2019) conducted a meta-analysis of the behavioral intervention for inappropriate mealtime behavior. While inappropriate mealtime behavior can encompass an eclectic array of potential topographies of problem behavior (e.g., aggression, swiping food, tantrums, food refusal), the authors found that (a) treatment procedures tended to rely on a standard practice of praise for cooperation and escape extinction for problem behavior regardless of if a functional assessment was conducted and (b) pretreatment functional assessments were unlikely to improve the efficacy of the behavioral intervention. This question that a clinician will ask themselves is a reminder to remain committed to focusing on that which can inform treatment design.

Is the Functional Assessment Feasible Given the Current Staff and Resources?

Depending on the functional assessment used, some models may be resource heavy and time-consuming (Iwata & Dozier, 2008). Clinicians may find it difficult to conduct a functional assessment in given circumstances. Feasibility may be a concern for clinicians working in more rural areas with large caseloads where they may have difficulty finding the time or resources to devote to an individualized assessment for each of their clients. However, the consideration of feasibility is continuously becoming difficult to defend as the functional assessment technology develops with elements of practicality of particular interest.

In some cases, it may be possible for the clinician to supervise the functional assessment via telehealth while it is being implemented by a caregiver (Wacker et al., 2013). Recent trends in the utilization of virtual meetings afford the clinician the ability to train caregivers and observe therapy sessions from anywhere in the world. Supervising the functional assessment via telehealth reduces travel that may be necessary when the child is admitted to an inpatient or outpatient clinic, while also ensuring the functional assessment is conducted in the ecologically relevant context of the child's home.

Even though virtual services have the potential benefit of reducing costs (Lindgren et al., 2016), concerns regarding feasibility may still remain for some clinicians. That is because caregivers will have to be trained and coached on how to implement potentially complex procedures and the clinicians will not be available to help in case of emergency, a perceptible risk when working with children who exhibit problem behavior. In such circumstances, problem behavior cannot be fully addressed until the clinician has the necessary resources available to arrange the environment in a manner they deem safe. Thus, feasibility should be a consideration for all clinicians before conducting a functional assessment. It is important to point out that concerns regarding the feasibility of conducting a functional assessment are carried over into the decision on implementing a subsequent intervention. A clinician is not to assume that an intervention will be any more safe, necessary, or feasible. Therefore, answering this question in the negative does not infer that an intervention should be introduced immediately in place of the functional assessment. This is especially considering that a functional assessment will often improve the socially relevant qualities of an intervention.

Functional Assessment Models

After determining that a functional assessment is necessary and should be conducted for the problem behavior of a given child, the clinician must then choose between a particular model to implement. Functional assessment is an umbrella term that could refer to different models depending on two properties of the procedures. First, the results of a functional assessment can be interpreted based on direct observation of the problem behavior or based on verbal reports. This is dependent on if the clinician (a) chooses to schedule to see the child and problem behavior with their own eyes or (b) is comfortable obtaining information regarding problem behavior via questioning of those who experience the problem behavior, such as caregivers. Second, the environmental events believed to be influencing problem behavior can be systematically manipulated in an experimental design or there may be no systematic changes involved. Of course, any systematic changes will inevitably involve direct observation of problem behavior as well (i.e., the clinician would not ask the caregiver to conduct a formal analysis with their child without some form of direct supervision). This allows for a potential of three functional assessment models based on the combination of those two procedural properties.

Indirect Assessment

The indirect assessment is the least intrusive model in that it does not include direct observation of problem behavior or systematic manipulation of environmental events. Indirect assessments do not require any contact with the client being evaluated and typically involve family members, caregivers, teachers, direct support personnel, or other professionals who interact with the individual. Indirect assessments can include a variety of methods such as interviews, checklists, and questionnaires (Sturmey, 1994). The overall goal is to ascertain information regarding the context in which problem behavior occurs or hypotheses regarding variables contributing to problem behavior from the verbal reports of others who have direct experience with the specific client of interest.

There are two general categories of indirect assessment depending on how information is gathered (i.e., closed-ended and open-ended). Closed-ended assessments prespecify options from which the respondent can choose and score using a legend, while open-ended assessments allow free-form responses and require more interpretation on the part of the clinician. For example, The Questions About Behavioral Function (QABF) includes 25 questions with a four-point rating scale pertaining to the problem behavior (Paclawskyj et al., 2001). Each question on the QABF is assigned a potential function (i.e., attention, escape, physical, tangible, and nonsocial) such that a score in the affirmative would contribute to a higher score implicating those variables as relevant to the occurrence of problem behavior. These scores can be interpreted to suggest potential function for the target behavior, with the highest scoring categories reflecting the most likely function.

Clinicians may often consider the closed-ended, indirect assessment as the primary means of identifying behavioral functions for multiple practical benefits. That is, there is often no formalized training or sophisticated knowledge of behavior analytic principles needed to implement the closed-ended approach. In addition, the questionnaires can often be completed in quite an efficient amount of time without the necessity of observing or evoking problem behavior. Nevertheless, reservations exist when considering using indirect assessments to replace other functional assessment models because of the lack of an empirical demonstration of environmental control over problem behavior and limited information regarding the individual circumstances that can be obtained with closed-ended questioning. Clinicians may find it more beneficial to use indirect assessments to inform rather than replace further assessments.

Open-ended assessments include interviews in which there are no prespecified options, providing the respondents with the opportunity to present descriptive information regarding particular experiences with the problem behavior of interest they may have had in the past. Open-ended assessments allow the respondents to provide additional context and details that are not collected in a closed-ended assessment, such as specific antecedents or consequences that the child has historically been exposed to. For example, Hanley (2012) developed an open-ended interview that consists of 20 questions designed to guide the respondent to provide qualitatively rich information regarding the context in which problem behavior occurred. The goal of the open-ended interview was not to identify function, but to inform the design of the subsequent functional analysis. In other words, the open-ended interview establishes a caregiver-informed test condition to be validated as a relevant context influencing problem behavior during a subsequent functional analysis. Any limitation regarding the treatment utility of the indirect assessment is therefore avoided when the assessment is used as a supplemental procedure to other more direct methods of assessment.

Descriptive Assessment

Rather than obtaining information regarding problem behavior through secondary means of reports from others, descriptive assessments involve direct observation of problem behavior. There are several formats of descriptive assessments, providing significant flexibility to practitioners using this method. However, similar to indirect assessments, the descriptive assessment continues to avoid the systematic manipulation of environmental events. The descriptive assessment tends to collect information regarding problem behavior as it occurs in the context of interest, aiding the clinician in recognizing (a) antecedents that precede problem behavior, (b) range of topographies of problem behavior, and (c) consequences that follow problem behavior.

Ecologically relevant descriptive assessments involve no interference with naturally occurring events in the observed setting and can be conducted at select times of the day or during specific activities in which problem behavior is reported to occur at higher rates. In ideal situations, each instance of problem behavior that is observed can be recorded in a continuous fashion, along with any correlated environmental events (Bijou et al., 1968). During the observation, the clinicians can decide to collect information using closed or open-ended methods. For example, a clinician may use an ABC format to collect information on observed antecedents, behaviors, and consequences (Groden, 1989). An ABC assessment with closed-ended options will have prespecified events and behaviors to choose from. This will limit the clinician’s recordings to a selection of target problem behavior (e.g., aggression, property destruction, self-injury) and generic antecedents (e.g., instruction provided, diverted attention, removal of tangible) and consequences (e.g., escape from instructions, access to attention, or access to tangible) to simplify interpretability. The open-ended options, often referred to as an ABC narrative, will leave availability for the clinician to expand on any specifics to the encounter with problem behavior that may not be represented in a standard list.

Observations of problem behavior during descriptive assessments can also be supplemented using conditional probability analyses to quantify correlations between problem behavior and particular environmental events (Vollmer et al., 2001). A conditional probability analysis calculates a probability of events given the occurrence of a target problem behavior. The temporal proximity of antecedents and consequences informs the identification of potential naturally occurring contingencies. The conditional probability is then compared to the background probability, which refers to the chances of an event or behavior occurring independent of any other variables. While conditional probability analyses can provide more precise interpretation of data collected in a descriptive assessment, it is important to point out that it is quite effortful and requires specialized training to conduct. It also requires the initial data collection to be accurate and extensive enough to provide the quantifiable information needed for clinicians to analyze.

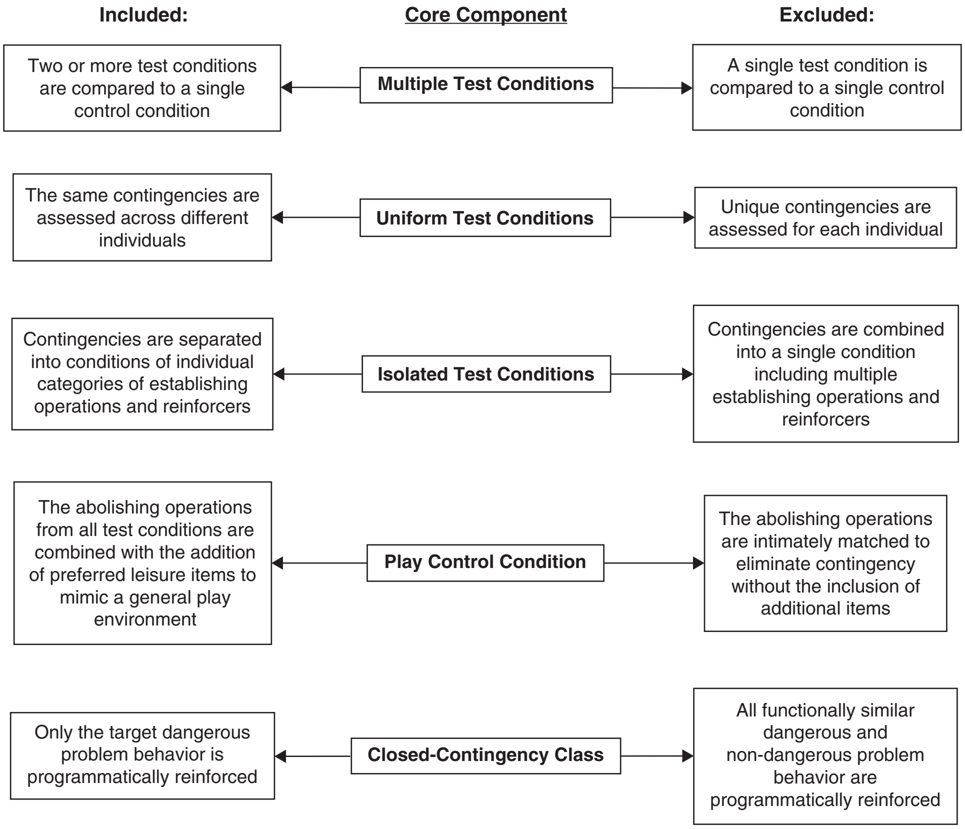
Although potentially reducing ecological relevance, descriptive assessments can be structured to increase contact with problem behavior and improve the efficiency of the assessment period. That is to say, clinicians can request caregivers or staff to introduce the child to contexts that are reported to result in problem behavior. As an example, Anderson and Long (2002) systematically introduced a child and caregiver dyad to four general conditions and asked the caregiver to respond to problem behavior as they naturally would. The researchers were attempting to arrange commonly presented antecedents to observe interactions of problem behavior and caregiver consequences. The results indicated that problem behavior could be observed in a semi-structured environment without having to spend extended amounts of time waiting for the environmental events to naturally arrange in the presence of problem behavior.

It is important to point out that exposure to certain environmental events does not necessarily infer that a contingency is contributing to the occurrence of problem behavior. Environmental events can be present in close temporal approximation to problem behavior without influencing its continued occurrence as evocative events or reinforcers (e.g., saying “god bless you” does not commonly reinforce sneezing but does tend to closely follow the response). Therefore, descriptive assessments, whether supplemented with quantified correlations or structured to ensure the child readily contacts certain antecedents and consequences, share the similar concern with indirect assessments regarding empirical demonstrations of control. For that reason, descriptive assessments may find better use as a collective process informing continued assessment.

Jessel et al. (2020b) designed a brief contingency probe that unsystematically arranges the context reported by the caregivers to be problematic as a way of calibrating (i.e., minor modifications to antecedents, behaviors, consequences) a hypothesized contingency to be evaluated in a subsequent functional analysis. The authors employed a three-part functional assessment process (i.e., open-ended indirect assessment, brief contingency probe, functional analysis) that collectively obtained qualitative information from each child to support the identification of a unique and individualized contingency contributing to problem behavior. The brief contingency probe allows the clinician to introduce potentially relevant conditions and directly observe the child’s reaction to these events. The benefit being that unsystematic changes can be made in real time to improve (a) operational definitions of problem behavior or (b) ecological relevance of the contingency. That is, the brief contingency probe can be used collectively with other functional assessment methods to improve the precision of functional interpretations, which may better inform treatment outcomes.

Functional Analysis

The functional analysis is the only model to include the direct observation of problem behavior and systematic manipulation of environmental events, thereby giving it the status as the most informative approach. Indirect assessments force the clinician to rely on the experiences of others and their ability to describe those experiences to develop hunches regarding functional accounts of problem behavior; whereas descriptive assessments can only go so far as to provide indications of environmental variables in the temporal vicinity of problem behavior but not the level of their influence. The functional analysis raises the clinical expectations to an empirical demonstration of controlling variables, creat-



Two or more test conditions are compared to a single control condition

A single test condition is compared to a single control condition

The same contingencies are assessed across different individuals

Unique contingencies are assessed for each individual

Contingencies are separated into conditions of individual categories of establishing operations and reinforcers

Contingencies are combined into a single condition including multiple establishing operations and reinforcers

The abolishing operations from all test conditions are combined with the addition of preferred leisure items to mimic a general play environment

The abolishing operations are intimately matched to eliminate contingency without the inclusion of additional items

Only the target dangerous problem behavior is programmatically reinforced

All functionally similar dangerous and non-dangerous problem behavior are programmatically reinforced

Fig. 19.1 Core procedural components of the functional analysis

ing a far more conservative account of what environmental events are contributing to problem behavior. The clinician can be more confident that a functional relation has been identified after conducting a functional analysis because they have (a) observed and measured the problem behavior for themselves and (b) used a single-subject experimental design during the assessment period.

From a methodological perspective, the functional analysis need only those two defining properties (i.e., direct observation and manipulation) and does not require adherence to a specific set of procedures. Some of the earliest demonstrations of functional analyses were particularly unique and used a more investigational approach (Lovaas et al., 1965; Lovaas & Simmons, 1969). However, a specific set of procedures began to emerge in the applied research literature as the functional analysis technology grew in popularity. The progressive development toward a standard set of procedures was likely a product of the ease of implementation and improved dissemination among researchers in applied laboratory settings. Contemporary functional analysis formats are now defined by the inclusion and exclusion of five core procedural components because they reflect adherence to a particular standard model (Jessel et al., 2020a). All five of the core components are presented and summarized in Fig. 19.1.

The first core component is the inclusion of multiple test conditions in a single functional analysis. The clinician may be interested in multiple contexts or separate contingencies that could influence problem behavior and conduct a functional analysis with a test condition for each of those contingencies, which are then compared to a single control condition. To improve the efficiency of the functional analysis, the test conditions and the control condition are typically rapidly alternated in a multielement design. Any functional analysis that excludes this core procedural component is implemented with a single test condition that is compared to a single control condition. Reducing the functional analysis to a maximum of two conditions (i.e., one test and control) comes with the added benefit of eliminating analytic clutter that could impair discrimination of conditions, which is more likely to occur when the child is presented with multiple and varying alternating contexts (Iwata, Duncan et al., 1994b).

The second core component arranges a functional analysis to include a standardized set of contingencies assessing generic classes of reinforcement for every child regardless of individual differences. Functional analyses with these uniform test conditions often include at least one test condition assessing the influence of positive reinforcement and another assessing negative reinforcement. What defines the inclusion of this core component is that these two test conditions will not vary between participants. During the condition assessing positive reinforcement, the clinician will provide generic statements of concern or common reprimands contingent on problem behavior. The negative reinforcement condition, on the other hand, will include the presentation of academic instructions. While using a set of uniform test conditions could potentially reduce effort in training clinicians in conducting the functional analysis (i.e., the clinician need only be trained on how to conduct one functional analysis that is then implemented with all children), it is likely to impact the ecological validity of the procedures. Functional analyses that exclude this core component instead introduce test conditions that are specifically informed by the child's experiences based on open-ended interviews and observations (e.g., Jessel et al., 2016). Doing so creates an individualized functional analysis that must be designed based on an intimate understanding of a specific history of reinforcement that could be contributing to the problem behavior. Therefore, a clinician conducting the functional analysis with unique test conditions in place of uniform test conditions will improve the probability of assessing variables relevant to the individual.

The functional analysis could include a third core component whereby classes of reinforcement contingencies are separated into isolated test conditions, even if they are reported to naturally co-occur in the child's environment. A clinician who includes this procedural component is committed to attempting to understand the independent effects of each reinforcement contingency. For example, a child may exhibit problem behavior when their activities are interrupted and a clinician may be interested in isolating the type of request, such as interruptions with requests to do something else or interruptions with requests to simply not engage with a certain activity (Hagopian et al., 2007). Teasing apart minute differences in arrangements of isolated contingencies may be interesting from a conceptual standpoint; however, it is unlikely to improve treatment outcomes (Slaton & Hanley, 2018; Slaton et al., 2017; Holehan et al., 2020). A functional analysis that excludes this core component instead assesses the contingency as it naturally occurs in the child's environment, which is inevitably going to be a synthesis of multiple contingencies. A noted strength of including synthesized contingencies is the focus on the problem as a whole as it exists for the child and caregivers.

The fourth core procedural component of a standardized functional analysis is the inclusion of an omnibus control condition that arranges items and events to be representative of a general play context. Praise is provided on a time-based schedule and the child is given noncontingent access to highly preferred activities. The play control attempts to eliminate problem behavior by creating an environment we would typically associate with a child's enjoyment. Practitioners who conduct a functional analysis with multiple test conditions will often conduct a play control to improve analytic efficiency. The alternative excluding this procedural component would be to implement individualized control conditions that are matched to each test, with the contingency being the only difference between the test and control conditions (i.e., contingent delivery of reinforcers in the test condition; noncontingent delivery of the same reinforcers in the control condition). For example, the clinician may be attempting to isolate the effects of attention and tangible reinforcement. The play control would allow the clinician to rapidly alternate all three conditions (attention, tangible, control) instead of a pairwise comparison of attention reinforcement with an attention-specific control and tangible reinforcement with a separate tangible-specific control. Of course, if the clinician were to assess a synthesized contingency in a single test condition (attention and tangible reinforcement) during the functional analysis, a single matched control with the identical synthesized reinforcement could be included without negatively impacting analytic efficiency while reducing potential confounds introduced in a play control. Therefore, when a practical option, the matched control is a far more experimentally rigorous procedural component.

The fifth and final core procedural component is designed to require low inferences regarding the function of the severe problem behavior by incorporating a closed-contingency class. A clinician conducting a functional analysis with a closed-contingency class will only reinforce the target problem behavior and, if multiple topographies of problem behavior are of interest, the clinician is committed to conducting multiple functional analyses specifically addressing each. This is juxtaposed with a functional analysis conducted with an open-contingency class, whereby all topographies of problem behavior that are assumed to be functionally related are reinforced. Using an open-contingency class is often considered when attempting to improve the practical utility of the functional analysis because it can reduce the probability of exposure to severe problem behavior (Jessel et al., 2021; Warner et al., 2020). Thus, the feasibility of conducting a functional analysis, especially in settings such as homes and classrooms, can be largely impacted by the decision to open the contingency class and reduce opportunities for escalation to dangerous and uncontrollable bursts of problem behavior.

Functional Analysis Formats

The functional analysis that embodies all five core procedural components has come to be termed the standard format and was introduced into the literature nearly 40 years ago. Iwata et al. (1982/1994a) conducted the standard functional analysis with nine participants admitted to an inpatient hospital who exhibited severe SIB. The researchers included three uniform test conditions assessing sensitivity of the rate of SIB to general classes of reinforcement (attention, escape, automatic) compared to a toy play control using a closed-contingency class.Although a highly replicated set of procedures in the applied literature, the standard format has often been regarded by clinicians to be burdened by multiple barriers to its widespread adoption in practice (Hanley, 2012; Oliver et al., 2015; Roscoe et al., 2015). For example, in one of the most extensive epidemiological collections of 152 applications, the authors found the standard functional analysis to require a mean of 6.5 hrs to conduct, reaching as high as 16.5 hrs (Iwata et al., 1994c). Considering that more efficient functional assessment methods exist without having to expose the child to hundreds of instances of severe SIB (e.g., indirect assessments), clinicians are unlikely to use a functional analysis that could pose a safety risk and requires days, if not weeks, to complete. Multiple functional analysis formats have since been developed to improve practical utility by adopting a different measure of problem behavior (Sigafoos & Saggers, 1995; Thomason-Sassi et al., 2011), reducing the number of sessions conducted (Northup et al., 1991), reducing the session duration (Wallace & Iwata, 1999); all the while maintaining the core procedural components of the standard functional analysis (see Fig. 19.2 for a summary of these modifications).

For example, Thomason-Sassi et al. (2011) evaluated the interchangeability of the measure of latency with rate for interpreting functions of problem behavior. Participants experienced the functional analysis with all five core components; however, the measure of latency allowed the researchers to terminate sessions after a single instance of problem behavior by measuring the time in which the response occurred from the beginning of the session. A functional relation was, therefore, determined based on the brief latencies to problem behavior observed in the multiple test conditions compared to

Format	Description	Core Components	Practical Importance
Standard	*Full functional analysis with repeated sessions and extended durations using rate as a measure of problem behavior*	☑ Multiple Test Conditions ☑ Uniform Test Conditions ☑ Isolated Test Conditions ☑ Play Control Condition ☑ Closed-Contingency Class	☐ Efficiency ☐ Safety ☐ Ecological Relevance ☐ Cost Effectiveness
Brief	*Abbreviated version of the standard conducted with a maximum of two sessions per condition*	☑ Multiple Test Conditions ☑ Uniform Test Conditions ☑ Isolated Test Conditions ☑ Play Control Condition ☑ Closed-Contingency Class	☑ Efficiency ☐ Safety ☐ Ecological Relevance ☐ Cost Effectiveness
Latency-Based	*Reduces sessions to a single instance of problem behavior and replaces the measure of rate with latency*	☑ Multiple Test Conditions ☑ Uniform Test Conditions ☑ Isolated Test Conditions ☑ Play Control Condition ☑ Closed-Contingency Class	☑ Efficiency ☑ Safety ☐ Ecological Relevance ☐ Cost Effectiveness
Trial-Based	*Trials conducted as they naturally occur and replaces measure of rate with percentage of trials*	☑ Multiple Test Conditions ☑ Uniform Test Conditions ☑ Isolated Test Conditions ☐ Play Control Condition ☑ Closed-Contingency Class	☐ Efficiency ☐ Safety ☑ Ecological Relevance ☐ Cost Effectiveness
IISCA	*Begins with an open-ended interview to inform a single test condition evaluating a unique, synthesized contingency using an open-contingency class compared to a matched control*	☐ Multiple Test Conditions ☐ Uniform Test Conditions ☐ Isolated Test Conditions ☐ Play Control Condition ☐ Closed-Contingency Class	☑ Efficiency ☑ Safety ☑ Ecological Relevance ☑ Cost Effectiveness

Fig. 19.2 Variations of the functional analysis

the extended latencies observed in the play control condition. The use of latency improved the efficiency of the standard functional analysis by 73% and reduced the instances of problem behavior observed during the entire functional analysis process to as few as three responses.Other functional analysis formats were designed to improve practical utility by avoiding the use of the core procedural components of the standard functional analysis (Hanley et al., 2014; Jessel et al., 2016). Hanley et al. introduced what has become known as the interview-informed synthesized contingency analysis (IISCA). The IISCA requires only a single test condition assessing a unique contingency informed by an open-ended interview with the caregiver, which is then compared to a matched control with the same reinforcers provided noncontingently. In addition, all topographies of problem behavior, including non-dangerous precursors, are targeted during an IISCA in an open-contingency class (Slaton et al., 2017). The IISCA can be conducted in 15 min (Jessel et al., 2020b) and multiple variations exist that can reduce other practical barriers further (Metras & Jessel, 2021).

Special Considerations

Application of Functional Assessment Models

The functional analysis is often recommended to be used because of its unique ability to raise the level of understanding of environmental contributors to problem behavior from what would be conjecture (indirect assessments) or correlational (descriptive assessments) to an empirical demonstration of control. Clinicians often share this standard of care with other health professionals in that simply asking or observing a client is hardly ever recognized as a sufficient assessment for serious ailments. This is not to say that indirect and descriptive assessments should be abandoned. Quite the contrary, indirect and descriptive assessments are vital for informing the procedures of a functional analysis. In fact, a functional analysis should not be conducted without those preceding assessments. Therefore, an evidence-based approach to functional assessment involves obtaining qualitatively rich information regarding a particular child before the implementation of an individualized functional analysis assessing a unique contingency. This ensures a highly informed process that incorporates immediate clinical experiences with best scientific evidence when implementing the functional assessment. Although the different functional assessment models were historically developed independent of one another and were often given hierarchical status based on perceived effort (i.e., begin with the indirect assessment and only conduct the descriptive assessment and functional analysis when necessary), clinicians may benefit from seeing the functional assessment as a collective set of tools not to be disentangled from one another.

There are, of course, exceptions to using this collective approach to functional assessment when a functional analysis cannot be conducted. Pragmatic boundaries do exist and a clinician may find themselves in a position whereby the putative contingencies cannot be systematically manipulated. Sleep-interfering behavior (e.g., tantrums, verbal protests, elopement from the bedroom) serves as a particularly relevant example because the act of falling asleep (i.e., behavioral quietude) is considered operant behavior, while the reinforcement it produces is the complex physiological change to sleep (Bootzin, 1977). A functional analysis cannot be conducted because escape from sleep is essential in defining the contingency and sleep as a reinforcer cannot be systematically presented or removed.[1] Furthermore, the intricacy of the environmental variables that could be interacting with each other to establish (e.g., insufficient sleep, poor-quality sleep) or signal (e.g., lighting, room temperature, sleep dependencies) the onset of sleep makes it difficult to determine what variables should and can be evaluated in a functional analysis.

Information regarding environmental variables that contribute to sleep-interfering behaviors can still be obtained through other functional assessment means and would still serve an essential purpose for informing subsequent function-based intervention. Jin et al. (2013) developed an indirect assess-

---

[1] This is not to say that a clinician is unable to conduct a functional analysis of problem behavior to escape from the bedroom. However, this functional analysis can only identify an isolated piece of the contingency, not in its entirety regarding escape from sleep. Therefore, a clinician may be able to develop strategies for reducing elopement from the bedroom, but this does not infer that it will improve the child's sleep.

ment that included open-ended questions targeting specific variables that could be contributing to delayed sleep onset, sleep-interfering behaviors, and night awakenings. The authors used the information from the interviews to design an individualized treatment package for each of the three participants, which involved enhancing behavioral quietude and eliminating any contingencies that could be supporting the sleep-interfering behavior. This function-based comprehensive approach helped to improve sleep and reduce the use of sleep aides such as medication or parent presence. Therefore, while clinicians may not be able to conduct a functional analysis of problem behavior in all situations, other functional assessment models seem like a sufficient alternative that can inform effective and socially validated treatments in those cases.

Automatic Reinforcement

Results of functional assessments implicating a socially mediated function for problem behavior tend to be a preferred outcome because it suggests a level of control that can be exerted by clinicians over the maintaining variables. In one of the most common function-based treatments for socially mediated problem behavior, the reinforcers historically contributing to problem behavior are withheld and reserved for only the occurrence of an appropriate form of communication (Hagopian et al., 1998; Jessel et al., 2018; Rooker et al., 2013). A special consideration emerges when the functional reinforcers for problem behavior are not so easily controlled and are a unique property of the response itself; such is the case of automatic reinforcement.

Problem behavior sensitive to automatic reinforcement will occur across a wide variety of conditions and is not influenced by others. That is because the operantly maintained problem behavior is assumed to be producing its own source of reinforcement. An indication that problem behavior is automatically reinforced includes its continued occurrence when the child is left alone. Although the properties of automatic reinforcement are difficult to discern—the categorization of problem behavior as being maintained by automatic reinforcement is more so a default designation rather than an informative implication of a particular function—clinical utility can still be improved through the use of functional assessment methods to delineate different subtypes of automatically reinforced problem behavior (Hagopian et al., 2015, 2017).

Indirect and descriptive assessments will first guide the clinician to postulate that the problem behavior is sensitive to automatic reinforcement using verbal reports from caregivers and direct observation, respectively. However, these approaches are limited to informing general hunches regarding the influence of automatic reinforcement. Further assessment with a functional analysis is required to delineate three subtypes depending on patterns of problem behavior observed during the systematic comparison of an enriched environment in one condition (i.e., child-directed play with highly preferred items) and a second condition devoid of external stimulation (i.e., alone or ignore condition without preferred items).

Potentially, problem behavior that is automatically maintained will be reduced when the child is presented with highly reinforcing stimuli in the enriched environment, indicating a categorization of Subtype 1. This differentiated pattern of responding suggests that problem behavior, although maintained by automatic reinforcement, is sensitive to environmental stimulation and that preferred items can successfully compete with the functional reinforcers produced by the problem behavior. In a second outcome, problem behavior may not be sensitive to enhanced stimulation in the environmental enrichment condition and problem behavior will continue to occur in both conditions. These patterns of undifferentiated and elevated levels of problem behavior across conditions of the functional analysis are indicative of a Subtype 2 categorization. The final delineated subtype, Subtype 3, is dependent on whether or not the child exhibits self-restraint (e.g., sitting on hands, covering limbs with blankets).

Problem behavior during the functional analysis may be reportedly low across conditions when the child has access to self-restraint and only observed when that self-restraint is blocked.

Conducting a functional assessment to delineate these three subtypes of automatically reinforced problem behavior is important to consider because the results may have implications for treatment (i.e., clinical utility). For example, problem behavior sensitive to the stimulation in an enriched environment (Subtype 1) would inform the design of a treatment that incorporates noncontingent access to preferred items that will compete with the automatic reinforcement produced by the problem behavior (Hagopian et al., 2015). On the other hand, such a treatment with reinforcement alone is unlikely to be effective when addressing Subtype 2 problem behavior and multiple components including response blocking or punishment will be necessary. Thus, functional assessment methods have widespread applicability for understanding operant influence of socially mediated and automatically reinforced problem behavior.

Conclusions

Functional assessment methodology has been a staple of behavioral intervention of problem behavior for decades because of its ability to inform effective action on the part of the clinician. The goal of the functional assessment is to provide the clinician with an operant understanding of environmental events contributing to problem behavior using indirect assessment, descriptive assessments, functional analysis, or any combination of those three broad methods. Although certain pragmatic boundaries may dictate the use of some methods over others, the functional assessment is a diverse set of procedures and is a sufficiently flexible technology that allows the clinician to assess environmental-behavioral relations in a wide variety of contexts. It is for these reasons that clinicians guided by evidence-based practice will often rely on functional assessment to inform the design of any further treatment for problem behavior.

Cognitive Behavioral Therapy (CBT) with Children and Adolescents

Eili N. Riise, Bente Storm Mowatt Haugland,
and Gro Janne H. Wergeland

Cognitive behavior therapy (CBT) is a diverse group of interventions targeted at identifying and addressing thoughts and behaviors that maintain psychological problems and promote more functional behaviors and thoughts. The goal of CBT is to achieve symptomatic and functional improvement, usually within a limited number of sessions (i.e., 8–20 sessions). CBT was initially developed to treat adults suffering from different mental health disorders (Clark, 1986; Kozak & Foa, 1997). However, during the last 30 years, CBT has also been adapted to treat various mental health problems in children and adolescents. Treatment manuals for internalizing and externalizing disorders have been developed, including anxiety (e.g., Kendall & Hedtke, 2006), obsessive-compulsive disorder (e.g., March & Mulle, 1998), depression (e.g., Brent & Poling, 1997), posttraumatic stress (Cohen et al., 2012) and conduct problems (e.g., Forgatch & Patterson, 2010). An increasing number of studies have supported the effectiveness and feasibility of CBT for children and adolescents. CBT has been found to be effective across different disorders, when delivered in various formats (group, individual), with varying degrees of parental involvement, for different purposes (treatment, indicated prevention, universal prevention), and in different contexts (mental health clinics, schools, public health centers, child welfare institutions).

Cognitive behavioral therapists need to master various competencies, and findings suggest that increased therapist competence is associated with improved therapy outcomes (Kuyken & Tsivrikos, 2009; Podell et al., 2013). As such, specialized training and experience are necessary for effective delivery of CBT. Learning strategies such as role-play, self-experiential work, or modelling are effective ways to enhance CBT skills (Bennett-Levy et al., 2009). Accordingly, CBT training and practice should not only rely on theoretical knowledge but also include active learning strategies to increase therapist competence.

In this chapter, the theoretical framework, the therapeutic relationship, and the therapist's attitude in CBT are described. Next, general CBT components as well as behavioral and cognitive techniques

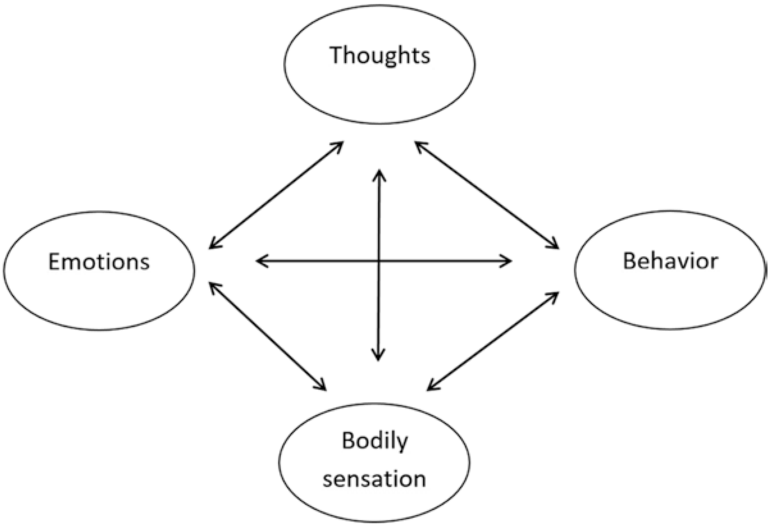
are explained. Further, the evidence base of CBT for internalizing and externalizing disorders is discussed. Finally, we will elaborate on issues to consider when using CBT with children and adolescents and ways of adapting the treatment to the child's developmental level.

Theoretical Framework

Cognitive behavioral therapy originates from behavioral traditions and the early work of Skinner (1938), Pavlov (1927), and Watson (Watson & Rayner, 1920), as well as the cognitive theory of Aron Beck (1976, 1979). The early proponents of behaviorism introduced the idea that behavior can be measured and changed, whereas cognitive theory highlights how thoughts and perceptions influence feelings and behavior. During the 1980s and 1990s, behavior therapy and cognitive therapy merged into CBT. Since then, a range of disorder-specific CBT models has been developed. A common factor across disorder-specific CBT models is that they emphasize the role of cognitive and behavioral mechanisms for the understanding and maintenance of psychological problems.

Cognitive behavioral therapy can be described as a group of therapies with a common theoretical framework. The cognitive diamond (Fig. 20.1) is a transdiagnostic model which is frequently used to describe the key principles of CBT. It illustrates the interplay between behavior, thoughts, emotions, and bodily sensations and how they continually and reciprocally influence one another. The cognitive diamond also illustrates how psychological problems are maintained, and how changes in any of the four components might help to break the "vicious circle" of psychopathology. Therapeutic interventions are tailored to identify connections between feelings, thoughts, and behaviors and are directed at reducing distress, changing unhelpful thoughts, and alleviating behaviors. Therapists work together with children, adolescents, and/or parents to observe, identify, and experience how the four components are connected to and influence one another. CBT aims to help the client adjust thoughts or behaviors that maintain the problem in question and replace them with more functional behaviors and thoughts.

Fig. 20.1 The cognitive diamond



Therapeutic Relationship and Therapist's Attitude

An inherent element in CBT is the assumption that cognitive distortions (i.e., styles or patterns of inaccurate thinking; Friedberg et al., 2012) and behavior may be changed through dialogue between therapist and client. Aron Beck (1979) emphasized that the relationship between the client and therapist should be based on *collaborative empiricism* and *guided discovery*. In the term collaborative empiricism, collaboration refers to "shared work" involving active participation and contribution from both client and therapist (Kazantzis et al., 2013), whereas empiricism highlights that the client's beliefs are seen as hypotheses to be tested (Beck, 1979). The term-guided discovery describes how the dialogue between therapist and client guides the client to explore cognitive processes. A well-known method that supports the process of guided discovery is Socratic dialogue (Padesky, 1993). Socratic dialogue attempts to help clients evaluate their reasoning (Chessick, 1982). Through systematic questioning and a nonjudgmental attitude, the therapist tries to understand the client's view and help the client discover illogical reasoning and explore solutions (Overholser, 1993; Padesky, 1993). In Socratic dialogue, the therapist asks questions that foster reflection and exploration, such as "What would you advise a friend who told you something similar?" "Have you ever noticed a problem like this before?"; "How did you deal with it then?"; "What other ways could you look at this situation?". In this manner, Socratic dialogue guides the client through a cognitive exploratory process. The idea is that the client has the capacity to change and that the therapist through questions and positive attitude supports the client in this process of change. However, as pointed out by Overholser (1993): "Systematic questioning should not be used when the client is unlikely to benefit from a cognitive exploratory process. Young children are too concrete to appreciate the complexities of the Socratic method." (p. 72). Accordingly, Socratic dialogue might be a useful approach when working with adolescents, but must be simplified when used with younger children. This is further elaborated in the last section of the current chapter. Furthermore, in CBT with children and adolescents, the principle of guided discovery is integrated in other techniques such as behavioral experiments, exposures, problem-solving, and cognitive restructuring adapted for use with children. Children and adolescents may for example be invited to actively investigate the accuracy and usefulness of their beliefs by "playing the role of a thought detective" (Friedberg & McClure, 2015).

CBT is characterized by collaboration among the child or adolescent, their family, the therapists, and in some cases school or kindergarten personnel. The presence, immediacy, and transparency when delivering the intervention have been pointed out as critical elements in the therapeutic relationship in CBT (Friedberg et al., 2013). More specifically, CBT therapists should attend to what is happening here and now in treatment, tolerate negative emotional states and discomfort, and stay in contact with the child or adolescent through emotionally arousing experiences. Furthermore, transparent communication should be integrated in all dialogue with the child, adolescent, and/or parents. Transparency is an important principle in CBT and is ensured in various ways, for instance, through psychoeducation, clear communication of the structure of CBT, and explanations of the rationale for the different methods applied (Friedberg et al., 2013).

General CBT Components

Assessment and Systematic Evaluation of Outcome

In CBT it is recommended that standardized and empirically validated instruments are used to assess symptoms. The assessment is usually carried out at pretreatment in order to measure the intensity of symptoms and repeated at evaluation points and at the end of therapy. The aims are to monitor progress and to evaluate whether the treatment has yielded the intended results. Systematic assessment of symptoms using standardized symptom rating scales has been shown to optimize therapists' ability to accurately assess treatment response and remission (McGuire et al., 2019). With children and adolescents, the assessment includes self-reports, parent reports, teacher reports, and/or standardized clinical interviews. For information on assessment tools for children and adolescents, the reader should consult the evidence base update on assessment tools for children and adolescents (Becker-Haimes et al., 2020). There are also several handbooks available that summarize the validity and reliability of various assessment tools (e.g., McLeod et al., 2013).

Case Conceptualization

Case conceptualization is a short summary of a child's developmental history, core cognitions, emotional responses, coping strategies, and behaviors. Developing a case conceptualization is a necessary foundation in CBT. It is typically created in a collaboration between the therapist, the child/adolescent, and his/her parents during the initial phase of treatment. It serves to create hypotheses about the development of the problems and maintaining mechanisms (Murphy & Christner, 2006). Case conceptualization helps therapists and clients to specify the target of treatment. As such, a well-formulated case conceptualization is helpful in order to individually tailor the interventions (Kuyken et al., 2009). There are various models of CBT case conceptualizations. A thorough discussion of these models is beyond the scope of this chapter. For further discussion on case conceptualizations, readers may consult the above-mentioned references.

CBT Structure

Cognitive behavioral therapy is organized according to an overall structure which describes the progress of treatment. Furthermore, the session structure describes the specific content to be covered in each session.

The overall treatment structure in CBT includes three phases: an initial phase, a middle phase, and a final phase. During the initial phase, the patient's motivation and expectations for treatment are assessed, the therapeutic alliance is built, goals are specified, and psychoeducation is provided. In the middle phase, cognitive and behavioral strategies are implemented. In the final phase, the therapist prepares the client for termination and emphasizes relapse prevention (Beck & Beck, 2011). Furthermore, most CBT manuals follow a session-by-session guide of the content to be covered throughout treatment. For instance, in the treatment of anxiety, the overall treatment structure typically starts with psychoeducation, followed by setting goals for treatment, introducing cognitive techniques, carrying out exposures, before ending treatment with a session focused on maintenance of treatment gains (Barrett, 2005; Kendall & Hedtke, 2006; Rapee et al., 2019). Cognitive behavioral therapy also involves homework assignments between sessions to practice and reinforce skills and to generalize these skills to everyday life situations. The treatment structure is usually presented to the child, adolescent, and/or their parents in the initial session to ensure predictability and transparency regarding the progress of treatment. The overall treatment structure is considered a framework to guide therapists and patients through treatment. However, therapists are advised to have a flexible approach and consider individual adaptations whenever needed. Some children might need certain interventions to be repeated, whereas others reach their goals early and treatment may be ended sooner than planned.

The session structure is a guiding outline that helps therapists organize and prioritize what they do in CBT sessions (Friedberg & McClure, 2015). Judith Beck (1995) described six components in CBT sessions: (1) check in; (2) homework review; (3) setting the agenda; (4) the actual session content; (5) homework assignment; and (6) feedback from child, adolescent, and/or parents on their perception of the session.

Psychoeducation

Psychoeducation is intended to provide a common understanding between patients and therapists of the treatment model and the rationale for the therapeutic interventions. Psychoeducation also aims to provide knowledge about the patient's disorder. Accordingly, the content of the psychoeducation varies depending on the presented problem. For instance, in the treatment of disruptive behavior, parents typically receive psychoeducation about child development and how different parenting practices affect children's behavior (Forgatch & Patterson, 2010; Webster-Stratton & Reid, 2003), whereas in the treatment of PTSD, information on traumatic stress, trauma responses, and reminders are important subjects to be covered (Cohen et al., 2012). The therapist tries to engage the parents, child, or adolescent in the psychoeducation through the use of various approaches such as illustrations, videos, discussions, examples, or metaphors. Psychoeducation is introduced in the early stages of treatment and repeated throughout treatment whenever necessary. Accordingly, psychoeducation serves as a supportive technique throughout the treatment process and might help to demystify the symptoms, modify inaccurate beliefs, and reduce the shame, guilt, or anger related to the child's or adolescent's disorder (Friedberg et al., 2012).

Setting Goals

An important element in the initial phase of CBT is to define what the child, adolescent, and parents want to achieve during the treatment. In order to succeed with CBT, it is essential that the child or adolescent is involved in the process of setting goals, and that the goals are consistent with the child's understanding of the problem. It is important to note that the child's goals for therapy might be different than the goals of their parents. For instance, parents might want their adolescents to do more homework. However, the adolescent might find this goal to be demotivating and uninteresting. In such cases, an important part of therapy is to positively reformulate and identify goals that are motivating for the child or adolescent, while at the same time taking the parents' concerns seriously. In this example, the therapist and adolescent might find that the adolescent is motivated to achieve better grades, have more fun at school, or perhaps have fewer conflicts with their parents around homework.

In parent management training, the parents define goals for their children and work towards these goals through making changes in their own parenting. Parents are trained to specify the goal and to positively formulate what behaviors they want to see more of, and to use specific parenting techniques such as rewards in order to achieve their goals (Webster-Stratton & Reid, 2003).

Whether the therapy is directed mainly at children, adolescents, parents, or families, the goals should be clear, achievable, measurable, and positively formulated. The acronym SMART (Specific, Measurable, Achievable, Relevant, and Time-Bound) might be a useful reminder in the goal-setting process. Stallard (2019) wrote:

> A good goal should be clearly and positively defined (specific) and which can be readily assessed (measured) to determine progress. The target should be motivating but not too large to feel impossible (achievable). Goals should be important to the young person (relevant) and be achievable within a reasonable timeframe (timely). (p. 24)

Monitoring Behaviors, Emotions, and Cognitions

In close cooperation with the patient, CBT therapists use methods aimed at observing and recording the individual's behavior, thoughts, and emotions. This process is a key element in most CBT treatments and is carried out in order to increase the patient's awareness and to ensure a common and thorough understanding of the problem in question (Friedberg et al., 2012). Monitoring behavior, thoughts, and emotions provide information on the intensity and frequency of unhelpful thoughts, emotional reactions, and unwanted behavior, how these interact, under which circumstances they occur, and how they are maintained. It serves to direct treatment and is regarded as a necessary procedure to create change and to make use of more helpful strategies.

Behavioral monitoring aims to identify the antecedents and consequences of a certain behavior. The individual or other observers such as parents or teachers might carry out the monitoring. First, the behavior in question is specified, next, the frequency of the behavior is registered as well as its antecedents and consequences. The technique is especially useful in the treatment of behavioral or anger problems where it helps identify triggers for unwanted behavior and reinforcing consequences (Hanley et al., 2003; Miltenberger et al., 2021).

Self-monitoring of cognitions and emotions may help children and adolescents to become more aware of their thoughts and beliefs and how these are associated with particular situations and emotions. In order for a child or adolescent to be able to word their own thoughts and feelings, it is usually necessary to have a thorough psychoeducation where the therapist introduces a simple classification system for feelings (e.g., mad, sad, worried, and happy; Friedberg et al., 2012). Furthermore, a visual rating scale such as the fear thermometer (March & Mulle, 1998) might be helpful to describe the intensity of the feeling. The therapist should work together with the child to identify thoughts and feelings in different situations. For instance, for a socially anxious boy, a relevant situation might be that he was asked to read out loud in the classroom. The therapists should direct the conversation around the situation in order to investigate what feelings and thoughts were present in that situation. Next, when the child begins to understand how his or her inner states can be categorized and worded, self-monitoring of cognitions and emotions might start. In the treatment of depression and anxiety, self-monitoring is often carried out as homework assignments. In the treatment of depression, adolescents might be instructed to pay attention to situations that have made them feel sad, or to feel happier, during the week (e.g., Curry et al., 2005). In the treatment of anxiety, the child or adolescent is typically instructed to pay attention to situations that have made them feel worried or anxious (Rapee et al., 2019). A common variant is to use a three-column table where the child or adolescent (1) describes the situation, (2) categorizes the feeling and rate the intensity of the feeling on a scale, and (3) writes down what thoughts went through their head in this situation.

Behavioral Techniques

Reinforcement of Desired Behavior

Reinforcement of desired behavior is theoretically founded in the operant conditioning paradigm, which suggests that a behavior is strengthened or weakened by its consequences (Skinner, 1938).

Accordingly, unwanted behavior might be maintained by its consequences (e.g., removal of distress, attention from others). In the same manner, the frequency of desired behaviors might be increased through positive reinforcement or through response cost (i.e., removal of a privilege or reward). In line with these principles of behavior modification, parents of children with disruptive disorders are taught how they can increase desired behaviors and reduce the number of unwanted behaviors in their child. In the early stages of parent management training, parents define a number of desired behaviors they want to see more of and reward the behavior by encouragement and/or reward systems in order to increase the frequency of such behaviors (Forgatch & Patterson, 2010; Webster-Stratton & Reid, 2003). When the number of desired behaviors increases, the frequency of unwanted behaviors usually decreases. However, the parents might still need strategies to cope with unwanted behaviors. Accordingly, in the later stages of treatment, parents practice how not to reinforce negative behavior. Mild problem behaviors might be handled by not paying attention to them, thus removing the reinforcing consequence of the behavior, or by paying attention to other desired behaviors that are incompatible with the unwanted behavior. More severe problem behaviors might be managed through removing a reward or privilege (i.e., response cost).

Reinforcement or rewards are also important elements in CBT treatment of other disorders and might help motivate children or adolescents to carry out behaviors necessary for change to occur. For instance, a child may achieve rewards after carrying out exposures in anxiety treatment or depressed adolescents may learn to reward themselves after doing an activity from the activity plan.

Behavioral Experiments and Exposures

Behavioral experiments and exposures are treatment components where the child or adolescent learns to face situations they have previously avoided. These are key elements in CBT for anxiety disorders, including OCD and PTSD, but might also be used in the treatment of various other disorders.

The term *behavioral experiments* is derived from the cognitive wing of CBT, where the aim of the experiment is to test a cognition through a real-life experience (Clark, 1989; Wells, 1997). It is especially relevant in the treatment of anxiety, where the behavioral experiments are carried out to test the validity of a catastrophic misinterpretation (Bennett-Levy et al., 2004).

The term *exposures* originates from behavioral theories suggesting that fear extinction is achieved through habituation by repeatedly exposing the individual to the anxiety-provoking stimuli (Foa & Kozak, 1986). More recent behavioral theories propose that fear extinction takes place because new learning inhibits access to the previously learnt association (Craske et al., 2008; Craske et al., 2012).

There is a general agreement that learning through experience is a powerful therapeutic strategy in the treatment of anxiety (Bennett-Levy et al., 2004; Kendall et al., 2005). Both behavioral experiments and exposures aim to help the child and adolescent recognize that the feared situation does not represent “real danger”.

In the treatment of anxiety disorders, repeated exposures are a core feature of treatment. In order to succeed with the exposures, the child or adolescent needs to understand the rationale for the exposures. In other words, the child needs to understand that going through discomfort in repeated exposures will help them overcome their anxiety, and that continued avoidance will make the anxiety worse in the long run. Accordingly, the rational for exposure should be thoroughly explained during psychoeducation, using metaphors and examples adjusted to the child’s developmental level. Through collaboration, the therapist and the child go through possibly anxiety-provoking situations, write them down on a worksheet, and categorize them as easy, medium, or challenging. Then the child places the exposures in a hierarchy, often illustrated as a pyramid, a ladder, or stairs, from the easiest task on the bottom to the most challenging tasks on the top. Once the hierarchy is constructed and the child understands the rationale for the exposure process, the exposures might start on the easiest tasks before gradually moving up the hierarchy. In the initial phase of exposure treatment, exposure tasks are typically carried out during the sessions. After having carried out initial exposures with the assistance of the therapist, the child or adolescent do self-administered exposures between sessions. It is important that the therapist prepare the child for self-administered exposures. This might be done through imaginary exposures in session, by carefully planning when and where to carry out the exposures and by going through the situation with the child beforehand. The therapist should also inform the child or adolescent that they will not be forced to do exposures, but that the therapist will support them and encourage them to carry them out. Furthermore, the therapist and/or parents should reward the child for carrying out exposures. It is important that the child knows what kind of reward he or she will achieve after carrying out the exposure. The therapist might also need to involve parents or other adults in the exposures between sessions. Graded exposure, in which a fear hierarchy is created in collaboration with the child or adolescent and the therapist, is mastered in a stepwise manner. This is the cornerstone of treatment for anxiety disorders, such as specific phobias, separation anxiety disorder, generalized anxiety disorder, and social anxiety disorder. In the treatment of OCD and PTSD, there are special features to the exposures that the therapist should be aware of. However, a discussion of specific features related to the exposure process of the different disorders goes beyond the scope of this chapter. We recommend clinicians to consult disorder-specific treatment manuals and other literature on the issue (e.g., Raggi et al., 2018) before carrying out exposures.

Usually, the exposures are supplemented with some sort of thought challenging. Interestingly, some findings indicate that exposures might be more effective when they also challenge cognitions (McMillan & Lee, 2010). For instance, the therapist might set up the exposures to challenge catastrophic beliefs. The child or adolescent writes down what they expect to happen. After the exposures, the therapist addresses how the child felt, what their thoughts were, what they learned from the exposure, and whether their expected beliefs were confirmed. A similar way of challenging cognitions when doing exposures is anxiety prediction. This simple, yet effective cognitive technique, supplements the exposures by inviting the child or adolescent to predict their level of anxiety before carrying out the exposures (Friedberg & McClure, 2015). Their predicted level of anxiety is typically rated on a scale, such as the fear thermometer. The exposures serve as a test of their predictions, and after the exposure, they rate their actual anxiety. If the actual anxiety turns out to be less intense than they predicted, the therapist might elaborate on this issue and focus on the fact that their anticipations are not always accurate. If their prediction was accurate, or if the feeling was more intense than what they predicted, the therapist might elaborate on the fact that the child was able to carry out the task and tolerate the intense feeling. For instance, in the Cool Kids Program (Rapee et al., 2019) anxiety prediction is a part of the preparation for exposures. The child is asked to describe and write down in their workbook their expectations to a specific exposure and rate their predicted level of distress. Then, after the exposure is carried out, the child is asked to describe and write down what he or she learned, the reward they achieved, and how worried they expect to be the next time they perform the exposure task.

Relaxation Training

Relaxation training is a behavioral technique used in most CBT manuals for anxiety to reduce physiological arousal (Barrett, 2005; Kendall & Hedtke, 2006; Rapee et al., 2019). Relaxation techniques include controlled deep breathing, guided imagery, and progressive muscle relaxation where the individual is taught to tense and relax specific muscle groups. The relaxation procedures are often supplemented with metaphors and imagery such as the belly breathing balloon or safe place used in trauma-focused cognitive behavioral therapy (Cohen et al., 2012).

Behavioral Activation

In the treatment of depression in children and adolescents, behavioral activation is a core component of CBT interventions. The aim is to increase participation in pleasant, mood-enhancing activities. This task can be challenging for depressed patients, as they might have lost interest in many activities that they previously found enjoyable. If this is the case, the therapist should ask for activities that they used to like. Furthermore, it is necessary that the rationale for behavioral activation has been explained through psychoeducation. Depression might be explained as a “downward spiral” of negative emotions, thoughts, and behaviors, and increasing participation in pleasant activities can turn this into an “upward spiral” (Curry et al., 2005).

A common strategy is to use an activity schedule with the days of the week. A list of pleasant activities is created in session and the adolescent chooses the activities he/she would like to increase. Next, the activities are carried out as homework between sessions, recorded on the activity schedule, and brought back to session. Similar to the anxiety prediction procedure described earlier, pleasure prediction is a commonly used cognitive strategy supplementing the behavioral activation. When the activities are written down on the activity schedule, the child or adolescent predicts how enjoyable he/she think the activity will be, using verbal descriptions or a feeling thermometer. After the activity, the child or adolescent should describe or rate how enjoyable he/she experienced the activity to be. This information is used in session to test the accuracy of their beliefs. If the activity was more enjoyable than expected, the therapist can elaborate on the fact that the predictions were inaccurate. If the actual emotional experience was worse than, or as predicted, the therapist can work with the adolescent to elaborate on the mere fact that the adolescent was able to carry out the activity despite their dissatisfaction and lack of motivation. This implies that there are alternative ways of coping, and that it is possible to direct one’s own behavior despite low motivation and negative predictions (Friedberg & McClure, 2015).

Cognitive Techniques

The aim of cognitive interventions in CBT is to increase cognitive flexibility and to foster more adaptive interpretations and thoughts about oneself, others, situations, or problems. The aim is not to eliminate all negative emotions or thoughts. In the current section, we have categorized cognitive techniques into cognitive restructuring techniques and problem-solving interventions.

Cognitive Restructuring

The aim of cognitive restructuring is to identify and challenge cognitive distortions. It is the most common strategy used in CBT programs for internalizing disorders (Fréchette-Simard et al., 2018). Self-instructional techniques are often useful methods where children learn more helpful self-talk that can support them when facing distressing situations. With younger children it is often necessary that the therapist teach the children to create more functional and calming thoughts (Friedberg et al., 2012). Rational analysis is a more advanced way of restructuring cognitions. The therapist coaches the child or adolescent to evaluate the accuracy of his or her own beliefs. This can be done through reattribution, in which the therapist helps the child see their explanations from multiple angles (Friedberg & McClure, 2015). The first step is to identify cognitions that maintain the problem. Through self-monitoring or dialogue, the child and therapist identify anxious or negative self-talk, e.g., “Everyone will laugh at me”, “I am hopeless”. Next, the therapist asks a series of open-ended questions to guide the adolescent's attention toward alternative explanations. Alternative explanations are written down and their plausibility rated. Finally, a conclusion based on all alternative explanations is developed. A similar procedure is decatastrophizing, a common method in the treatment of anxiety (Beck & Beck, 2011). The focus is on challenging the child or adolescent's catastrophic predictions. Through asking questions about their predictions (e.g., "What will most likely happen?"), the therapist guides the child to arrive at a more realistic and helpful belief. It is essential that the child believes in the more realistic thought. Another common method to arrive at more realistic thoughts is a test of evidence (Friedberg & McClure, 2015). This is done through looking for supporting and contradicting evidence for the catastrophic prediction. Once a list of supporting evidence and a list of disconfirming evidence are created, a more realistic conclusion is generated. The conclusion should include evidences that support their catastrophic belief and evidences that disconfirm it.

Problem-Solving

Problem-solving in CBT is a cognitive technique that helps the child or adolescent to define the problem and identify alternative adaptive coping strategies when they face a difficult situation. A common problem-solving procedure is to evaluate the advantages and disadvantages of a specific choice, behavior, or decision (Friedberg et al., 2012). For instance, if a depressed adolescent stays in his or her room when feeling sad, the therapist might address the advantages and disadvantages of this solution. In cases where a child faces tasks or challenges that seem too overwhelming, the therapist can help the child to break them down into smaller tasks (Friedberg & McClure, 2015). The therapist helps the child to analyze the situation and arrive at smaller tasks to cope with the problem. The problem will seem more manageable as each task will move the child closer to a solution (Stallard, 2019). Several CBT manuals offer specific stepwise problem-solving interventions (e.g., Curry et al., 2005; Rapee et al., 2019) where the child or adolescent first identifies the problem and brainstorm possible solutions, before evaluating all the solutions. Finally, the best solution is chosen, carried out, and evaluated.

Empirical Support for CBT in Internalizing and Externalizing Disorders in Children and Adolescents

Internalizing disorders such as anxiety disorders, obsessive compulsive disorder (OCD), posttraumatic stress disorder (PTSD), and depressive disorders represent as a group the most common mental health disorders among children and adolescents (Costello et al., 2005; Merikangas et al., 2010). Likewise, externalizing behavior disorders such as attention deficit hyperactivity disorder (ADHD), conduct disorder (CD), and oppositional defiant disorder (ODD) are among the most common reasons for referral to mental health services for children and adolescents (Smith et al., 2018). Both internalizing and externalizing disorders are associated with numerous adverse developmental consequences for children and adolescents and can lead to emotional, cognitive, social, and academic impairments (Abramowitz & Mahaffey, 2014; Clark et al., 2002; de Lijster et al., 2018; DuPaul et al., 2016; Hammen et al., 2008; Piacentini et al., 2003; Trickett et al., 2011). The high prevalence of internalizing and externalizing disorders and the severe consequences for the individual and the society highlight the necessity of providing evidence-based interventions.

Cognitive behavioral therapy programs for internalizing and externalizing disorders in children and adolescents have been developed during the last 30 years. For these disorders, CBT is documented as a well-supported and evidence-based treatment that improves both symptoms and functioning. Chambless and Hollon (1998) established criteria for determining the standard of evidence that is needed for a treatment to be considered empirically supported, i.e., whether the efficacy of a psychological treatment is well-established, probably efficacious, or possibly efficacious. A treatment is considered well-established when it has demonstrated equivalent or superior efficacy to an alternative treatment in at least two between-group design experiments, demonstrated by at least two independent research teams at two different sites. According to these criteria, cognitive behavioral therapy has solid empirical support and is considered well-established for anxiety disorders, OCD, PTSD, and depressive disorders (Dorsey et al., 2017; Freeman et al., 2018; Higa-McMillan et al., 2016; Weersing et al., 2017). Treatment formats have included individual delivery, group delivery, treatment with or without parental involvement, and for some of the anxiety disorders and OCD also self-administered (self-help materials in booklets or online) or internet-delivered therapy (e.g., Higa-McMillan et al., 2016).

For externalizing disorders, well-established CBT treatments include behavior therapy programs for parents, children and/or teachers, and programs addressing the organizational problems of children with ADHD (Evans et al., 2014; Kaminski & Claussen, 2017; McCart & Sheidow, 2016). Across internalizing and externalizing disorders, CBT is found effective in reducing symptoms of the targeted disorder and increasing remission. Across the different internalizing disorders, the pre-post-treatment effect size for disorder-specific outcome measures has been large, and over half of the youth who started treatment achieved remission. Furthermore, outcomes have been maintained or improved at follow-up, and the attrition during CBT has been low (varying from 6% drop-out for OCD to 15% for depression and PTSD). For externalizing disorders, the effect sizes have been moderate to large for behavioral outcomes (Fabiano et al., 2015), and moderate for disruptive behavior (Battagliese et al., 2015), and with a low attrition rate (<12% for ADHD and CD-ODD).

Effectiveness of CBT in Routine Care

The evidence of empirically supported treatments such as CBT rests mainly on randomized controlled trials (RCTs) conducted in specialized university research clinics. An important question has been how well CBT holds up when transported and delivered in routine clinical practice. Concerns about the generalizability of results from RCTs arise from the assumptions that clients, therapists, and treatment contexts may all differ in important ways between research clinics and routine clinical care (e.g., Weisz et al., 2013b). For instance, studies from research clincs often apply more rigorous inclusion and exclusion criteria, resulting in more homogenous samples compared to clients in routine clinical care. Furthermore, studies from research clinics may apply more extensive traning, supervision and treatment monitoring of therapists and have staff and facilities dedicated to research. As such, treatment programs developed and evaluated under highly controlled conditions in specialized research settings may not produce similar results when delivered in routine clinical practice (Weisz et al., 2013a).

During the last 20 years, a growing number of effectiveness studies in nonuniversity clinics have been published. Findings from such studies provide important information to clinicians and decision makers as to whether empirically supported treatments can be expected to yield the intended results when implemented in routine clinical care.

Importantly, CBT has shown favorable outcomes in routine clinical care for internalizing disorders (Wergeland et al., 2021) and externalizing disorders (Riise et al., 2021), with treatment outcomes (within-group effect sizes and remission) comparable with results obtained in university research clinics. These results show that substantial effects can be obtained when delivering CBT for internalizing and externalizing disordes in routine clinical care, and that clinicians and patients can be confident about the effectiveness of CBT interventions with already established efficacy when delivered in routine clinical care.

The Need for Developmental Sensitive Adaptations of CBT

The first CBT manuals for treating mental health problems among children and adolescents were developed in the early 1990s (e.g., Coping Cat by Kendall & Hedtke, 1992). These manuals were adaptions of CBT to fit the developmental level (cognitive, emotional, social) of school children and adolescents. Later a range of manuals have been developed for different psychosocial problems and disorders in youth, adapted to different age groups, including preschool children (e.g., Rapee et al., 2010). Knowledge about and competence regarding how to deliver developmental-sensitive CBT are critical for *all* therapists who want to do CBT with children and adolescents.

Cognitive behavioral therapy involves active participation from youth in defining the goals for the treatment, practicing new skills between sessions (e.g., coping and self-control skills), and exploring inner mental states, i.e., thoughts, feelings, and physical sensations. Cognitions and cognitive processes are assessed and challenged (i.e., cognitive restructuring), new behaviors and strategies are learned (e.g., problem-solving, relaxation techniques, exposure, behavioral activation), and connections between thought, feelings, and behavior are established. Also, children receive psychoeducation introducing them to CBT rational and methods. All these therapeutic tasks need to be adjusted to the developmental level of the youth.

To explore and challenge one's own thinking requires that the youth can think about his/her own thinking (meta-cognition). Whereas early metacognitive skills have been observed in preschool years (e.g., awareness of the source of one's knowledge), the cognitive and affective abilities required for more advanced meta-cognitive skills (assessing and reflecting upon one's own thought processes) are not fully developed before adulthood (Kuhn, 2000). Thus, the cognitive restructuring, the Socratic dialogue techniques, as well as other cognitive, emotional, and behavioral techniques used in CBT need to be adjusted to fit the developmental level of the child.

Cognitive behavioral therapists need to understand and recognize normative stages in the cognitive development of youth. This is necessary to evaluate whether cognitions and cognitive strategies need to be challenged (whether they are "unhelpful" or not). For example, what is found to be normal cognitive processes among preschool children (e.g., egocentric thinking or "black and white - thinking") is considered as cognitive distortions when working with older adolescents or adults (Grave & Blissett, 2004).

The role of youth developmental status may also impact treatment outcomes from CBT. For example, treatment outcomes have been found to be worse for teenaged school refusal compared to younger children with school refusal, probable due to adolescents with school refusal being more depressed and more social anxious than their younger counterparts (Heyne et al., 2014). However, more generally, treatment effects from CBT seem to be better among adolescents compared to younger children (Grave & Blissett, 2004). An explanation of this could be that psychosocial problems among younger children to a larger degree are caused by lack of knowledge, experience, or skills (e.g., deficiency in social skills), whereas problems in older children and adolescents are more related to cognitive distortions (e.g., such as "nobody likes me", "others think I'm stupid"). This has consequences for the choice of treatment strategies, as treating problems due to lack of knowledge or skills involve psychoeducation and learning new skills, whereas cognitive distortions should be treated with cognitive techniques.

Strategies to Make CBT Developmental Sensitive

In the following, we discuss some common strategies that have been suggested to make CBT developmental sensitive (Friedberg & McClure, 2015; Grave & Blissett, 2004; Haugland, 2011).

Level of Parental Involvement CBT with youth usually includes involvement of parents and other significant persons in the youth's life (teacher, coach, siblings, grandparents, friends) who may also be included in the therapy. Having a systemic approach is considered crucial for a developmental sensitive CBT. Thus, important persons in the youth's life need to be involved in assessment, case formulation, and treatment (Friedberg & McClure, 2015). However, in general, level of parental involvement is lower in CBT with adolescent patients where autonomy and self-determination are important developmental issues. Considerable higher level of parental involvement is found in CBT with young children. In some manuals, parents of preschool children may even participate in parent guidance programs where minimal or no child involvement is included (e.g., Rapee et al., 2010; Webster-Stratton, 2012). In addition to developmental level, the child's diagnosis and presence of parental psychopathology also influence level of parental involvement (Barmish & Kendall, 2005).

Engagement in Treatment Goals Children are here-and-now oriented. This may represent a challenge for their maintenance of treatment motivation, especially if treatment goals are expected to be reached sometime in the future, and if the youth has not been actively engaged in deciding treatment goals. We need to ensure that the treatment goals are in accordance with the youth's experience of the situation, his/her interests, and that the goals comply with important developmental tasks (e.g., establish relationship with peers, learn to be independent).

Frequent Use of Positive Reinforcements Youth motivation may also be maintained through frequent use of positive reinforcement. Therapists, parents, and teachers are encouraged to apply verbal praise (e.g., "you are doing a great job practicing to control your angry outbursts", "I am impressed by the ideas you have on how to make friends with other kids during recess"), to introduce rewarding activities (e.g., having a friend over for the night, choosing what to have for dinner), and administer tangible rewards (e.g., a small toy, a magazine). This is done to reinforce the youth when showing positive behavior, practicing skills, and participating in treatment activities. Importantly, all rewards need to be adjusted to the youth's developmental level, interests, and desires.

Applying Behavioral Techniques Due to the limited cognitive development in prepubertal children, CBT therapists often rely on behavioral techniques (e.g., skills training, modelling, behavioral activation) rather than cognitive techniques, in the treatment of preschool and early school-aged children (Friedberg & McClure, 2015; Shirk, 2001). For example, direct or in vivo exposure to feared object or situations is recommended for young children, instead of imagined or in vitro exposures, because visualization of imagined situations or objects can be challenging for young children (Ollendick et al., 2001). The use of behavioral techniques may also be important since problems in young children may partly be related to deficiencies in knowledge, experience, and skills, rather than cognitive distortions.

Applying Less Complex Cognitive Techniques CBT therapists also use cognitive interventions with children. In the same manner as with adults, youth may demonstrate different types of unhelpful thoughts associated with different psychological disorders ("the cognitive content-specificity hypothesis"; Schniering & Rapee, 2004). For example, depressed youth more frequently express thoughts about being a failure, whereas youth with disruptive behavior more frequently express thought of hostility and revenge. In CBT with youth who are cognitive immature and have limited ability for abstract thinking and metacognition, we often choose less sophisticated and more simple cognitive interventions. These can be to introduce differences between "helpful" and "unhelpful thoughts" and to search for positive self-instructions or identify coping statements. For young children, the positive self-statements should be closely related to the challenge they need to face (e.g., "I am brave who dear to walk past dogs on the side-walk"), whereas for older children, self-instructions or coping statements can be more generalized (e.g., "I am willful and strong and often succeed in achieving my goals"). The more sophisticated levels of cognitive restructuring (e.g., analyzing, synthesizing, and reevaluating one's own cognitive distortions) are used with mature adolescents, whereas less advanced cognitive interventions, such as identifying thoughts and the relationship between thoughts, feelings and behavior, are applied also with younger children (Grave & Blissett, 2004).

Making Interventions Relevant, Engaging, and Fun Not only the content of the interventions, but also how interventions are presented needs to be developmentally sensitive (Haugland, 2011). Limited abilities for logical reasoning and metacognition are compensated by using familiar concepts, words, ideas, and examples from the everyday life and experience of the youth (e.g., "the same way you needed to practice when learning to swim and to ride your bicycle, you also need to practice your CBT anxiety management skills"). Therapeutic goals and technique may be linked to the youth's interests and hobbies (e.g., "to be able to endure disappointments and to achieve success, a football player needs to remind herself about her strengths, skills, and spirit, as well as the goals she wants to achieve"). Therapeutic issues are frequently introduced through metaphors, play activities, analogies, acronyms, and by applying concrete tools and materials (e.g., stories, pictures, films, games, songs, heroes, and cartoons). The last 20 years a range of CBT manuals and guides have emerged with ideas and examples on how to make treatment interesting, engaging, and fun for youth with different developmental levels and with different problems (e.g., Friedberg et al., 2009; Phifer et al., 2017; Stallard, 2019). Through stories, heroes, metaphors, and externalizations, abstract concepts and processes are made concrete and understandable. Negative self-talk can, for example, be identified through computer games where the youth fights with enemies that are trying to make her believe she is worthless, stupid, a failure, and have no control over her feelings, thoughts, or behavior. Metaphors (e.g., "controlling the volcano threatening to burst with anger") may make youth understand complex issues such as ambivalence, negative thoughts, self-control, etc. However, to be engaging and fun, creative techniques need to be closely adapted to the interests and developmental level of the youth. Being too childish, as well as being too advanced, in the choice of heroes, metaphors, activities, etc. will increase the likelihood of losing the youth's interest and failing to engage him/her in the therapeutic process.

Summing Up

CBT is an effective treatment for a range of common mental health disorders during childhood and adolescence. However, the models, interventions, material, and treatment procedures need to be adjusted to fit the developmental level of the individual youth, as well as his/her problem and situation. By implementing developmental-sensitive CBT, therapists increase the likelihood that youth establish and maintain motivation, engagement, treatment alliance, and achieve a positive treatment outcome.

Classical Conditioning

21

Christiane Hermann and Matthias F. J. Sperl

Introduction

Classical conditioning (also called *Pavlovian* conditioning; Pavlov, 1906) is presumed to contribute to the etiology of mental disorders such as anxiety disorders, and its principles underlie various intervention strategies for childhood psychopathology. How, for example, does a child with a dog phobia develop such an exaggerated fear of dogs? And how can intervention techniques based on classical conditioning mechanisms help to ameliorate psychopathological symptoms? Classical conditioning describes a learning mechanism through which external (e.g., visual, auditory, olfactory, haptic, contextual) or internal (e.g., interoceptive) stimuli become associated with motivationally relevant events, which can be either appetitive (e.g., the delivery of food or a psychotropic substance) or aversive (e.g., pain). Thus, through classical conditioning, individuals learn that certain cues (i.e., so-called "conditioned stimuli") predict pleasant or unpleasant events. Aversive conditioning enables individuals to avoid potential dangers before they occur or to prepare for unpleasant events and thus reduce negative consequences (Domjan, 2005). Conversely, through appetitive conditioning, new stimuli can acquire reward-related motivational salience (Martin-Soelch et al., 2007).

Aversive Conditioning: Learning to Fear

Being able to anticipate and predict potentially dangerous events has been highly advantageous in the evolutionary past. During aversive conditioning (often referred to as "fear conditioning"), an innocuous cue (e.g., a visual stimulus) is paired with an unpleasant *unconditioned stimulus* (US). The US (e.g., a loud noise in experimental studies) is often a motivationally salient stimulus that automatically and naturally evokes a defensive response, which does not require prior learning. If infants are startled by a loud noise or movement, they throw their arms and legs out symmetrically. This reflexive behavior, which occurs naturally in response to the US, is called the *unconditioned response*. After being paired with the US, the innocuous cue becomes a so-called *conditioned stimulus* (CS), which predicts the occurrence of the US and, thus, evokes fear. The CS does not necessarily have to be an external

cue; internal bodily sensations (e.g., irregular or racing heartbeat, nervousness) can also serve as a CS (Mineka & Oehlberg, 2008). The learned threat response that is elicited by the CS is called the *conditioned response*. Conditioned and unconditioned responses are often similar, but can also be qualitatively different. Under certain circumstances, the conditioned response may even be opposite in direction to the unconditioned response. Prominent examples are drug-like and drug-opposite conditioned responses in drug abuse; this is particularly important for understanding conditioned tolerance and withdrawal symptoms, which will be explained later in this chapter.

The key concepts of classical conditioning can easily be illustrated (see Fig. 21.1). Being bullied at school during childhood and adolescence, for example, can cause significant negative emotional experiences (the unconditioned response). Bullying would be the US in the classical conditioning terminology. After repeated bullying experiences, students may associate the school environment (the CS in the classical conditioning terminology) with “being bullied.” Afterward, the school environment may trigger excessive fear (the conditioned response). This may even terminate in a persistent refusal to go to school and severe mental health problems (Heyne et al., 2014). Similarly, if students are humiliated in a math course by their teacher (this experience would be the US), this could contribute to major learning and attentional problems. In future encounters with mathematics-related challenges (the CS), the previously conditioned aversion may be activated. This could lead to the avoidance of learning, and the affected child will probably not develop enthusiasm for mathematics. Thus, conditioned fear may act as a mediator that could ultimately terminate in persistent math problems throughout the student’s academic career. From a conditioning perspective, it would thus be crucial for teachers to create opportunities in the classroom that allow students to associate positive emotional experiences (i.e., an appetitive US) with learning (i.e., the CS).

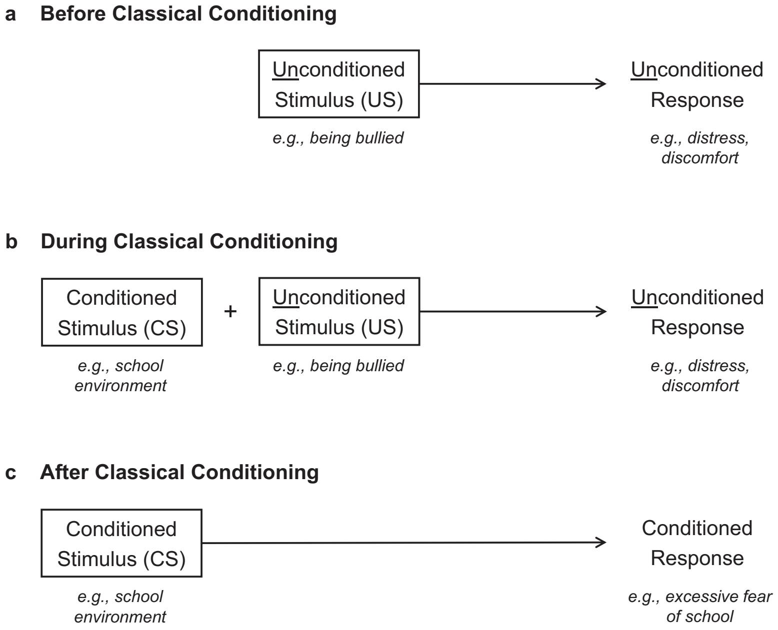

Fig. 21.1 Schematic illustration of classical conditioning. (**a**) Before conditioning, an unconditioned stimulus (US) is an event (e.g., being bullied) that automatically and naturally evokes an unconditioned response (e.g., distress, discomfort). (**b**) When the US (being bullied) is repeatedly paired with certain environmental cues (the conditioned stimuli, CSs; e.g., the school environment), an excitatory CS–US association becomes established. (**c**) After successful conditioning, the CS evokes a conditioned fear response (e.g., an excessive fear of school), even in the absence of the US

Even before researchers began to study classical conditioning extensively in adult humans, mechanisms related to aversive learning were investigated in an 11-month-old child ("Little Albert"); this became famous as the first human fear conditioning study (Watson & Rayner, 1920). In this study, the child "Albert" acquired a robust fear of a white rat after this rat (i.e., the CS) had been paired with an aversive noise (i.e., the US). In addition, it was tested whether fear responses would extend beyond the white rat (the CS). Indeed, "Albert" was also afraid of other animals and objects that were similar to the rat (e.g., a rabbit, a fur coat, and cotton wool). This observation was later called "fear generalization" (Van den Bergh et al., 2021). Generalization of conditioned fear occurs when a threat response, which has been acquired for a particular CS, transfers to other related stimuli that are perceptually, conceptually, or symbolically similar (but have never been paired with the US). Referring to the example above, the child's fear of mathematics could also transfer to other school subjects (e.g., physics). Experimental studies have identified generalization gradients. The greater the physical difference between the CS and the generalization stimulus, the smaller the fear response to the generalization stimulus (Dymond et al., 2015).

From today's perspective, the methodology of the "Little Albert" study raises many ethical concerns and methodological pitfalls (Fridlund et al., 2020). Nevertheless, it became one of the most famous studies in psychology and contributed to the awareness of conditioning principles in young children. The "Little Albert" experiment describes a "single-cue" protocol, as threat responses were conditioned to *one* CS (the white rat). Modern conditioning studies typically apply protocols that involve the presentation of *two* CS types (Lonsdorf et al., 2017). One of the two CSs (the so-called CS+) is repeatedly paired with a US, while the second CS (the so-called CS−) remains unpaired. Larger threat responses (e.g., perceived valence of the CS, heightened autonomic arousal, and activation of the amygdala) to CS+ versus CS− indicate successful fear acquisition. The use of two CS types allows researchers to disentangle excitatory (CS+, "threat") and inhibitory (CS−, "safety") learning processes.

The majority of experimental fear conditioning studies have used neutral visual stimuli like geometric shapes (e.g., Waters et al., 2017) or pictures of faces (e.g., Chauret et al., 2014) as the CS. Male faces seem to be particularly well suited for fear conditioning in adults, due to their relevance in the evolutionary history (Kret & De Gelder, 2012). Chauret et al. (2014) investigated the associability of male versus female faces as the CS in 10- to 17-year-old adolescents. Male (compared with female) faces triggered increased fear ratings in both boys and girls, although CS-evoked skin conductance responses suggested a proneness for "own-sex" faces to become a fear-conditioned CS (Chauret et al., 2014). With regard to the US, most fear conditioning studies in adults have employed highly unpleasant stimuli like loud noise bursts or electric shocks (e.g., Sperl et al., 2016). However, intense stimuli such as an electric shock are not appropriate for fear conditioning research in certain populations, like infants, children, and adolescents. Several researchers have developed US types that are more suitable for these groups, which include an air blast to the larynx (Pine et al., 2001) or a fearful female face paired with a shrieking female scream (Glenn et al., 2012; Lau et al., 2008).

Both contiguity and contingency are important for learning (Papini & Bitterman, 1990; Rescorla, 1988). Contiguity means that the CS and US are connected in time and space. Events that are experienced at a similar time and/or place tend to become associated. Depending on how small or large the temporal and spatial distance between the CS and US is, conditioning is more or less effective. Furthermore, the more often the CS and US are experienced as contiguous, the more strongly they become associated. Thus, contingency refers to the informational value of the CS as a predictor of US occurrence. After successful conditioning, the CS predicts the US with a certain probability. A positive CS–US contingency (i.e., the US is *more* probable with the CS than without it) leads to excitatory conditioning. Conversely, a negative CS–US contingency (i.e., the US is *less* probable with the CS than without it) results in inhibitory conditioning. Finally, if there is zero contingency between the occurrence of the CS and the US, the US does not depend on the presence or absence of the CS. A strong fear of school may develop, for example, if a student experiences bullying at school (contiguity) almost every day (contingency). Fear conditioning typically requires several learning experiences. Nevertheless, experimental research suggests that, under certain circumstances, a single CS–US pairing may actually be sufficient for fear learning (Lipp et al., 2015). Thus, classical conditioning also helps to explain the etiology of trauma-related disorders, which are often triggered by a single terrifying event.

During threatening experiences, both explicit (conscious) and implicit (nonconscious) memory traces are encoded in the brain (Tao et al., 2021; LeDoux, 2014). Some individuals experience distress in certain situations even though they know that they are objectively safe. When threat is processed explicitly, the fearful nature of a stimulus or situation is obviously recognized by an individual. In contrast, implicit threat processing can occur even when a person is not subjectively aware of the threat. Over time, explicit memories often fade or become altered. However, even if somebody forgets about a threatening situation, implicit (nonconscious) memory traces with regard to the threatening event may persist. Confrontations with certain environmental cues or situations can then elicit bodily fear symptoms, even if one cannot explicitly remember the origins of the threat. Implicit threat associations are particularly enduring and resistant to change. The differentiation between explicit and implicit memory processes helps to explain why aversive conditioning events may be responsible for long-lasting experiences of distress, even if one is eventually unable to explicitly recall a threatening event (Alberini & Travaglia, 2017).

In terms of a precise terminology, classically conditioned fear needs to be differentiated from anxiety (Perusini & Fanselow, 2015; Schmitz & Grillon, 2012). When faced with an immediate danger, humans react with hardwired defensive behavior (i.e., the unconditioned response). Fear is part of an alarm reaction (i.e., the conditioned response) in anticipation of an imminent threat that is very close in time. As outlined above, fear can be learned through classical conditioning. In contrast, anxiety is not necessarily elicited by a specific (conditioned) stimulus. Instead, it refers to a rather sustained state of worry about *potential* danger in the future. Unlike fear, anxiety usually does not reliably and validly predict the occurrence of future danger. When moderate, anxiety can be helpful, as it prepares an individual for possible threat. A state of heightened anxiety may *facilitate* the activation of classically conditioned fear.

The Developmental Trajectory of Fear Learning

Despite its origins in the “Little Albert” study, experimental fear conditioning research in humans has mostly focused on adult participants (Biggs et al., 2020; Lonsdorf et al., 2017). However, epidemiological studies show that childhood and adolescence are high-risk periods for the pathogenesis of anxiety disorders (de Araújo Scattolin et al., 2021; Solmi et al., 2021); these observations could be related to altered, age-related changes in the relative importance of excitatory, inhibitory, and generalization mechanisms (Casey, 2015; Ferrara et al., 2021). Children report many fears, and these childhood fears are often part of their normal development (Muris et al., 2000; Weems & Costa, 2005). In most individuals, these fears decrease with age as adolescents learn to differentiate between threat and safety (Gullone, 2000; Lau et al., 2011). This shift can be attributed to improved discrimination learning, as adolescents acquire the ability to better distinguish between excitatory threat cues and inhibitory safety cues. Notably, this developmental change is also visible in basic fear conditioning paradigms. Experimental studies suggest that the magnitude and speed of fear conditioning increase with age from childhood to adolescence and adulthood (Glenn et al., 2012; Jovanovic et al., 2014; Lau et al., 2011; Reinhard et al., 2022; Waters et al., 2017). In particular, children younger than 10 years show diminished differential (i.e., CS+ versus CS−) fear acquisition (Jovanovic et al., 2014), which has been linked to higher anxiety and an altered amygdala–prefrontal circuitry (Gee et al., 2013). In younger children, discrimination between threat and safety seems to rely more on subcortical (e.g., amygdala) activity (Lau et al., 2011). Greater maturation of the prefrontal cortex may contribute to better differential fear conditioning (i.e., threat/safety differentiation) in older subjects (Ferrara et al., 2021). Implicit and explicit threat processing are mediated by (at least partially) different brain circuits (Tao et al., 2021). While implicit threat processing involves mainly subcortical brain regions (e.g., the amygdala), cortical regions are of greater importance in explicit learning (Alberini & Travaglia, 2017; LeDoux, 2014, 2017). Implicit threat learning is especially prominent in younger childhood (Ferrara et al., 2021; Lau et al., 2011); these implicit memories (e.g., childhood trauma) may have great impact on adult behavior, even though adults are often not explicitly aware of these experiences ("childhood amnesia"; Alberini & Travaglia, 2017). With increasing age, explicit learning processes become more dominant, which leads to higher levels of contingency awareness during fear conditioning. In line with this hypothesis, differential fear conditioning increases with age, which has been linked to a decline in threat overgeneralization (Reinhard et al., 2022). Specifically, children (compared with adolescents and adults) require more CS–US pairings (i.e., more learning opportunities) to acquire differential conditioned fear responses (Reinhard et al., 2022; Waters et al., 2017). In addition, after the presentation of safety signals (CS− trials), children are more uncertain about the absence of the US (Waters et al., 2017). At younger ages, this elevated generalization of fear is highly adaptive. Generalization stimuli are typically similar but not identical to the fear-conditioned CS. In terms of a "better safe than sorry" strategy (Van den Bergh et al., 2021), generalization of fear to ambiguous stimuli leads to somewhat cautious behavior in potentially dangerous situations during childhood, which can be highly protective and critical for survival. Overgeneralization of fear, i.e., heightened generalization to a wider range of stimuli similar to the CS, is particularly important when encountering new environments as a child. Nevertheless, it becomes less efficient with more and more experience during adolescence. Concomitantly, discrimination learning is sharpened across development, and generalization of conditioned fear decreases with increased age (Reinhard et al., 2022; Schiele et al., 2016). If, however, a child maintains a tendency to overgeneralize, this could be a critical risk factor in the etiology of anxiety disorders. In line with this hypothesis, overgeneralization of classically conditioned fear has been linked to anxiety disorders in adult patients (Dymond et al., 2015).

Fear Conditioning – A Promising Translational Model for Anxiety, Fear, and Trauma-Related Disorders?

Over the past decades, several theories (De Houwer, 2020; Lissek et al., 2005; Mineka & Oehlberg, 2008; Ressler, 2020) have linked classical conditioning to the etiology and pathogenesis of anxiety disorders (e.g., specific phobias, social anxiety disorder), obsessive-compulsive disorders, and trauma-related psychopathology (e.g., posttraumatic stress disorder, abbreviated as "PTSD"). Given that anxiety disorders are the most frequent mental disorders affecting children and adolescents (Polanczyk et al., 2015), classical conditioning in the context of pathological anxiety and fear is of particular relevance for clinical child psychology.

The "conditioning model" of anxiety disorders suggests that direct experiences (i.e., CS–US pairings) lead to the development of pathological fear and anxiety. Accordingly, a child who has been bitten by a dog (the bite would be the US), for example, should be at elevated risk of developing a phobia of dogs (the dog would be the CS). Being trapped in an elevator (this frightening event would be the US) could be an important traumatic conditioning experience for the etiology of claustrophobia and lead to an exaggerated fear of using elevators (the elevator would be the CS). A young girl who experiences an unexpected panic attack (the US) during a stressful oral examination (the CS) could develop a heightened fear of social situations. Highlighting the role of aversive conditioning events for the subsequent development of psychopathology, adults with social anxiety disorder experienced childhood teasing experiences more frequently (McCabe et al., 2010). A history of teasing or bullying has also been related to earlier symptom onset and additional problems in childhood and adolescence (McCabe et al., 2003), emphasizing the critical role of direct conditioning early in life. Similarly, children experiencing natural disasters, sexual abuse, or serious car accidents (i.e., examples of USs) are at risk of developing PTSD. Child survivors (10–13 years) of a severe lightning-strike disaster (the US) in Illinois reported significantly more numerous and intense fears of storms (the CS) when compared with a matched nontraumatized group (Dollinger et al., 1984). In particular, implicit conditioning leads to a broad range of potential triggers for intrusive memories in trauma-related disorders (Brewin, 2014). A certain noise, smell, word, or image (the CS) that has been associated with the traumatic event (the US) may later elicit reexperiencing or intrusion, with the child not necessarily being aware of the actual trigger (the CS) of the emotional response.

At first glance, classical conditioning seems to have difficulty explaining the symptoms of panic disorder. In this anxiety disorder, patients experience unexpected panic attacks, which often occur in the absence of obvious (external) cues or triggers. Panic attacks literally seem to come "out of the blue." Bouton et al. (2001) have emphasized the critical role of interoceptive conditioning in understanding panic disorder. Through this process, panic attacks are conditioned to internal cues. Internal bodily sensations (e.g., modest changes in heart rate or respiration) that go along with the early onset of a panic attack become a predictor of the full-blown panic attack. These interoceptive sensations become a CS through classical conditioning and might become sufficient to trigger panic attacks in the future (Mineka & Oehlberg, 2008).

The Two-Factor Theory: Learning About Escape and Avoidance

Individuals with anxiety disorders tend to avoid certain and specific things or situations (e.g., attending a party may be hard to tolerate for a patient with social anxiety disorder). Mowrer's (1951) two-factor theory proposes that avoidance and escape behaviors result from both classical and operant conditioning. In the first step, individuals learn through classical conditioning that a particular stimulus (the CS) is followed by an aversive event (the US). Children who have received negative feedback from their teacher (the US) may feel anxious before their next presentation (the CS) in class. In the second step, the individuals learn (through operant conditioning) that escape or avoidance behavior causes a reduction of fear. In the example, these children may feel sick in the morning before their presentation and stay home. In the short term, this leads to a reduction in fear and anxiety. In the long term, however, this avoidance behavior confirms the child's assumption that being at school is "dangerous," which provokes increased anxiety symptoms when preparing for school. Ultimately, this vicious circle may lead to a severe anxiety disorder. As another example, somebody who has experienced a panic attack (the US) in a shopping mall (the CS) may stay home and avoid going shopping.

This theory can also be applied to obsessive-compulsive disorder. Consider a young boy who has a disgust-provoking experience in a dirty school restroom. Just as he is about to use the toilet (the CS), he finds a urine stain (the US) on the toilet seat. Through this experience, the boy might acquire a fear of toilet germs (classical conditioning). Subsequently, he tries to avoid using public restrooms whenever possible. When the use of restrooms at school cannot be avoided after all, he experiences high distress. This negative feeling can be reduced by compulsive hand washing and disinfecting rituals (operant conditioning). The etiology of obsessive-compulsive disorder cannot always be explained exclusively by classical and operant conditioning. In particular, cognitive processes play a major role in many cases (Salkovskis, 2007). Nevertheless, the two-factor model is particularly powerful in explaining the *maintenance* of obsessive-compulsive symptoms.

Biological Dispositions in Classical Conditioning

The two-factor theory helps to explain avoidance and escape behaviors, which are often observed in anxiety disorders. It cannot explain why people are more likely to acquire fear of certain situations or objects (e.g., snakes, spiders) than of other things (e.g., cars, chainsaws). The concept of "preparedness" (Seligman, 1971) suggests that humans are evolutionarily "prepared" to quickly associate certain stimuli or events (the CSs) with an unpleasant outcome (the US). A similar theory emphasizes the CS–US "belongingness," which refers to the conceptual relation between both stimuli (Garcia & Koelling, 1966). Accordingly, certain CS–US stimulus pairs are better associable because they "belong" together, for example because of their semantic or sensory relatedness (Hamm et al., 1989). Lissek et al. (2008) demonstrated elevated fear conditioning in patients with social anxiety disorder (compared with healthy controls) when socially relevant CSs (neutral facial expressions) and socially relevant USs (critical facial expressions combined with verbal insults) were used. Their findings (Lissek et al., 2008) emphasize the importance of considering CS–US "belongingness" (Hamm et al., 1989) in experimental paradigms when researchers attempt to detect classical conditioning patterns that are altered in patients with anxiety disorders.

Supporting the "preparedness" theory, several experiments (Mineka & Öhman, 2002) demonstrated better conditioning to fear-relevant, potentially "phobic" CSs (e.g., illustrations of snakes and spiders) relative to fear-irrelevant CSs (e.g., flowers and geometric figures). Notably, infants as young as 6 months of age show increased pupillary dilation (i.e., high physiological arousal) to spiders and snakes compared with flowers and fish (Hoehl et al., 2017), supporting the notion that certain stimuli are "prepared" to elicit distinct responses, even very early in life. For a long time, there was a debate about the origin of fears that seem to be evolutionarily "prepared." Traditionally, two explanations have been discussed. On the one hand, it has been suggested that humans show an innate fear (Poulton & Menzies, 2002) of certain animals (e.g., spiders, snakes) or situations (e.g., heights), which dissipates with repeated nonnegative experiences throughout childhood (Gullone, 2000; Lau et al., 2011). On the other hand, facilitated conditioning has been assumed to account for fear acquisition, especially for biologically "prepared" CSs (Mineka & Öhman, 2002). Given that many children show fears of spiders and snakes, infants may have an innate predisposition to associate these animals with fear. LoBue and Adolph (2019) argue that both views are too simplistic. Instead, they propose that "prepared" conditioning to evolutionarily relevant stimuli is not necessarily adaptive. Rather, it seems better to *flexibly* learn a particular fear as soon as a specific situation requires it. LoBue and Adolph (2019) argue that children have early perceptual and attentional biases for detecting certain animals like snakes and spiders, for example. When confronted with these animals, the children respond with changes in heart rate, vocalization, exploration, and sometimes even approach behavior. In the past, these behavioral and physiological responses were often mislabeled as "fear," rather than as concomitant responses to the allocation of attentional resources (LoBue & Adolph, 2019). Importantly, their view extends classical conditioning. When infants and children show increased attention to certain animals, such as snakes, this allows them to flexibly develop a fear when the animal is actually dangerous. However, other emotions (e.g., joy) can also be learned if the animal is cute, for example. This flexible adaptation occurs through learning processes, such as aversive (or appetitive) classical conditioning.

The Flexibility of Aversive Conditioning

Does everyone who experiences a threatening or traumatic event develop a serious mental disorder? Certainly not. The presence of multiple cues potentially serving as a CS (so-called "cue competition"; Boddez et al., 2014) and prior exposure to a stimulus (Miller et al., 2022) both help to understand why classical conditioning can be prevented or delayed under certain circumstances. Fear acquisition is most effective when both the CS and the US are *new* to an individual. Latent inhibition describes the phenomenon that prior experiences (i.e., before conditioning) with the to-be CS (without the US) impair subsequent fear conditioning (Miller et al., 2022). In the clinical context, this would mean that people who undergo a highly aversive dental treatment are less likely to develop phobic fear if they have a history of neutral or less aversive experiences at the dentist's office (De Houwer, 2020). Indeed, preventive measures based on latent inhibition seem to be promising in protecting against exaggerated dental anxiety (Miller et al., 2022). Similarly, if a child has had good experiences with a dog (e.g., playing with a dog, petting a dog), this positive learning history can "immunize" (Panitz et al., 2021) the child against later development of dog phobia, even if the child has an unpleasant encounter with a dog later on (e.g., being bitten). Behavioral strategies based on latent inhibition principles may open new avenues for preventing anxiety and related disorders. Not only does pre-exposure to the CS lead to retarded fear learning, but familiarization with the US (known as "US pre-exposure") can also interfere with subsequent conditioning and reduce its effectiveness as a US (Lonsdorf et al., 2017). Depending on prior experience with certain stimuli or situations, a conditioning event can lead to a number of different consequences.

In the aftermath of aversive or traumatic experiences (in the range of hours to days), hyperconsolidation of conditioned associations seems to be critical for the development of anxiety or trauma-related disorders. In particular, emotionally arousing events (e.g., a car accident, rape, or sexual assault) go along with enhanced memory consolidation (LaLumiere et al., 2017). Emotional arousal activates brain systems (e.g., through noradrenergic and glucocorticoid actions) that influence how these memories are processed, stored, and consolidated (Giustino & Maren, 2018; Merz & Wolf, 2017; Sperl et al., 2022). Estradiol status further modulates fear conditioning (Bierwirth et al., 2021; Merz et al., 2018), which could explain why girls and women (compared with males) are more vulnerable to developing anxiety and trauma-related psychopathology (Seligowski et al., 2020). It has been suggested that sex differences in the brain's noradrenaline arousal systems may be responsible for elevated arousal levels in females (Bangasser et al., 2016), which could lead to stronger consolidation of aversive associations.

Exaggerated Fear: Elevated Excitatory and/or Deficient Inhibitory Responding?

Several theories suggest that individuals who are prone to develop pathological anxiety may more easily be conditioned (Lissek et al., 2005; Mosig et al., 2014; Orr et al., 2000). Possibly, heightened excitatory (i.e., elevated and more rapidly acquired fear responses to threat cues) and deficient inhibitory (i.e., a failure to inhibit fear in the presence of safety cues) conditioning may account for facilitated fear acquisition (Dvir et al., 2019). Experimental studies provide mixed support for these hypotheses (Marin et al., 2017; Pöhlchen et al., 2020). Inconsistent findings may arise from many studies employing relatively nonspecific stimuli for CS and US, disregarding the relevance of "preparedness" and "belongingness" (Hamm et al., 1989; Mineka & Öhman, 2002). Based on their meta-analysis, Lissek et al. (2005) reported stronger fear acquisition in patients with anxiety disorders and PTSD compared with healthy controls, but the effects were small. These findings are complemented by a more recent meta-analysis of Duits et al. (2015), which included patients with anxiety disorders, PTSD, and obsessive-compulsive disorder. Relative to healthy participants, patients robustly showed elevated threat responses to conditioned safety cues (the CS− in differential conditioning experiments), indicating an impaired ability to suppress fear and an enhanced fear generalization to safe stimuli.

Generalization of conditioned fear is adaptive during childhood, but usually decreases with increasing age (Waters et al., 2017). A recent meta-analysis (Dvir et al., 2019) explicitly focused on fear conditioning in childhood/adolescence and compared clinically anxious with non-anxious youth. The groups did not differ in differential (i.e., CS+ compared with CS−) fear acquisition. Nonetheless, Dvir et al. (2019) found that anxious (versus non-anxious) youth showed greater threat responses for both danger (CS+) and safety (CS−) cues. Such a response pattern in patients may be interpreted as potentially indicating elevated excitatory responding to threat (CS+) and reduced inhibitory responding to safety (CS−) cues (Craske et al., 2008); this would be in line with the assumption of threat overgeneralization in anxious individuals (Dymond et al., 2015). It should be noted that, in this meta-analysis (Dvir et al., 2019), studies focusing on different anxiety disorders were collapsed; this makes it even more difficult to identify patterns that are related to a specific disorder (Lang & McTeague, 2009).

Fear Conditioning in the Absence of Direct Aversive Experiences

The classical conditioning model suggests that direct aversive experiences (i.e., CS–US pairings) play a critical role in the acquisition of pathological fear and anxiety. Yet, many patients cannot recall direct traumatic US experiences (such as a dog bite) in their past (Moscovitch et al., 2011). Indeed, direct experiences of CS–US associations are actually not necessary for the development of robust conditioned threat responses. Specifically, observational/vicarious learning, verbal information transmission, and imagery-based conditioning are examples of how fear can be conditioned through indirect paths.

Observational fear conditioning describes a learning process through which an individual acquires fear vicariously through watching the fearful response of another person who experiences an unpleasant situation (Haaker et al., 2017). It is important that the observer does not receive any aversive US (e.g., a painful noise or shock). Instead, the US is perceived vicariously by the observed model. The observer acquires a conditioned fear response by watching the model's distress in response to the CS. Marin et al. (2020) experimentally investigated observational fear conditioning in child–parent dyads. Children watched videos in which their parents were fear-conditioned with an electric shock US. Even though the children themselves did not receive a shock, they acquired fear. When exposed to the CS+, the children showed elevated skin conductance responses. Observational learning is of particular relevance for threat learning in children. By observing their parents' responses, children learn what is potentially dangerous and what is not. Observational learning may also, at least partially, contribute to the etiology of anxiety disorders in children. If a child observes the behavior of a parent suffering from an anxiety disorder (e.g., the mother screams when seeing a spider), vicarious learning may promote transmission of this maladaptive fear.

Verbal information is another indirect pathway for fear acquisition (Muris & Field, 2010). If parents provide threatening information about certain stimuli or situations, childhood fears may develop and eventually become a serious anxiety disorder. Telling a child that a certain animal is dangerous (e.g., "Watch out, the dog could be dangerous!") may elicit a mental representation of threat (the US), which becomes associated with characteristics (the CS) of this animal (e.g., a dog in a park) through classical conditioning. Muris et al. (2013) demonstrated successful transmission of verbal information from mothers to their offspring. The mothers provided information about a novel animal to their children. Half of the mothers talked about disgusting attributes of the animal. Disgusting characteristics were used because disgust (in addition to threat) plays a critical role in animal phobias. The other half of the mothers referred to neutral information about the animal. The children in both groups saw the same drawing of the novel animal. Notably, the children reported significantly elevated levels of disgust and fear of the animal when they had received disgust-related information. The results suggest that parental communication may also play a crucial role in the transfer of fear within families.

Finally, an imagined aversive event is sufficient for *de novo* fear conditioning (Mertens et al., 2020). In a study by Mueller et al. (2019), participants were trained to produce unpleasant mental images (e.g., experiencing pain when stepping on a thumbtack) upon presentation of a specific cue. Most importantly, the CS+ was never paired with any physical US, but only with the aversive imagery. Remarkably, the CS+ elicited a robust subjective and physiological fear response. Clinically, it is therefore possible to develop a dog phobia even if never bitten by a dog. When encountering dogs, the mere imagination of a dog bite (the US) could be sufficient for fear learning. In children, the imagination of dangerous animals or monsters (the US) could lead to strongly pronounced fear and avoidance of certain situations (the CS). Similarly, distressing images of oneself in an aversive situation at a party (the US; e.g., “people are laughing and pointing at me”) may contribute to the development and maintenance of social anxiety disorders (Clark & Wells, 1995). Intrusive mental images associated with aversive events are particularly important in the pathogenesis of obsessive-compulsive disorders (Maloney et al., 2019). A boy who meets a stranger and shakes the person’s dirty or sweaty hand (the CS) may have images of becoming contaminated with harmful germs (the US). Subsequent handshakes may now trigger obsessive thoughts, which can be reduced by ritualized handwashing behavior (compulsions) and/or avoidance.

Altogether, different pathways can explain how fear can be acquired, even in the absence of a direct aversive experience. Conditioning processes that do not require direct CS–US pairings are highly adaptive. In the example of dangerous spiders or snakes, it would not make sense to require being bitten or killed by these animals for successful fear acquisition.

Nature Versus Nurture in Pathological Fear

Some individuals are predisposed (e.g., based on their genetic background and early life experiences) to developing psychopathology throughout their life (Bowers & Ressler, 2015; Parsons & Ressler, 2013). The children of mothers with anxiety disorders and PTSD are at elevated risk of experiencing mental health problems (Hartzell et al., 2022; Schreier et al., 2008). For example, maternal PTSD increased the risk of PTSD in the offspring of Holocaust survivors (Yehuda et al., 2008). In principle, environmental information experienced by an ancestral generation can be transferred to descendants by social transmission and biological inheritance. Indirect conditioning experiences of the child (e.g., observational fear learning and verbal information from the parents, see above) are possible pathways for social transmission. In addition, *in utero* exposure to maternal stress and fear is another indirect mechanism that may explain the transmission of mental health risks across generations (Yehuda et al., 2005). When considering biological inheritance, *in utero* exposure must be differentiated from preconceptional experiences of the ancestral generation (Dias et al., 2015). In humans, (epi-)genetic inheritance and effects of social transmission are difficult to disentangle. Intriguingly, research in mice suggests that transmission of fear-conditioned behavior may, at least partially, contribute to the transgenerational transmission of risk for mental health problems (Dias et al., 2015). Dias and Ressler (2014) used olfactory conditioning to train mice to become afraid of a particular odor. Note that the mice were fear-conditioned *before* the conception of their offspring. Impressively, their offspring showed enhanced odor-potentiated startle, which was interpreted as an increased behavioral sensitivity to this odor. Critically, this effect persisted across two generations, even though the pups had never been exposed to this odor before testing. These results suggest that traumatic experiences can affect people so indelibly that impacts can even be observed on their children.

Fear Extinction: A Model for the Treatment of Pathological Fear and Anxiety

Excessive fear and anxiety are core symptoms of anxiety and trauma-related disorders (Ressler, 2020). A better understanding of fear inhibition is critical to improving the efficacy of therapeutic interventions for patients with exaggerated threat responses. Fear extinction is considered to be a key learning mechanism in exposure therapy (Craske et al., 2018; Raeder et al., 2020). In the laboratory, fear extinction paradigms are widely used to experimentally study the reduction of fear (Milad & Quirk, 2012). During fear extinction, the previously conditioned CS+ (and the CS−) are presented without the US. Repeated unreinforced CS+ presentations result in a decrease in conditioned fear responses. Hence, the conditioned responses become “extinguished” (Milad & Quirk, 2012). It is important to emphasize that the original excitatory CS–US association is *not* erased during extinction learning (Craske et al., 2022). Instead, the CS+ acquires a new inhibitory meaning during extinction (i.e., CS+ → no US), which then competes with the previously established excitatory fear association (Bouton, 2017). If the new “CS+ → no US” association is sufficiently strong, the expression of conditioned fear responses will be inhibited (i.e., “extinguished”).

Pattwell et al. (2012) examined age-related changes in fear extinction. Relative to both children and adults, adolescents showed attenuated extinction learning. These findings suggest that fear associations are less easily destabilized during adolescence. Thus, it has been argued that behavioral interventions for anxiety and trauma-related disorders could be less effective during this developmental period (Casey, 2015; Drysdale et al., 2014).

Two meta-analyses (Duits et al., 2015; Lissek et al., 2005) investigated altered fear extinction in anxiety disorders, obsessive-compulsive disorder, and PTSD. Compared with healthy individuals, patients showed slower and reduced extinction learning. Thus, an impaired ability to extinguish conditioned fear might be a risk factor contributing to the maintenance of pathological fear and anxiety. A prospective study in Dutch soldiers supports this hypothesis. Soldiers showing reduced fear extinction in a learning paradigm about 6 weeks before a 4-month deployment to Afghanistan reported a higher severity of PTSD-related symptoms after returning home (Lommen et al., 2013). In individuals with public speaking anxiety, impaired fear extinction predicted weaker exposure treatment outcomes (Ball et al., 2017). Intriguingly, there is evidence that extinction deficits may be attenuated by successful treatment (Duits et al., 2016).

Delayed or diminished extinction learning has also been discussed as a maintaining factor in *children* with anxiety disorders (Liberman et al., 2006). Nevertheless, according to a meta-analysis (Dvir et al., 2019), there is little empirical evidence that the differential conditioned response (CS+ versus CS−) is slower to extinguish in youth with anxiety disorders compared with healthy children. Yet, as outlined above (in the context of fear acquisition), children and adolescents with anxiety disorders maintain elevated fear responses to both threat (CS+) and safety (CS−) cues during extinction learning.

Exposure Therapy and Its Underlying Mechanisms

Similar to adults, in children, exposure interventions are empirically supported and highly effective in treating anxiety disorders (e.g., specific phobias, social anxiety disorder, separation anxiety disorder, generalized anxiety disorder), obsessive-compulsive disorder, and PTSD (Higa-McMillan et al., 2016;

Peris et al., 2020). Exposure therapy entails prolonged and repeated confrontation with the feared object or situation. By staying in the feared situation, a patient learns that the feared outcome does not occur.

“In vivo” exposure (i.e., actually facing the feared object or situation) can be distinguished from “in sensu” exposure (i.e., confrontation with the *imagined* feared object or situation). In the case of a child with dog phobia, an in vivo exposure would include going to places where dogs are playing or even interacting with a dog. Conversely, for in sensu exposure, the child could be asked to vividly imagine being near a dog or touching it. For exposures with younger children, puppets and toys can be utilized for “play-acting” feared situations. When bodily sensations (i.e., interoceptive signals) are threatening, interoceptive exposure can also be useful. In children with panic disorder, for example, feared sensations can be triggered by hyperventilation, exercising, or spinning (Bouchard et al., 2004).

Exposure therapy can be conducted in a massed (sessions are very close together in time) or spaced (longer time between sessions) format. Antony et al. (2006) recommend performing exposure exercises multiple times per week, in particular at the start of treatment. Similarly, a graduated approach can be distinguished from an intense form (Craske et al., 2014). This distinction determines whether exposure exercises start with a situation that is more likely to cause low/moderate or extreme intensities of fear. Exposure protocols usually involve the formulation of a fear hierarchy. In children and adolescents, fear hierarchies are often introduced as a stepladder (Mobach et al., 2020), with increasing steps in difficulty. In case of a dog phobia, for example, the first steps could be looking at photographs of a dog, while later steps could comprise standing close to a dog and petting the dog. After putting together such a stepladder, it needs to be decided which steps should be taken first during early exposure sessions. The most typical exposure strategies consist of a graduated (i.e., stepwise) procedure. This means that children first become exposed to mildly or moderately difficult situations, before moving on to more difficult ones (Bouchard et al., 2004). Depending on the circumstances, massed and intense approaches are also possible (Southam-Gerow, 2019). This implies that patients are immediately exposed to the most frightening situation. If a patient does not have enough time to undergo the more typical graduated approach, it can sometimes be helpful to start an exposure intervention with the most challenging tasks in the fear hierarchy. A possible situation would be a major class presentation for a child with social anxiety disorder. To ensure that a child will engage in confrontation with the threatening situation, the therapist must first prepare for it cognitively and explain the treatment rationale in a way that is understandable. For example, the therapist may explore with the child how likely (e.g., “has this ever happened in class before?”) the worst fears (e.g., “the whole class will laugh at me during my presentation”) are. Exposure therapy should be introduced as a way to “experimentally” test the child’s expectations, so that the child is motivated to make new experiences with this object or situation. To deliver psychoeducation in a more engaging way, hand puppets, cuddly toys, and cartoon stories can be helpful. The child might be encouraged to draw a picture of a threatening situation. To identify physiological symptoms of anxiety and how they wax and wane, the therapist and child might watch a scary movie together. Instead of a traditional Likert scale, an illustration of an “anxiety thermometer” can be used to visualize the child’s symptom severity (Lavell et al., 2020).

As illustrated above, patients are guided to gradually expose themselves to fear-provoking situations until their fear and distress begin to decline. In obsessive-compulsive disorders, the treatment strategy is complemented by response prevention. Under the guidance of the therapist, patients become repeatedly exposed to situations (e.g., touching a toilet) that initiate their compulsions. Importantly, patients are instructed to resist their urge to carry out compulsive behavior in order to have the chance to experience how the fear and the urge decrease. To support children during exposure, fantasy figures can be used. For example, children could be instructed to imagine their favorite hero or a comic character that accompanies them (virtually) and helps them stay in the feared situation. Through this exposure procedure, patients shall experience that their uncomfortable feelings will eventually start to fade over time, even if they do not engage in their compulsive behavior.

Abramowitz (2013) has pointed out that knowledge of underlying learning mechanisms helps clinicians to implement exposure therapy in a most successful way. Interestingly, one of the first reports of exposure therapy is a case study with a two-year-old boy named "Peter" in the 1920s (Jones, 1924a, b). "Peter" had a fear of rats, which generalized to other objects like rabbits. In this case study, "Peter" received food when he was confronted with a rabbit. The rationale was "*reciprocal inhibition*," i.e., the assumption that anxious behavior can be reduced by pairing a threatening object with a response that is physiologically and motivationally incompatible with anxiety and fear, because an individual cannot be relaxed or reward-seeking and anxious at the same time. Based on this idea, systematic desensitization therapy was developed (Wolpe, 1961). First, patients with anxiety disorders learn to relax with the idea that relaxation is incompatible with fear. A young girl with dog phobia, for example, could be trained in progressive muscle relaxation. In a similar vein, Kissel (1972) suggested utilizing therapeutic empathy and an office environment attractive for children (e.g., toys) as "fear inhibitors." Second, the therapist helps the patient to put together a fear hierarchy (e.g., watch a video of dogs, …, give a dog a cuddle). Third, when the patient is in a relaxed state, the patient is encouraged to imagine distress-provoking situations starting with the least fear-eliciting one. Compared with adults and adolescents, it is much more difficult for young children to engage in "in sensu" exposure, as they use thought and imagery considerably less proficiently (Kissel, 1972). To facilitate their imagination, children could be instructed to imagine a fear-provoking situation in which they are accompanied by superheroes from their favorite television series or movies (Lazarus & Abramovitz, 1962). Yet, research suggests that the relaxation component is unnecessary for successful fear reduction during systematic desensitization (Vinograd & Craske, 2020). Thus, reciprocal inhibition does not seem to be the central mechanism of exposure therapy. Nonetheless, it can help to overcome a child's motivational barriers to engage in the exposure.

The observation that subjective discomfort and physiological arousal gradually decrease during exposure has been interpreted as evidence for a *habituation* of the fear response (Benito & Walther, 2015; Tryon, 2005). Habituation can occur both within an exposure session (i.e., fear declines toward the end of exposure) and across sessions (i.e., the initially elicited fear response declines from session to session). According to the habituation model, in situations that activate fear (e.g., for a child with separation anxiety going to a sleep-over), the patient learns that fear and anxiety naturally decline ("habituate") by staying in the situation. Over several exposure sessions, the experienced peak level of distress will gradually diminish. Many patients with exaggerated levels of fear and anxiety have benefited from exposure interventions designed to promote habituation. However, habituation alone does not explain the efficacy of massed and intense exposure formats. Typically, habituation is smaller for high-intensity than low-intensity stimuli. Thus, when fear and anxiety are high, the effect of habituation will be modest.

Being confronted with stimuli high in the fear hierarchy can result in a substantial *expectation violation* (Craske et al., 2018). As explained earlier, fear conditioning is due to the formation of an excitatory association between the CS+ and the US, i.e., the CS+ eventually predicts the US. During extinction, a new inhibitory association (CS+ → no US) is established, i.e., it is learned that the CS+ is *no longer* a predictor of the US. This "CS+ → no US" association inhibits fear expression. For example, a girl with separation anxiety ("Susi") might have exaggerated fears in situations with no parent present, because she has acquired excitatory associations (i.e., fear expectations) due to previous frightening experiences when being alone or due to her parents having agoraphobic fears. During exposure, safety learning (i.e., fear extinction) would occur, and situations without her parents present acquire new meaning (e.g., "nothing bad will happen"; "it can be fun when no parent is there"). Whenever Susi is confronted with situations without her parents, the new "safety" memory trace competes with the previous “danger” memory trace. Repeated exposure experiences violate Susi’s expectations about the danger of not having her parents around (Panitz et al., 2021). The continued experience of expectation-violating situations strengthens inhibitory associations (Vinograd & Craske, 2020). When safety learning is sufficiently strong, the newly acquired inhibitory association inhibits excitatory associations of danger, ultimately leading to reduced subjective fear and anxiety (Milad & Quirk, 2012). Repeated exposure sessions modify Susi’s catastrophic beliefs, as she will learn that feared outcomes will not happen and that she can tolerate her distress.

Why do people benefit from exposure therapy? Should therapists design exposure situations that promote expectation violation (inhibitory learning) rather than habituation? Recent studies suggest that both mechanisms contribute to beneficial treatment effects (de Kleine et al., 2017; Elsner et al., 2022; Lange et al., 2020). Thus, therapists should aim at addressing both habituation and inhibitory learning (Jassi & Kindynis, 2020). Exposure interventions should allow the child to revise the maladaptive (disorder-specific) and individually relevant expectations (Becker et al., 2020; Craske et al., 2014). Note that the terms habituation and extinction learning are often (imprecisely) used interchangeably in the literature (McGuire & Storch, 2019). From a learning theory perspective, habituation refers to a nonassociative learning process, whereas extinction learning is inherently associative as it entails attenuated conditioned responses due to inhibitory learning.

Strategies to Enhance Inhibitory Learning During Exposure Therapy

As outlined, extinction, i.e., inhibitory learning, is a key mechanism of exposure therapy. Based on what is known about factors affecting the efficacy of fear extinction, several strategies can be derived to bolster the effects of exposure interventions (Craske et al., 2018; LeDoux, 2015; Lipp et al., 2020; McGuire & Storch, 2019; Mobach et al., 2020).

First, inhibitory learning can be augmented by increasing the degree of expectation violation during exposure. Specifically, exposure sessions should be designed in a way that allows the child to make experiences that maximally violate the child’s expectations. Thereby, the child experiences a situation that is less threatening than expected (e.g., for a patient with spider phobia: “the spider crawls actually away from me and does not bite me”). To direct the child’s focus toward the expectation violation, the therapist should explicitly ask the child before exposure to describe what specifically is feared and what the concerns are. After completing the exposure session, the child should be asked about whether these feared outcomes actually happened, and what was different than expected. To further enhance the correction of these expectations, dysfunctional beliefs should be questioned, by taking into account the exposure experience. Indeed, clinical data suggest that the treatment duration for childhood anxiety disorders can be shorter when exposure is implemented relatively early during treatment (Gryczkowski et al., 2013). If exposure is practiced early in treatment, an earlier and greater violation of threatening expectations can be achieved. Often, anxiety coping strategies are taught as an adjunct to the exposure sessions, in order to promote the patient’s self-efficacy.

Second, safety signals and behaviors should be removed during exposure. In social anxiety, safety behaviors might involve practicing beforehand what to say in a certain social situation. A distinction can be made between safety behaviors that are already part of the psychopathological problem and safety behaviors that may occur for the first time during exposure. For example, as part of her symptoms, a young girl with separation anxiety disorder may constantly use her cell phone to text her parents while at school. As exposure intervention, the therapist might suggest that the girl’s mother could leave the therapy room for half of the session and wait outside. In this situation, the girl might repeatedly ask the therapist how much time is left. Although these safety behaviors may reduce discomfort in the short term, they are detrimental to treatment success. Safety behavior can be thought of as an additional "conditioned inhibitor" that becomes associated with the (excitatory) fear-related stimulus or situation (the CS), which the exposure targets. Symptom relief during exposure (e.g., the decrease in discomfort during a social interaction) becomes dependent on the presence of the safety signal or behavior (e.g., practicing of what to say, asking the therapist for the remaining time) through classical conditioning. Thus, fear may return when safety signals and behaviors are eliminated. Exposure might not be possible, at least initially, without safety behavior. For example, a child with heightened anxiety in the dark could be too scared when entering a dark situation without a flashlight. Under these circumstances, the use of such safety behaviors/signals might be warranted in the beginning, as long as they still allow the expected outcome to be mitigated. Later, such safety behaviors/signals need to be faded out over time. Therapists or parents can become safety stimuli if they are always present during exposures. To counteract this effect, it is helpful, if possible, to also perform some exposure exercises without the therapist. The involvement of parents is varied, ranging from close supervision to arranging the setting of being within a reachable distance, depending on the age of the child.

Third, introducing reminder cues can promote the stability of inhibitory safety learning. After a successfully mastered confrontation session, a photo can be taken (e.g., in spider phobia: of the patient touching a spider; in separation anxiety disorder: of the patient in the classroom). Alternatively, a child could draw a picture or write a short story about what it was like. Classical conditioning leads to the establishment of a positive association between the photo/picture and successful extinction learning. Thus, the photo serves as a reminder cue for the previously experienced reduction of discomfort and successful mastery of the exposure. During future exposures, these cues can act as priming stimuli to facilitate the retrieval of inhibitory extinction associations (Blakey & Abramowitz, 2016). Nevertheless, an attempt should be made to reduce and eventually eliminate reminder cues toward the end of treatment in order to ensure that the therapeutic effects (i.e., extinction recall) do not depend on safety signals ("I can only handle a situation if I have my photo with me").

Facilitating the Generalization of Exposure Treatment Effects

During classical conditioning and extinction, information about the occurrence of the US does not only become associated with discrete cues such as the CS. The US contingency is also associated with the context of the learning experience (Maren et al., 2013). Context does not only refer to the setting (i.e., the place where conditioning/extinction occurs), but also entails temporal (the time), interoceptive (i.e., physiological states like thirst, hormonal status, level of stress hormones), emotional (e.g., angry, anxious, ashamed), and social (e.g., presence of peers, being with a therapist) cues. Hence, both conditioning and extinction learning are highly dependent on contextual features.

Exposure therapy should take contextual factors into account. Exposure interventions are usually conducted in therapy rooms, thus in a very different context than the one in which fear was acquired. Even if exposures are successful in the safe therapeutic situation, it is likely that extinction learning does not sufficiently generalize to everyday situations. Although excitatory fear associations generalize readily across similar stimuli and situations, the transfer of inhibitory extinction learning during exposure therapy is often limited and insufficient (Craske et al., 2018; Lipp et al., 2020). Thus, it is necessary to boost the generalization of inhibitory learning by implementing exposure sessions in multiple contexts (Craske et al., 2022; LeDoux, 2015; McGuire & Storch, 2019; Mobach et al., 2020). This includes, for example, different situations, different locations, different times of the day, and varying days of the week.

Exposure sessions should not be run only at the therapist's office, but also in the child's daily life. If necessary, exposure can be performed at the patient's home. For example, after some exposure sessions for separation anxiety, it might be possible that the child is able to be alone in a room with the therapist, while the parents are in the waiting room. Yet, it might still be difficult for the child to visit friends without the parents, or to take the school bus alone. In this example, it would be essential to conduct exposure sessions in different contexts (e.g., staying at a friend's home, taking a bus). In obsessive-compulsive disorder, exposure combined with response prevention such as compulsive washing or checking can initially be run at the therapist's office, but should be continued in the contexts in which these symptoms typically occur (e.g., the front door of the patient's house). In social anxiety disorder, exposure sessions need to incorporate situations of everyday life (e.g., asking a teacher at school, inviting a friend to a party, denying the request of another child). Most importantly, internal states also need to be considered as contexts. Thus, exposure sessions should be performed with the patient being in different internal states (e.g., negative versus neutral mood; stressed versus calm; fatigued versus energized). Taken together, exposure sessions should be varied in order to provide sufficient opportunities for the patients to correct their expectations taking into account contextual modulation.

Preventing the Return of Fear

Even successfully treated patients may relapse. As outlined earlier, extinction entails inhibitory learning, thus the originally acquired excitatory association is not erased from memory. Rather, the new inhibitory association competes with the previously acquired excitatory association. As a result, it depends on the strength of the newly acquired extinction memory trace whether the patient's fear might return, i.e., a relapse occurs (Bouton, 2002; LeDoux, 2015).

When exposed to the originally fear-provoking situation, successfully extinguished fear can return with the mere passing of time (i.e., "spontaneous recovery"). For example, a child successfully treated for separation anxiety might again experience a stronger fear response when going to school alone after the summer recess. From an evolutionary perspective, successful fear learning is more important for survival than extinction learning. Inhibitory associations (i.e., fear extinction) are less stable than excitatory conditioned responses (Mueller & Pizzagalli, 2016). Therefore, it is particularly important that patients are encouraged to continue confronting themselves with the feared object, even after therapy is completed. Similarly, reexposure to the US (i.e., the experience of the US without the CS) can also reverse extinction effects; this phenomenon is referred to as "reinstatement." Consider the young girl Cindy who successfully underwent exposure therapy for social anxiety disorder. If Cindy is laughed at by her friends sometime after the end of therapy, her social anxiety related to performance situations in school may reappear.

As explained above, extinction learning is highly context-dependent. If a child is confronted with a novel context after exposure, the expression of conditioned fear may return, i.e., a so-called "renewal" occurs. Internal states (e.g., being stressed versus calm) are among the most important contextual factors. In particular, highly stressful experiences, even if entirely unrelated to the original fear, can reactivate conditioned fear. In Cindy's example, this might be a very stressful exam period that could lead to a return of social anxiety symptoms. In children and adolescents, age and associated hormonal changes during puberty are also important contextual factors. Moving to another city, transferring to a different school, beginning the first job after completing school, or starting an (under-)graduate program are further examples of major contextual changes during development. To prevent fear from returning, it is essential for children and adolescents to confront themselves with (previously) feared situations again and again after therapy is completed, especially when major developmental changes occur.

Exposure Therapy with Children and Adolescents

Exposure interventions for children and adolescents compared with those for adults require additional considerations (Bennett & Albano, 2020; Jassi & Kindynis, 2020; Kingery et al., 2006; Vinograd & Craske, 2020). When working with children and adolescents, it is important to take into account the child's age, cognitive development, and the role of parents and family during planning and conducting exposure sessions. To facilitate inhibitory learning, it has been recommended that therapists ask patients to explicitly articulate their threat-related expectations at the beginning of the exposure sessions, in order to maximize the violation of dysfunctional expectations (Craske et al., 2018). Especially young children may have difficulties describing what they specifically are afraid of (Vinograd & Craske, 2020). In this case, exposure therapy may focus more on habituation and learning to tolerate and cope with fear and anxiety until it decreases. Through exposure, children learn that they are able to tolerate distress and that they can function when being confronted with the feared stimulus or situation (Vinograd & Craske, 2020). Using stories or examples from daily life is helpful to explain the rationale for exposures. Habituation can be illustrated by using swimming in a cold pool as an analogy (Jassi & Kindynis, 2020). The longer one stays in the cold pool, the more the body gets used to the low temperature (i.e., habituates). Alternatively, the therapist and the child can put a small stone in their shoes and notice how the unpleasant sensation will fade after some time (Bennett & Albano, 2020).

Because younger children have shorter attention spans and limited memory capacity (Kingery et al., 2006), it may be necessary to schedule shorter exposure sessions, to incorporate more in-session breaks, and to include more opportunities for rehearsal for successful extinction memory consolidation (Craske et al., 2022; Jassi & Kindynis, 2020). To increase the child's engagement, it is helpful to praise the child and reward successful exposure with a few minutes playing at the end of the session. Giving the anxiety disorder a name (e.g., the "Anxiety Monster"), using puppets, or talking about cartoons can make it easier to "tame the Anxiety Monster" (Jassi & Kindynis, 2020).

Treatment of young children usually involves their parents and families. Some children may not be able to completely understand psychoeducation that explains the rationale behind exposure therapy. In this case, it is even more important for treatment success that their parents are informed and aware of the underlying concepts and encourage their child to engage in exposure sessions (Jassi & Kindynis, 2020). If the child has difficulties with tolerating fear and anxiety, parents may be tempted to step in and reduce the child's fear. For example, parents may engage in well-intentioned over-accommodation of anxiety symptoms and overprotection of the anxious child (Bennett & Albano, 2020). Therapists should discuss this behavior with the parents and explain how their behavior may counteract habituation and expectation violation (Benito & Walther, 2015; Craske et al., 2018; Jassi & Kindynis, 2020). Similarly, if parents are solicitous about the child's level of anxiety and give in when their child tries to avoid or escape from a feared object, this parental behavior could also undermine exposure effects. In addition to parents, exposure exercises may also include the school environment (Kingery et al., 2006). A child with social anxiety disorder, for example, may have difficulty asking questions in the classroom. Similar to exposure interventions for adults, therapists should be aware of subtle safety behaviors. In adolescents, for example, social media use can constitute critical safety behavior as it enables them to avoid real-life social situations (Bennett & Albano, 2020). Also, a socially anxious adolescent might wear headphones in order to avoid being approached by someone.

Altogether, when conducting exposure therapy in children and adolescents, the patient's age and developmental stage need to be considered. Psychoeducational material needs to be adapted to the patient's level of cognitive development. Finally, the therapist should involve the patient's social environment (e.g., parents, family, and teachers).

Exposure Therapy Beyond the Treatment of Fear and Anxiety

Thus far, exposure interventions have mainly been discussed in the context of anxiety and fear-related problems. Yet, exposure therapy and its underlying mechanisms can be applied to other mental disorders. For example, exposure interventions are an important component of treatment programs for eating disorders (Becker et al., 2020). Anxiety and eating disorders are often comorbid and share certain symptom features (e.g., fear of being too fat; Melles et al., 2021). Mirror exposure is a good example of how confrontation principles have been made use of in the treatment of eating disorders. This intervention aims at reducing body image dissatisfaction by repeatedly viewing of oneself in a mirror. The exact mechanisms of action of mirror exposure are still to be elucidated (Griffen et al., 2018). The most frequently cited explanation is based on findings that patients with eating disorders, especially anorexia nervosa, tend to overestimate their body size (Vocks et al., 2007). It has been proposed that mirror exposure enables patients to correct this inaccuracy about their body dimensions, which may ultimately lead to a reduced fear of weight gain.

Yet, Griffen et al. (2018) suggested that, at least partially, classical conditioning might play a role in mirror exposure. According to this theory, the patient's own body image in the mirror may serve as a CS, which activates a conditioned response of fear and anxiety. Repeated exposure sessions may then reduce this response by inhibitory extinction learning and habituation. Although this explanation seems plausible, it has been questioned as to whether fear and anxiety are the core emotions that need to be considered in the treatment of eating disorders. Rather, patients may primarily experience disgust toward their own body (von Spreckelsen et al., 2018). In contrast to conditioned fear, disgust can be better changed by counterconditioning (Engelhard et al., 2014). Counterconditioning refers to the notion that conditioned responses can be modified by substituting the original US with a novel stimulus of the opposite or neutral valence. From this perspective (Griffen et al., 2018; Klimek et al., 2016), mirror exposure may improve body image dissatisfaction by pairing the body image (the CS) with a rather neutrally or even positively valenced US. During mirror exposure, patients are usually encouraged to describe their body nonjudgmentally or take the perspective of a neutral observer, i.e., a "neutral US" (Klimek et al., 2016). Nevertheless, further research is needed to clarify the precise underlying processes of mirror exposure. It seems clear, however, that learning processes underlying exposure therapy are qualitatively different in eating disorders than in anxiety disorders.

Appetitive Conditioning as a Fundamental Learning Process in Children and Adolescents

Aversive conditioning refers to the learning of predicting threats. Hence, the US is an unpleasant event, like a painful sting from a wasp, a dog bite, rejection by others, being left alone, or a loud noise in experimental settings. Being exposed to such stimuli is aversive and potentially harmful, thus it is highly adaptive learning to activate adequate "fight-or-flight" behavior in response to the CS (Roelofs, 2017). From an evolutionary perspective, it is not only important to learn about threat. It is also pivotal to learn about potential reward. Appetitive conditioning refers to the learning of CSs that are good predictors of reward, including outcomes for meeting basic needs (e.g., food, sexual stimulation). In combination with operant processes, appetitive cues trigger approach behavior. Consider a mother who often comes home with a shopping bag containing candy for her children. Whenever the children watch their mother coming home with a shopping bag, they will be excited and expect candy. In appetitive conditioning, the US is a pleasant and desirable event. This can be a primary reinforcer like delicious food (Andreatta & Pauli, 2015), a pleasant smell (Exner et al., 2021), drugs (LeCocq et al., 2021), or sex (Klucken et al., 2016), but also a secondary reinforcer like money (Kruse et al., 2020).

Appetitive conditioning is highly adaptive and can already be observed in newborns. Newborns need to rapidly locate the nipples of their mother; this is associated with certain cues (i.e., CSs; Hym et al., 2021; Jouhanneau et al., 2016) like maternal odor, temperature, and tactile stimulation (e.g., stroking the infant's head or a certain posture of the mother's arm). The mother's nipple that delivers milk (i.e., the US) triggers sucking in the infant (i.e., the unconditioned response). If a certain behavior of the mother (e.g., stroking the baby, attaching the baby to the breast, preparatory movements of the mother) is repeatedly associated with milk flow, the infant may show a conditioned sucking behavior that is elicited by this maternal behavior (the CS). Blass et al. (1984) impressively demonstrated successful appetitive conditioning in newborns just 2–48 h after birth. In their experimental group, the experimenter gently stroked the forehead of an infant. This tactile stimulation (i.e., the CS) was followed by an intraoral delivery of a sucrose solution (i.e., the US) through a pipette to imitate breastfeeding of the infant. Compared with a control group given *delayed* sucrose delivery after stroking, the children in the experimental group showed more head-orienting and sucking behavior during the stroking intervals, thus indicating successful acquisition of a conditioned response. Remarkably, this experimental study demonstrates contingency learning at a very young age, highlighting the crucial role of this learning mechanism for the development of early mother–infant bonds.

Though not necessarily conceptualized as such, appetitive conditioning also plays a subtle role in making the psychotherapeutic setting a positive context. If children tend to associate the therapeutic setting with positive valence, this helps to promote a good working alliance. Playing with toys, for example, is a vital component of psychotherapy with children, which facilitates positive learning experiences during therapy.

Appetitive Conditioning: Risk-Taking, Sensation-Seeking, and Substance Use

Relative to children and adults, adolescents show reduced impulse control to appetitive cues (Casey, 2015; Somerville et al., 2011). This observation could explain heightened risk-taking and sensation-seeking during adolescence, presumably due to enhanced appetitive conditioning during this developmental stage (Ernst et al., 2011). Adolescence is a transition period of social reorientation, which prepares the individual for becoming an adult. Adolescents spend less time with their parents, but more and more time with their peers. These behavioral changes are typically accompanied by elevated risk-taking and exploration. On the one hand, heightened reward responsivity during adolescence may explain elevated risk-taking and sensation-seeking, which peak during late adolescence (Ernst et al., 2011). On the other hand, heightened appetitive conditioning during adolescence seems to increase the vulnerability for certain mental disorders. Thus, the developmental trajectories of appetitive conditioning may help to explain why adolescence is a high-risk period for the onset of several mental disorders.

Appetitive conditioning presumably plays a crucial role in mental disorders characterized by acquired motivation, such as substance use disorders (Martin-Soelch et al., 2007). Specifically, the drug (i.e., the US), due to its psychotropic actions, automatically initiates intense pleasurable feelings including euphoria (the "high"). Substances are often consumed in certain situations (e.g., hanging out with friends, being at a party, dancing). Through repeated use, these situations become associated with the pleasurable effects of the drug, i.e., they serve as the CSs. Critically, unconditioned responses elicited by drug consumption and conditioned responses to the associated cues are qualitatively different (Berridge & Robinson, 2016; Koob & Le Moal, 2006). Especially in the beginning, substance use triggers a pleasant feeling (the unconditioned response, "liking"). With increasing drug consumption, incentive salience ("wanting") becomes assigned to the CS (e.g., being at a party). With repeated drug consumption, these cues as well as the context can elicit craving (i.e., intense "wanting").

Critically, conditioned craving responses are not necessarily hedonically pleasant. The psychological process of motivationally "wanting" recruits brain mechanisms that are distinct from hedonically "liking" the same reward. Due to sensitization of the mesolimbic dopamine system in the brain, persistent substance abuse leads to excessive "wanting" (Berridge & Robinson, 2016). In the case of highly addictive drugs, associated cues trigger strong craving (i.e., increased "wanting"), even though substance use itself is associated with diminishing feelings of pleasure (i.e., reduced "liking"). Smoking illustrates the pivotal role of appetitive conditioning in substance use disorders. Most smokers start smoking when they are teenagers. Nicotine is a US triggering pleasant feelings (the unconditioned response, "liking"). The setting when smoking (e.g., meeting with friends, at a party, during a school break), places (e.g., being in a pub, passing a tobacco store), or certain situations (e.g., at the school bus stop, before an exam) become associated with the rewarding effects of nicotine and serve as the CSs. Internal cues (e.g., feelings of nervousness, restlessness, or sadness) can also become CSs. If nicotine is not consumed, these stimuli can trigger craving symptoms ("wanting"). This increased urge to smoke is called cue-reactivity.

Appetitive conditioning processes early in life may contribute to the risk of later substance abuse. Prenatal alcohol exposure through maternal alcohol intake predicts later development of alcohol use disorders among affected children (Duko et al., 2022). Intriguingly, animal research suggests that this relation may at least partially be mediated by *in utero* appetitive learning (Gaztañaga et al., 2020). This is due to alcohol crossing the placenta, such that the fetus acquires an association between sensory properties of alcohol (the CSs) and its pharmacological effects (the appetitive US). In humans, the differential effects of the adverse influences of alcohol on neurodevelopment and appetitive conditioning are difficult to ascertain.

Cues associated with drug use can trigger conditioned emotional and physiological responses that are similar to the unconditioned response itself (e.g., euphoric, calming, stimulating, analgesic). In some cases, conditioned responses can also be opposite to the unconditioned drug response (e.g., dysphoric, depressed mood, increased pain sensitivity; O'Brien et al., 1990). Whether a drug-like or drug-opposite conditioned response occurs depends on the substance and the CS. Importantly, conditioned responses opposite to the drug effect explain conditioned tolerance and conditioned withdrawal symptoms in substance use disorders (Banasikowski & Beninger, 2015). Conditioned compensatory responses, which are often similar to the symptomatology of drug withdrawal syndrome, can be critical triggers for relapse. If drug-opposite conditioned responses occur just before drug intake, they can lead to an attenuation of the drug effect ("tolerance"). This effect partly explains why drug effects usually diminish with repeated use of the same dose (O'Brien et al., 1990). For this reason, classical conditioning has also been proposed as an explanation for heroin overdose deaths (Siegel, 2016). In some cases, individuals with a heroin addiction died after taking heroin at a dosage that they had learned to tolerate. Drugs are typically used in specific situations (e.g., at a certain time of the day, together with friends, "drug scene"). Thus, through classical conditioning, specific environmental cues become associated with the systemic effect of the drug. Upon repeated drug consumption, these cues elicit conditioned responses that counteract the drug effect and, therefore, mediate drug tolerance. If the drug is taken in a novel environment, these drug-compensatory responses are reduced and the acquired drug tolerance is attenuated (Koob & Le Moal, 2006).

Inspired by extinction-based treatment approaches for anxiety disorders, cue exposure therapy has been developed to treat substance use disorders. The rationale is to expose patients to drug-related cues (i.e., the CSs) without consuming the drug (i.e., the US), in order to extinguish cue-induced craving. In smoking, cue exposure therapy could involve confrontation with smoking-related cues (e.g., cigarettes, ashtrays, lighters, cigarette vending machines) or situations (e.g., being in a pub, waiting for the school bus, passing a tobacco store). However, research on this therapeutic approach yielded mixed findings and its efficacy seems to be rather poor (Mellentin et al., 2017; Vinci et al., 2021). A recent study on cue exposure therapy for smokers revealed that this technique may even increase the risk of relapse (Pericot-Valverde et al., 2019). Overall, cue exposure appears to be rather ineffective for substance use disorders, at least when this technique is applied in the way that it is commonly used for anxiety disorders (i.e., focusing on habituation and inhibitory learning). One reason for this could be that, in addition to classical conditioning, operant learning processes are particularly important in substance use disorders (Koob & Volkow, 2016; Wise & Koob, 2014). For example, reaching for a cigarette (habit learning) is operantly reinforced by subsequent smoking (Bouton, 2021). Therefore, when exposure interventions are applied to substance use disorders, it seems necessary to extend these techniques by including other abstinence strategies. For example, one promising possibility might be to expand cue exposure to incorporate urge-specific coping skills (Mellentin et al., 2017). Once craving-triggering cues have been identified, alternative behaviors to drug use (e.g., smoking) can be explored in therapy. For example, if an adolescent has always smoked during school breaks, the patient might try to avoid the smoker's corner and chat with classmates who do not smoke. If a patient has smoked when feeling nervous before an exam, relaxation techniques, drinking a glass of water, or exercising could be options to replace tobacco.

Appetitive Conditioning and Depression

Interestingly, *impaired* appetitive conditioning has been discussed as a mechanism in the etiology of depression (Martin-Soelch et al., 2007; Webb et al., 2017). Kumar et al. (2008) compared appetitive conditioning between patients with major depressive disorder and healthy controls. Participants learned to predict rewarding water delivery (the appetitive US), which was preceded by visual cues (the CSs). Intriguingly, patients showed reduced reward learning, as indicated by blunted brain activity in the ventral striatum. This brain region is typically activated during the anticipation of rewards (Daniel & Pollmann, 2014). Similarly, Arrondo et al. (2015) found reduced ventral striatal activity in depressed individuals during reward anticipation. These findings indicate that situations are less likely to acquire a positive connotation in patients with depression, presumably due to appetitive conditioning deficits. Anhedonia, i.e., hyposensitivity to rewards, is a core depressive symptom (Pizzagalli, 2014). However, it is yet to be determined whether anhedonia is a consequence or a causal factor of impaired appetitive conditioning. Given that lower US intensities lead to poorer learning (Rescorla & Wagner, 1972), attenuated reactivity to pleasurable stimuli (Pizzagalli, 2014) could affect perceived US intensity (i.e., less reward) in depressed individuals, and thereby interfere with conditioning. Clearly, blunted reward processing does not only affect classical conditioning, but also operant conditioning processes (Weinberg et al., 2022).

Beyond Exposure – Other Interventions Based on Classical Conditioning

As a clinical intervention, classical conditioning has been most influential in advancing exposure treatment techniques. Yet, classical conditioning is an important learning mechanism that also underlies other cognitive-behavioral interventions in adult, child, and adolescent psychopathology. To illustrate this, two examples will be given.

Many mental health problems during childhood and adolescence are accompanied by severe sleeping problems (Short et al., 2019). Classical conditioning mechanisms are critical for the development of effective therapeutic interventions for sleeping difficulties (Harris et al., 2012). Acute periods of stress often lead to transient sleep disturbances. However, with repeated episodes of insomnia, the bed, bedtime, and other contextual cues in the bedroom become CSs for emotional distress (the US), which is associated with persistent wakefulness, autonomic arousal, and difficulties with falling asleep. If patients repeatedly toss and turn in their bed for hours, going to bed will automatically elicit sleeplessness and worrying about not being able to sleep. Many patients report watching TV, surfing the internet, or even eating in their beds. These stimulating activities go along with elevated arousal, which is incompatible with sleep and further adds to associating being in bed with being awake and alert. In depression and anxiety disorders, excessive rumination and worrying in bed also contribute to elevated arousal; the bed is no longer a cue for sleeping. Based on this classical conditioning model of insomnia, so-called stimulus control therapy has been developed (Edinger et al., 2021), which can lead to rapid improvements in sleep and daytime functioning (Harris et al., 2012). The goal of stimulus control therapy is to extinguish bed–wakefulness associations and to restore functional bed–sleep contingencies (Edinger et al., 2021). Therefore, a consistent separation of lying in bed and wakefulness/distress is required. The bed situation should be reconditioned with pleasant emotions and relaxation. Individuals with sleeping difficulties are instructed to use their bed for sleep only, and to avoid stimulating activities in bed (e.g., reading, eating, or watching TV). If somebody cannot fall asleep within 20 min or experiences rumination in bed, it is recommended that they leave the bed and return only when becoming tired, to avoid the formation of dysfunctional associations. Conversely, waking up at the same time every morning helps to establish functional associations between sleeping and bedtime (Edinger et al., 2021).

Relaxation procedures represent a second example of applying classical conditioning. Relaxation techniques (e.g., progressive muscle relaxation, breathing exercises) are widely used in psychotherapy to reduce stress, anxiety, and depression symptoms (Gao et al., 2018). It has been discussed that the beneficial effects of relaxation could be partially mediated through classical conditioning mechanisms, and that cue-controlled (i.e., conditioned) relaxation could improve its efficacy (Hayes-Skelton et al., 2013). Relaxation techniques may be too time-consuming and complicated in specific anxiety-provoking situations; classical conditioning can simplify the induction of a relaxed state (Poser et al., 1965; Russell & Sipich, 1973). Relaxation instructions (the US) typically elicit a pleasant state of relaxation and well-being (the unconditioned response). After getting into a relaxed state, the patient may be instructed to repeat the word “relaxing” (a self-produced cue) with each exhalation. Through this procedure, the word “relaxing” becomes a CS and, eventually, induces a relaxed state (the conditioned response). This method enables the patient to generate a relaxed state easily and quickly in everyday life or in feared situations (e.g., before an exam at school or at a party). In addition, relaxation exercises can be practiced in a certain body posture (e.g., the so-called “cabman’s position” in autogenic training; Linden, 2021). Thereby, the body posture functions as a CS and facilitates the elicitation of a conditioned relaxation response.

Classical Versus Operant Conditioning

In addition to classical conditioning, operant learning processes are important for understanding and treating psychopathology in children, adolescents, and adults. Operant conditioning describes the process through which individuals learn to make (or not to make) certain behavioral responses, with the goal to obtain a desirable outcome or to avoid an unpleasant consequence. To explain avoidance behavior in pathological fear, Mowrer’s (1951) two-factor theory has already been described above. While classical conditioning is particularly important for the etiology of mental disorders, operant conditioning is pertinent for their maintenance. For example, in PTSD, hyperarousal and reexperiencing traumatic events can be explained by classical conditioning, whereas avoidance and escape symptoms are accounted for by operant mechanisms. The key difference between classical and operant conditioning is whether or not the outcome is contingent on a behavioral response. In classical conditioning, individuals receive an outcome (the US) regardless of whether they show a conditioned response or not. After repeated pairings of the CS and the US, the CS triggers a conditioned response. In contrast, in operant conditioning, the outcome (i.e., the reinforcement) occurs only when a particular behavior is shown. In addition, antecedent stimuli, i.e., discriminative stimuli, enhance the likelihood of a certain behavior in a given situation depending on which reinforcement is associated with it. The probability of a behavior being increased or decreased depends on whether an appetitive reinforcer ("reward") or an aversive consequence ("punishment") follows, or whether an (un-)desired outcome is removed ("negative reinforcement/punishment").

Classical and operant conditioning are often not clearly distinguishable, especially since both learning processes co-occur. This already becomes clear when looking more closely at the highly cited example of "Little Albert" (Watson & Rayner, 1920), which was introduced at the beginning of this chapter. Although this experiment is most frequently used to illustrate the basic concepts of classical fear conditioning, the child's learning in this example cannot be solely explained by "pure" classical conditioning mechanisms. Critically, the unpleasant noise (the US) was administered when "Albert's" hand *touched* the rat (the CS). Thus, this procedure also includes operant conditioning mechanisms.

In clinical practice, classical and operant conditioning procedures often go hand in hand and are difficult to distinguish. This interaction can be easily illustrated in behavioral treatment strategies for children with nighttime bed-wetting. Nocturnal enuresis describes the involuntary loss of urine at night at an age when a child could be expected to be dry. After organic causes have been excluded, so-called alarm interventions are an effective behavioral treatment strategy (Glazener et al., 2005; Peng et al., 2018). As part of this treatment, an alarm (e.g., a bell) is triggered by micturition, i.e., when a sensor in the sheets or nightclothes of the child is activated by urine.

Alarm interventions were originally designed based on a classical conditioning account (Doroshow, 2010; Ploog, 2012). Accordingly, the sensation of a full bladder (the CS) becomes associated with the alarm (the US), which automatically triggers an unconditioned response (waking up). After successful conditioning, the child learns to recognize sensations of the bladder being full during sleep and to wake up (conditioned response). Eventually, the child gets up in time to go to the bathroom without urinating in bed. It also has been proposed that voiding inhibition during sleep is conditioned (Caldwell et al., 2020). Specifically, being woken up by the alarm causes contraction of the urethral sphincter and the pelvic floor muscles, thus stopping urine flow (Butler, 2004). Thereby, the child learns to contract the urethral sphincter and the pelvic floor muscles (conditioned muscle response; Forsythe & Butler, 1989). Both classical conditioning accounts assume that the sensation of a full bladder becomes a cue (i.e., the CS) to either wake up or to inhibit urination. However, classical conditioning cannot fully explain the therapeutic effects of alarm interventions. In particular, it is unclear why removal of the alarm typically does not lead to extinction learning and associated relapse (Forsythe & Butler, 1989). Thus, it has been suggested that operant mechanisms also play a role.

From an operant perspective (Butler, 2004; Doroshow, 2010; Lovibond, 1963), the child learns to stay dry (i.e., to wake up or to hold back urine) by avoiding the annoying noise of the bell. In addition, avoiding bed-wetting is facilitated by preventing aversive consequences that typically follow a bed-wetting accident (e.g., parental criticism or accusations, changing the bed sheets, and the need to wash oneself). Regardless of the exact mechanism of action, alarm interventions are highly effective (Glazener et al., 2005; Peng et al., 2018).

In summary, the relative contribution of classical versus operant learning mechanisms is often difficult to disentangle in practice. Classical conditioning tends to be particularly important for the development of psychopathological symptoms, whereas operant learning seems to be of greater relevance for their maintenance. When designing new therapeutic interventions, care should be taken to address the implications that arise from both conditioning mechanisms. In this way, treatment efficacy can be maximized, while trying to reduce the risk of relapse.

Conclusions

Classical conditioning is one of the fundamental ways in which infants and children learn about the world around them. By discovering "what seems to come before what," the world becomes more predictable for children. In clinical psychology, classical conditioning has added substantially to our understanding of a wide variety of mental disorders in youth, which led to the development of effective interventions. The transition from childhood to adulthood is a high-risk period for the pathogenesis of mental health problems. The developmental trajectories of fear conditioning show that, with increasing age, children learn to differentiate between threat and safety. Some adolescents, however, continue overgeneralizing conditioned fear. This seems to be a critical risk factor in the etiology and maintenance of anxiety, fear, and trauma-related disorders. Exposure-based therapy, which is founded upon the principles of classical conditioning and extinction learning, is the treatment of choice for pathological fear and anxiety. Understanding exposure therapy from an inhibitory learning perspective allows for further optimizing its efficacy. Specifically, exposure should be conducted in multiple contexts (internal and external), safety behavior should be reduced, and the degree of expectation violation should be maximized. Several studies have confirmed the excellent effectiveness of exposure therapy. Nevertheless, exposure-based interventions are not necessarily used in routine care, even by therapists trained in cognitive-behavioral therapy (Pittig et al., 2019). It will be important to better understand what keeps clinicians from doing so. The dissemination of conditioning-based interventions needs to be improved, and practical or systemic barriers should be identified and removed. Conditioning procedures are most frequently referred to in the context of pathological fear and anxiety and their treatment. As outlined earlier, classical conditioning is a powerful learning mechanism, which has proven beneficial for treatments of a wider range of mental health problems during childhood and adolescence (e.g., eating disorders, substance use disorders, nocturnal enuresis, or sleeping difficulties).

Glossary

Appetitive Conditioning Classical conditioning with a pleasant unconditioned stimulus (US).

Aversive Conditioning Classical conditioning with an unpleasant unconditioned stimulus (US). Often referred to as "fear conditioning."

Classical Conditioning A learning mechanism through which external or internal stimuli become associated with motivationally relevant events, which can be either pleasant (appetitive conditioning) or unpleasant (aversive conditioning).

Conditioned Response A learned response that is elicited by the conditioned stimulus after successful classical conditioning. A conditioned response is associated with affective, physiological, and behavioral changes. The conditioned response is often similar to the unconditioned response, but can also be qualitatively different, as it is closely related to the motivational state induced by the expectation of the unconditioned stimulus (US).

Conditioned Stimulus (CS) An external or internal stimulus that becomes associated with the unconditioned stimulus (US) during classical conditioning. After successful conditioning, the CS predicts the pleasant (appetitive conditioning) or unpleasant (aversive conditioning) US and elicits a so-called conditioned response. Experimental conditioning paradigms typically entail two different CS types. A CS+ is repeatedly paired with the US, while a CS− remains unpaired. The difference between responses to the CS+ and the CS− is referred to as *differential* conditioned response.

Exposure Therapy A behavioral intervention that is mainly based on extinction learning. Exposure therapy is best researched and most established for the treatment of anxiety and trauma-related disorders. Patients are guided to confront themselves with the feared object or situation. By staying in the feared situation, the patient learns that the anticipated negative outcome does not occur (or is less threatening than expected). Besides pathological fear and anxiety, exposure-based strategies can be applied to a variety of mental health problems (e.g., mirror exposure for eating disorders or cue exposure for substance use disorders).

Extinction The decline of conditioned responses when the conditioned stimulus (CS) is repeatedly presented without the unconditioned stimulus (US). An individual learns that the US is no longer predicted by the CS. Extinction is due to inhibitory learning.

Generalization Responses that have been acquired to a particular conditioned stimulus (CS) transfer to stimuli that are perceptually, conceptually, or symbolically similar, but have never been paired with the unconditioned stimulus (US). Children and adolescents show elevated fear generalization, which usually declines with increasing age. In adults, overgeneralization of conditioned fear (i.e., heightened generalization to a wider range of stimuli similar to the CS) has been linked to the etiology and maintenance of anxiety disorders.

Unconditioned Response An innate response, which occurs naturally in response to the unconditioned stimulus (US) and does not require prior learning.

Unconditioned Stimulus (US) A motivationally salient stimulus that is either pleasant (appetitive conditioning) or unpleasant (aversive conditioning).

Mindfulness

Hay Ming Herman LO

Mindfulness is defined as paying attention to the present moment nonjudgmentally (Kabat-Zinn, 2013; Segal et al., 2013). Mindfulness practice originates from Eastern traditions, and its recent popularity in Western psychology is largely due to the development and widespread application of two standardized mindfulness-based programs for adults (MBPs): mindfulness-based stress reduction (MBSR) and mindfulness-based cognitive therapy (MBCT) (Kabat-Zinn, 2013; Segal et al., 2013).

MBPs that integrate mindfulness practices with psychoeducation on stress reduction, often for managing specific health issues, can strengthen competence in coping. Most MBPs consist of group-based learning, and participants are trained in a range of formal mindfulness practices, including body scan, mindful stretching, mindfulness of breath, sounds, and thoughts, and informal mindfulness practices for daily activities such as walking and eating (Kabat-Zinn, 2013; Segal et al., 2013). A growing body of robust evidence from randomized controlled trials (RCTs) demonstrates that MBPs are effective in improving a range of clinical and nonclinical psychological outcomes in adults, including anxiety, stress, quality of life, chronic pain, attention-deficit/hyperactivity disorder (ADHD), autistic spectrum disorder (ASD), and other psychological symptoms in patients with chronic conditions (Galante et al., 2021; Gu et al., 2015).

What Is Mindfulness?

In addition to the above-mentioned concise definition of mindfulness provided by Kabat-Zinn (2013), mindfulness has been operationally defined in psychological science as “the self-regulation of attention so that it is maintained on immediate experience, thereby allowing for increased recognition of mental events in the present moment [and] adopting a particular orientation toward one’s experiences in the present moment, an orientation that is characterized by curiosity, openness, and acceptance” (Bishop et al., 2004, p. 232). Although the concept of mindfulness has long been a part of many religious and spiritual traditions, the current Western interest in this concept can be traced to Buddhist meditation. However, many mindfulness practices used in psychosocial interventions are secular, requiring no compliance to Buddhist doctrine.

Mindfulness practice is often presented as beginning with focused attention on the breath, followed by more critical open monitoring of present-moment experiences and awareness of the whole body (Lutz et al., 2008). In the practice mindfulness of the body, focused attention requires concentrating one's attention on a chosen object, typically on the breath, and refocusing on the breath when the mind wanders away, thereby enhancing volitional attentional focus. Open monitoring requires nonreactive focused attention on the contents of one's moment-by-moment experiences of whatever feelings and thoughts arise. Increased awareness leads to an understanding of the nature of thoughts, feelings, emotions, and perceptions as they arise and dissolve of their own accord (Kabat-Zinn, 2013; Segal et al., 2013).

Mindfulness meditation leads to enhanced attention and awareness of internal and external environmental cues. In essence, by being present and aware of what is happening in each moment, we can learn to discriminate between our preconceptions and the actual experience of the moment. This enables us to change our relationship with the experience of our feelings, thoughts, emotions, and perceptions. Instead of trying to change them, we simply accept them for what they are. Individuals who practice mindfulness regularly are more likely to notice when they adopt the mode of avoidance when encountered with threats or situations requiring them to take self-preserving action such as physical avoidance or defensive attack (i.e., the fight/flight reaction). Mindfulness practice can enable the person to pause and approach their experience, regardless of whether it is pleasant or unpleasant, with a sense of openness and willingness to experience it as it is and to respond consciously to internal and external events (Crane, 2017). This can greatly change one's lifestyle, leading to improved health and wellness.

Assessment Scales for Child Mindfulness

Due to the complex nature and qualities of the mindfulness construct, measuring mindfulness is challenging in children and adolescents. Fewer instruments are available to measure mindfulness in these younger populations than in adults. Some issues that need to be considered when assessing mindfulness in children include age-appropriateness of the items, perceived comprehensibility (e.g., abstract and concrete), limitations regarding self-reflection, and tailoring factor structure and sophistication to respondents' developmental stage (Potts et al., 2021). The most commonly used mindfulness scale in adults is the Five-Facet Mindfulness Questionnaire (FFMQ, Baer et al., 2006). It has multiple subscales that assess how aware the respondent is at the moment based on five aspects: describing, observing, acting with awareness, nonreactivity, and nonjudgment. However, responses to some of these subscales require more advanced metacognitive skills. Thus, most of the current child mindfulness scales are unidimensional (Potts et al., 2021).

The Child and Adolescent Mindfulness Measure (CAMM; Greco et al., 2011) is the first mindfulness scale developed specifically for use in children and adolescents aged 10–17 years. The CAMM assesses trait mindfulness, which is defined as acting with awareness instead of responding instinctively, and accepting without judgment (Greco et al., 2011, p. 2). Many items of the CAMM are based on the Kentucky Inventory of Mindfulness Scale, an adult mindfulness measure (Baer et al., 2004), and it was originally developed to assess three factors: the first factor reflected observation, the second factor reflected lack of awareness of the ongoing activity and judgmental responses to thoughts and feelings, and the third factor reflected non-accepting and avoidant stances toward unpleasant thoughts and feelings. However, the CAMM did not gain adequate support in confirmatory factor analysis, although it demonstrated good reliability in single-factor analysis (Kuby et al., 2015).

The CAMM has 20-item and 10-item versions, and both are supported by empirical evidence. The scale has been translated into many languages including Dutch (de Bruin et al., 2014), Spanish

(Guerra et al., 2019), French (Dion et al., 2018), Chilean Spanish (Garcia-Rubio et al., 2019), Italian (Chiesi et al., 2017), Greek (Theofanous et al., 2020), and Chinese (Lo, 2021).

The Mindful Attention and Awareness Scale (MAAS; Brown & Ryan, 2003) is a 15-item unidimensional measure that assesses trait mindfulness, defined as the tendency to pay attention to and be aware of life experiences. After modifications, the MAAS has been formally adapted for use in children aged 9–13 years (MAAS-C; Lawlor et al., 2014) and adolescents aged 14–18 years (MAAS-A; Brown et al., 2011). The MAAS-A has demonstrated strong internal consistency in different populations including secondary students, psychiatric patients, and incarcerated adolescents. Unlike the CAMM, the MAAS-A and MAAS-C emphasize the "presence" quality of mindfulness. The MAAS has been translated into many languages and has been adapted to adolescents in different countries and cultures with some modifications; for example, some researchers have developed shorter versions of the MAAS for the younger population, such as a 5-item version for Norwegian adolescents (Smith et al., 2017).

The Comprehensive Inventory of Mindfulness Experiences – Adolescents (CHIME-A; Johnson et al., 2017) is a 25-item trait mindfulness measure developed for use in adolescents aged 12–14 years. The CHIME-A is adapted from the CHIME, which was developed for mindfulness assessment in adult populations (Bergomi et al., 2015). The CHIME-A assesses mindfulness in eight domains: awareness of internal experiences, awareness of external experiences, acting with awareness, accepting and nonjudgmental orientation, decentering and nonreactivity, openness to experiences, relativity of thoughts, and insightful understanding. Recently, a study in Belgium used the CHIME-A to investigate mindfulness in adolescents with chronic conditions (Kock et al., 2021). While this measure may be particularly helpful for measuring specific components of mindfulness, use of its total score is not recommended due to the unsatisfactory internal consistency. Further studies on the psychometric properties and external validity of this measure are warranted.

Although the assessment scales currently available for child and adolescent mindfulness are few, each has its strengths and shows good psychometric properties. Further studies are needed to inform the development of improved mindfulness scales for younger populations (Pallozzi et al., 2017). Future research should focus on clarifying the factor structure and content being assessed by these mindfulness scales. This is challenging in children, given that single-factor solutions often function better, but the content of these single factors varies, and the scales are lacking items relevant to the definitions of mindfulness in adults. It is also worth investigating whether the factor structure of a mindfulness scale should vary by the developmental stage of the respondents. There is a lack of scales for measuring state mindfulness in the younger population, which suggests another research direction for future studies. Overall, assessing mindfulness using adapted scales in children and adolescents is imperative to advance our understanding of mindfulness and promote the application of MBPs in this population.

Mindfulness-Based Programs and Practices for Children

Mindfulness-Based Stress Reduction and Mindfulness-Based Cognitive Therapy for Children

Mindfulness-Based Stress Reduction (MBSR; Kabat-Zinn, 2013) is the first benchmark evidence-based secular program that provides brief but intensive mindfulness training for people with a wide range of medical, psychological, and psychiatric conditions. Mindfulness-Based Cognitive Therapy (MBCT; Segal et al., 2013), which incorporates elements of MBSR and cognitive therapy, was initially developed as an intervention to prevent relapse of major depression but has subsequently been used in people with a wide range of clinical issues and problems. Some MBPs for children have been claimed to be adapted from the MBSR or MBCT program for adults, although their formats are different from the adult versions.

Biegel et al. (2009) conducted an RCT of MBSR in adolescent psychiatric outpatients aged 14–18 years, most of whom had mood or anxiety disorders. This study intervention closely followed the format of MBSR, comprising a 2-h class per week for 8 weeks, home practice for 20–35 min, and no day retreat. Relative to control participants who received the usual treatment, those receiving MBSR self-reported reduced symptoms of anxiety, depression, and somatic distress, and improved self-esteem and sleep quality. However, the author paid relatively little attention to ensuring the developmental appropriateness of this adult MBSR-based intervention in adolescents, apart from reducing the practice intensity.

Huppert and Johnson (2010) studied the effects of a brief mindfulness program on 155 male students aged 14–15 years. The program was claimed to be a modified version of MBSR. It involved four 40-min classes and three 8-min audio files for use as home practice guidance. Video clips were produced to highlight the values of mindful awareness. Students after such mindfulness program did not report significant between-group differences, probably due to the limited intensity of the program and the lack of individual practice outside classroom. This protocol has been relabelled as ".breathe," (read as "stop and breathe") a brief mindfulness-based program, under the umbrella of the Mindfulness in Schools Project. Some recently developed MBPs for children and adolescents are claimed to have been developed based on MSBR or MBCT and are labeled with different names.

Two studies evaluated an MBSR intervention comprising a 50-min session per week for 12 weeks in low-income urban youth. The study population included 41 school-going boys in one study (Sibinga et al., 2013) and 33 HIV-infected adolescents in a hospital in another (Sibinga et al., 2011). The MBSR program was adapted to the target population by modifications such as giving reminder phone calls to the participants before the sessions, providing snacks, and using simplified and clear language to present the materials. However, the authors emphasized that the intervention retained the core content of adult MBSR. In the first study, the boys in the MBSR group reported significant improvements in anxiety, ruminations, and negative coping, but no improvements in other outcome measures such as emotional awareness, anger expression, conflict, and perceived stress were found. In the second study, the MBSR group reported reductions in hostility, general discomfort, and emotional discomfort after the program. Both studies did not include control groups for comparison and included small sample sizes. While the programs concern about the suitability of child MBPs following the structure of adult MBPs and developed shorter sessions and practices, there may be an issue of intervention fidelity of MBSR.

Semple and Lee (2007) developed a manualized MBCT program for children (MBCT-C) aged 9–12 years. It consists of 12 weekly 90-min sessions delivered in groups of up to eight children. The first three sessions of the MBCT-C focus on introducing the basic concepts of mindfulness to the participants, followed by six sessions dedicated to providing experiential learning of mindfulness. The last three sessions of the MBCT-C focus on cultivating self-compassion and applying mindfulness skills to manage intrusive thoughts and emotions. An open trial showed the feasibility of the MBCT-C in reducing negative emotional symptoms in adolescents aged 9–12 years (Lee et al., 2008). Semple et al. (2010) further conducted a waitlist-controlled trial involving 25 schoolchildren. The study produced mixed results but showed improvements in the anxiety symptoms and behavior problems of children with clinical anxiety.

The MBCT-C has been adapted to other child populations in two studies in Iran. Esmaeilian et al. (2018) conducted an RCT of a modified version of the MBCT-C in 83 10–13-year-old children of divorced parents. At the end of intervention, the children from the mindfulness group showed significantly fewer symptoms of depression, trait anxiety, state anxiety, trait anger, and state anger in comparison with the control group. Abedini et al. (2021) randomly assigned 40 11–13-year-old children with cancer to the MBCT-C or treatment-as-usual control group. The MBCT-C group showed significant reductions in internalizing and externalizing problems, and these effects were maintained at the 2-month follow-up. Another recent study applied the MBCT-C to 24 youth at risk of bipolar disorder (Cotton et al., 2020). There were significantly greater improvements in overall clinical severity after MBCT-C compared to the waitlist period, but not in clinician- and child-rated anxiety, emotion regulation, or mindfulness. The main limitation of most studies on the MBCT-C is their relatively small sample sizes.

In another study, Bögels et al. (2008) developed an MBCT-based MBP for adolescents with externalizing disorders such as ADHD, ASD, oppositional-defiant disorder, and conduct disorder, and for their parents. The 8-session MBCT program (1.5 h per session) was adapted to provide mindfulness training for the adolescents and their parents in parallel groups. The program included all mindfulness practices from MBCT, and a worksheet and CD were provided for practice. In the last session, the adolescents were required to develop an action plan to continue their mindfulness practice in the 8 weeks following the termination of formal training. The pilot study included 14 adolescents with mixed clinical diagnoses. Compared with the waitlist group, the adolescents in the MBCT group self-reported improvements in internalizing and externalizing problems, attention problems, self-control, and attunement to others (Bögels et al., 2008). A follow-up study further reported the positive effects of the MBCT program in ADHD children and their parents (van der Oord et al., 2012). Based on these initial attempts, Bögels developed a treatment approach called MYmind for children with ADHD and ASD and their parents (a following section discusses the application of this program in clinical populations).

.b and Paws b

The Mindfulness in Schools Project in the UK has developed a series of child MBPs, starting from “.b” (read as “dot-be”) for secondary school students. In the original design of the MBP, one session is scheduled weekly to be taken place during normal lesson time. The content includes the basic practices of mindfulness of breath, body, and thoughts, mindful eating, mindful walking, and coping with stress. It is supported by home practice, a guidance manual, an indicative script for teachers, and a student booklet. The course designers have also created PowerPoint files with interactive, experiential, and lively resources, such as video clips, and challenging activities to facilitate classroom teaching and make the content attractive to teenagers.

A total of four curricula have been subsequently developed for different age groups, “dots” for children aged 3–6 years in preschool settings, “Paws b” for children aged 7–11 years, “.breath” for children aged 9–14 years, and “.b” for adolescents aged 11–18 years in secondary schools. Each program has a different structure adapted to the developmental stage of the target population. “Dots” consists of 30 sessions that can be delivered in discrete 10–20-min sessions and can be repeated throughout an entire week or even weeks. “Paws b” can be delivered as twelve 30–60-min lessons or can be grouped into six sessions. “.breathe” is a brief course of four sessions and consists of fewer mindfulness practices than “.b” or “Paws b,” which include more extensive training.

Large-scale studies have been conducted to investigate the feasibility and effectiveness of the “.b” program. The first cohort-controlled study recruited 522 secondary school students aged 12–16 years to participate in “.b” or in the usual school curriculum as the control group. Students who participated in the program reported fewer depressive symptoms at posttest and significant improvements in stress and well-being at follow-up (Kuyken et al., 2013). In an RCT, Johnson et al. (2016) assessed the effects of “.b” on 132 students in comparison with those of the usual treatment on 176 students. They did not find significant between-group differences in anxiety, depression, body concerns, or well-being at posttest and the 11-week follow-up.

A large-scale cluster RCT was conducted in Finland to evaluate the effects of ".b" on 3519 adolescents aged 12–15 years. The students were randomized into a 9-week ".b" program, a relaxation program, or teaching as usual (the control group) (Volanen et al., 2020). The ".b" program showed no beneficial effects on most outcomes compared with the control treatment, but it had a positive effect on resilience at post-intervention in comparison with the relaxation group. Compared with the control treatment, the ".b" program reduced depressive symptoms in girls at the 26-week follow-up but not in boys. This lack of significant difference in the depressive symptoms in boys may be because their depression scores were already low at baseline.

Furthermore, Sanger and Dorjee (2016) attempted to uncover the impacts of ".b" using neuroscientific methodology. They found that students after the ".b" program showed more negative N2 amplitudes in response to color-deviant and standard nontarget stimuli in a visual oddball paradigm. These improvements were thought to be associated with self-reported negative-thought controllability and reductions in students' hypercritical self-beliefs (Sanger & Dorjee, 2016).

Vickery and Dorjee (2016) conducted a non-RCT to investigate the acceptability and emotional well-being outcomes of the "Paws b" program in 71 children aged 7–9 years. Compared with the control participants, the students after the program showed significant decreases in self-reported negative affect at follow-up and improvement in teacher-rated metacognition. However, these findings are limited by the small sample size and lack of randomization. Other limitations are that the same teachers who delivered the program also rated the students' metacognition, and that the improvements in metacognition were not supported by the parents' ratings.

Overall, ".b" is one of the most studied school-based MBPs. It is not surprising that a classroom-delivered program can only yield modest effects; therefore, further studies are warranted to explore optimal ways to adapt and deliver MBPs in the school context, particularly so that students are motivated to perform home practice and maintain the benefits even after the termination of formal training (Volanen et al., 2020).

MindUP

MindUp is mindfulness-based social and emotional learning program that consists of fifteen 45-min lessons, one lesson taught per week. It has been developed for children from pre-kindergarten to 8th grade, with three versions adapted to different age groups: pre-kindergarten to grade 2, grades 3–5, and grades 6–8. Each lesson incorporates mindfulness practices with classroom activities to learn about the brain, understand how thoughts and feelings affect actions, and learn strategies to become caring people. The Core Practices (for 3 min, three times a day) consist of focusing on one's breathing and attentively listening to a resonant sound. Children learn how training their focused awareness offers a self-regulatory strategy to calm themselves when they are overwhelmed with emotions. The MindUP program includes one lesson dedicated to teaching children about the brain, particularly the amygdala and the prefrontal cortex and their roles in emotions and cognition. This helps them to understand the links between the brain's neurology, positive psychology, and mindfulness practices and motivates them to perform those practices to improve their attention and calmness.

Studies have demonstrated the effects of the MindUP program in promoting mindfulness and positive development in children and young adolescents. The first study adopted a waitlist-controlled design involving 246 early adolescents from the 4th to 7th grades (Schonert-Reichl & Lawlor, 2010). In the study, the adolescents in the mindfulness group showed significant increases in optimism and teacher-rated attention and classroom social competent behaviors, compared with those in the control group. The second study randomly assigned 99 adolescents from the 4th and 5th grades to the MindUP program or the regular social responsibility school program (Schonert-Reichl et al., 2015) and performed multiple outcome assessments, including objective cognitive tasks; salivary cortisol assessment; social–emotional competence assessment via self, peer, and teacher ratings; and assessment of end-of-year math grades. At posttest, compared with the control group children, the mindfulness group children had significantly shorter response times on average in the cognitive control tasks, indicating improvements in inhibition, working memory, and selective attention. They also had higher cortisol secretion in the morning and a stable diurnal pattern, both implying a healthier stress physiology. Furthermore, the mindfulness group children also showed significant improvements in optimism, emotional control, empathy, perspective-taking, prosocial behaviors, and mindful attention and decreases in depressive symptoms; a significant increase in self-reported school self-concept (i.e., perceived academic abilities and interest and enjoyment thereof); and a 15% gain on average in teacher-reported math grades.

The positive outcomes of the MindUP program reported in the above studies are promising (Schonert-Reichl et al., 2015; Thierry et al., 2016, 2018). However, many outcome measures evaluated in the program correspond to the social–emotional learning components, and it remains uncertain whether the mindfulness component of this program provides additional benefits for children relative to the other social–emotional learning programs. The MindUP program has been translated into different languages in countries including China, Finland, and Qatar, and quasi-experimental studies have reported the effects of the program in 223 Portuguese children (de Carvalho et al., 2017) and 200 Northern Ugandan children, as well as the process of adaptation to the local culture (Matsuba et al., 2020).

Learning to Breathe

The Learning to Breathe (L2B) curriculum teaches adolescents to be mindful of their present moment through lessons on awareness, reducing self-judgment, and being mindful in everyday life (Broderick, 2013). It can be implemented in 6-, 12-, or 16-week versions in a group setting. Each 45-min lesson includes core practices common to most MBPs, such as body scan, mindfulness of thoughts and emotions, and mindful movement, in addition to loving-kindness practice where students are asked to bring someone to mind, including themselves, and wish them well. Students are provided with workbooks and CDs for mindfulness practice at home.

After a pilot study reporting positive effects of the L2B program in 23 marginalized youth (Eva & Thayer, 2017), the impact of the program was investigated in a sample of 251 high-school students who were randomly assigned to a teacher-delivered L2B program or the usual health curriculum (the control group) (Frank et al., 2021). The L2B program group students did not show significant improvements in any self-reported measure in mindfulness, emotion regulation, mental health symptoms, or social connectedness but unexpectedly reported higher levels of rumination and difficulties in goal-directed behavior (a subscale of emotion regulation) compared with the control group students. In behavior assessments of executive functioning, the mindfulness group reported better reaction times in cognitive interference and working memory tasks than the control group. The study further investigated the effects of adequate L2B practice, i.e., practicing at least once per month, according to student's self-reported in one-third of the whole sample, and found a moderating effect of practice with greater improvements in emotion regulation, emotional awareness, emotional clarity, impulse control, mind wandering, and social connectedness.

In view of the unexpected findings, a few implementation issues were highlighted (Frank et al., 2021). First, despite providing school teachers with extensive support while delivering MBPs, including supervision, live observations, and weekly feedback calls, none of the teachers achieved a high level of implementation fidelity. This suggests that it is unrealistic to expect teachers to become competent mindfulness instructors after a short training. Second, effects of the MBPs on clinical symptoms could not be detected as the majority of the students in the study samples were relatively healthy (Greenberg & Abenavoli, 2017). Lastly, despite efforts to integrate mindfulness practice into the regular school day, only one-third of the adolescents reported practicing mindfulness at least once a month. Thus, students may need more support and guidance to incorporate the practice into their daily lives.

Mindful School

The Mindful School program consists of eighteen 20-min lessons, delivered at the rate of three a week for a total of 6 weeks. To maintain consistency in implementation, the teachers are provided with a manual based on which to deliver each lesson. In this program, children practice focusing their attention on breathing, walking, eating, and seeing. The program includes lessons on "heartfulness," which helps students explore themes on kindness toward and caring about themselves and others. Following each lesson, children are asked to write or draw in their journals about what they learnt from the new mindful awareness practice that day. Children are also encouraged to practice what they learned and teach their family members at home and to share about these experiences at the beginning of each session.

An earlier study of the program effect was conducted in 409 children from ethnic minorities and disadvantaged backgrounds (Black & Fernando, 2014). Teachers were asked to deliver 2-min practices to their students on the days when the Mindful School instructors were absent. At post-intervention, the teachers reported improved classroom behaviors including attention, self-control, and caring for others, and the effects were maintained at 7 weeks post-intervention. Unfortunately, no control group was included in the study design. Viglas and Perlman (2018) studied the effects of the program on the self-regulation, prosocial behavior, and hyperactivity of 127 preschool children aged 4–6 years using an RCT design. Compared with the control group, the mindfulness group showed greater improvements in self-regulation, prosocial behavior, and hyperactivity with moderate effect sizes. Similar to many other studies of school-based MBPs, the study by Viglas and Perlman (2018) involved children from low-income households; therefore, the generalizability of the findings to children from other socioeconomic backgrounds is uncertain.

MYmind

MYmind is a standardized mindfulness-based program for children and adolescents and their parents (Bögels, 2015). This program lasts 8 weeks with 1.5-h sessions for children and their parents conducted in parallel groups of 5–6 children and 6–12 parents and includes a booster session 8 weeks after the last session. The MYmind program incorporates a brief version of the Mindful Parenting program created by the same authors (Bögels & Restifo, 2014), and both programs for parents and children emphasize on practices to focus and sustain attention, to be aware of being distracted and regain attention on the original focus, and to enhance bodily awareness. The practices include short meditations, yoga, playful exercises, and games. Parents and children receive session handouts describing the session theme, instructions for practice, homework completion diaries, and recordings of mindfulness exercises to practice at home for 15 min each day.

The targets of the MYmind program are children with ADHD and adolescents with ASD. To encourage participation and retention, tokens are given as rewards to children for completing homework and participating in exercises during the sessions. With accumulation of tokens, rewards such as a small gift or additional play time will be given to the children. Other strategies to increase intervention compliance, such as creating a highly structured program, establishing ground rules, allowing breaks at regular intervals, and including a helper in addition to the instructor, are also adopted. Empirical studies of this program are included in a later section focusing on clinical populations.

Soles of the Feet

Soles of the Feet (SoF) is a brief mindfulness practice that enables an individual to move the focus of attention from an emotionally arousing thought, event, or situation (e.g., anger, aggression, worry, anxiety, and fear) to an emotionally neutral part of the body, such as the soles of the feet (Singh et al., 2011c). The practice allows children and individuals to tap into the interoceptive awareness of emotional and physical changes that may manifest in their body and to pay attention to the source of the emotional changes and encourages them to insert a pause between the eliciting stimulus and their typically instinctive reaction to this stimulus. The pause enables the individual to discern the individual components of the situation and then produce a mindful response that is socially acceptable. Training on task analysis is delivered either on an individual basis or in a group (Felver & Singh, 2020). The SoF practice has been widely used as a self-management intervention in various populations and settings, including child residential homes, schools, community settings, eldercare settings, clinics, and hospitals. Empirical studies of this program in children with clinical problems are presented in a later section.

Age and Sex Effects on the Outcomes of Child Mindfulness Programs

Until 2009, fewer than 10 studies had been published on mindfulness programs for children and adolescents annually. However, the number has grown rapidly in recent years, with 164 papers being published by 2019 (Saunders & Kobers, 2020). Thus, evidence on the effectiveness of MBPs in children has been accumulating. In this section, we discuss the effects of age and sex on the outcomes of the mindfulness programs, discuss the key findings in systematic reviews and meta-analyses of clinical populations, and present some recent representative studies that provide a picture of the current state of research in this area.

Can Mindfulness Programs Benefit Preschool Children?

A recent systematic review focused on studies on the application of mindfulness in preschool-aged children (Sun et al., 2021). Although most studies reported some positive improvements in selected domains of child development, the methodological quality of many of the included studies was concerning and many studies had moderate-to-serious overall risk of bias. As mentioned in the earlier section, Viglas and Perlman (2018) studied the effects of the Mindful School program on 127 preschool children aged 4–6 years and reported significant improvements in their self-regulation, prosocial, and hyperactivity. However, this study sample included only children from low-income households, which prevents the generalization of the findings to children from other socioeconomic backgrounds.

A recent RCT evaluated the effects of the Kindness Curriculum on 68 preschool students from families from a higher-income district. The program integrates mindfulness practices with gratitude and compassion to cultivate prosocial behavior (Flook et al., 2015). It is a 12-week program that includes two 20–30-min lessons each week. At the end of the program, the students in the mindfulness group in the RCT showed greater improvements in prosocial behavior and teacher-reported social competence, and also received higher academic grades at the end of the school year, than the students in the control group. The teacher-rated improvements in both the mindfulness and control groups showed large effect sizes. However, the between-group difference in terms of prosocial behavior and emotion regulation was small (d = .29 and .25 respectively).

The feasibility of the OpenMind program, which integrates mindfulness practices with social–emotional learning, was studied in an RCT in 262 children aged 3–5 years (Jackman et al., 2019). Children were assigned to the mindfulness program or a social–emotional learning intervention. Compared with the active control group, the students from the mindfulness group showed greater improvements in self-regulation, as reflected by their performance in the Head, Toes, Knees, and Shoulders task. However, the students from the mindfulness group showed deterioration in cognitive flexibility and no significant differences in inhibitory self-control, metacognition, or overall executive functioning when compared with the active control group (Jackman et al., 2019).

To date, three studies have focused on the MindUP program on preschool children, as reported in the earlier section (Crooks et al., 2020; Thierry et al., 2016, 2018). Thierry et al. (2016) studied the effects of the MindUP program on 47 students (mean age = 4.56 years, SD = 0.33 years) in comparison with those of the usual treatment in the control group. Although the parent-reported scores of children in the mindfulness group did not reveal significant changes, the teacher-reported scores revealed significant improvements in working memory and planning/organizing with large effect sizes (d = 1.02 and 1.17 respectively). The mindfulness group also had higher vocabulary and reading scores than the control group. Thierry et al. (2018) then replicated the study in a larger preschool sample of African American and Latino students (n = 157) of similar age and a matched control group. At the end of the school year, the students in the mindfulness group showed greater improvements in executive functions than those in the control group with small-to-moderate effect sizes (ds = .31 to .56). Crooks et al. (2020) recruited 261 preschool children and evaluated the impact of the program, with a comparison group of 323 children, in districts that were characterized as high social risk and disadvantaged. Students who received the program demonstrated improvements in adaptive skills, reduction in behavioral problems, and executive functioning, relative to the control group counterparts.

Thus, more studies with a rigorous design are warranted to conclude the benefits of this program in preschool children. Nevertheless, the findings of the two studies suggest that mindfulness is a promising approach in children, but they should be interpreted with cautions due to two limitations. First, the sample sizes of these studies were small, probably because more resources are required when conducting intervention studies targeting preschool children as they often include their parents/guardians as well. One study (Thierry et al., 2016) reported teachers' ratings but not parents' ratings. Second, the younger the program participants, the more modifications are required in the intervention components to adapt to the younger population, and it becomes a delicate problem to judge whether a program is mindfulness-based or a multiple-intervention program.

Can Children and Adolescents Benefit Equally from Mindfulness Programs?

A few large-scale clinical trials are described in this section to elucidate the current state of research on this specific question. Gómez-Odriozola and Calvete (2021) conducted a waitlist RCT of the L2B curriculum in 300 students aged 13–21 years who were randomly assigned to the program (Broderick, 2013). Older adolescents in the control group showed significant increases in depression and somatic symptoms implied the L2B program may have a preventing effect. Moreover, interpersonal difficulties decreased among older adolescents who completed the program. In contrast, younger adolescents in the program group showed increases in depression and somatic symptoms, whereas no significant changes in those factors were observed in the control group. These findings suggest the need for age-appropriate adaptation of mindfulness programs and satisfaction survey results suggested that students expect a program more enjoyable and stimulating (Gómez-Odriozola & Calvete, 2021). Besides, the relevance of mindfulness practice in younger adolescents without serious health or mental health issues should be rigorously evaluated for better program efficacy.

A recent meta-analysis investigated the effects of age on the outcomes of school-based mindfulness programs and found similar evidence (Carsley et al., 2018). Studies conducted in late adolescents ($n = 7$; Hedges' $g = .28$) revealed larger program effects on mental health and well-being outcomes than those conducted in children in middle childhood ($n = 6$; $g = .20$). Program effects on early adolescents were not significant ($n = 6$; $g = .11$). Late adolescents showed significant but small effects at follow-up in both the within-group ($n = 4$; $g = .33$) and between-group analyses ($n = 3$; $g = .22$). However, a meta-analysis (Odgers et al., 2020) of studies on anxiety found significantly larger effect sizes in studies on children ($n = 6$, $d = .41$) than in studies on adolescents ($n = 13$, $d = .21$).

Sex Effects on the Outcomes of School-Based Mindfulness Programs

Most previous findings suggest that adult women benefit more than adult men from mindfulness programs (Katz & Toner, 2013). Of the six studies that have investigated the potential moderating effect of sex on the outcomes of school-based mindfulness programs, two reported greater benefits in female students than in male students (Johnson et al., 2016; Kang et al., 2018), one indicated greater benefits in male students than in female students (Salmoirago-Blotcher et al., 2018), and two reported no significant differences between the sexes (Johnson et al., 2017; van der Gucht et al., 2016).

Sheinman et al. (2018) investigated the perception of mindfulness practice among 646 students aged 9–12 years in Israeli public schools that had implemented a mindfulness curriculum. They reported that girls had a higher tendency than boys to apply mindfulness strategies in coping with stress, regardless of their age. Although most studies show that girls benefit more than boys from child MBPs, further studies are warranted to explore the moderating effect of sex in different age ranges and with different clinical problems.

Application of Mindfulness Programs in Clinical Populations

Attention-Deficit/Hyperactivity Disorder (ADHD)

Mindfulness practices offer a training for children to maintain focused attention and to bring their attention back when it wanders. With such practices, children with ADHD can learn to focus and sustain their attention and respond mindfully to thoughts, feelings, and situations rather than to react impulsively. In the practice of Buddhist meditation, there is a metaphor called the monkey mind, describing the mind with scattered attention that jumps from one thing to another; this is a particularly challenging aspect to control for children with inattention, hyperactivity, and impulsivity problems. Some children with ADHD also have difficulties with or a reduced capacity for emotion regulation probably due to their thin anterior cingulate cortex (part of the frontal lobe) (Bledsoe et al., 2013).

Mindfulness training may help to tame the monkey mind and improve emotion regulation with kindness, compassion, and acceptance, and by practicing mindfulness regularly, children with ADHD can learn to take a pause and act mindfully, thus reducing their impulsive behavior as well as other ADHD symptoms such as hyperactivity and inattention.

Several systematic reviews and meta-analyses of studies on the application of mindfulness in children with ADHD have been published in the past few years (Cairncross & Miller, 2016; Chimiklis et al., 2018; Evans et al., 2018; Mak et al., 2018; Tercelli & Ferreira, 2019; Vekety et al., 2021; Xue et al., 2019). Cairncross and Miller (2016) meta-analyzed 10 studies on child MBPs, six of which reported the effectiveness of MBPs on inattention in children with ADHD, with an average moderate effect size of $d = .66$, and five reported the effectiveness of MBPs on hyperactivity/impulsivity, with an average small-to-moderate effect size of $d = .47$. Most of the studies included in the meta-analysis by Evans et al. (2018) reported significant effects of MBPs on ADHD symptoms but also had a high risk of bias. In contrast, two of the included studies that incorporated yoga and marital arts in the MBPs showed no effect or even negative effects on ADHD symptoms. Mak et al. (2018) reviewed 13 studies reporting the effects of child MBPs on neuropsychological measures of attention and executive functioning. Five of these studies showed medium-to-large effect sizes, while the other eight studies showed no effects. A review of 10 studies by Tercelli and Ferreira (2019) revealed positive effects of child MBPs on attention deficits but found less conclusive evidence of the effects of the programs on hyperactivity. They emphasized that the included studies had several methodological limitations and concluded that the current evidence on the impact of MBPs on ADHD is inconclusive.

Chimiklis et al. (2018) reviewed 11 studies on the effects of yoga and mindfulness interventions on youth with ADHD and reported that these interventions significantly reduced hyperactivity and inattention in this cohort and improved executive functioning. However, evidence of MBPs with ADHD are not comparable to pharmacological approach and behavioral training. Vekety et al.'s (2021) review of 21 studies revealed that the MBPs significantly decreased children's inattentive and hyperactive symptoms with small effect sizes ($g = .38$). However, these positive outcomes were significant only in teachers' ratings, while nonsignificant in parents' ratings and the children's self-reported ratings. Finally, Xue et al.'s (2019) review of 11 studies found that the mindfulness interventions had significant positive effects on inattention ($g = .83$) and hyperactivity/impulsivity ($g = .68$) relative to the control interventions. The results of subgroup analyses showed significant positive outcomes in both self- and observer-reported ratings of ADHD symptoms in the intervention groups. However, self-reported ratings of ADHD core symptoms had a greater impact on heterogeneity across the studies than did observer-reported ratings. Overall, although the inclusion criteria of and results reported by the included studies varied, most of them suggested that mindfulness is a potential complementary therapy for children with ADHD.

We further discussed some recent studies that had not been included in recent meta-analyses. After a few small open trials, three large-scale RCTs were conducted on the outcomes of the MYmind program in the Netherlands. One of these was a large multiple-baseline study of the effectiveness of the MYmind program in 187 children and their parents (de Bruin et al., 2021). The study reported no changes in children's ADHD symptoms in the waitlist group while significant reductions in the symptoms in the MYmind group at posttest, 2 months later, and 1 year later relative to the pretest levels. Improvements were also reported in the parents' ratings of the children's internalizing and externalizing symptoms in the MYmind group, in addition to significant improvements in the children's executive functioning at the 1-year follow-up.

In another RCT, 103 children and adolescents aged 8–16 years with ADHD were randomized to the standard care plus mindfulness program or the standard care alone (Siebelink et al., 2021). The mindfulness plus standard care group showed a small nonsignificant posttreatment improvement in the self-control deficits, but more children showed reliable posttreatment improvements following mindfulness training versus standard care only group (32% versus 11%). The parents' and teachers' ratings of the children's ADHD symptoms showed significant positive trends at posttest. However, only parents' ratings of hyperactivity and impulsivity remained significant at the 6-month follow-up. Between-group differences in other secondary outcomes were mostly nonsignificant at posttest and follow-ups.

Another RCT compared the effects of an 8-week mindfulness program with those of an 8-week methylphenidate treatment (Meppelink et al., 2016) in a randomized sample of 91 children aged 8–18 years with ADHD. After randomization into the trial, 8-week mindfulness or methylphenidate treatment is administered. Due to ethical concerns, between the first and second follow-ups, the children and their families were free to choose another treatment, stop treatment, or transfer to the other intervention group. The two interventions performed better in different outcome measures, and details of the results will be reported in an upcoming publication. Apart from studies in the Netherlands, pilot studies of MYMind program have also been conducted in Hong Kong Chinese children with ADHD (Zhang et al., 2017), and a large-scale RCT is currently ongoing with an active control group being administered cognitive behavior therapy (Chan et al., 2018).

Another RCT adopted a similar design to investigate the effects of an 8-week parallel program that integrated the Mindfulness Matters child mindfulness program (Snel, 2014) with a brief MBP for parents (Lo et al., 2017). The study recruited 100 children aged 5–7 years with ADHD and their parents (Lo et al., 2020). The families were randomized to the mindfulness group or a waitlist control group. According to the parents' ratings, the children from the MBP group showed greater improvements in inattention (d = .60) and hyperactivity (d = .59) than those from the waitlist group. The parents' ratings of child behavior, attention, and conflict monitoring also showed small effect sizes. Changes in ADHD symptoms were found to mediate improvements in overall child behavior (Lo et al., 2020).

All meta-analyses have pointed out that many of the published studies on child MBPs have major methodological limitations. In fact, some well-controlled studies did not find significant between-group differences, suggesting that the effects of mindfulness should not be overstated. Further studies with a rigorous study design are warranted to investigate whether the effects of mindfulness programs can be sustained after the intervention.

Autistic Spectrum Disorder (ASD) and Intellectual Disability (ID)

Although mindfulness may not be suitable for all children with ASD and ID, MBPs may benefit those with high-functioning autism, especially indirectly through offering mindfulness training to their parents and caregivers. Hartley et al. (2019) reviewed 10 studies investigating the effects of mindfulness on children and adults with ASD. However, only three of these study focused on children and adolescents, and moderate effects were noted across all of these studies.

De Bruin et al. (2015) assessed the effects of the MYmind program on 23 adolescents aged 11–23 years with ASD through an open trial design. The adolescents self-reported increased quality of life and decreased rumination at post-intervention. Although no changes were reported in the core symptoms of ASD or worry, improvement was noted in social responsiveness. Ridderinkhof et al. (2018) delivered the same program to 45 adolescents aged 8–19 and their parents. The children self-reported improvements in externalizing problems and attention problems at posttest and follow-up, while the parents reported improvements in their children's social communication, internalizing problems, and externalizing problems at posttest and follow-up. Salem-Guirgis et al. (2019) evaluated the effects of the MYMind program on 23 youth aged 12–23 with ASD and their parents in Canada, using a within-subject repeated-measures design. The parents reported a small but significant decrease in their children's behavioral symptoms, but this change was not maintained at the 10-week follow-up. A small significant increase in adaptive skills was reported at posttest and follow-up. The parents also reported improvements in the overall symptoms of autism and social motivation at posttest and follow-up. These three studies provided initial evidence of the effectiveness of mindfulness programs on adolescents with ASD. Another feasibility study of the program was conducted in Hong Kong, using a waitlist control design (Ho et al., 2021). Both parent's ratings of social competence and behavior problems showed significant improvements after the program, but similar changes were found in waitlist control group. The program had high satisfaction and attendance, but no between-group difference was found at posttreatment. However, all studies had a relatively small sample size and lacked a control group. Thus, further studies are required with larger samples sizes and control interventions for comparison to obtain more robust evidence.

Hwang et al. (2015) conducted an outcome study of a mindfulness program in six dyads of children aged 8–15 years with ASD and their mothers in Australia. The mothers participated in a program similar to MBSR consisting of a weekly 2.5-h session for 8 weeks, but there was a 4-week break between the last two sessions, allowing the mothers to practice independently as a transition from the end of intervention to home practice. After the end of 8 weeks, the mothers delivered mindfulness training to their children with the support of the trainer through home visits and online meetings. The results revealed improvements in the children's overall behaviors and anxiety.

As introduced in the earlier section, the Soles of the Feet (SoF) program adopts a one-to-one approach to training children with ASD or ID and their parents. In a study with a multiple-baseline design, 1 month after receiving SoF training, the mothers taught their three adolescents with ASD to practice the SoF approach to self-manage their physical aggression at home and during community outings (Singh et al., 2011b). Following baseline observations of the adolescents' aggressive behaviors, the mothers taught them the SoF practice in a 15-min session daily for 5 days and prompted them to follow the SoF practice when they anticipated the children's anger or aggression. The adolescents were provided with audiotapes for self-practice outside of the training sessions and were required to practice twice a day and whenever an incident occurred that could elicit aggressive behavior. The results showed that the three adolescents reached the training outcome of no aggressive behaviors for three consecutive weeks during week 17, 22, and 24, and all three of them maintained the lack of aggressive behaviors during the 4-year follow-up. In another study using a similar research design and methodology, three adolescents with autism were taught by their mothers to use the SoF procedure to self-manage their aggression (Singh et al., 2011a). Compared with the adolescents in the previous study, these adolescents with autism took longer to achieve the training outcome of no aggression for four consecutive weeks and displayed a few aggressive behaviors during the 3-year follow-up.

In another such study, Ahemaitijiang et al. (2020) taught mothers of three Chinese adolescents with ASD a foundational meditation practice before teaching them the SoF practice. The results showed clear benefits of the SoF practice, and the adolescents' frequency of physical aggression and destructive behavior decreased to zero and was maintained at this level during the 12-month follow-up. This study thus demonstrated the applicability of the SoF practice in mainland Chinese culture.

Studies on mindfulness training of individuals with ID are scarce and are mostly based on adult samples. In a small waitlist RCT, 34 individuals aged 17–31 years with mild ID were randomly assigned to either the SoF group or a waitlist control group (Singh et al., 2013a). The results showed that verbal and physical aggression were significantly reduced only in the SoF group, and that the waitlist group showed similar reductions when they were provided training in SoF. This suggests that mindfulness training is effective for late adolescents, but evidence on its effectiveness in younger children is still lacking.

The benefits of integrating mindfulness in health promotion programs for children with ID were evaluated in a pilot study of 32 overweight or obese adolescents (Myers et al., 2018). This program included a 10-week training to the parents via online platform and the content including mindfulness practice and health education including physical exercise, healthy eating and nutrition, mindful eating, mindful responses to thoughts of hunger, and a mindfulness practice to control the urge to eat. Parents delivered the training to their children afterwards. The 30 participants who successfully completed the whole program lost an average of 38.27 lb (17.36 kg) by the end of intervention and maintained their target weight for four consecutive years.

Another such study evaluated the effectiveness of an MBP in a sample of 14 school students aged 9–12 years with severe learning difficulties and borderline IQ (Malboeuf-Hurtubise et al., 2018). The program consisted of eight 1-h sessions and was adapted to the developmental level of the students. Unexpectedly, the students reported a significant reduction in need satisfaction after the program. This suggests issues in the implementation and study of mindfulness training among children with ID, including potential harmful effects, inadequate language adaptation for special-needs children, and selection of meaningful outcome measure in match with the target population.

In summary, studies on the efficacy of MBPs in children with ASD and ID are limited in the literature. A meta-analysis concluded that children with ASD demonstrate fewer short-term benefits from mindfulness practice relative to adult cohorts. However, they may benefit from indirect effects of the mindful parenting that their parents are usually trained for in a parallel intervention (Hartley et al., 2019). It is therefore recommended that parents also receive training in mindful parenting during their children's mindfulness training. Currently, there is no evidence supporting the application of mindfulness training to children with ASD or ID alone; thus, practitioners should be aware of the potential risks of delivering mindfulness to this special-needs population. Notably, mindfulness training can be provided for parents and caregivers alone if such a training is deemed infeasible for their children with ASD or ID. Studies on mindfulness training for the parents of children with ASD or ID are discussed in a following section.

Anxiety and Depression

Anxiety and depressive disorders are common mental disorders, and the effects of MBSR/MBCT on these disorders are well studied in adult populations. There is also increasing interest in the application of MBPs to treat child anxiety and depression in view of their potential benefits in emotion regulation for children experiencing emotional challenges. In addition to several early attempts in developing MBCT for children (Semple et al., 2010) and a clinical trial of an MBP for adolescent outpatients (Biegel et al., 2009), which has been reviewed in an earlier section, evidence of the efficacy of MBPs in school-going population and clinical samples is accumulating. Three recent systematic reviews and meta-analyses have reported the effects of MBPs on anxiety and depression in children (Borquist-Conlon et al., 2019; Chi et al., 2018; Odgers et al., 2020). Borquist-Conlon et al.'s (2019) review of five studies revealed a moderate and significant effect of mindfulness on anxiety disorders in children ($g = .62$). Furthermore, Odgers et al.'s (2020) review of 20 studies identified a small positive effect of MBPs on anxiety at posttreatment ($d = .26$), but RCTs conducted in Western countries demonstrated no significant effects of MBPs compared with control interventions ($d = .05$). In fact, the posttreatment effect on adolescents ($d = .21$) was smaller than children ($d = .21$) and the effect was further reduced when compared to passive control intervention ($d = .33$) and active control intervention ($d = .12$), respectively. The effect size in clinical samples was weak ($d = .13$). Two authors provided contrasting conclusions on the effects of mindfulness on child anxiety. As the number of rigorous RCTs is limited, further studies are warranted for a clearer picture of the effectiveness of MBPs on anxiety in children.

Chi et al.'s (2018) review of 18 studies identified a moderate effect of an MBP in reducing the depressive symptoms at posttreatment ($g = .45$), but effects at follow-up were not significant ($g = .24$). Notably, although the review included studies on adolescents and young adults, the moderating effect of participants' age was not significant and therefore, the conclusion is likely applicable to adolescents.

Lastly, it should be emphasized that many studies in this research area assessed anxiety and depression symptoms in general child and adolescent populations, and not on those with psychiatric diagnoses. Thus, robust RCTs with well-defined control groups and studies focusing on clinical populations in this age range are warranted.

Aggression and Disruptive Behaviors

Several studies have provided evidence of the effects of MBPs on reducing aggression in children and adolescents. Tao et al.'s (2021) meta-analysis of 18 studies identified that mindfulness had a moderate effect size on aggression. In subgroup analyses, clinical samples ($g = .59$) were found to benefit more from MBPs than nonclinical samples ($g = .45$). However, it should be emphasized that very few studies on the effects of MBPs on aggression had an RCT design and that many studies applied a single-subject design that has a limitation of small sample size. Furthermore, different procedures were adopted to deliver the interventions across studies, which makes a direct comparison of effects more challenging.

Other Chronic Conditions

A small pilot study investigated the effects of an MBP on 20 adolescents aged 13–17 years with chronic pain (Waelde et al., 2017). The results indicated no significant changes in pain or depression, but functional disability and the frequency of pain-related functioning complaints improved, with small effect sizes. However, this study had a small sample size and lacked a control group for comparison.

Another study tested the effects of MBSR on 72 HIV-infected youth aged 14–22 years using an RCT design (Webb et al., 2018). The MBSR group reported higher levels of mindfulness, problem-solving coping, life satisfaction, and lower aggression than the control group at the 3-month follow-up. The participants from the mindfulness group were also more likely to have reductions in HIV viral load at the 3-month follow-up than those in the control group, suggesting better HIV disease control, possibly due to higher levels of medication adherence.

Impact of Mindfulness Training for Parents and Teachers on Children

Many studies have evaluated MBPs for parents and teachers, especially those of children with developmental disabilities. However, many of these studies focused on the effects on the adults (parents and teachers) themselves and not on their children. This section discusses studies that have investigated the transferability of program effects on children.

Parents

Mindful parenting, a concept first proposed by Jon Kabat-Zinn and Myla Kabat-Zinn (2014), is defined as the ability to intentionally and nonjudgmentally pay attention to children and parenting in the present moment. It is a continuous process through which parents can develop greater awareness of their child's unique nature, feelings, and needs and a stronger ability to be present and listen with full attention; this further helps them to recognize and accept things as they are in each moment, whether pleasant or unpleasant, recognize their own reactive impulses, and learn to respond more appropriately and imaginatively with greater clarity and kindness (Kabat-Zinn & Kabat-Zinn, 2021). An increasing number of studies have found that mindful parenting can benefit both parents and children. A recent study found that mindful parenting can be assessed in four dimensions: compassion for the child, nonjudgmental acceptance of parenting, emotional awareness in parenting, and listening with full attention (Lo et al., 2018). Mindful parenting is associated with better child well-being, including the physical, emotional, mental, social, and behavioral aspects, and reduced psychopathological symptoms, including internalizing and externalizing problems (Parent et al., 2016; Turpyn & Chaplin, 2016).

A recent meta-analysis suggested that MBPs for parents significantly reduce parenting stress and psychological symptoms and have a positive influence on children's development, psychological functioning, and overall quality of life (Burgdorf et al., 2019). Bögels and Emerson (2018) emphasized that most mindfulness-based interventions are directed toward the individuals themselves; however, there is growing evidence supporting that individual mindfulness improves relational functioning. This explains how mindfulness in parents can improve child outcomes, possibly via stress regulation within family relations. This suggests that mindfulness-based interventions should target not only the individual with a health condition, but also the whole family system, including other family members and their interrelationships.

Unlike MBSR and MBCT for general adult populations, there is no standardized program for parents or families. As an early initiative, Bögels and Restifo (2014) developed a Mindful Parenting program that largely retains the content and structure of the MBCT program. All mindfulness practices (body scan, mindful eating, 3-min breathing space, and mindful sitting) and yoga exercises from MBCT are included and adapted to the parenting context, such as automatic pilot parenting, parental doing and being mode, parental self-compassion, and beginner's mind in parenting. Specific in-session and homework practices are added to promote mindful parenting. One example of an informal home practice is to observe one's child with a beginner's mind, after experiencing the use of nonjudgmental awareness in the raisin exercise in the first session. Parents are encouraged to become aware of automatic patterns in their interactions with their child and to use breathing space to delay automatic reactions to their children. After all core mindfulness practices are introduced, the theme of conflict in parent–child relationship is included in class 6, and mindful limit-setting in parenting is addressed in class 7. Consistent with MBCT, parents are asked to maintain formal and informal practices at home, six times per week for approximately 1 h each time.

In the MYmind program that is specifically developed for children with ADHD and ASD and their parents, there is an interesting mindfulness practice called "distraction exercise" that can be especially useful in the parenting context. In this exercise, the children take turns being the "meditators" versus the "distractors," and the meditators sit in a small circle with the trainer leading a meditation practice focusing on the breath, while the distractors walk around the room and make various distracting noises. The meditators experience how hard it is to keep meditating with all these distractors around them. This exercise can help parents monitor improvements in their children's ability to sustain focused attention on the breath after a few weeks of practice and develop a nonjudgmental acceptance toward children.

Another study investigated the acceptability and effects of the 8-week Mindful Parenting program in mental health care using a waitlist-controlled design (Bögels et al., 2013). Eighty-six parents were referred to the program because of their children's and/or their own psychopathological symptoms. Post-intervention improvements were observed in the children's internalizing and externalizing problems and were generally maintained at follow-up. A follow-up study compared the effects of the program as a preventive intervention for 98 parents who experienced parental stress or problems (nonclinical sample) with those of a curative intervention for 87 parents in mental health care for their own or their children's psychiatric problems (clinical sample). At baseline, the parents from the nonclinical sample showed greater well-being and fewer behavior problems but similar levels of parental stress levels, parental overreactivity, mindful parenting, and partner relationship when compared with the parents in the clinical sample. The results further revealed improvements in child well-being and behavior problems with small effect sizes and improvements in child functioning were associated with improved mindful parenting, suggesting the transferability of MBP for parent effect on children.

In a recent study, this Mindful Parenting program was delivered to Chinese parents of children with a clinical disorder (Liu et al., 2021). One hundred and thirteen parents of children with ADHD were randomly assigned to the 8-week program or treatment-as-usual. The children of parents from the mindfulness group showed significant improvements in hyperactivity, conduct, and learning problems, although the children had not participated in the MBP. Notably, the children from the treatment-as-usual group also experienced improvements, albeit to a lesser extent, indicating no significant between-group differences.

Some practitioners and researchers have explored alternative program structures as many parents who are working full-time or preoccupied with household chores may find participating in an 8-week intensive program challenging. A few brief mindfulness programs have been developed for this purpose and are also consistent with the low-intensity public health intervention approach, which is more cost-effective for the health and social care system (Dykens et al., 2014; Neece, 2014). Lo et al. (2017) developed a brief MBP consisting of one 1.5-h session per week for 6 weeks. The program includes all mindfulness practices, including body scan, mindful stretching, mindful sitting, loving-kindness exercise, and informal practice (mindful eating and mindful walking), followed by brief practice enquiry and psychoeducation for stress management in parents. In the study, parents were encouraged to perform 10 min of home practice daily using audio files. In a feasibility study, 180 eligible parents of children with developmental disability were recruited and were allocated to the intervention group or treatment-as-usual. The results indicated significant improvement in stress from dysfunctional parent–child interactions but not in children's behavioral problems.

Inspired by these outcomes, Lo et al. (2020) developed a family-based mindfulness intervention that integrated the brief MBP for parents with an 8-session MBP for children (Snel, 2014). The first clinical trial was conducted in children with ADHD symptomology and their parents, the outcomes of which are reported in the previous section (Lo et al., 2020). The second trial was conducted in 102 children aged 5–7 years and their parents from economically disadvantaged families, using a waitlist randomized controlled trial (Lo et al., 2019). The children from the mindfulness group showed more significant improvements in attention and self-regulation than those from the control group. In addition, saliva samples to measure cortisol levels were collected from some randomly selected dyads to investigate whether their improvements were related to the mindfulness program. The children from the mindfulness group showed increased morning cortisol levels and decreased diurnal cortisol slopes, suggesting that this brief family-based MBP benefited the children's neuroendocrine functioning (Ho et al., 2020).

Finally, it should be emphasized that most of the MBPs for children with ADHD or ASD also targeted their parents. This suggests that the involvement of parents in mindfulness programs is crucial to transfer the benefits of the program to children, especially young children and those with special needs.

Teachers

Many studies have investigated the effects of MBPs on teachers' well-being, including psychological stress, burnout, and teaching practices (Hwang et al., 2017). However, most of the studies on MBPs for teachers have measured the effects on teacher variables, while few have evaluated the impact on students. In a small study, Singh et al. (2013b) evaluated the benefits of an 8-week MBP in three teachers and the effects on 18 preschool children with mild ID. When compared with baseline, the students showed significant reduction in socially unacceptable behaviors, enhancement of compliance with teacher requests, and improvement in social interactions with peers after the teachers' mindfulness training.

In a large cluster RCT involving 185 teachers across 20 Australian schools, Hwang et al. (2019a, b) evaluated the effects of an 8-week MBP on teachers' well-being and quality of teaching. Outcome measures included teachers' rating of their relationship with students, students' rating of their sense of relatedness to teachers, and teachers' verbal interactions with their students by independent observers. The results indicated no significant change in teachers' ratings of teacher–student relationships, but there was a significant increase in students' ratings of their sense of connectedness to teachers (Hwang et al., 2019a). Classroom observations based on a subsample of 60 teachers showed significant positive changes in person-centered teaching practices, as demonstrated by reduced teacher talk, increased indirectivity in teaching, and increased student talk immediately after the program and at the 6-week follow-up.

Another RCT evaluated the effects of an MBP on teachers in Portugal (de Carvalho et al., 2021). A follow-up study was then conducted using a subsample of 41 teachers from the intervention group and 18 teachers from the waitlist control group. Based on the subsample, 1503 students and 1494 parents from the intervention group and 947 students and 913 parents from the waitlist group were recruited to participate in the study. Compared with the control group, significant improvements were found in independent observers' ratings of the teacher's competence in engagement of students in classroom after MBP. There were also improvements in students' perceptions of the quality of their teachers' involvement in classroom relationships, student's self-reported affect, and parent-perceived social competencies, compared with the students from control group counterparts.

In sum, although the related literature is limited, evidence supports the benefits of MBPs to teachers, including positive changes in the teaching quality, teacher–student interactions, and students' social–emotional well-being. As suggested by a mindfulness educator, it would be more helpful for teachers to be mindful and to teach mindfully, before they equip themselves with additional knowledge and skills to teach mindfulness to students (Hawkins, 2017).

Conclusions

Evidence on child mindfulness-based programs has been accumulating rapidly in the last two decades. Practitioners and researchers are investigating strategies for effective program adaption and implementation to the different target populations. Due to the early developmental stage of children and the multicomponent structure of child mindfulness programs, research on children mindfulness programs can be challenging. Thus, caution should be exercised when considering MBPs as an intervention for this population. Mindfulness is an experiential and embodied practice that requires the person delivering the program to not only follow a regular disciplined personal meditation practice but also have extensive knowledge about developmental psychology and various physical or mental health conditions that may affect children's capacity to practice mindfulness. Proper program implementation and professional training are important to ensure that children benefit from such an innovative approach.

Several published studies on MBPs have adopted rigorous randomized controlled designs, large sample sizes, assessment of multiple outcome measures, and replications in other sociocultural contexts. However, some studies showing positive outcomes were conducted in clinical populations, had smaller sample sizes, and had integrated other components such as positive psychology and social–emotional learning components in the MBP. Children reporting more clinical symptoms may exhibit greater benefits of mindfulness than their healthy counterparts. Further, studies have shown that early adolescents report fewer benefits than individuals of other age ranges, indicating that the mindfulness protocols should be adequately adapted to the target population. As there are increasing attempts to apply mindfulness programs as health promotion programs in schools, practical issues such as intervention fidelity, implementation quality, dosage, and contextual and structural factors to improve program effectiveness warrant more attention in future studies. Finally, it is challenging to measure changes or improvements due to an MBP, especially when the program has multiple components, and it cannot be ascertained whether the observed changes are attributable to the mindfulness practices. It is likely that some children may not find mindfulness appealing; thus, practitioners and researchers should find a balance between motivating the students to practice and respecting their choice and freedom. Some children may also benefit indirectly from mindfulness training delivered to their parents and teachers.

Family Therapy

Alan Carr

Introduction

Family therapy is an approach to clinical practice that involves conceptualizing individual psychological problems and their treatment within a family context (Fiese et al., 2019; Wampler, 2020). It is one of a number of interventions for child and adolescent problems in which parents play a key role (Carr, 2019). Other family-based interventions include parent-child psychotherapy and parent training. These are considered elsewhere in this volume.

Family therapy emerged simultaneously in the 1950s in the USA and the UK within a variety of different professional, therapeutic, and research traditions (Carr, 2012, 2015). The central insight that intellectually united the pioneers of the family therapy movement was that psychological difficulties are essentially interpersonal, not intrapsychic. Therefore, their resolution requires an approach to intervention which directly addresses relationships between people. This insight contravened the prevailing view that all psychological problems are manifestations of essentially individual disorders and so require individually focused psychodynamic, behavioral, client-centered, or biomedical interventions.

Family therapy was developed partly in response to the ineffectiveness, in some cases, of individually oriented treatment approaches, and partly in response to research findings which indicated that family factors contribute to the etiology of psychological disorders. To inform their approach to clinical work with families, the pioneers of family therapy drew on insights from general systems theory and cybernetics. Ludwig von Bertalanffy (1968), in general systems theory, proposed that in any biological or social system the whole is more than the sum of its parts. Therefore, any element of a system can best be understood with reference to the system as a whole. Applied to families, this principle suggested that one family member's problematic behavior, beliefs, or feelings, can most usefully be understood with reference to the behavior, beliefs, or feelings of other family members.

Norbert Wiener (1961), in his cybernetic theory, proposed that mechanical systems use feedback to remain stable (i.e., to maintain homeostasis) or to adapt to new circumstances so as to achieve goals (i.e., to achieve morphogenesis). The implication of this principle for family systems is that families use feedback to balance the tendency to maintain stability with the need to adapt to the changing

demands of the family life cycle. In line with this principle, family therapy pioneers suggested that in some instances problematic behavior, beliefs, or feelings of one family member may serve the useful function of helping the whole family maintain stability when it lacks the resources for adaptive change. For example, a child's behavior problems may motivate parents experiencing marital distress to postpone separation, so as to jointly manage their child's problematic behavior.

In the early years of the family therapy movement, there was no single shared unified, integrated overarching framework. Rather, a range of models of family therapy were developed by a number of skilled clinicians, drawing on insights from systems theory and cybernetics combined with observations made while conducting family therapy in clinical practice. These models may be classified into three groups in terms of their primary emphasis (Carr, 2012). Some models focused predominantly on problem-maintaining relational patterns and methods of disrupting these rigid repetitive cycles of family interaction. For example, structural and strategic family therapy (Haley, 1976; Jackson & Landers, 2020; Minuchin, 1974). Others addressed family members' belief systems, scripts, and narratives about the causes of and solutions to psychological problems and the most appropriate way for family members to manage distress and conduct their relationships which underpinned problem-maintaining relational patterns. For example, social constructionist and narrative approaches to family therapy (Anderson, 1997; Chenail et al., 2020; White & Epston, 1990). A third focus of therapeutic concern in some early family therapy models was understanding and addressing the broader historical and social context out of which problem-related belief systems, scripts, and narratives and rigid problem-maintaining relational patterns had emerged. For example, transgenerational and psychoanalytic family therapy approaches (Boszormenyi-Nagy & Spark, 1973; Bowen, 1985; Hargrave & Houltberg, 2020; Slipp, 1988). Early models of family therapy laid the foundation for contemporary integrative, research-informed, or evidence-based models of family therapy practice, which are the main focus of this chapter. Contemporary models are integrative in that they synthesize ideas and practices from a range of earlier family therapy models. They are also evidence-based, and/or research-informed, unlike early models which relied predominantly on clinical observation and case studies. Pioneers of family therapy trained the next generation of family therapists who developed contemporary models through a process of live demonstration and live supervision using video recording and one-way mirrors (Liddle et al., 1988). This approach to training and supervision was a major innovation in the wider field of psychotherapy.

The effectiveness of family therapy for child and adolescent clinical problems is supported by a growing evidence base. In a meta-analysis of 56 studies, Riedinger et al. (2017) found that family therapy was an effective intervention for a range of child and adolescent problems including externalizing behavior problems such as disruptive behavior and substance use disorders, internalizing behavior problems such as depression and anxiety, and eating disorders. Family therapy showed small-to-medium effects in comparison with waiting list control groups and alternative interventions after treatment and at follow-up. At follow-up, longer interventions produced larger effect sizes. These results are consistent with those of extensive narrative and systematic reviews (Carr, 2019; Retzlaff et al., 2013; von Sydow et al., 2013). There is preliminary evidence to support the provision of family therapy online using video-conferencing technology (McLean et al., 2021).

A number of factors common to many different models of family therapy for different types of disorders across the lifespan may underpin its effectiveness (D'Aniello & Fife, 2020). These include convening regular family sessions; establishing therapeutic alliances with, and between family members; reframing child-focused problems in relational terms; disrupting dysfunctional problem-maintaining, relational patterns; mobilizing family members to collaborate in resolving the presenting problem; and empowering families to use lessons learned in family therapy to prevent relapse. Of these common factors that contribute to the effectiveness of family therapy, establishing a therapeutic alliance with, and between, family members has a particularly strong evidence base. For example, in a meta-analysis of studies of 40 samples involving over 4000 families, Friedlander et al. (2018) found moderate correlations between therapeutic alliances with, and between, family members on the one hand, and therapy outcome on the other.

While common factors contribute to the effectiveness of family therapy, these operate through model-specific factors. For example, the common factor of disrupting family-maintaining relational patterns is operationalized in different ways in functional family therapy (FFT) for conduct problems (Sexton, 2019) and attachment-based family therapy (ABFT) for depression (Diamond et al., 2016). This is partly because different types of relational patterns maintain depression and conduct problems. Most contemporary evidence-based or research-informed models of family therapy have been developed to address specific clinical problems. In the remainder of this chapter, some examples of such models will be presented with reference to supporting evidence.

Delinquency and Disruptive Behavior Disorders

FFT (Sexton, 2019) and Multisystemic Therapy (MST, Henggeler & Schaeffer, 2019) are two family therapy models that were developed initially to treat juvenile delinquency and adolescent disruptive behavior disorders. FFT was the first clearly articulated integrative evidence-based model in the field of family therapy, having emerged in the 1970s. MST was developed in the 1980s and currently has the largest evidence base of any family therapy model.

Functional Family Therapy
