The use of statins has also been implicated strongly in the improvement of claudication. A prospective study of 392 patients with PAD compared lower-extremity functional performance between statin users and nonusers. When controlled for age, sex, comorbidities, health insurance, and education, statin users had significantly better lower-extremity functioning compared to statin nonusers. Leg function was measured using 6-min walking distance, 4-m walking speed, time to rise from a chair 5 times in a row, and standing balance [41]. A randomized trial of simvastatin versus placebo in symptomatic PAD patients demonstrated significant increases at 6 months and 12 months (24% and 42%, respectively) in treadmill exercise time until onset of claudication symptoms in the simvastatin arm. No significant differences in treadmill times were noted in the placebo arm at 6 or 12 months [42].

A study of 49 patients comparing 6-min walk test and treadmill exercise time until onset of claudication to real-life self-reported outdoor equivalents and noted no significant difference between the treadmill and outdoor values. Interestingly, based on subjects' responses on the Vascular Quality of Life Questionnaire, the 6-min walk test was the only test modality that correlated with quality of life assessments [43]. Unless patients notice intolerable side effects, statin use is indicated for the reduction in disease progression and mortality as well as for the improvement in quality of life and amputation-free survival in all PAD patients, regardless of serum cholesterol levels. Current recommendations provide goal LDL of less than 100 mg/dL for patients with PAD and less than 70 mg/dL for very high-risk individuals [44].

Obesity

Obesity is most frequently quantified with the body mass index (BMI), which is calculated as weight in kilograms divided by the square of the height in meters (kg/m^2). Being overweight or obese has been associated with increased all-cause mortality [45]. A compilation of 19 prospective study participants totaling 1.46 million subjects found an inverse relationship between BMI and all-cause mortality, with the lowest all-cause mortality rate in the BMI range of 20–24.9 [46]. While obesity has not been directly linked as a risk factor for PAD or adverse lower-extremity outcomes, weight loss in obese PAD patients can

improve claudication symptoms by reducing weight and stress on the lower extremities.

A prospective study of 297 patients with symptomatic PAD characterized factors associated with various degrees of sedentary lifestyles and noted that the most sedentary subjects had higher BMI and diabetes prevalence as well as lower walking economy and maximum walking distance [47]. Another study of 46 symptomatic PAD patients compared subjects with normal weight and those with risk of obesity (BMI 28 or greater). Investigators compared claudication times and total walking times as well as time to recovery of baseline ABI. The risk of obesity subset had shorter times to onset of claudication as well as longer delays in recovery of baseline ABI after exercise [48]. PAD patients should be counseled to maintain healthy body weight to reduce mortality, decrease risk of diabetes, and possibly improve claudication symptoms.

Exercise

In an effort to avoid symptoms of claudication, patients may self-limit their activity level. Numerous studies have shown that sedentary lifestyle is not only linked with overall poorer outcomes, but it is also associated with decreased walking distance and quality of life [49]. A study following activity levels of subjects with PAD demonstrated that higher physical activity level was associated with lower all-cause and cardiovascular disease mortality in the studied population [50]. Simple verbal prescription of a home exercise regimen is insufficient. Patients have various obstacles including poor adherence and fear that the pain of mild claudication is deleterious which require supervision and positive feedback from a clinician vital to the success of any walking program.

Similar to smoking cessation, a simple admonishment to continue walking is not as effective as supervised exercise therapy (SET) [51]. The Claudication: Exercise Versus Endoluminal Revascularization (CLEVER) study is a multicenter randomized prospective trial comparing supervised exercise to endovascular revascularization and best medical therapy. It was found that both SET and stent revascularization improved peak walking times similarly, and both were significantly superior to best medical therapy alone in terms of improved exercise tolerance [52].

The safety of SET has been studied given PAD patients' higher baseline risk of adverse cardiovascular events and mortality. A large-scale review of clinical trials studying SET compiling a collective 82,725 h of training found that a total of 8 adverse events were reported, only 6 of which were cardiovascular in origin [53]. The safety of SET and its exceedingly low complication rate is likely related to its supervised nature.

Antiplatelets

Antiplatelet therapy is recommended to reduce risk of both fatal and nonfatal CV events in patients with symptomatic PAD. The Antiplatelet Trialists' Collaboration, an analysis of combined data from over 135,000 subjects, determined that prolonged antiplatelet therapy with aspirin was associated with a significant 25% reduction in adverse vascular events in high-risk subjects. More to the point, when looking at symptomatic PAD patients specifically, there was an association with significantly reduced overall vascular occlusion rates in the antiplatelet group versus controls (15.7% versus 24.9%), as well as when broken down to native (19.5% versus 39%) and graft (15.8% versus 23.6%) patency rates [54].

While antiplatelet use has been well supported in the literature for secondary prevention in appropriate patients, its use as a primary preventative measure in PAD and diabetes patients has not yet been as well established.

The Prevention of Progression of Arterial Disease and Diabetes (POPADAD) trial was a blinded, randomized placebo-controlled trial of aspirin and antioxidants (alone and in combination) compared to placebo in diabetics with asymptomatic PAD as defined by abnormal ABI but no symptomatic cardiovascular disease. It demonstrated no difference in primary endpoints (nonfatal MI or CVA, major amputation, death from MI or CVA) in the aspirin and non-aspirin arms, providing no evidence in support of aspirin use for primary prevention of these events in diabetics with subclinical PAD [55]. The ASCEND (A Study of Cardiovascular Events in Diabetes) trial looked at the role of aspirin for cardiovascular prevention in diabetic patients over the age of 40 and without established cardiovascular disease [56]. Aspirin use resulted in an absolute reduction of 0.17% per year in MI, stroke, TIA, and death, at the cost of an excess annual risk of bleeding of 0.13%. A 2016 meta-analysis of six studies evaluating aspirin's safety and efficacy in primary prevention of adverse vascular events was unable to find a difference between aspirin and placebo in these vascular endpoints [57]. As a result, there have been some suggestions that aspirin use be limited to those with added risk factors such as positive family history, high coronary calcium score, elevated lipoprotein A1, or other inflammatory markers [56].

A subset of PAD patients exists that continues to experience adverse vascular events despite long-term aspirin therapy. Symptomatic PAD patients on long-term aspirin were studied prospectively for aspirin responsiveness and adverse vascular outcomes for a period of up to 2 years. Aspirin responsiveness was determined by performing a platelet function test, and 25.8% of study participants were found to be aspirin-resistant. Primary adverse endpoints were more likely in the aspirin-resistant group compared to the aspirin-responsive group (32.3% versus 14.6%). The secondary end-

point of peripheral revascularization or tissue loss was not significantly different between the two groups. This study suggested that aspirin resistance is not only highly prevalent among the symptomatic PAD population but that resistance is an independent predictor of adverse vascular events and mortality, raising the question that these patients may be better served with alternative antiplatelet agents [58].

A number of alternative antiplatelet agents exist today. Clopidogrel is the oldest and most studied of these medications. The Clopidogrel Versus Aspirin in Patients at Risk of Ischaemic Events (CAPRIE) trial was a blinded, randomized trial that compared efficacy of aspirin and clopidogrel in preventing major adverse vascular events and mortality in a population of subjects with symptomatic PAD or recent MI or CVA. A relative risk reduction in these primary endpoints was noted in the clopidogrel arm compared to the aspirin arm at a mean follow-up of 1.9 years. In the subset of patients with symptomatic PAD, the relative risk reduction was 23.8% for clopidogrel compared to aspirin [59]. This suggests that clopidogrel may have better efficacy in symptomatic PAD patients.

The CHARISMA(Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance) [60] and CASPAR (Clopidogrel and Acetylsalicylic Acid in Bypass Surgery for Peripheral Arterial Disease) [61] trials both demonstrated the superiority of an aspirin/clopidogrel combination over aspirin alone in preventing cardiac and limb events, with no increase in major bleeding complications in patients with established cardiovascular disease. These were not primary prevention trials and were not limited to diabetic patients.

Another newer agent still is vorapaxar which prevents thrombin from binding to the PAR-1 receptor on platelets. It has been shown to be of benefit in secondary prevention in diabetic patients and decreases acute limb ischemia events as compared to other standard antiplatelets agents, at a cost of an increase in some bleeding complications [62].

Pharmacologic Treatment of Claudication

The principle that peripheral vasodilators should relieve ischemic muscular beds has been addressed with various classes of agents (e.g., calcium channel blockers, alpha-blockers, prostaglandin analogues). Effects of these agents on walking distance and claudication have been largely disappointing. The reason for failure of symptomatic relief may be related to the fact that peripheral vascular beds are already maximally dilated in patients with PAD especially during exertion. Cilostazol, on the other hand, has shown a positive impact on claudication and walking distance. A phosphodiesterase III inhibitor decreases smooth muscle tone and platelet aggregation. It is important to note that while it did significantly reduce symptoms of claudication and increase exercise tolerance, it did not have an effect on mortality [63]. According to the 2016 AHA/ACC guidelines on PAD management, 100 mg twice daily of cilostazol is recommended for relief of claudication and improvement in exercise tolerance. The rheologic agent pentoxifylline is no longer recommended as it has failed to demonstrate any benefit in the treatment of claudication [5].

Revascularization

Indications

While most patients with symptomatic PAD generally are able to stabilize or slow disease progression with risk factor modification, 20–30% will have lifestyle-limiting or limb-threatening progression of their disease requiring invasive management [27]. Revascularization in PAD is indicated in lifestyle-limiting claudication or critical limb-threatening ischemia despite best medical therapy. The decision to perform an intervention should also be weighed against the individual patient's comorbidities, especially age and cardiac and renal functions. In claudicants, for instance, the presence of comorbidities such as arthritis, degenerative disc disease, and cardiac disease may negate any potential benefits of a vascular intervention. It is also important to note that objective measures of vascular disease correlate poorly with severity of disability. The ABI, for example, has not been found to correlate with patients' subjective assessment of quality of life [64]. Therefore, the decision to intervene should not be based solely on objective findings of disease severity but rather on the patient's reported level of disability which can then be supported by these objective findings. Invasive interventions on minimally symptomatic or asymptomatic patients are unlikely to provide significant benefit and may cause harm. According to Trans-Atlantic Inter-Society Consensus statements, a revascularization procedure should "avoid a general anesthesia, pose a lesser systemic stress, and have fewer serious complications" [65].

Furthermore, the presence of an ulcer does not always mandate intervention. Prior to revascularization, a distal wound's healing potential must be assessed based on objective parameters. This information is usually available in the patient's diagnostic workup. For instance, an ankle pressure of 70 mmHg is typically sufficient to heal a foot wound; however, in diabetics 90 mmHg might be preferred. A toe pressure of 40 mmHg in nondiabetics and 60 mmHg in diabetics is ideal [66]. Transcutaneous oxygen pressure measurements (TCOM) are also commonly utilized to determine tissue perfusion and wound healing potential. A TCOM greater than 40 mmHg is generally adequate for wound healing [67]. It is important to note

that TCOM values may also be decreased due to systemic perfusion issues such as heart failure and cardiac valvular disease. Edema and infection may also lead to erroneously low values as well.

In multisegment disease, the most proximal significant lesion should be addressed first, which may relieve symptoms without distal interventions. Treatment of isolated infrapopliteal disease is not recommended for relief of intermittent claudication alone, given the higher risks of complications and recurrence. That said, treatment of infrapopliteal lesions is indicated frequently to heal ulcers. Even though these therapies often do not have long-term patency, they can allow enough perfusion to heal tissue loss or to bridge a complicated patient for optimization before more definitive surgical bypass.

Interventional Challenges

As noted previously, interventions on PAD in diabetes present a particular challenge due to disease severity, presence of other comorbidities including CAD and nephropathy, immune suppression predisposing to wound infections, and more distal heavily calcified disease that is both difficult to traverse percutaneously as well as challenging to find a suitable distal bypass target in open surgery. The presence of diabetes also is a risk factor for restenosis after percutaneous revascularization procedures [68].

Despite these challenges, revascularization in diabetics with CLTI is not only feasible but also associated with lower early amputation rates and higher survival compared to late or no intervention. An analysis of 537 diabetics with CLTI found early amputation rates to be significantly lower in those who underwent revascularization compared to those who did not (1.7% versus 51.9%), and those who did not undergo revascularization had severe CV comorbidities that precluded any type of intervention [69]. Therefore, barring any prohibitive systemic comorbidities, prompt intervention as soon as a patient fails best medical therapy is generally recommended in patients with CLTI regardless of diabetes status, given that limb salvage is significantly worse without intervention [70]. A study of 376 patients with CLI comparing diabetics to nondiabetics found that early revascularization was associated with higher amputation-free survival in both groups compared to those with delayed interventions. The accelerated form of atherosclerosis and intimal hyperplasia at intervention sites in diabetics makes early intervention critical [71].

Endovascular Versus Open

The choice of revascularization procedure is dependent on multiple factors including available resources, operator experience, and patient-specific characteristics such as location and severity of the lesions, presence of skin lesions, activity level, comorbidities, compliance, availability of adequate autogenous conduit, and personal preference. Treatment guidelines from the American Heart Association and the revised Trans-Atlantic Inter-Society Consensus document recommend endovascular therapy as the first-line treatment of focal and moderate-length lesions (Fig. 52.3), while bypass is reserved for diffuse or long-segment disease (Fig. 52.4) [72].

Fig. 52.3 Digital subtraction angiography (DSA) of crural occlusive disease (left) with restoration of inline flow to the foot after angioplasty of the posterior tibial artery (right)

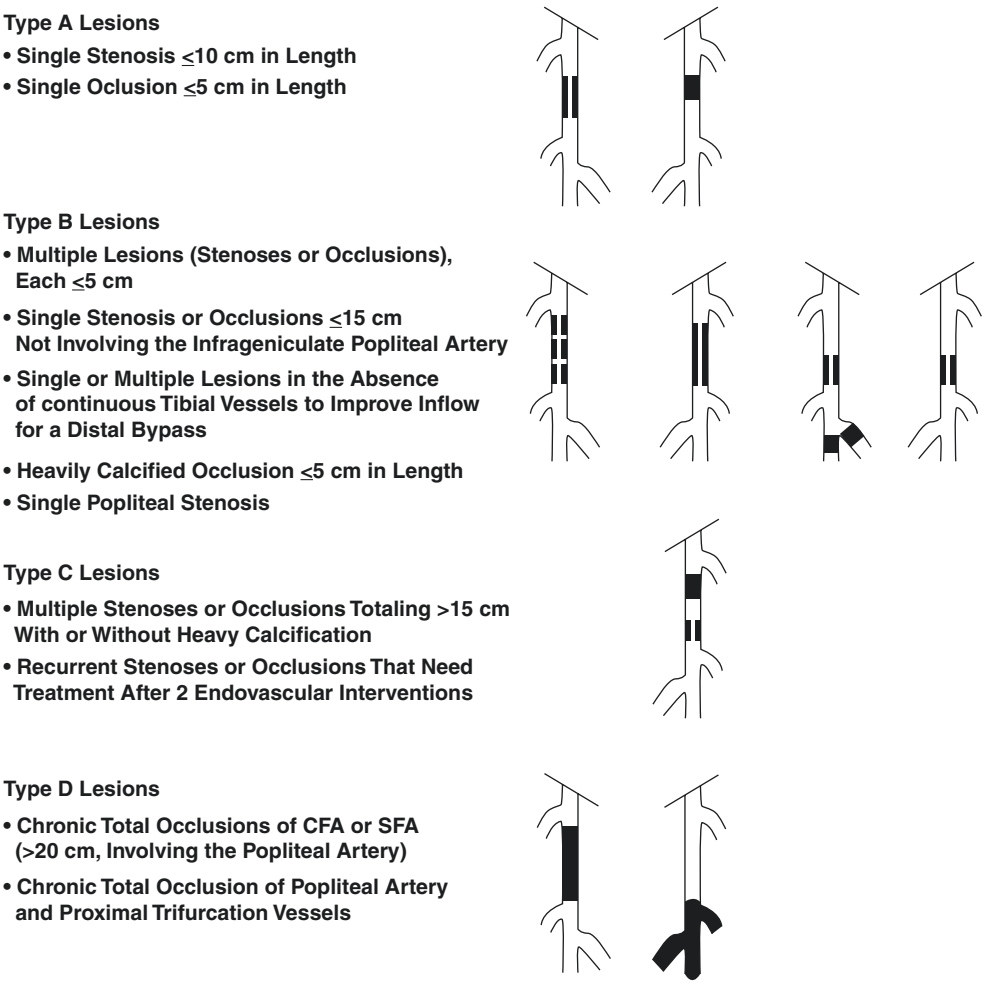

Fig. 52.4 Trans-atlantic Inter-society consensus classifications of femoropopliteal disease

Endovascular and open surgical options should be viewed as complimentary and not necessarily competitive. For example, a patient with severe coronary artery disease with a depressed ejection fraction and poorly controlled diabetes presenting with an ischemic foot ulcer secondary to multi-segment crural disease may not have the physiologic reserve to tolerate open bypass surgery, but tibial angioplasty may provide improved flow and a chance for the ulcer to heal and avoid limb loss or sepsis while the patient undergoes coronary artery bypass and gains better glycemic control.

More recently, with the development of more advanced endovascular techniques in appropriately selected patients, the choice of revascularization modality has had no significant effect on amputation-free survival or all-cause mortality [73]. A systematic review of 57 articles encompassing 9029 patients with diabetic foot ulcers and PAD who had undergone revascularization examined outcomes and characteristics of these patients. Ulcer healing rate was 60% at a 12-month follow-up with any kind of revascularization. In three studies that utilized a PTA-first strategy, mortality and limb salvage rates were comparable to other studies that did not follow a PTA-first strategy, and there was a reported 11% failure rate of endovascular therapy requiring subsequent open bypass [70]. In one study of 1188 diabetics admitted for CLTI, PTA was performed as a first-line intervention in 993 consecutive patients. During a mean follow-up period of 26.2 months, primary patency at 5 years was 88%. The 30-day major amputation rate was 1.7%, and a 5-year survival was 74%, demonstrating in this series a comparable result to open interventions [73]. There are however many other studies that suggest that restenosis rates in diabetics undergoing endovascular interventions are high and that while adequate limb salvage can be achieved, it comes often at the cost of repeated endovascular interventions.

Similar results were demonstrated in a British study. The Bypass Versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial found that amputation-free survival and all-cause mortality were similar between PAD patients randomized to endovascular and open surgical arms; however, the surgical arm had greater morbidity in the first year. Interestingly, after 2 years, the surgical arm did surpass the endovascular arm in terms of amputation-free sur-

vival. This study reinforced that while endovascular and surgical interventions had equivalent short-term results in terms of revascularization and limb salvage, open bypass provided a more durable yet more morbid treatment option [74]. The BASIL trail was not limited to diabetic patients however.

A single-center series also from the United Kingdom found that with an aggressive multidisciplinary approach to the diabetic patient with CLTI, they were able to yield similar limb salvage and overall survival rates as in the nondiabetic patients [75]. In a retrospective study of 1977 infrainguinal open bypass patients for CLTI, inhospital mortality rates were found to be equivalent between diabetics and nondiabetics. However, rates of major adverse events (major amputations, renal insufficiency, MI, dysrhythmia, CHF, and wound infection) were significantly higher in diabetics [76]. The increased perioperative morbidity of bypass surgery must therefore be weighed against its superior long-term durability during the mindful patient selection process.

There are as of this writing two ongoing trials that specifically compare open and endovascular interventions below the knee (an area where diabetic PAD is common). These are the BASIL-2 trial and the BEST-CLI trial. Hopefully, they will help better select therapies for individual patients.

Percutaneous Therapy

Endovascular interventions continue to push the envelope. Initially only indicated for select, focal, short-segment disease, they are now often used for long-segment total occlusions (Fig. 52.5) and multifocal disease. For example, a patient with severe coronary artery disease with a depressed ejection fraction and poorly controlled diabetes presenting with an ischemic foot ulcer secondary to multi-segment crural disease may not have the physiologic reserve to tolerate open bypass surgery, but tibial angioplasty may provide improved flow and a chance for the ulcer to heal and avoid limb loss or sepsis while the patient undergoes coronary artery bypass and gains better glycemic control.

For example, a patient with severe coronary artery disease with a depressed ejection fraction and poorly controlled diabetes presenting with an ischemic foot ulcer secondary to multi-segment crural disease may not have the physiologic reserve to tolerate open bypass surgery, but tibial angioplasty may provide improved flow and a chance for the ulcer to heal and avoid limb loss or sepsis while the patient undergoes coronary artery bypass and gains better glycemic control.

Endovascular therapy options include percutaneous balloon angioplasty with or without stent placement, atherectomy, and any combination thereof. There has been some suggestion in registry data that atherectomy may be of benefit in diabetic patients in terms of a reduced restenosis rate. In general, endovascular procedures are well tolerated and result in shorter hospital stays, more rapid recovery, and less wound complications with equivalent limb salvage rates compared to open surgical revascularization in most cases. That said, as noted, endovascular interventions are generally less durable than surgical bypass and more frequently require reintervention to maintain patency [77]. A study observing 101 diabetics with CLTI who underwent endovascular infrapopliteal intervention noted successful PTA in 87.8%. The seven patients in whom PTA failed had heavily calcified, chronically totally occluded lesions that were not amenable to PTA nor to surgical bypass. The 1-year target vessel restenosis rate was 42%. However, over a mean follow-up of 2.9 years, major amputations occurred in only 7%, and all-cause mortality was 5% [78]. The major amputation rate in this series is comparable to that in another series of 508 diabetics with CLTI who underwent revascularization, with no distinction between endovascular and open, in which 10.3% underwent major lower-extremity amputation [19]. These series demonstrate the utility of endovascular interventions in terms of limb salvage despite high rates of target vessel reocclusion. Diabetes has been shown to be a risk factor for lower long-term patency rates following endovascular revascularization [79].

Fig. 52.5 Spidery collateralizations due to infrapopliteal occlusive disease (left). Note their disappearance after angioplasty (right) of the anterior tibial artery (arrow)

The technique of subintimal angioplasty wherein the intima is intentionally dissected and the lesion angioplastied subintimally has been used with some success in chronic total occlusions which either precluded or failed PTA or open bypass attempts. Technical success rates typically range between 80 and 90%, with notably worse outcomes in CLTI compared to claudication, and primary patency rates at 1 year range from 56 to 70% [80]. Ulcer healing rates have been excellent as well, cited at 75% over a mean 23-month follow-up for a series of 60 consecutive diabetic patients with CLTI who were deemed unfit for surgical bypass. This is comparable to ulcer healing rates with open bypass surgery [81]. A recent study in China examined the outcomes for subintimal angioplasty in diabetics with chronic distal (dorsalis pedis or plantar artery) occlusive CLI who were deemed poor candidates for open bypass or PTA. Thirty-seven such patients underwent subintimal angioplasty with an 83% success rate and 95% 1-year limb salvage rate. Complications occurred in 13% of these patients, the most common being vessel perforation followed by failed reentry [82].

Stents are sometimes needed when an angioplasty fails because of recoil or flow-limiting dissection. Critical to stent patency is the maintenance of lifestyle modifications and antiplatelet therapy. The MIRROR (Minimally Invasive IntRaceRebral HemORrhage) study, a randomized, double-blinded study of 80 patients who underwent percutaneous intervention (with and without stent placement), studied dual antiplatelet therapy (DAT) with aspirin and clopidogrel versus aspirin alone. Primary endpoints were direct measurements of two platelet activation factors from whole blood samples taken from subjects after loading doses and just before intervention as well as clinical outcome at 6 months. Markers of platelet activity were lower in the DAT group and recurrence of disease in the target lesion was lower [83]. The findings of this study favor DAT over aspirin monotherapy in PAD after endovascular stent therapy.

More recent developments in angioplasty have included the use of drug-coated angioplasty balloons to prevent restenosis. The main drug used is paclitaxel which prevents smooth muscle proliferation that causes intimal hyperplasia and recurrent stenosis. Drug-coated angioplasty has shown benefits in improving primary patency when used in the superficial femoral artery, but the results have not been as encouraging to date in the vessels below the knee (where diabetics have a high rate of atherosclerotic burden) [84].

A review of 14 randomized trials of antiplatelet therapies around the time of peripheral vascular interventions concluded that aspirin should be administered 6–24 h before PTA and continued afterward to reduce periprocedural thromboembolic events. Regarding DAT versus aspirin alone, a commonly adopted practice was noted to be indefinite use of aspirin as well as 4 weeks of post-procedural clopidogrel given the benefit noted in multiple studies with loading doses of aspirin and clopidogrel [85]. However, more long-term studies comparing dual versus monotherapy as well as long-term outcomes with newer antiplatelet agents are needed prior to making recommendation changes regarding antiplatelet therapy in PAD.

Open Surgery

Bypass surgery is the gold standard intervention for symptomatic PAD, and while it is being supplanted by the rapidly growing use of endovascular therapies, its efficacy in restoring inflow and relieving claudication symptoms and salvaging limbs is undisputed. In fact, despite the growing popularity of utilizing endovascular-first treatment algorithms, a recent retrospective analysis found that in comparing propensity-matched lower-extremity bypass versus endovascular intervention for CLTI, the former was associated with a significantly lower rate of 30-day major adverse limb events and no higher rate of 30-day major adverse cardiovascular events [85]. Therefore, it cannot be dismissed as an unjustifiably risky invasive intervention in appropriately selected patients. Lower-extremity bypass also remains the solution for lesions that are not traversable percutaneously or have failed previous percutaneous interventions. Its use is limited by severe systemic illness (e.g., severe heart failure) that may pose unacceptable operative risk, lack of adequate bypass conduit, and presence of active infection or sepsis (a commonality in diabetic CLTI patients). It is estimated that about 30% of CLTI patients will need a surgical bypass.

The best outcomes for open bypass surgery are obtained using a one-piece greater saphenous vein as the conduit. Conduit choices are as follows in order of preference: ipsilateral greater saphenous vein, contralateral greater saphenous vein, composite (spliced) vein grafts, lesser saphenous vein or arm vein, and nonautologous vein or synthetic graft. Up to 40% of bypass candidates lack adequate ipsilateral greater saphenous vein conduit and require an alternative conduit choice.

Again there exists a correlation between diabetes and treatment complications. In a cohort study of 6112 individuals who underwent open lower-extremity bypass, stratified by indication for intervention, insulin-dependent diabetes was associated with a significant 1.27 odds ratio of readmission, the majority (62.9%) of these admissions being for wound complications. This is unsurprising given diabetics' propensity for wound infection [86]. This further emphasizes the importance of perioperative glycemic control in diabetic PAD patients.

Interestingly, diabetes has not been shown to be an independent predictor of decreased bypass graft patency [87]. This finding has been demonstrated in multiple studies,

including the Veterans Affairs National Surgical Quality Improvement Program (VA NSQIP) which identified 14,788 patients who underwent infrainguinal arterial bypass procedures and found that diabetes was in fact significantly protective from early graft failure [88]. The PREVENT III trial, a double-blinded randomized controlled trial of 1404 patients comparing ex vivo application of edifoligide to vein grafts versus placebo just prior to lower-extremity bypass for the prevention of graft failure, found that diabetics, while significantly more likely to present with tissue loss, did not have a higher risk of graft failure at any stage through the 12-month follow-up period [89]. Although diabetes in PAD is independently associated with a higher risk of amputation and mortality, it is not a risk factor for graft failure.

A successful graft depends on adequate inflow, outflow, and conduit quality. Bypass graft failure is classically described in three phases: early (0–30 days), intermediate (30 days to 2 years), and late (beyond 2 years). Early failure is typically attributed to technical factors or judgment error, such as poor conduit, retained venous valves, technical error, and inadequate inflow/outflow. Intermediate failure is secondary to intimal hyperplasia. Some degree of intimal hyperplasia occurs in all grafts; however, where and why this becomes pathologic and flow limiting is not well understood. There is a propensity for this to occur in areas of endothelial trauma (e.g., where a valvulotome was utilized), which strongly suggests that this process is related to a dysfunctional endothelium. Late failure is seen as a progression of the primary atherosclerotic process causing graft narrowing as well as deficiency of inflow and/or outflow.

The incidence of early graft failure is around 5%. This incidence of intermediate failure is 1–2% per month for the first year, and then it further declines to 2–4% per year thereafter. Early surveillance with duplex ultrasonography can detect stenosis before progression to occlusion. A prospective study of 68 lower-extremity vein bypasses in diabetics undergoing intensive postoperative surveillance with duplex ultrasonography found that, after a mean follow-up of 12 months, duplex US (ultrasound) could predict graft thrombosis and amputation [90].

Current literature suggests that some variation of a duplex scan should be done every 3–6 months for the first 1–2 years after bypass, with a follow-up arteriography for abnormal findings. Duplex scan is also indicated specifically if a patient has return of claudication symptoms, ABI decreases by 0.15 from highest postoperative value, or a previously palpable pulse diminishes or disappears. A peak systolic velocity (PSV) greater than 180 cm/s or velocity ratio (V_r) greater than 2 suggests a focal stenosis greater than 50%, while a mean graft velocity less than 45 cm/s indicates a low flow state that is conducive to graft thrombosis. According to Tinder et al., a PSV greater than 300 cm/s or a V_r greater than 3.5 indicates a need for graft revision, and with appropriately tailored surveillance according to an individual graft's risk profile and postoperative duplex scan, this early detection leads to reintervention that prolongs graft patency [91]. While the most recent TASC II guidelines do not recommend routine duplex ultrasonography for lower-extremity bypass (instead they support clinical surveillance through palpation and ABI measurements every 6 months for at least the first 2 years after bypass), multiple studies have demonstrated that surveillance with duplex ultrasonography detects early lesions before progression to thrombosis [92, 93]. Tinder et al. found that more aggressive duplex surveillance for those bypasses with high-risk characteristics or an abnormal first postoperative scan was associated with higher primary-assisted patency and lower graft failure rates [94].

Patency, while important as a metric of durability, is not the only measure of a revascularization's success. Likewise limb salvage and mortality, while the typical primary outcomes, are not the only measures of patient satisfaction and quality of life. The PREVENT III trial established quality of life as a secondary endpoint and noted that after lower-extremity bypass, quality of life as assessed by the Vascular Quality of Life Questionnaire improved progressively at 0, 3, and 12 months postoperatively [89]. Another study comparing objective measures of lower-extremity function and patient perceptions of quality of life found that while objective measures such as knee flexion and extension, a 6-min walk distance, walking speed, and balance showed absolute improvements, none reached statistical significance. Despite this, there was a significant improvement of subjective quality of life and pain perception postoperatively [95].

Areas of Current Interest

Figure 52.6 summarizes a current algorithm for approaching diabetic patients with suspected peripheral arterial disease. One of the major limitations in interpreting all the studies in PAD and DM has been the inherent difficulty in having truly equivalent groups in whom to compare open and endovascular interventions. In addition to PAD, the major factors that increase the risk of limb loss are the presence of foot infection and the existence of a foot wound and its extent. In an effort to account for this, a WIFi score has been proposed, which included an assessment of the Wound, any Ischemia, and Foot infection [96]. Each category is scored from 0 to 3, and a final score is obtained allowing classification of each limb into one of four categories. Limbs staged as I are considered as low risk for limb loss while those classified as IV are considered high risk for limb loss, with known predicted limb loss rates. Each limb can be restaged following revascularization or control of infection, thereby producing a new estimated risk of limb loss. The system allows for meaningful benchmarking of results and counselling of patients.

Diabetes and PAD are not only frequently comorbid but also result in an accelerated natural history and more com-

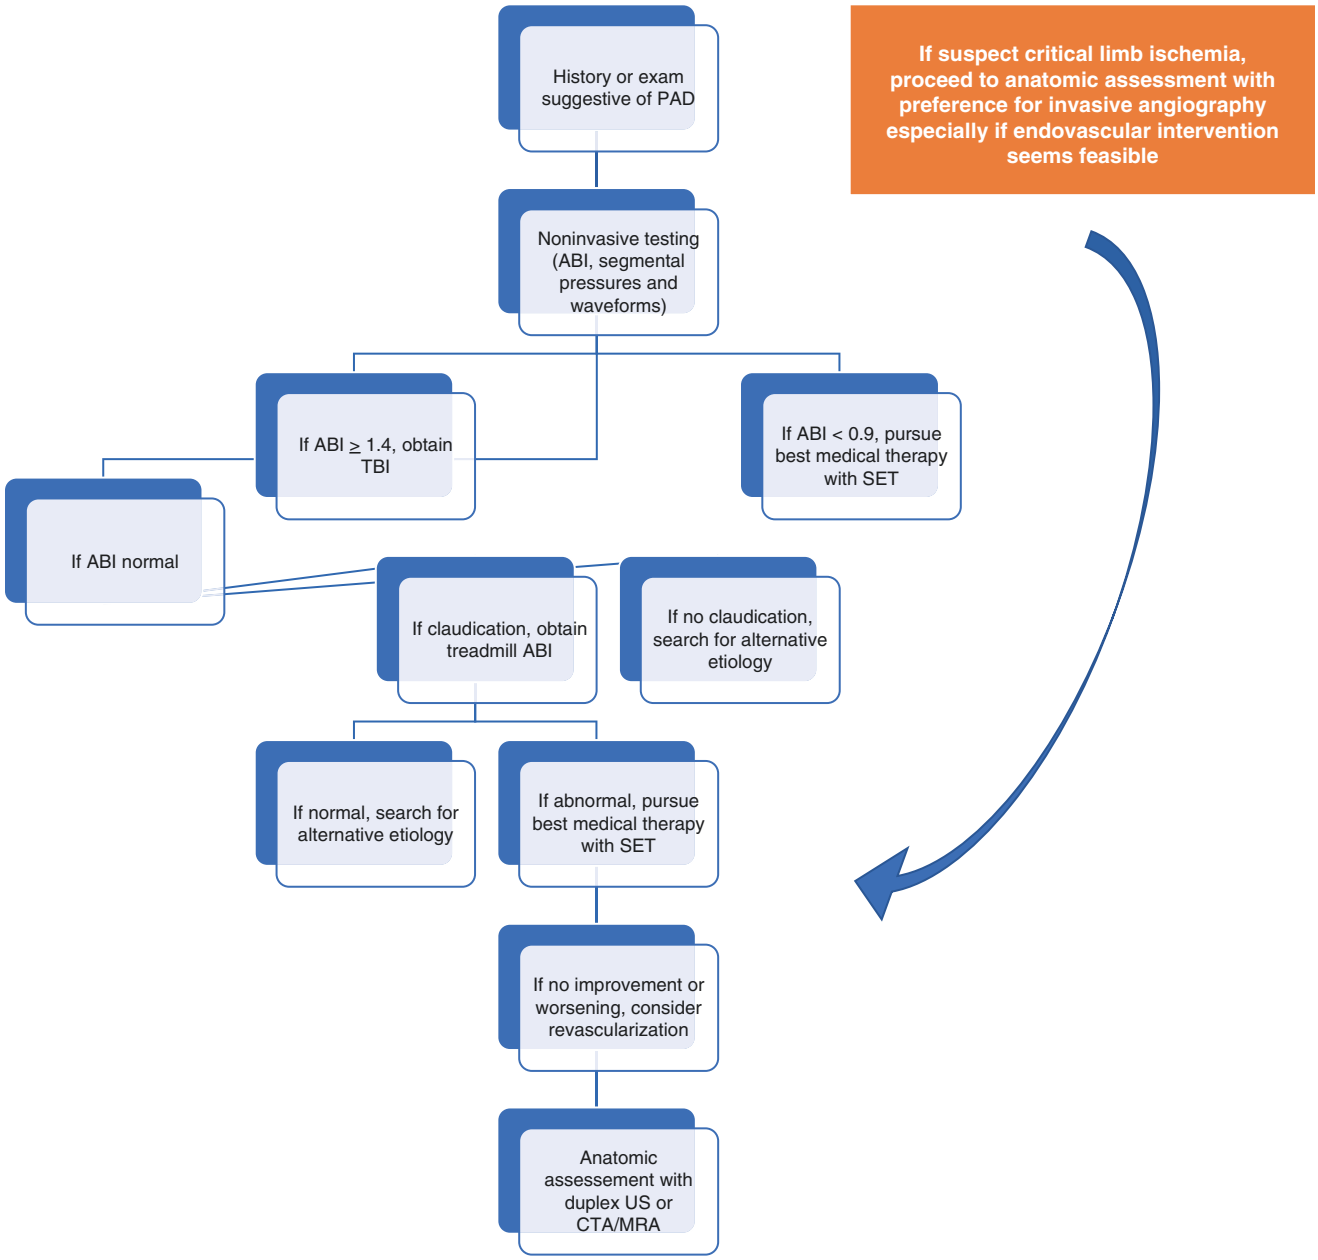

Fig. 52.6 Algorithm for suspected PAD

plicated outcomes and mortality after intervention. Therefore treatment of these patients begins with an appreciation of the significance and risk involved with their comorbidity and the importance of early intervention with lifestyle and risk factor modification. That said, once lower-extremity disease has progressed to the point of requiring an invasive intervention, the presence of diabetes should not deter attempts at revascularization. Treatment options have and continue to become more sophisticated, and with an aggressive multidisciplinary approach, they have the potential to yield noninferior outcomes in the diabetic population.

Multiple Choice Questions

1. Which of the following is *not* a known risk factor for atherosclerotic peripheral arterial disease?
   (a) Smoking
   (b) Age
   (c) Diabetes
   (d) **Trauma**
   (e) Hyperhomocysteinemia
2. According to NHANES (National Health and Nutrition Examination Survey) data, what is the prevalence of peripheral arterial disease in the general population?

(a) 1%
(b) **6%**
(c) 29%
(d) 50%
(e) 85%

3. Which of the following constitutes an abnormal ankle-brachial index?
   (a) 1.0
   (b) 0.6
   (c) 1.5
   (d) A and B
   (e) **B and C**
4. History and physical exam findings of peripheral arterial disease include all of the following *except*:
   (a) Lower-extremity claudication
   (b) Diminished pulse exam
   (c) Hair loss
   (d) Dependent rubor
   (e) **Pain with lower-extremity elevation**
5. Diabetics with peripheral arterial disease
   (a) Should aim for a hemoglobin A1c level of 5%
   (b) **Are at higher risk for limb loss than nondiabetics with peripheral arterial disease**
   (c) Should have regular CT angiograms to monitor their disease burden
   (d) Have reliable pulse exams for detecting the presence of flow-limiting lesions
   (e) Do not benefit from supervised exercise therapy programs because of the risk of falling
6. Critical limb ischemia
   (a) Is defined by the presence of rest pain and/or tissue loss secondary to a flow-limiting lesion
   (b) Represents the end stage of peripheral arterial disease
   (c) Risk increases with comorbid diabetes
   (d) Can be masked by diabetic neuropathy
   (e) **All of the above**
7. Constitutive production of nitric oxide by a functional endothelium confers upon the vessel antiplatelet, anti-atherogenic, vasodilatory, and anti-inflammatory properties.
   (a) **True**
   (b) False
8. Pharmacotherapy for intermittent claudication has been shown to be effective in reversing atherosclerotic disease progression.
   (a) True
   (b) **False**
9. Percutaneous intervention for lower-extremity peripheral arterial disease is:
   (a) Reserved only for frail patients unfit for the morbidity of open surgical bypass
   (b) Absolutely contraindicated in cases of completely occlusive lesions
   (c) **Less durable than open bypass in the long term**
   (d) Not recommended in diabetic patients due to inferior outcomes
   (e) Associated with higher amputation rates compared to open surgical bypass
10. Open surgical bypass
    (a) Is reserved only for severe critical limb ischemia
    (b) **Requires adequate inflow and outflow as well as an appropriate conduit**
    (c) Can achieve equivalent results using autogenous vein and synthetic grafts
    (d) Is a definitive treatment and does not require regular surveillance

Introduction

Diabetes mellitus (DM) is a chronic multisystemic metabolic disease, which is an effect of persistent hyperglycemia and causes deleterious effects in the micro- and macrovasculature [1–4]. It is expected that its incidence and prevalence will continue to increase globally, making it one of the great pandemics of the twenty-first century [5–8].

The eye is one of the main organs affected by this pathology, mainly causing diabetic retinopathy (DR), which is one of the most important microvascular complications of DM [2, 3, 9]. DR has been reported to be one of the leading causes of blindness in the working age population [10–15]. From 1990 to 2010, in England, as a result of the policies of screening and early treatment, DR is no longer considered as the leading cause of blindness and moderate to severe vision loss [16]. Although less known for non-ophthalmologists, there is a spectrum of eye disease related to diabetes that can lead to eye problems or even loss of vision [17–20].

Epidemiology of Diabetes and Diabetic Retinopathy

The diabetic patients are at 25 times more risk of blindness compared to nondiabetic individuals. This was documented by a study that estimated untreated proliferative diabetic retinopathy (PDR) results in an irreversible visual loss in 50% of individuals at five years after diagnosis [21]. The impact of this visual dysfunction is globally recognized [13, 18, 21, 22], involving several countries like the UK that has set up screening programs for early detection and treatment of DR [21]. In the literature, although there is some heterogeneity in the epidemiological data on DR [15, 18], there is an agreement on the fact that this is a current problem with a strong public health impact.

A meta-analysis involving 35 studies carried out worldwide from 1980 to 2008 provided data from 22,896 individuals with diabetes. The estimated global prevalence of DR was 34.6%: 6.96% for PDR, 6.81% for diabetic macular edema (DME), and 10.2% for vision-threatening DR (VTDR) [15].

Studies in the European population showed a prevalence of DR of 36.5–93.6% in type 1 diabetes, 16.3–34.2% in type 2, and 16.3–48.8% in mixed cohorts [13], with VTDR prevalence estimated between 6.7 and 34.9% [13].

In population-based studies, the prevalence of DME among patients with type 1 diabetes was between 4.2 and 7.9%. In patients with type 2 diabetes, it was between 1.4 and 12.8% [13]. Non-stereoscopic fundus photography was used in most of the studies, which affected the accuracy of DME assessment. About half of the studies defined macular edema using the clinically significant macular edema (CSME) criteria, and hence, only the more severe spectrum of DME was captured in these studies [13]. A Cochrane review of the prevalence of DME as assessed by optical coherence tomography (OCT) has found a large range of prevalence rates (19–65%) [13]. This should be considered as a new reference standard for assessment of DME, even in some screening settings [23].

Ling et al. [22] indicated a DR prevalence of 49% in type 1 diabetes and 24.2% in type 2 diabetes in the UK, with a global prevalence of 21.4% for NPDR (nonproliferative diabetic retinopathy), 2.8% for PDR (proliferative diabetic retinopathy), and 6.1% for CSME (clinically significant macular edema).

An important topic in epidemiological DR-related studies is the prevalence of VTDR—either PDR and/or DME. According to a meta-analysis study by Yau et al. (2012), VTDR prevalence was found to be 10.2% globally. These patients need referral and urgent treatment. Some of the studies do a segmentation of the two forms of VTDR [13].

Variability in the Results of Epidemiological Studies

The analysis of the results of multiple studies based on a review of Lee et al. [13] revealed that the prevalence varies depending on the geography and studies reflecting the precociousness DR or its late identification with more advanced disease. Also, there is a difference between diabetes type 1 and type 2. Depending on the epidemiological studies carried out on patients, those who visited hospitals showed a higher prevalence of VTDR compared to those from the community (population-based) who showed lower prevalence of DME and PDR. A wide range of prevalence observed may also be due to the differences in healthcare systems and socioeconomic factors between the studied populations. However, conclusions cannot be drawn as key characteristics, such as known duration of diabetes, vary significantly between the sampled populations [13]. The studies performed in newly diagnosed patients have a lower prevalence of DR since it increases with the duration of the diabetes [13, 24]. It is also higher in Western countries due to urbanization, diet, obesity, and sedentarism [13]. Eastern populations (except in the surrounding regions of Singapore) and the less urbanized and industrialized rural areas have a lower prevalence [13].

Incidence and Progression of DR

In the Wisconsin study, Klein et al. [25] evaluated the progression of DR in individuals with type 1 diabetes over a period of 25 years. The authors have documented a cumulative progression rate of DR of 83%, a progression to PDR of

42%, and improvement of DR in 18%. In addition, the cumulative incidence of macular edema and clinically significant macular edema was 29% and 17%, respectively.

In Portugal, Dutra Medeiros et al. [26] proceeded to assess the incidence and progression of DR in a prospective population-based cohort of type 2 diabetics with five years of follow-up. Referral diabetic retinopathy (RDR) was set to all patients classified with moderate to severe NPDR or PDR, with or without maculopathy or mild NPDR with maculopathy (a little more comprehensive than set to VTDR). The annual incidence of any DR in patients without retinopathy at baseline was 4.60% in the first year, reducing to 3.87% in the fifth year; the cumulative incidence at five years was 14.47%. The risk of any degree of DR, non-referable DR, or RDR was strongly associated with increased duration of diabetes and earlier age at diagnosis.

The Impact of the Nordic (European) Diabetic Classification on Screening of Diabetic Retinopathy

Data-driven algorithms reflect a larger heterogeneity in DM subtypes when compared with the classical division into T1DM and T2DM or glycemic and HbA1c level [27]. Recently, Ahlqvist, E. et al. published a study [28] where six variables were used to carry out a CLUSTER ANALYSIS: age at diagnosis, BMI, HbA1c, GADA, C-peptide, and HOMA-B and HOMA-IS. A Cox and logistic regression was made, and they found 5 clusters [28] (Table 53.1).

The groups 4 and 5 corresponded to 62% of the diabetic patients, who have low complications level; this is the reason why it is advisable to screen these patients only every 2 or 3 years. On the other hand, more attention should be paid to the higher-risk group of eye complications, namely, group 2 and group 1 which correspond to the conventional DM1.

Currently, it is not possible to identify these groups, in our daily practice. However, this screening strategy should be implemented as soon as we can routinely use those tests in diabetic patient care.

OCT as a Current Screening Tool and AI as an Adjunct to Screen Activity

In addition, we should incorporate the new trends toward the use of portable or home OCT and current use of AI in the screening of diabetic retinopathy. Indeed, RetMarkerDR software, a CE-marked Class IIa medical device developed in Portugal, has been used in local DR screening for some years [29]. It has been implemented into a co-existing, human grader-based DR screening program conducted in Portugal. In this case, Retmarker is used to select between "disease" and "no disease" groups. A human grader assessment is only needed for the "disease" subgroup, avoiding the use of this time-consuming practice to analyze normal images. The human resources are directed to those who really need surveillance from an ophthalmologist.

Table 53.1 The Nordic study (European study of Ahlqvist, E. et al. (2018) points to a new diabetic classification: five clusters of recently diagnosed diabetic patients were obtained

Cluster	Name	INITIALS	Prevalence %	Characteristics
1	**Severe autoimmune diabetes**	SAID		**High incidence of retinopathy**
2	**Severe insulin-deficient diabetes**	SIDD		**highest incidence of retinopathy**
3	Severe-insulin resistant diabetes	SIRD		
4	Mild obesity-related diabetes	MOD	**22%**	Low complictions level if it do.
5	Mild age-related diabetes	MARD	**40%**	Low complictions level if it do.

The four and five clusters have a low incidence of diabetic complications, namely, eye complications, and correspond at 62% of the diabetic patients. Consequently, the resources should be directed toward the 38% of the patients of the higher risk of developing diabetic retinopathy

OCTA and OCTA as Part of Multimodal Imaging in Diabetic Retinopathy

Structural OCT is a precious tool on assessing DR, showing qualitative and quantitative imaging of macular area and foveal morpho-structure. A multimodal imaging report integrates also IR and color fundus photography, color ultrawide field photography, AF (autofluorescence), en face structural OCT, and OCTA, which can depict the superficial and deep capillary plexus as well as the choroidal plexus. Currently, this multimodal imaging is essential to establish diagnosis and classifying the DR [30].

Diabetic Retinopathy Physiopathology

Several pathophysiological mechanisms are concerned. It is thought that in the retina, there is a change in response to insulin that exists in the peripheral tissues. As a consequence, there is a decrease in the "signaling" PEDG-derived platelet growth factor, which causes a decrease in the survival of pericytes. The capillary walls disappear [31], which has been marked as an early event in the physiopathology of DR. Microstructural and functional changes appear at the vascular and neuronal levels because of the chronic inflammatory state of the retina induced by maintained hyperglycemia. Indeed, it is in the context of the neurovascular retinal unit [32] that the chronic hyperglycemia acts as a key factor in the pathogenesis of DR [2, 3, 9].

This leads to activation of a cascade of events that, without treatment, culminates in the accumulation of fluids in the extravascular space, ischemia, proliferation of abnormal vessels, and blindness [9, 33].

In DR, the first histological changes occur at the level of the retinal capillaries with basement membrane thickening, loss of pericytes, and change of the tight junctions. This leads to loss of the inner blood-retinal barrier incompetence, promoting vascular hyperpermeability, and vaso-occlusive phenomena [9, 33, 34].

At present, the research focuses on the identification of molecular and biochemical mechanisms that contribute to the changes described above [9].

Several potential biochemical mechanisms have been implicated and activated by chronic hyperglycemia, polyols [9, 35–38], the accumulation of advanced glycation products (AGE) [9, 35, 37, 39–42], activation of protein kinase C (PKC) [9, 35, 43], and leukostasis [9, 34, 35]. These channels promote oxidative stress [33, 44], vascular dysfunction, and the emergence of pro-inflammatory cytokines, such as the vascular endothelial growth factor (VEGF) [9, 33, 34, 45], TNF α [9, 33], nitric oxide (NO) [9], prostacyclin [9], IGF-1 [9, 33], NF-*k*B [33], PlGF [9], and interleukins 1 and 6 [33]. Of these factors, VEGF has assumed a particular importance, having been identified in the vitreous and retina of individuals with DR [9, 45] and being considered as one of the main stimuli for DME and PDR [46].

VEGF is a potent mitogen of endothelial cells with a molecular weight of about 45 kD [46–48] and is one of the main cytokines expressed as a result of persisting hyperglycemia, resulting in pathologic angiogenesis, vascular permeability, and increased expression of pro-inflammatory cytokines [47, 48]. In this way, VEGF is also been targeted as a therapeutic tool in DR, with anti-VEGF drugs being considered the treatment of choice for DME, alone or in combination with corticosteroids and laser therapy [48].

Another mechanism discussed as responsible for edema in DR is related to the deregulation of the activity carrier of water molecules resulting from the retinal metabolic activity. This was carried out by the Muller cells, in particular, by the change in the activity of water channels (Aquaporin-AQP4) and potassium channels (Kir, Kir 2.1 4.1) with potassium accumulation in the cells of Muller and their hydration and retinal edema [49, 50], which can be reversed by corticosteroids [50].

There is some evidence that in the earliest stages of the disease, VEGF is the main factor implicated in the DME. However, with the evolution of the disease into later phases, DME becomes chronic. Other cytokines [51], in particular IL-1, IL-6, IL-8, IP-10 (protein interferon-inducible protein), and MCP-1 (monocyte chemoattractant protein), related to aggravation and chronicity of the inflammation, are considered responsible for the inadequate response of the anti-VEGF.

DR is the result of complex and multifactorial mechanisms that lead to edema and retinal neovascularization.

Classification of Diabetic Retinopathy and Diabetic Macular Edema

Clinical international classification/disease severity level of diabetic retinopathy (Diabetic Retinopathy GDRPG—Global Project Group 2002) is based on the dilated fundoscopic or color fundus photograph examination [52–54] (Tables 53.2 and 53.3).

Table 53.2 GDRPG—global diabetic retinopathy project group 2002 classification of diabetic retinopathy (DR)

Proposed disease severity level	Findings observable
No apparent retinopathy	No abnormalities
Mild non-proliferative DR	Microaneurysms only
Moderate non-proliferative DR	More than just microaneurysms but less than severe NPDR
Severe non-proliferative DR (if instead of "or" if "and" could be considered very severe non-proliferative DR)	Any of the following: – More than 20 intraretinal hemorrhages in each of the four quadrants – Venous anomalies (venous beading) in two or more quadrants – Intraretinal abnormalities (IRMA) in at least one quadrant No signs of proliferative retinopathy
Proliferative DR	– Neovascularization – Vitreous/preretinal hemorrhage
The Portuguese Retina Study Group believes that any PDR should be subclassified according to gravity as follows [51]:	
Low-risk PDR	Neovascularization in or within 1 DD of the disc (NVD) with area <1/3 of DD or NV beyond 1 DD of the disc (NVE) with an area <0.5 DD
High-risk PDR	Neovascularization in or within 1 DD of the disc (NVD) with area ≥1/3 of DD or NV beyond 1 DD of the disc (NVE) with area ≥0.5DD or any NVD with vitreous hemorrhage
PDR with advanced diabetic eye disease	Any of the following: • Vitreous/preretinal hemorrhage • Rubeosis iridis • Tractional retinal detachment • Fibrovascular proliferation with traction

Table 53.3 GDRPG—diabetic retinopathy global project group 2002 classification of EMD. DD means diameter optic disc

Proposed disease severity level	Findings observable
Macular edema apparently absent	No retinal thickening or hard exudates in the posterior pole
Macular edema apparently present	Retinal thickening or hard exudates in the posterior pole
If macular edema is present, it can be further classified as follows:	
Mild: some retinal thickening or hard exudates in the posterior pole but distant from the center of the macula	
Moderate: retinal thickening or hard exudates approaching the center of the macula but not involving the center	
Severe: retinal thickening or hard exudates involving the center of the macula	

ESASO Classification of Diabetic Maculopathy

An OCT-based classification of diabetic maculopathy has recently been proposed by ESASO (European School of Advanced Studies in Ophthalmology). It includes seven qualitative and quantitative features, scored according to a grading system: central sub-foveal thickness, intraretinal cysts size, status of ellipsoid zone and external limiting membrane, disorganization of the inner retinal layers (DRIL), presence of hyperreflective foci, and presence of subretinal fluid and vitreoretinal relationship. The maculopathy is classified in four different stages, which reflect progressive severity of the disease: early, advanced, severe, and atrophic maculopathy. Some of these OCT parameters could also have prognostic value, such as the DRIL and alteration of ellipsoid zone which are predictors of poor treatment response, and subretinal fluid and hyperreflective foci which are considered inflammation biomarkers [55]. However, this classification based on OCT structural features does not take in consideration the hard exudates and lipoprotein plaques as a signal of chronicity and bad prognosis for visual function nor visual acuity per se, as prognostic and therapeutic biomarkers.

Current Treatment of Diabetic Retinopathy

To address the issue of the treatment, we need to consider both the severity of the disease and the importance of early diagnosis and treatment.

We must take into account that DR can present with different severity levels, depending on the time of evolution of the disease and, as recently shown [28], the subgroup of diabetes. The level of severity is essential to plan the level and complexity of the intervention. In this way, we can adequately plan and allocate human and financial resources according to the level and complexity of each case [56] (Fig. 53.1).

On the other hand, a screening program for early detection and treatment allows an earlier intervention. It has been estimated that only 10% of resource consumption is needed at this time, instead of what would be required in the advanced stages of the disease and with very encouraging results [56]. Preferably, early detection and treatment programs must be carried out with a standard performance of proximity to the diabetic patient, including screening mobile units and use of telemedicine [56].

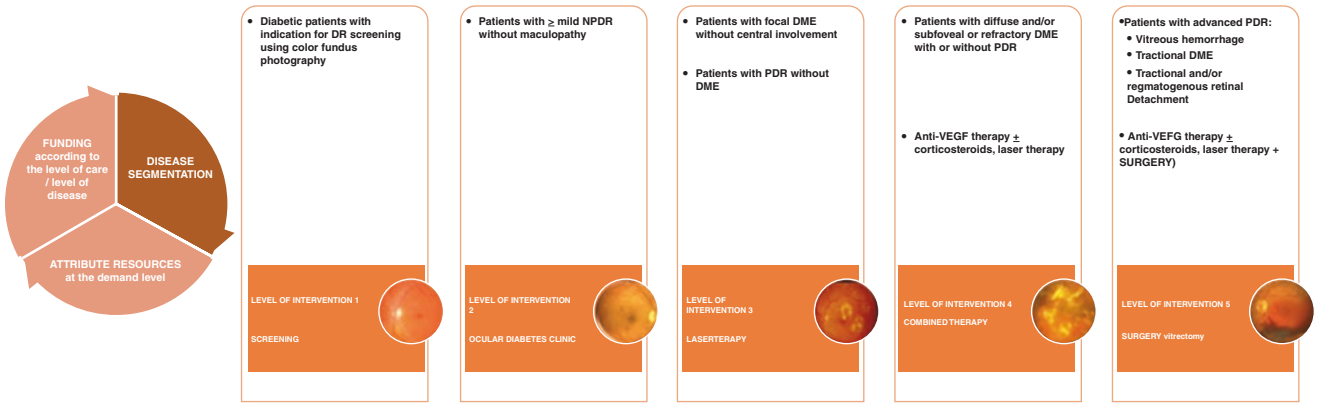

Fig. 53.1 DR levels of intervention and their relevance in health planning. We defined five levels of disease according to the level of severity. Each level of disease corresponds to a level of care. Note that there is an increase in complexity as the level of disease increases

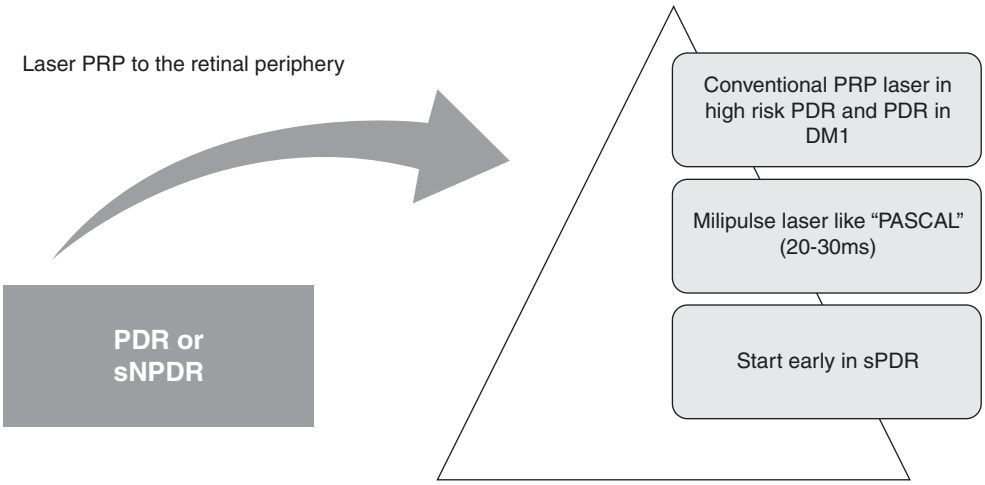

Fig. 53.2 Laser therapy for PDR. Conventional PRP laser should not be avoided in cases of high-risk PDR and PDR in type 1 DM patients. When using a multispot laser, treatment should be more intense so as to be equivalent to conventional PRP laser. Do not wait in severe PDR, particularly in patients with high-risk characteristics

It should be noted that, in each patient, DR can manifest with a predominantly ischemic or exudative component, sometimes mixed. In the first case, we are dealing with an evolution toward very severe NPDR or PDR. In this situation, although there are references to positive results with the use of anti-VEGF [57], the therapy of choice continues to be thermal laser. The treatment is carried out to the periphery of the retina, with the panretinal photocoagulation (PRP) [58] technique or more smoothly, with a technique called targeted retinal photocoagulation (TRP) using a multispot laser [59] (Fig. 53.2). The thermal laser, with a photocoagulation effect, has been a standard therapy of PDR [60] with very long-lasting results. Laser is truly recommended in contexts of low availability of resources, difficulty to follow patients, poor compliance, patients with reduced mobility, PDR in patients with type 1 diabetes, and advanced PDR where it is mostly combined with vitrectomy. In addition to being an effective treatment in the PDR, laser phototherapy has also been used as an efficient eye treatment procedure, thus preventing the onset of blindness due to hyperglycemic conditions [56, 61–63]. Advanced PDR with vitreous or preretinal hemorrhage and fibrovascular proliferation, particularly associated with retinal or macular detachment, are approached with surgical procedures—vitrectomy associated with intraoperative laser in a PRP pattern [56]. In this setting, a very early vitrectomy, with previous (2–3 days) anti-VEGF IV injection associated with endolaser PRP is an effective long-term treatment for PDR and vitreous hemorrhage.

The exudative component predominates in DME. Early stages of vascular edema, either focal or multifocal, do not imminently threaten fovea. In this case, the laser can still lead to better clinical outcomes [56, 61–63]. It should be emphasized that the laser treatment performed in the macular area follows the softer parameters and small spot diameter to avoid any damage to the microstructure of the macular retina.

It should be emphasized that a clear cut exists between center involving macular edema and other forms of DR with less severe edema [64]. The DRS and ETDRS trials [65, 66] in the 1970s showed that the results of laser photo-

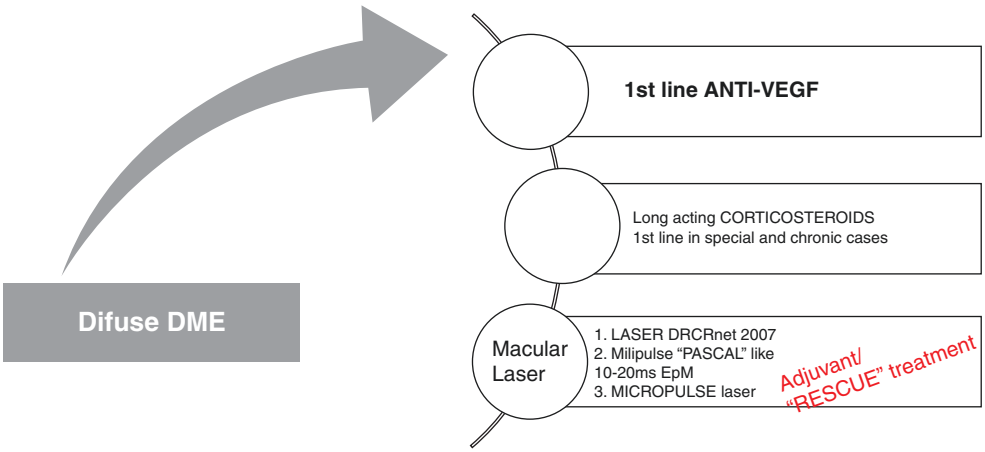

Fig. 53.3 Treatment options for diffuse DME: first line, anti-VEGF; second line, long-acting corticosteroids (eventually as first line in special and chronic cases); third line, which uses laser therapy at macular area for DME (with or without PRP at retinal periphery) as rescue or adjuvant therapy

therapy in DME were not encouraging [65, 66]. Only 3% of the treated patients had a gain of 15 ETDRS scale letters at the end of three years, and more than half continued to lose vision despite the laser monotherapy treatment [65]. Many of these patients presented with a diffused or subfoveal exudative component (diffuse DME) and with more advanced levels of disease. We can even say that the treatment paradigm of DR has changed, mainly for diffuse and advanced DME with large lipoprotein exudates, where anti-VEGF (bevacizumab, ranibizumab, aflibercept) [67, 68] therapy is now indicated as the first-line therapy (Fig. 53.3).

Indications for laser use as first line include the vasogenic subform which is clinically characterized by the presence of focally grouped MA and leaking capillaries [69], eyes affected by DME with CRT less than 300 μm [69], PEVAC-like lesions which requires the use of a milipulse low power laser [70], and eyes with persisting vitreomacular adhesion [67]. Subthreshold grid laser treatment can be helpful in eyes with better visual acuity affected by early diffuse DME, in order to avoid the collateral thermal diffusion and the consequent chorioretinal damage [69]. Deferring laser led to superior results, especially in eyes with BCVA at baseline lower than 69 letters [71]. Laser therapy can also be used as rescue after failure of anti-VEGF therapy [72].

Indications for anti-VEGF use as first line include concomitant presence of *neovascularization*, increased *intraocular pressure*, *young age* and the *presence of the lens* because corticosteroids are cataractogenic, *aphakic eye* or *iris-sustained anterior lens* due to possible migration of the device to anterior chamber, and consequent corneal edema. The absence of *inflammation biomarkers* such as subretinal fluid (SRF), hyperreflective retinal spots (HRS), and hard exudates points to the use of anti-VEGF as first line of treatment [64].

Indications for corticosteroids use as first line include *recent cardiovascular disease/recent arterial thromboembolic events*, *pregnancy*/breastfeeding, *noncompliance* or impossibility to return to treatment or follow-up visits, and *vitrectomized eyes.*

Combined therapy: thermal laser with VEGF and prolonged action steroids and surgery. However, the evidence gathered continues to support individualized and multifaceted approach to the patient with DR [73], in which the anti-VEGF agents can be used in combination with the reference treatments, such as corticosteroids [74] and laser phototherapy [68, 75], which act as an adjuvant factor and long-term stabilizer [76] (Fig. 53.4). Currently, the thermal laser with the techniques identified as retinal saving [56, 77, 78] can be combined with an anti-VEGF and/or sub-tenon or intravitreal triamcinolone [79, 80] or extended release devices of dexamethasone [81] or fluocinolone [82]. The last are particularly indicated in patients who have been vitrectomized [83] and as first line in patients with contraindications to anti-VEGF use.

This approach has been rationally demonstrated by enhanced efficacy in clinical trials [72, 84–87] and in better and more efficient management of a healthcare provider system. In about 40% of patients, the response to anti-VEGF monotherapy was not satisfactory [72], and it might make sense to change drug class, shifting for a prolonged action corticosteroid [82], and/or associate the laser treatment (and/or macular periphery) [56].

The combination of drugs appears to be a valid option in order to enhance their global beneficial effects. The different drugs and/or laser therapy act synergistically in the various mechanisms of action that cause edema. The gain in efficacy achieved by combining drugs can reduce the total number of required treatments, decrease the adverse effects of the individual drugs [76], and improve the therapeutic *burden* on the patients [56]. Treatment procedures like vitrectomy and phacoemulsification also go along well with the combination therapy.

The laser therapy, like the vitrectomy, acts as the stabilizing element of the retina in the long term. This has been dem-

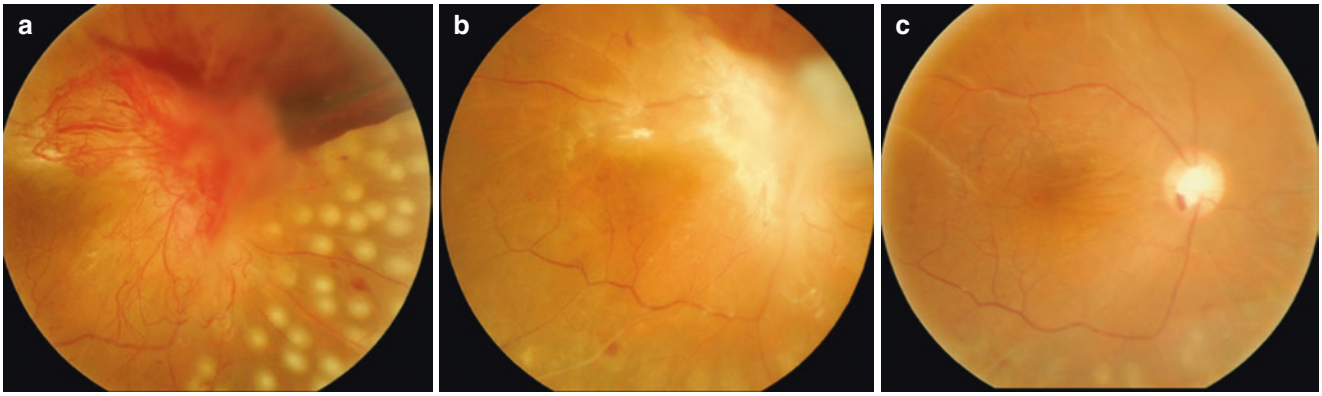

Fig. 53.4 Advanced PDR with vitreous and preretinal hemorrhage in a 35-year-old woman. (**a**) Laser photocoagulation was performed as there was optical transparency. (**b**) Two days after intravitreal ranibizumab injection: there was total regression of neovascularization and a fibrotic "shift" of fibrovascular tissue. (**c**) Two days after vitrectomy with "peeling" of the fibrovascular complex. The result was excellent with the maintenance of visual acuity of 0.8 due to early action in combining therapies. However, this was a highly resource-consuming procedure, which included laser, vitreoretinal surgery, anti-VEGF, and corticosteroids. The treatment could have been simpler by using fewer resources if it was held earlier before reaching advanced PDR

onstrated by the clinical stabilization achieved in laser-treated diabetic patients that lasts for decades.

In the near future, we will continue to use anti-VEGF as well as long-acting steroids in slow-release devices with the features of modulators of neovascularization and edema. The association of genetic therapy opened new frontiers, including the use of viral vectors for transfer of PEDF (pigment epithelium-derived factor) [88–90]. This cytokine has shown to have anti-inflammatory and antioxidant properties [91], as well as the ability to reduce capillary hyperpermeability and edema. The knowledge that laser phototherapy induces retinal environment modeling for production of chemical mediators [92], along with PEDF, either by activation of microglia or the call of medullary stem cells with repair functions, allowed us to further explore this therapy using the laser in earlier phases. Associate methods of improvement of metabolic control [12, 93] and neuroprotection [32] will be the major challenge in treating DM and DR. We anticipate a customized therapy for the individual patient, where the method of treatment will allow to maximize the results and have fewer side effects and fewer visits to the hospital, reducing the burden and treatment cost [93].

Ocular Manifestations of DM Other Than DR

As mentioned above, diabetic eye disease is not limited to DR, even though DR is the best-known microvascular complication (Table 53.4).

Other ocular manifestations of DM can be divided into vitreoretinal, when affecting the vitreous or retina such as the DR, or non-retinal, if they affect other ocular structures [18, 94].

Table 53.4 Ocular manifestations of DM other than DR

Ocular manifestations of DM other than DR	
Blepharitis	Non-arteritic ischemic optic neuropathy
Chalazion	Oculomotor nerve palsy
Dry eye	Asteroid hyalosis
Corneal ulcer	Retinal artery occlusion
Neurotrophic keratitis	Retinal vein occlusion
Loss of accommodation	Ocular ischemic syndrome
Refractive fluctuation of vision	Lipemia retinalis
Cataract	Diabetic papillopathy
Glaucoma	Pupillary abnormalities

Vitreoretinal Manifestations

These include the retinal arterial and venous occlusions and the ocular ischemic syndrome, conditions in which DM is a predisposing factor [18, 94].

The retinal vein occlusions correspond to the second most common vascular retinopathy after DR and are characterized by dilated and tortuous veins associated with intraretinal hemorrhages, cotton-wool spots (localized retinal ischemia), and macular edema. The central retinal vein occlusion involves the whole retina, occurring at the level of the optic disc, and the branch retinal occlusion involves a sector of the retina and is located usually at the level of pathological arteriovenous crossings [18].

The ocular ischemic syndrome (OIS) is a less frequent condition that results from chronic eye hypoperfusion due to significant stenosis/occlusion of the ipsilateral internal carotid or ophthalmic artery. Individuals with this pathology often have multiple systemic risk factors, which include DM, high blood pressure, and dyslipidemia. DM is even considered a major risk factor for carotid disease and consequently the OIS [18, 95].

The appearances of retinal emboli and the retinal arterial occlusions (RAO) are other complications that reflect multiple cardiovascular risk factors of diabetes, especially hypertension and dyslipidemia. The suspicion of an RAO is an ophthalmic emergency, and individuals should be immediately referred to a high-level ophthalmological care center. Symptoms include sudden and painless loss of vision [18]. Changes in the choroidal circulation have also been described [96].

Non-Retinal Manifestations

This group includes disease of eyelids and cornea, crystalline lens, glaucoma, and neuro-ophthalmic disorders.

Eyelids

Blepharitis (inflammation of the eyelids) and chalazion may be the first signs of DM [94].

Cornea

Diabetic patients exhibit reduced corneal sensitivity, resulting in a greater predisposition to infectious keratitis, neurotrophic ulcers, intolerance to contact lenses, erosions, and epithelial defects. There is also a slower healing of the corneal and structural changes in the hemidesmosome of the basal membrane, which leads to persistent epithelial defects even after a minor trauma. Corneal disease symptoms include pain, photophobia, and blurred vision, and the treatment usually consists of lubrication and therapeutic occlusion [18, 94].

Crystalline Lens

Refractive Error

Refractive fluctuation of vision can be a sign of DM and metabolic decompensation due to the change of the power of the lens diopter. This is due to the accumulation of sorbitol by increased activity of the enzyme aldose reductase, which leads to acute lenticular swelling that promotes a hypermetropic shift [94]. It is common when there is a sharp rise in hyperglycemia, often considered an inaugural symptom of DM.

Cataract

Cataracts are also an important cause of impaired vision in diabetic patients, with the risk of cataract increasing with the duration of DM and metabolic control [18]. Patients with type 1 diabetes can sometimes appear with a special type of cataract, a cortical snowflake cataract, which can be rapidly progressive [18]. In individuals with type 2 diabetes, there is worsening of the senile cataract and earlier appearance compared to nondiabetics [18]. Regarding cataract surgery, there are also particularities of DM: (1) preoperative macular edema can compromise visual recovery; (2) DR can rapidly worsen with surgery; (3) there is a prolonged healing time; (4) there is higher risk of postoperative inflammation and infection; and (5) there is higher risk of surgical complications [18, 94].

Glaucoma

Glaucoma is a progressive optic neuropathy, usually associated with increased intraocular pressure and changes in the optic disc and visual field [18].

Case-control trials show a relative risk of primary open-angle glaucoma of 1.6–4.7 in diabetics [18, 94]. DM also disturbs the short posterior ciliary artery self-regulation, exacerbating glaucoma optic neuropathy [18]. Also in DM, there is a greater risk of closed angle glaucoma due to an abnormally large crystalline. Moreover, a crisis of angle closure can also be a complication of an acute hyperglycemia crisis due to the abrupt lenticular edema [94]. Neovascular glaucoma is another type of glaucoma that can arise in diabetics. This type of secondary glaucoma is due to the neovascularization of the iris and angle induced by VEGF, whose production is stimulated by the ischemic retina. In a terminal phase, there is an obstruction of the aqueous humor drainage caused by the fibrovascular tissue in the trabecular meshwork and angle [94].

Neuro-Ophthalmic Disorders

Pupillary Abnormalities

Autonomic neuropathy leading to a denervation of the sphincter and pupillary dilator muscles can contribute to myopic pupils in scotopic conditions and an incomplete response to mydriatic agents [94].

Oculomotor Nerve Palsy

DM has been reported to be a cause of oculomotor palsy in 25–30% of individuals aged over 45 years [18, 94]. These are very common, usually isolated paresis of the III, IV, or VI pairs, and result from microvascular occlusion [18, 94]. Symptoms include binocular diplopia. Usually, there is a spontaneous recovery in 3 months, although recurrence may exist. The presence of other focal neurological signs must lead to the exclusion of compressive injury [18, 94].

Non-Arteritic Ischemic Optic Neuropathy

This condition results in anterior segment ischemia of the optic nerve, and it is estimated that 25% of people with this problem are diabetics [18].

There is an acute and painless decrease in visual acuity, with the presence of a relative afferent pupillary defect and optic disc edema [56]. There is no proven treatment, and the benefit of aspirin remains limited; but even without treatment,

this neuropathy usually remains stable [18]. The arteritic variant should be excluded with erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) and biopsy of the temporal artery due to its reserved prognosis and the need for urgent treatment with intravenous corticosteroids.

Conclusion

This chapter is a review focusing on ocular manifestations of DM, particularly DR, but not neglecting other lesser-known complications. We believe this matter is of particular relevance to the medical doctors who deal with diabetics, sensitizing them on the diabetic eye disease in order to promote a regular ophthalmologic evaluation and enable early detection of these visual debilitating changes.

We live in exciting times, with a constant innovation in prevention, diagnosis, and treatment of DR—the most important ocular complication of DM. However, more evidence with clinical trials on new therapies, clarifying their role, and the use of monotherapy or in combination are required. Other ocular and periocular structures, vessels, and nerves can also be affected by DM. The acquisition of knowledge regarding this issue enables us to diagnose and treat diabetes in a timely manner.Conflicts of InterestJosé Henriques declares having carried out consulting work for Novartis-Alcon, Bausch + Lomb, Bayer, Allergan, and Alimera.

Diabetes and Oral Health

54

Rosa Maria Díaz-Romero
and Manuel Salvador Robles-Andrade

Objective

- To provide healthcare personnel the necessary elements of the etiology, diagnosis, and treatment of disease in the oral cavity affecting people living with diabetes.
- Analyze systemic interaction models of periodontal disease and poor blood sugar control.

Introduction

For decades, oral health has not been considered among the priorities of government and international organization agendas, perhaps because most of the time poor oral health has affected morbidity and not mortality. Recently, there has been greater awareness from government organizations and even from the population that oral health is part of a person's general well-being. Also, more comprehensive studies have indicated that oral infections constitute a risk factor that generate or increase harmful health events in individuals. This change started in 2000 with the report of the US Surgeon General that was continued in 2002 in the Oral Health Program of the World Health Organization [1] that approved the resolution that urges the inclusion of oral health in chronic disease prevention programs. That is why we are interested in including this work in this chapter. We will provide the main concepts of the dentistry field to the entire multidisciplinary team allowing them to include this component in the comprehensive care of the diabetic patient.

We will start by stating how oral health affects quality of life. We will explain the interaction models of periodontal disease when blood sugar levels are uncontrolled. We will analyze how caries affect the teeth of diabetic people, as well as the repercussions of hyposalivation in the generation of swallowing disorders. We will present how the dentist and/or the periodontist diagnose an oral condition and the different phases that constitute periodontal treatment.

This chapter includes the protocol of diabetic care in the dental office with a clinical guideline followed by the physician, the dietitian, the endocrinologist, the nurse, and the diabetes educator, to detect an oral disease. We will also present the recommendations for the use of antibiotics and antimicrobial prophylaxis useful for the dentist.

Recently, there has been greater awareness that oral health is part of a person's general well-being with more in-depth studies of how oral infections constitute a risk factor for health in general.

Oral Health and Quality of Life

Oral health is an essential component of good overall health and it is also a basic human right. According to the World Health Organization (WHO) [1], oral diseases have a significant impact in individuals and in society due to the pain these cause, leading to a decreased function and quality of life. The effects of oral diseases are considerable and expensive; it is estimated that treatment represents between 5% and 10% of the health expense in industrialized countries and it is above the resources of many developing countries.

Poor oral health can have severe repercussions in overall health; in the document *Vision 2020 of the International Dental Federation* in 2016 [2], it is stated that pain, dental abscesses, mastication problems, tooth loss, and pigmented or damaged teeth have significant effects in life and in the daily well-being of people. Some of these manifestations can even increase the risk of poor blood sugar control in people living with diabetes. The preservation of oral health is part of the comprehensive well-being of people with diabetes.

Oral health is a basic human right and its contribution is essential for good quality of life. Oral health is an essential component of good health.

Box 54.1
It is important for the multidisciplinary team involved in the care of diabetic patients, to be aware of the most important elements the dentist uses to diagnose and provide dental treatment to patients with diabetes.

Periodontal Disease and Systemic Interaction Models

Periodontal Disease and Systemic Interaction Models

The periodontium is a group of tissues that support the tooth, and it is made up of bone, periodontal ligament, radicular cementum, and gingiva. The only visible periodontal tissue is the gingiva that in normal healthy conditions the color is salmon, pink, or coral pink with variations that can be due to the degree of keratinization or to melanic pigmentations; these pigmentations are observed more frequently in Black patients. The external gingival portion is made up of a stratified keratinized epithelium that is firmly attached to a dense base of connective gingival tissue whose main function is to protect the underlying periodontal tissue from external stimuli; this epithelium continues to the gingival groove margin that extends from the crest of the gingival margin to the junctional epithelium; the latter maintains direct attachment to the surface of the tooth [3]. The most frequent periodontal disorders are due to the formation of a bacterial biofilm on the tooth surface; once the biofilm comes into contact with the sulcular epithelium at the level of the gingival margin, an inflammatory response begins in the underlying connective tissue that in 3–4 days becomes powerful enough to begin the destruction of connective tissue, losing up to 70% of the collagen within the inflammatory focus [4]. The clinical manifestation of the interaction between the bacterial biofilm that colonizes the tooth surface and that is in contact with the sulcular epithelium (Fig. 54.1) and the junctional epithelium is called periodontal disease; this term encompasses the two main infections that affect the tooth's supporting tissue: gingivitis and periodontitis.

Gingivitis is an inflammatory process that only affects the gingiva, and it is associated with the accumulation of bacte-

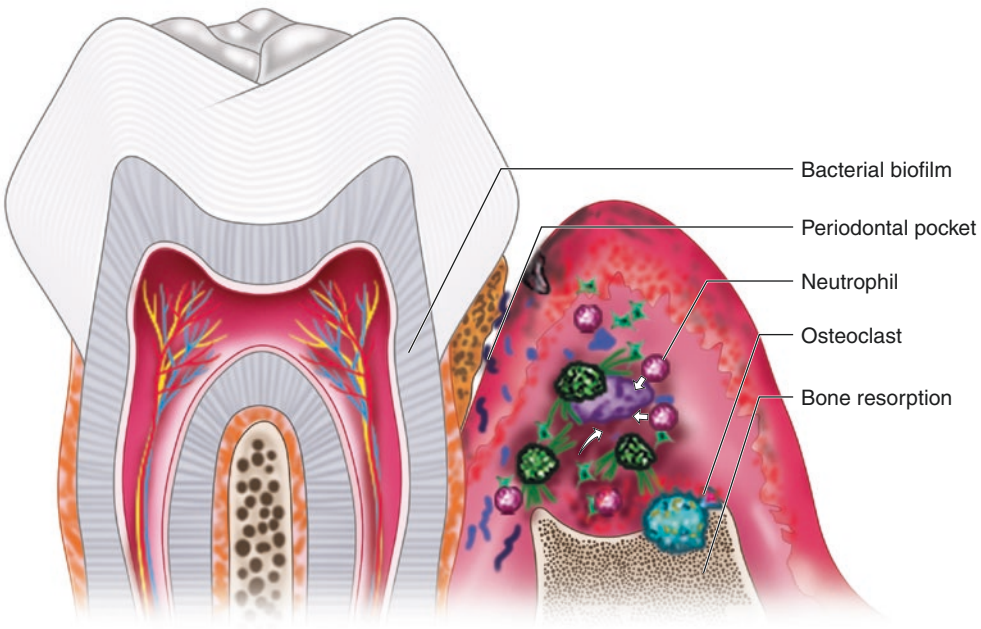

Fig. 54.1 Interaction between the bacterial biofilm and the sulcular and junctional epithelium. The progression of gingivitis to periodontitis involves the proliferation of epithelial cells apically throughout the radicular surface forming periodontal pockets; as these progress, the inflammatory infiltrate increases, starting the bone destruction

Fig. 54.2 Gingivitis. There is swelling of the gingival margin; it looks erythematous, associated with deposits of bacterial plaque on the teeth

Table 54.1 Strategies suggested to patients for personal plaque control [7]

Strategy	Justification
Teeth brushing at least twice a day	Patients who brush with this frequency keep their teeth for a longer period of time
Use of dental floss once a day	It significantly reduces gingivitis compared to only brushing
Routine use of toothpaste containing triclosan/copolymer	These are more effective in reducing bacterial plaque and gingivitis compared to fluoridated toothpastes
Routine use of mouthwash containing essential oils is suggested	These are effective in reducing bacterial plaque and gingivitis, even in proximal areas

rial plaque on the dental surface; when the bacteria of the plaque interact with gingival tissue, there is an inflammatory response characterized by an increase in the volume of the gingival margin, a change in the gingival color that looks erythematous and gingival bleeding in the presence of a stimulus (Fig. 54.2) [5]; this infectious process is reversible once the bacterial plaque is removed mechanically with the implementation of personal plaque control (PPC) where patients are instructed to follow an appropriate brushing technique and daily use of dental floss to achieve resolution of the clinical picture a few days after the correct PPC [6] (Table 54.1).

Periodontitis represents the progression of gingivitis to a destructive infectious process associated with the microbiological change of the bacterial biofilm and with a proinflammatory response of the host [8, 9]; this interaction is responsible for the periodontal destruction that causes dental mobility and tooth loss, making this the second cause of tooth loss [10] (Figs. 54.3 and 54.4).

Depending on the individual's susceptibility, the progression of gingivitis to periodontitis may vary; it has been suggested that the progression takes more than 6 months [11, 12]. The main microorganisms associated with periodontitis are *P. gingivalis*, *T. forsythia*, and *T. denticola*; these microorganisms produce enzymes and toxins that damage periodontal tissue and trigger an

Fig. 54.3 Periodontal probing is a tool used to diagnose periodontitis. Under normal conditions, the probe penetrates the gingival groove 0.5–3 mm; in this case, the probe penetrates 5 mm, reflecting the presence of a periodontal pocket

Fig. 54.4 When removing the periodontal probe, we observe bleeding, suggesting an active infection

inflammatory response. Once the inflammatory response is triggered, the red blood cells, fibroblasts, and structural cells of periodontal tissue release proteases, cytokines, and prostaglandins [13]. Proteases degrade collagen fibers

giving way to more inflammatory infiltrate. While the connective tissue is destroyed, epithelial cells proliferate apically throughout the radicular surface forming periodontal pockets; as these progress, the inflammatory infiltrate increases, starting the bone destruction mediated by osteocytes [14]. As more plaque accumulates, the microbial density increases, creating a chronic and more destructive response until the tooth is lost at some point [15]. The National Health and Nutrition Examination Survey (NHANES) reported that between 2009 and 2010, 47.2% of the American population over 30 years presented periodontitis [16]. The high prevalence of periodontitis represents a public health issue since it has been associated with a risk factor for the development of cardiovascular diseases [17, 18], to blood glucose control in diabetic patients, where the severity of periodontitis has a negative impact on glucose levels [19], on preterm birth and low birth weight, and on respiratory infections [20], among other chronic inflammatory diseases; furthermore, recently, it was observed that the severity of COVID-19 symptoms significantly increased in patients with poor oral health status and the recovery period was significantly delayed in those with poor oral health, while patients with good oral health had a faster recovery [21]. Among people with diabetes, periodontitis is associated with more diabetes complications. There is evidence that patients with periodontitis and with either type 1 or type 2 diabetes have significantly more renal complications and retinopathy [22].

Periodontal disease is considered as the sixth complication in diabetic patients; in the year 2000 [23], the American Academy of Periodontology stated that "the incidence of periodontitis increases among diabetic patients, increasing the frequency and severity in diabetics with more systemic complications" [24]; the increase in susceptibility is not related to the levels of dental plaque or to dental calculus [25]; collective evidence supports the relationship between both diseases, especially in poorly controlled diabetics [26, 27]. In an epidemiologic study carried out in the United States (NHANES III), individuals with poorly controlled diabetes have 2.9 times higher risk of developing periodontitis, compared to those without diabetes; on the other hand, those who controlled their diabetes properly did not experience any risk increase [28]. It has also been observed that in people with poorly controlled type 2 diabetes, the risk of alveolar bone loss was 11 times greater after 2 years, compared to nondiabetic control individuals [29]. This could be explained by the effect diabetes has in the changing adherence of neutrophils, in chemotaxis, and in phagocytosis that could favor bacterial persistence in the periodontal pocket increasing periodontal destruction significantly. The formation of advanced glycation end products, a key factor in many diabetic complications, is also produced in the periodontium, and its harmful effects over other organ systems may also be reflected in periodontal tissue [30]. Likewise, another study identified a 50% increase in the messenger RNA for the receptor of end products of advanced glycation in subgingival tissue of people with type 2 diabetes, compared to nondiabetic controls [31].

The systemic impact of periodontitis is due to the fact that the extension of the epithelium of periodontal pockets can reach 44–76 cm^2; if we put this into perspective, this represents infected tissue the size of the palm of our hand, having the ability to induce bacteremia and cytokinemia, inducing a low-grade systemic chronic inflammatory process [32]. These bacteremias are the result of mechanical stimulation of the periodontal pocket that became ulcerated during routine activities such as brushing or mastication, where not only do bacteria disseminate but also their products and endotoxins such as lipopolysaccharides [33]. Bacteria and bacterial antigens disseminated from periodontal tissue induce a systemic inflammatory response mediated by white blood cells, endothelial cells, and hepatocytes through the production of IL-1b, IL-6, TNF-a, and PGE2; with continued exposure in the systemic circulation, proinflammatory cytokines induce leukocytosis as well as the production of acute phase proteins such as CRP, fibrinogen, plasminogen, and complement proteins, among others [34, 35]. This bacterial and inflammatory mediator dissemination may have a significant impact on the metabolic condition of a diabetic patient; this is because systemic inflammation can start and disseminate insulin resistance. From an epidemiological standpoint, it has been observed that severe periodontitis is associated with an increase in HbA1C [36] in individuals diagnosed with T2DM [37]. On the other hand, in nondiabetic patients, progression of periodontitis has been associated with an increase in HbA1C and with carbohydrate intolerance; likewise, moderate and severe periodontitis has been linked to a greater risk of triggering diabetic complications like macroalbuminuria, kidney disease, atheroma plaque calcification, and cardio renal mortality [38].

In a systematic review of controlled clinical trials [39], we observed that when periodontal treatment is performed and periodontal infections are eradicated, the average reduction of HbA1C was 0.36%; one of the trials showed that periodontal treatment can even decrease HbA1C levels from 0.4% to 0.5%; this metabolic effect is similar to the one achieved when adding a second glucose-lowering drug to the therapy of diabetic patients [40].

Based on biological plausibility models, epidemiological and therapeutic evidence that link DM to periodontitis in a bidirectional manner (Table 54.2), it is imperative for the attending physician to promote oral health in diabetic patients, by requesting in all cases a consultation with the dentist.

Table 54.2 Evidence in the literature that supports a bidirectional relationship of periodontal disease and diabetes

Author	Key item
Eke PI, dye BA, Wei L, Thornton-Evans GO, Genco RJ	The National Health and Nutrition Survey (NHANES) reported that 47.2% of the American population over 30 years presented periodontitis between 2009 and 2010
Khader YS, Albashaireh ZS, Alomari MA	The high prevalence of periodontitis represents a public health issue. It has been associated with a risk factor for the development of cardiovascular diseases
Mealey BL, Rose LF	To blood glucose control in diabetic patients, where the severity of periodontitis has a negative impact on glucose levels
Haffajee AD. et al.	Periodontitis is a destructive infectious process linked to a microbiological shift in the bacterial biofilm and to a proinflammatory response of the host
Eke PI, et al.	The prevalence of periodontitis in the American population over 30 years is 47.2%
Kinane DF, et al.	Periodontitis has the ability to induce bacteremia and cytokinemia, inducing a low-grade chronic system inflammatory process
Löe H	Periodontitis has been considered the sixth complication of diabetes
Mealey BL, et al.	The severity of periodontitis has a negative impact on glucose levels
Engebretson S, et al.	When periodontal treatment is given and periodontal infections are eradicated, the average HbA1C reduction is 0.36%

The systematic impact periodontitis can have is because the extension of the epithelium of the periodontal pockets can go from 44 to 76 cm^2; in perspective, this represents infected tissue the size of the palm of our hand, having the ability to induce bacteremia and cytokinemia, inducing a low-grade chronic systemic inflammatory process.

Eradicated periodontitis can decrease levels of HbA1 from 0.4% to 0.5%; this metabolic effect is similar to the one achieved when adding a second glucose-lowering drug to the therapy of diabetic patients.

Based on biological plausibility models, the epidemiologic and therapeutic evidence that link DM bidirectionally to periodontitis, it is essential that the attending physician promotes oral health in diabetic patients, requesting an interconsultation in all cases with the dentist.

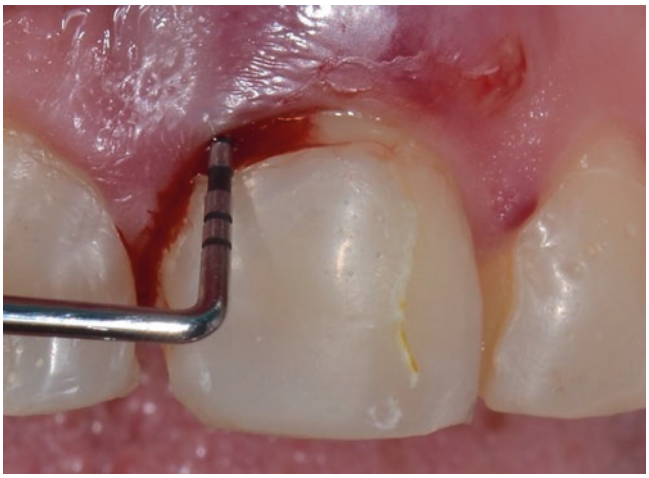

Fig. 54.5 Patient diagnosed with T2DM and periodontitis. We observe that the probe penetrates 9 mm; there is suppuration and bleeding, suggesting an active infection

Periodontal Diagnosis and Treatment

Diagnosis of periodontitis is clinical and based on the loss of clinical insertion levels, bony loss (Figs. 54.5 and 54.6), periodontal pocket depth, dental mobility, pathological dental migration, and signs of gingival inflammation (change in color, bleeding on probing, volume increase and exudate on probing) [7]. Overall, periodontal treatment is divided into three phases. In phase 1, therapy focuses on eliminating the causal agent (bacterial plaque), defective repairs that contribute to the retention of plaque are removed, and risk factors are controlled (such as smoking, diabetes mellitus, etc.). One of the most important aspects of periodontal phase 1 is providing patients instructions on personal control of bacterial plaque, instructing them on the proper use of dental floss, an appropriate brushing technique and the items that could facilitate proper oral hygiene [41]. It is absolutely essential to constantly assess the patient's personal plaque control since the long-term therapeutic success depends on it. Treatment of gingivitis consists of eliminating bacterial plaque through mechanical means; as was said before, one of its characteristics is that it is reversible once the bacterial plaque is removed; therefore, patients diagnosed with gingivitis only require periodontal phase 1 (Figs. 54.7 and 54.8).

Unlike gingivitis, periodontitis has an irreversible destructive pattern; in the most recent classification of periodontal diseases, glycemia in diabetic patients is used as an indicator of the rate of periodontitis progression [42]. Periodontitis has to be treated first with nonsurgical means like scaling and root planing, a treatment by means of which bacterial plaque and subgingival calculus are removed using curettes and ultrasonic instruments; on specific clinical scenarios, the use of antibiotics as well as mechanical treatment is necessary

Fig. 54.6 X-ray corroborating the presence of vertical bony defect

Fig. 54.7 Gingivitis. We observe increased volume of the gingival margin, with an erythematous aspect

Fig. 54.8 After dental prophylaxis and correct oral hygiene instructions, we observe the resolution of the inflammatory process

[43]. If the periodontal pockets persist after the scaling and root planing, periodontal phase 2 is carried out; this is a surgical phase where a flap is lifted in order to perform a deeper periodontal debridement and therefore eliminate the infectious foci. In this phase, the periodontist can place biomaterials that stimulate the periodontal regenerative process [44].

Once the periodontal disease has been controlled, patients start the periodontal phase 3 or maintenance phase. In this phase, patients are reevaluated at 3–6-month intervals to identify if there is any site that has recurred; if so, it is treated at that moment, reinforcing the knowledge so that the patient can follow a good personal plaque control. The maintenance therapy should be carried out for the patient's whole life since the periodontitis can recur.

Periodontal treatment is divided into three phases. In phase 1 therapy which focuses on eliminating the causal agent (bacterial plaque), the defective repairs that contribute to the retention of plaque are removed, and risk factors are controlled (like smoking, diabetes mellitus, etc.). Periodontal phase 2 is a surgical phase where a flap is raised to perform a deeper periodontal debridement and thus eliminate the infectious foci. In phase 3 or maintenance phase, patients are reassessed in 3–6-month intervals to identify if there is a recurring site; if so, treatment is given at that moment and the knowledge is reinforced so that the patient can perform a proper personal plaque control.

Fig. 54.9 Cervical caries in a diabetic patient

Dental Caries in Diabetics

According to the World Health Organization (WHO), dental caries can be defined as a pathological process characterized by a series of complex chemical and microbiological reactions that end up destroying the tooth. This destruction is the result of the action of acids produced by bacteria in the environment of the dental plaque. Clinically, a caries is characterized by a change in color, loss of transparency, and decalcification of the affected tissue. As the process advances, the tissue is destroyed and cavities are formed.

Throughout the world, around 60%–90% of school-age children and close to 100% of adults have dental caries, often accompanied by pain or a feeling of discomfort.

In diabetics, we observe cervical and atypical caries developed in areas that are not often affected in the rest of nondiabetic patients (Fig. 54.9); however, there is not a unanimous criteria on this theory.

Several reports support the increase in the caries index among diabetics, although there are others who point out a similar risk in nondiabetic patients. These discrepancies have been attributed to the inconsistent characteristics of the clinical evaluations performed, going from the use of several indices like decayed, lost, and filled teeth (CPOD) to bacteriological evaluations; other discrepancies come from the type of populations studied that go from children with type 1 diabetes to elderly patients with type 2 diabetes; however, it is a fact that glucose level in the saliva of nondiabetics is between 0.20 and 2.30 mg/dL, while in diabetics, it goes from 0.45 to 6.30 mg/DI [45]; this condition and the decreased saliva secretion are risk factors for the genesis of decaying processes. These factors alter saliva's buffering capacity that has an effect in the pH of bacterial plaque in teeth, and it affects the rate and the development of caries favoring the growth of microorganisms such as *Streptococcus mutans (Sm)* and *Lactobacillus acidophilus (Lb)* [46]. These are considered bacteriological indicators for their acidogenic and aciduric capacity; in fact, the quantification of these microorganisms has shown a correlation with the decaying process. Scientific evidence indicate that *Streptococcus mutans* is the microorganism associated with the onset of the lesion and *Lactobacillus acidophilus*, with the progression of the lesion; both bacteria are strong producers of acid; therefore, it is considered that the concentration level in saliva, in colony-forming units (CFU) of *Sm* and *Lb* (>105), is associated with intense cariogenic activity, and it is used as an indicator of the high content of fermentable carbohydrates in the oral media, an essential element for greater acidity and thus a greater risk factor. On the other hand, a diabetic patient often develops odontalgias with pulpitis, whose genesis is justified by the microangiopathic processes; the presence of these manifestations is a fact reported in the literature, as well as the repercussions that can cause the dissemination of microorganisms of the oral cavity to the rest of the body (CITA), with the generation of bacteremias that can be the initial factor to trigger generalized bacteremias that have led to death in diabetic patients.

Diabetic patients are more prone to infections; therefore, we have to take the following into account:

- Dental caries is an infection that as it progresses generates the formation of dental abscesses; therefore, this disease should be treated.
- Any dental abscess has to be treated actively to prevent dissemination of bacteria to the blood flow.
- Antibiotic coverage will depend on the type of intervention and the degree of control of diabetes. In some cases, to avoid complications, it is recommended to start preoperative and especially postoperative antibiotic coverage [47].

In diabetics, we observe cervical and atypical caries developed in areas that we do not often see in nondiabetic patients.

Dental caries is an infection that as it progresses generates the formation of dental abscesses; therefore, this disease should be treated. Any dental abscess has to be treated actively to prevent dissemination of bacteria to the blood flow.

Hyposalivation and Xerostomia

Another anomaly present in diabetics is xerostomia; according to some authors, this disorder is more exacerbated in females. This feeling of "dryness" is caused by the increase in diuresis and a decrease in the volume of extracellular fluid and to changes in the microcirculation of salivary glands that produce hyposialia; xerostomia is often accompanied by glossodynia, taste disorders, burning in the tongue, and halitosis; the decrease of salivary secretion favors the decrease of salivary pH and therefore cariogenic aciduric microorganisms like *Streptococcus mutans* and *Lactobacillus Acidophilus* which proliferate easily. The salivary flow rate is lower in diabetic patients; Screeby in Diabetes Care (1992) states that 63% of patients with T2D refer xerostomia; the authors of this chapter reported 35% [48].

The xerostomia observed in diabetic patients is not only conditioned by poor blood sugar control but also by changes in saliva composition (high protein and potassium content) and autonomic neuropathy that deteriorate glandular secretion.

Xerostomia is the subjective feeling of dryness in the mouth, a symptom reported by the patient. It can be the result of decreased salivary secretion or it can occur in the presence of normal salivary production. Xerostomia is present in 40–60% of diabetic patients who have poor control of the disease with very little salivary production stimulus from the parotid gland compared to patients who are capable of controlling the disease and normal subjects [49].

Hyposalivation in decompensated diabetic patients is explained by the increase in diuresis and polyuria that can affect the production of saliva.

On the other hand, since xerostomia is considered a subjective sensation of dry mouth, it may or may not be attributed to the decrease or interruption of the salivary gland function. Xerostomia not only causes psychological, social, and physical consequences; it also alters food swallowing (Figs. 54.10 and 54.11).

Xerostomia and hyposalivation can be manifestations present in patients with T1D with inappropriate blood glucose control. However, these manifestations can also be related to neuropathy [50].

Fig. 54.10 Patient diagnosed with T2DM who presents xerostomia. Clinically, we can see a dehydrated oral mucosa, as well as thick saliva

Fig. 54.11 The same patient where we see dehydration of the lip skin

Box 54.2
Xerostomia is a frequent oral condition that can affect oral functions as well as the patient's general well-being.

Box 54.3
Xerostomia in diabetic patients is not only conditioned by poor blood glucose control but also by the changes in saliva composition (high protein and potassium content) and autonomic neuropathy that will deteriorate glandular secretion.

Given its complexity, its treatment requires an interdisciplinary approach that should be focused on improving quality of life, decreasing possible complications, and promoting palliative care. Its etiology has been associated, among other factors, with the presence of systemic diseases including diabetes mellitus. The results of this systematic review and meta-analysis showed a global xerostomia prevalence of 42, 22% (CI of 95%: 33, 97%, and 50, 92%) in people with diabetes and a statistically significant association [51].

Frequent Mucosal Lesions in Diabetics

Candidiasis

Diabetics are prone to fungal infections; this is frequent in our setting. These are produced by the excess growth of *Candida* in the mouth, the digestive tract, the vagina, and other tissues. These are the skin—mucosa disorders that are sometimes systemic and produced by the *Candida* species (the most frequent type is *Candida albicans*). There are local factors such as smoking and the use of total dental prosthesis (Fig. 54.12) that can promote the appearance of candidiasis in the oral cavity as well as by extended periods of hyposalivation in uncontrolled diabetics.

Poor metabolic control is responsible for more fungal infections in diabetic patients than in the rest of the population since the glucose level in saliva acts as a substrate for *Candida*. Taking high doses of antibiotics or prolonged antibiotic use also increases the risk of oral candidiasis. Antibiotics destroy some of the healthy bacteria that prevent candida from proliferating too much.

Fig. 54.12 Candidiasis associated with a movable prosthesis in a patient diagnosed with T2DM

Symptoms. Oral candidiasis appears as velvety whitish lesions in the mouth and tongue. Under this whitish material, there is reddish tissue that can bleed easily. Ulcers may increase slowly in number and size.

Exams and Tests. The physician or the dentist can often diagnose oral candidiasis by examining the mouth and tongue since ulcers have a distinctive appearance. If diagnosis is unclear, one of the following tests can be performed to look for candida organisms:

Culture of oral lesions.

Microscopic test of oral scrapings.

Treatment. For oral candidiasis in babies, treatment is often not necessary since it clears on its own after a couple of weeks. If it is a mild case of oral candidiasis after taking antibiotics, eating yoghurt or taking over-the-counter acidophilus capsules may help. The use a soft bristle tooth brush and rinse with a hydrogen peroxide water solution at 3% several times a day can help. Good control of blood sugar levels in people with diabetes can eliminate an oral candidiasis infection. The doctor can prescribe an antifungal mouthwash (nystatin) or chewable tablets (clotrimazole) if the oral candidiasis is severe or if there is a weakened immune system. These products are generally used for 5–10 days. If they do not work, other drugs can be prescribed [52].

Wound Healing and Changes in the Mucosa

Diabetic patients have impaired scarring. There are several theories that try to explain this phenomenon, like poor vascularization, decrease in platelet activity, or disorders in collagen synthesis [53]. Diabetes makes scarring or wounds slower and more difficult than normal. Diabetic patients not only have impaired scarring in acute wounds and slower closure of tissue making them more prone to chronic wounds. This is caused by an early inhibited or impaired inflammatory reaction and by a decrease in the ability to release growth factors and cytokines and the intercellular communication substances with several beneficial functions. When repair cell migration is interrupted, cell repair is hindered, thus decreasing the quality of the granulation status (scarring from the bottom to the top).

There is also diabetic microangiopathy present in the lower limbs, thus reducing the transport and repair capacity of tissue through the blood.

Diabetic patients often develop odontalgia with pulpitis; its genesis is justified by the microangiopathic processes, the frequent appearance of oral ulcers with a delay in wound healing, fissured tongue, and angular cheilitis; one of the most frequent and striking manifestations is reddening and atrophy of the mucosa.

Candidiasis is a frequent disorder in diabetics. Poor metabolic control is responsible for the fungal infections in diabetic patients more than in the rest of the population.

Healthcare Protocol of Diabetics in the Dental Office, Dental Management, Clinical History, and Patient's Level of Control

If we consider the statistics published by the WHO in 2014, the world prevalence of diabetes was 9% among adults over 18 years old. It is calculated that 1.5 million people died as a direct consequence of diabetes in 2012. More than 80% of the diabetes-related deaths were recorded in low- and medium-income countries.

According to WHO forecasts, diabetes will be the seventh cause of mortality in 2030; it is very likely that this type of diabetic patients will seek a dentist's consultation, and these patients may have an asymptomatic disease therefore going undiagnosed.

Clinical Management of Diabetic Patients in the Dental Office

It is very important for the dentist to be prepared to provide dental treatment to the diabetic patient. This includes an appropriate diagnosis of the prediabetic or the diabetic condition, as well as of the oral status of said patient. A full assessment should be performed including a medical and dental history, essential for an accurate diagnosis to create a treatment plan and to manage the patient's condition appropriately. It is important to specify the type of diabetes, the duration, the treatment modality, diet, exercise, oral drugs, or insulin (type and frequency of administration); patients who use insulin with a subcutaneous pump should be properly identified since they are often at risk of developing hypoglycemia since they have tighter control of the blood glucose levels.

Every dental office should have a glucose monitor, and the staff should be familiar with its use in order to measure the patient's capillary blood glucose (whether the patient has a diabetes mellitus diagnosis or not), before any procedure. However, sometimes it is recommended that the patients bring their own glucose monitor to the dental office if they have one at home, to avoid significant variations in the measurements. All the information on the blood glucose levels and HbA_{1C} should be included in the patient's medical record.

Practical recommendations are the following:

1. It is important to highlight the importance of preserving oral health in diabetics. Patients should be instructed on oral self-examination in front of a mirror and if they find an abnormal condition to consult the dentist.
2. What to do before the dental consultation? Blood glucose control should be at appropriate levels. The medication prescribed by the attending physician should not be suspended. When going to the dentist's office, bring a record of the last blood glucose measurements. Medication and therapies are used and information of the attending physician.
3. During the consultation, we must consider that stress causes changes in the body increasing the blood glucose levels. The dentist's consultation generates stress, as dentists are aware of that, so the consult is given early in the day and we recommend the patients no to change their diet or medication.
4. We highlight that the dentist will provide a detailed explanation of the patient's oral condition. He will perform prophylaxis and will instruct the patients on the use of oral hygiene instruments and will provide the next appointment. We recommend diabetic patients to visit the dentist every 4 months for a routine assessment and detection of possible infection foci.
5. If treatment is surgery, what to do before, during, and after the procedure are as follows: Before surgery, work with your dentist to create the safest surgery plan for you. Focus more on your diabetes control weeks before surgery. The dentist will examine and talk to you about your health. It is important to know all the drugs you are taking.
6. During surgery. You will see your dentist before surgery to discuss the control plan for your blood sugar during surgery.
7. After surgery. The dentist or the nursing staff will monitor your blood glucose level frequently. You may have more problems to control it if you have problems to eat, if you are stressed after surgery, or if you have pain or discomfort.

Be aware of signs of infection such as fever, an incision that is red or warm to the touch, swollen, more pain, or oozing. We recommend being prepared to call the dentist if any questions arise [54].

8. Diabetic patients should be informed that they are at greater risk of developing periodontitis, and if they develop it, blood glucose control will be more complicated having a greater risk of developing diabetes-associated complications like cardiovascular and kidney disease.
9. Patients diagnosed with T1DM, T2DM, or gestational diabetes should have a comprehensive oral examination that includes a periodontal assessment.

10. If periodontitis is diagnosed, it should be managed appropriately; if there is no periodontitis, the patient should follow a preventive program to monitor periodontal changes.
11. Diabetic patients who have extensive tooth loss should be encouraged to have dental rehabilitation in order to have proper mastication and nutrition. When patients loses all their teeth, intake of fibrous food becomes difficult, thus having to change to a softer food diet.
12. Annual oral exams are recommended in children and adolescents diagnosed with diabetes starting at age 6.
13. Patients who are not diagnosed with diabetes but who have obvious risk factors for T2DM and signs of periodontitis should be informed that they are at risk of developing diabetes; we suggest using a HbA1C test and refer them to the doctor for diagnosis.

Antibiotics and Antimicrobial Prophylaxis

The main objective of dental treatment is to eradicate infectious processes and then maintain dental and periodontal health. Controlled diabetic patients are treated the same way nondiabetic patients are; therefore, it is unnecessary to adjust the doses or modify the use of routine drugs in the dentist's consultation. It is important that before the consultation, patients continue their normal diet and their drugs according to the medical prescription. Emergencies and acute infectious processes (with a prior medical interconsultation) should be treated only in uncontrolled diabetic patients; routine treatments should be postponed until blood glucose levels are under control. It is important to consider the presence of organ damage (cardiomyopathy, kidney failure, cirrhosis, emphysema, or alcoholism) since special pharmacological considerations have to be given.

Antibiotics and Antimicrobial Prophylaxis

There is no scientific evidence to support that controlled diabetic patients are prone to postoperative infections when undergoing uncomplicated dentoalveolar surgery; therefore, it is not justified to prescribe antibiotics in these cases; however, if there is a picture of disseminated infection (fever, trismus, lymphadenitis, general discomfort, cellulitis), it is necessary to apply the principles of infection treatment (drainage, elimination of the etiological factor, empirical administration of antibiotics and reassessment).

Antibiotic prophylaxis should not be given routinely to diabetic patients (unless the patient presents another systemic condition that requires it). Routine treatments should be avoided in uncontrolled diabetic patients who have blood glucose levels greater than 250 mg/dL. If an emergency surgical procedure is necessary, appropriate antibiotic prophylaxis is warranted (even though there is no evidence to support it), following the same AHA principles to prevent infectious endocarditis (2 g of amoxicillin 1 h before the procedure). Infections in these patients should be treated aggressively regardless of blood glucose levels.

Guidelines the Physician Should be Aware of to Suspect an Oral Disease

Given that there is a high risk of developing periodontitis and other oral disorders, in a consensus carried out between the American Association of Periodontology and the European Federation of Periodontology on diabetes and periodontitis, the following clinical recommendations were made for physicians and other healthcare professionals:

1. Diabetic patients should be informed that they are at greater risk of developing periodontitis, and if they develop it, blood glucose control will be more complicated, thus making them at risk of developing complications associated with diabetes such as cardiovascular and kidney disease.
2. As part of the initial evaluation, patients diagnosed with T1DM, T2DM, or gestational diabetes should receive an oral and a periodontal examination.
3. Patients diagnosed with T1DM and T2DM should undergo an oral and a periodontal examination annually (even if they do not have an initial diagnosis of periodontitis).
4. Diabetic people who present clinical signs of periodontitis like tooth mobility, dental separation, or gingival oozing should receive immediate dental care.
5. Diabetic patients who present extensive tooth loss should be encouraged to undergo dental rehabilitation for proper mastication and adequate nutrition.
6. All diabetic patients should receive dental education.
7. We recommend oral examinations every year in children and adolescents diagnosed with diabetes starting at age 6.
8. Diabetic patients should be informed that they may present xerostomia and burning mouth and that they are at greater risk of developing candidiasis unlike nondiabetic patients.

Conclusions

Diabetes mellitus has a profound effect on the overall health of patients. Many clinical manifestations are seen in the oral cavity compromising quality of life. When infections are odontogenic, blood sugar control becomes difficult in these patients. That is why there should be a close relationship between the attending physician, the dentist, and other members of the interdisciplinary team who will provide specialized control of any risk factor that may influence the natural history of diabetes.

Concluding Remarks

- Oral health is an essential component of good health and it is a basic human right.
- Poor oral health can have severe repercussions in overall health.
- Periodontal disease is a highly prevalent infection that increases among diabetic patients.
- Periodontal disease increases the frequency and severity in diabetics with more systemic complications.
- Periodontal treatment can help to lower blood glucose levels.
- It is essential that the attending physician promotes oral health in diabetic patients.

Multiple Choice Questions

1. Do oral health and quality of life have any relationship in diabetic people?
   (a) Yes, because treatments constitute 5–10% of the health expense.
   (b) Only if patients do not control their blood glucose levels.
   (c) They do not have any relationship.
   (d) **Yes, because if the mouth is healthy, the person feels well.**
   (e) It depends on the type of diabetes.
2. How is the infectious process that affects support tissue of teeth and characterized by the destruction of teeth called?
   (a) Gingivitis
   (b) **Periodontitis**
   (c) Dental abscess
   (d) Gingival abscess
   (e) Periodontal abscess
3. It is one of the main bacteria associated with periodontitis.
   (a) *S. mutans*
   (b) *S. sanguis*
   (c) ***P. gingivalis***
   (d) *S. aureus*
   (e) *L. acidophilus*
4. Dental caries is an infection that as it advances it causes the formation of dental abscesses that should be treated in diabetics only when:
   (a) There is no blood sugar control.
   (b) **They should always be treated to avoid dissemination of bacteria.**
   (c) When purulent abscesses are formed and there is fever.
   (d) When they go to a specialized hospital.
   (e) They should not always be treated; it depends on the depth of the caries.
5. Diabetics are prone to fungal infections such as candidiasis for the following reasons:
   (a) Because the germ is opportunistic
   (b) Because they are immunosuppressed and they have blood glucose that serves as a substrate for candida
   (c) For smoking and having little saliva
   (d) From the effects of the drugs taken by diabetics
   (e) **Due to the poor blood sugar control, the hyposalivation and glucose in the saliva that serves as a substrate for candida**
6. Xerostomia is present in 40–60% of diabetic patients and the causes are:
   (a) The increase in diuresis and the presence of infection foci
   (b) The decreased platelet activity or the changes in the collagen synthesis
   (c) **The increase in diuresis and changes in the microcirculation of salivary glands**
   (d) The periodontal disease and cervical cavities present in the oral cavity
   (e) That diabetics are thirsty constantly
7. What is periodontal phase 1?
   (a) To perform surgical procedures to eradicate infectious foci
   (b) **To eliminate the causal agent in a nonsurgical manner and control risk factors**
   (c) To perform tooth cleaning
   (d) To use antibiotics to eliminate infectious foci
8. What is the effect of periodontal therapy in HbA1c levels?
   (a) They are maintained the same.
   (b) They increase after periodontal treatment.
   (c) They decrease but not significantly.
   (d) **They decrease up to 0.5.**
9. What do we recommended the diabetic patients do before, during, and after the dentist's consultation.
   (a) **Do not suspend medication for going to the dentist and have records of the attending physician and recent blood glucose levels.**
   (b) Have a dental card.
   (c) Have the attending physician's telephone number and all the prescriptions of drugs taken.
   (d) Take the last appointment of the day to avoid any stress.
   (e) Fast before the appointment without brushing their teeth so that the dentist can see the oral condition.
10. Diabetic patients should take prophylactic medication when they present infection in the oral cavity.
    (a) It is always necessary.
    (b) Never.
    (c) Only if they have type 1 diabetes.
    (d) Only elderly patients.

11. An inflammatory process associates to bacterial plaque characterized by an increase in gingival volume and bleeding on probing and is reversible when the bacterial plaque is eliminated.
    (a) Periodontitis
    (b) **Gingivitis**
    (c) Candidiasis
    (d) Linear gingival erythema
    (e) Periodontal abscess

Renal Disease in Diabetes

55

Carlos A. Garza-García, Virgilia Soto-Abraham, and Magdalena Madero-Rovalo

History

Urinary anomalies in diabetic patients have long been described; many long-standing historical documents refer, for example, to the characteristic sweet taste or smell in the urine of these population. The first description of renal anomalies in diabetic patients goes back to the 1700s, when Domenico Cotugno de Bari described proteinuria in this population [1]. In the next century, Claude Bernard found nephromegaly in diabetic kidneys in 1840 [2], and it was not until 1936 that Kimmelstiel and Wilson described nodular-fibrotic lesions in the glomeruli and diabetic nephropathy, a syndrome characterized by hypertension, proteinuria, and loss of kidney function. Later, in 1969, Harry Keen did a landmark discovery in diabetic nephropathy with the description of albuminuria in diabetic patients and established it as a surrogate for glomerular damage. With all the former discoveries, Mogensen et al. proposed the clinical picture of the natural history for diabetic nephropathy in 1983 [3]. As of today, Mogensen's sequence of diabetic nephropathy continues to be the accepted paradigm with some new features being considered.

Epidemiology of Diabetic Nephropathy

As it is widely known, diabetes has epidemic proportions with a global estimated prevalence of 8.3% in the 2014, corresponding to an approximate of 387 million people worldwide [4], and it is expected to increase to 592 millions of affected individuals by 2035 [5], likely a reflect of worldwide obesity pandemia. Another inherent partner of this world's expected increase in diabetes mellitus is diabetic kidney disease (DKD). For type 1 diabetes, DKD develops in approximately 30% of patients [6] and in about 40% of those with type 2 diabetes. Diabetic population, both types 1 and 2, account for 30–45% of chronic kidney disease (CKD) patients, but since DKD diagnosis is based on the presence of albuminuria as diagnostic criteria, DKD is probably more prevalent when ophthalmologic examination, estimated glomerular filtration rate, and kidney biopsies are included as additional diagnostic criteria.

Pathophysiology

Even though hyperglycemia plays a major role in the development of DKD, other mechanisms have been proposed [7]. Hemodynamic, metabolic, inflammatory pathways, autophagy, and enhanced sodium-glucose transporter-2 (SGLT-2) expression have also been involved in the DKD progression.

Hemodynamic Pathway

Renin-angiotensin-aldosterone system (RAAS) activation, mainly through angiotensin II and endothelin-1, produces a vasoconstriction effect on the efferent arteriole and leads to the widely known hyperfiltration phenomenon. Along with this hemodynamic effect, both molecules enhance mesangial cell hypertrophy and proliferation, extracellular matrix deposition, hypertension, endothelial dysfunction, inflammation, and fibrosis [8].

Fi. 55.1 Glycolysis in hyperglycemia. Glycolysis biochemistry is altered by hyperglycemia; it inhibits GADPH and increases upstream pathways, end products of such pathways

Metabolic Pathway

First described in 2001 by Brownlee [9], he showed that hyperglycemia activates superoxide, which inhibits glycolysis last enzymatic step at GADPH (glyceraldehyde-3-phosphate dehydrogenase) preventing formation of 1,3-diphosphoglycerate. The former increases upstream metabolic steps which end up in increased polyol pathway, hexosamine pathway, advanced products of advanced glycation end products (AGEs), and protein kinase C (PKC) (Fig. 55.1).

Polyol Path

Glucose is converted to sorbitol and into fructose afterward. Sorbitol production decreases intracellular NADPH, which ends up in less available glutathione that increases cellular stress and apoptosis. Oxidation of sorbitol leads to fructose generation, which increases NADPH to NAD proportion. This particular change enhances glycolysis inhibition by blockade of GADPH activity. Fructose generated by polyol pathway has shown to be nephrotoxic in mice models [8]; it increases glomerular and tubular damage along with proteinuria and decreases glomerular filtration rate (GFR).

Hexosamine Pathway

This track starts with fructose-6-phosphate which is then converted into glucosamine-6-phosphate, a transcription inducer of inflammatory cytokines such as tumor necrosis factor alpha (TNF-a) and transforming growth factor beta 1 (TGF-B1). The latter has well-known pathogenic effects such as mesangial matrix expansion and renal cell hypertrophy.

Advanced Glycation End Product (AGE) Pathway

AGE is a generic name for a group of products generated during hyperglycemia due to aberrant glycolysis. The process starts in glyceraldehyde-3-P and ends up in products such as glyoxal and methylglyoxal. These end products damage cells by impairing and/or modifying function of intra- and extracellular proteins, such as laminin and type IV collagen of the glomerular basal membrane (GBM), and increase permeability and thereby proteinuria [10–12]. Also AGEs increase the expression of profibrotic molecules such as fibronectin and collagen types I and IV, leading to extracellular matrix expansion. AGEs by themselves have the property of binding to pro-inflammatory receptors and induce expression of IL-1, IL-6, and TNF-a (tumoral growth factor alpha), TGF-B1 (transforming growth factor beta 1), connective tissue growth factor (CTGF), and vascular endothelial growth factor (VEGF) [11, 13–15].

Protein Kinase C Pathway

Similar to the AGEs, the protein kinase C pathway (PKC) metabolism begins with glyceraldehyde-3-P; hyperglycemia leads to dihydroxyacetone phosphate (DHAP) and ultimately diacylglycerol (DAG). This last element contributes to the activation of PKC, which in turn upregulates prostaglandin E2 and nitric oxide in the afferent arteriole leading to vasodilation and increases angiotensin II over the efferent

arteriole ending in vasoconstriction at this point. This vascular phenomenon increases glomerular pressure and corresponds to what is known as glomerular hyperfiltration [16–19]. PKC also mediates VEGF, leading to increased permeability of GBM, and induces CTGF and TFG-B1 which favor thickening of GBM and deposition of extracellular matrix [16].

Inflammatory Pathway

Chronically activated immune system and persistent low-grade inflammation in diabetes have been proposed as contributors to DKD. The latter through an inflammatory transcription factor, NF-kappa-beta (NFKB), is present in human kidney cells along glomerulus and tubule-interstitium. Hyperglycemia induces NFKB, which correlates with interstitial inflammation and proteinuria. Proteinuria by itself further enhances NFKB expression closing a positive feedback loop with hyperglycemia [20–25]. Inflammatory cytokines such as TNF-alpha, IL-1, IL-6, and IL-8 are much more expressed in renal tissue of diabetic models when compared to nondiabetic controls [26, 27]. Inflammatory cytokines correlate positively with the degree of albuminuria in diabetic patients. Also, contribution to GBM thickening, increase in endothelial permeability, apoptosis, and direct toxic effect to renal cells have been proposed as potential pathogenic mechanisms [7].

Autophagy

Autophagy is considered a protective phenomenon that allows cells to maintain homeostasis during starvation or oxidative stress [28, 29]. It allows cells to degradate intracellular proteins and organelles to self-sustain [29, 30]. Podocytes usually have a high level of autophagy. In vitro studies of podocyte exposure to hyperglycemia have shown impairment of this phenomenon and subsequent cellular injury [31–33].

SGLT-2

Hyperglycemia upregulates SGLT-2 in the kidney. This mechanism had been initially considered an evolutionary benefit for glucose claiming and energy storage; however, it has been now shown to have deleterious effects in diabetic patients by further contributing to hyperglycemic state and activation of all the physiopathologic pathways and autophagy impairment [34, 35].

Albuminuria

Emphasis on albuminuria across the scientific literature is explained by its correlation with the loss of glomerular filtration rate and increased cardiovascular risk [1, 2, 36]. Albuminuria is the consequence of a wide, and still not completely understood, interaction within functional (reversible) forces and histopathologic (irreversible) changes [37]. Functional forces are systemic and glomerular hemodynamic disturbances that lead the anatomical structures (glomerular basal membrane, podocyte, and mesangium) to develop irreversible changes. Nonetheless, neither is completely responsible for albuminuria. High hemodynamic pressure over non-damaged structures may not end up in albuminuria, as hemodynamic control over structurally damaged nephrons may not lead to albuminuria either. It has been proposed that the link that regulates interaction between the hemodynamic forces and anatomical structures is the endothelial glicocalix. Endothelial glycocalyx receives sheer stress, hypertension forces, hyperglycemia, and inflammation, among other factors, that ultimately end up in glicocalix degeneration and with it the loose of mechanical and electrical sieving that allows albuminuria.

Albuminuria is also the most sensitive screening tool to diagnose diabetic kidney disease. It is present in up to 55% of patients with DKD regardless of glomerular filtration rate. Only 13% of patients fulfill DKD diagnosis by albuminuria with decreased glomerular filtration rate and as little as 9% have only decreased glomerular filtration rate without albuminuria, as shown in the DEMAND Global [38].

Natural History of Diabetic Nephropathy: The Clinical Picture

From a clinical standpoint, DKD is the dynamic result of multiple risk factors divided as demographic (older age, gender, ethnicity), hereditary (family history for DKD, genetic conditions), systemic conditions (hyperglycemia, obesity, hypertension), kidney injuries (acute kidney injuries, toxins, smoking), and dietary factors (high protein intake). All the former leads to a sequence of susceptibility, initiation, and progression of DKD. The last two stages of this sequence (initiation and progression) correspond to the known and now changing natural history of DKD. Even though the description of DKD natural history involves mainly type 1 diabetics, it is widely accepted for both type 1 and 2 scenarios. A five-stage continuum through time is the result of two main variables, glomerular filtration rate (GFR) and albuminuria (Fig. 55.2).

Stage	Timeline	Histology	GFR	Baseline Albumin Excretion	Blood pressure	Reversible	Comments
I. Hyperfiltration	At diagnosis	Nephron hypertrophy	Increase 20 to 41%	Normal Excretion	Normal	Yes	Reversable
II. Silent Nephropathy	After 2 years	Increase in BM Mesangial Expantion	Increase 20 to 30%	Normal excretion	Normal	Structural Unknown Albuminuria Yes	Progress to clinically overt in 30-40% patients
III. Incipient Nephropathy	After 10-15 years	Not well defined	Increase 20 to 30%	Moderatly Increased	Incipient increase	Structural Unknown Albuminuria Yes	Manage risk factors
IV. Overt Nephropathy	After 15-20 years	Nodular sclerosis Capsular drops Arteriolar hyalinosis	Decline 1ml/month	Severe and progressive Increase	Hypertensive	No	Delay progression
V. End Stage Renal disease	After 25-30 years Final outcome	Glomerular global esclerosis	<15 ml/min	Slight decline	Hypertensive	No	Renal replacement

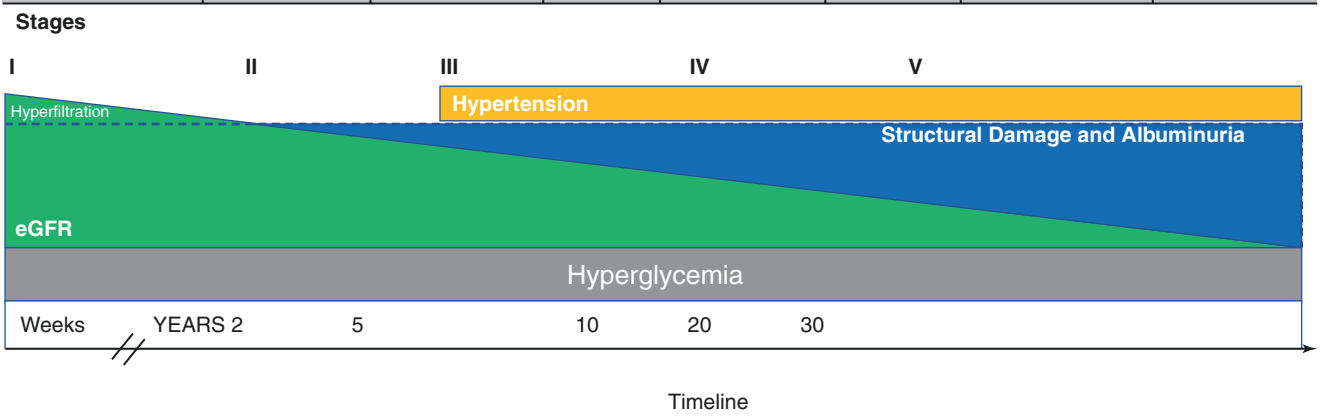

Fig. 55.2 Diabetic nephropathy. (Adapted and modified from Mogensen CE, Christensen CK, and Vittinghus E of the incipient diabetic nephropathy. 1983;32(June))

Early Hypertrophy and Hyperfunction (Hyperfiltration)

Structural, biochemical, and renal function changes are described. Within the structural anomalies, the most remarkable is the increased growth of both kidneys. Such phenomenon is a consequence of tubular hypertrophy and interstitial expansion related to SGLT-2 increased glucose reabsorption along with sodium and water. Hyperglycemia enhances nitric oxide, TFG-B1, CTGF, VEGF, and angiotensin II [1]. Such biochemical environment dilates the afferent arteriole and closes the efferent arteriole, leaving the glomerulus without appropriate autoregulation. The latter allows an elevated intra-glomerular pressure with an enforced 20–40% increase in GFR, a phenomenon known as renal hyperfiltration [2, 3]. Aside from hyperfiltration, dilation of afferent arteriole allows systemic arterial pressure to reflect directly on the glomerulus, further increasing glomerular stress and hyperfiltration effect.

All the abovementioned mechanisms are clinically silent since the main clinical features used to diagnose DKD (GFR and albuminuria) are absent at this stage. Nonetheless, when diabetic patients in this stage of nephropathy exercise with a $\geq$ 55% of the maximum expected heart rate (MEHR), they develop albuminuria. This is a lower threshold when compared to nondiabetic healthy individual, where $\geq$65% of MEHR is needed to start with some degree of albuminuria [3].

Up to this stage of nephropathy, hyperfiltration and exercise-induced albuminuria are reversible by glycemic control within 6 days [3], a fact that further emphasizes that kidney damage from diabetes comes from a long-standing process.

Silent Nephropathy (Glomerular Lesion Without Clinical Disease)

Diabetic patients remain in this stage for many years, without decrease in GFR of development of albuminuria in a steady state. Nonetheless, 30–40% of this group of patients will progress to overt diabetic nephropathy due to multiple histopathologic anomalies established through the glomeruli, tubule-interstitium, and blood vessels. Most remarkable modifications are thickening of the glomerular basal membrane, mesangial expansion, glomerulosclerosis, interstitial inflammation, and fibrosis [2].

Incipient Diabetic Nephropathy

Timeline for this stage corresponds to approximately 10–15 years of diabetic disease, and it is expected in about one-third of diabetic patients. The main characteristic of this phase is the onset and consistency of moderately increased albuminuria in the range between 30 and 300 mg/day. Likewise, steady increase of blood pressure adds on to the development of albuminuria at a rate of about 3 mmHg/year until overt hypertension is detected [2]. Type 1 diabetic patients with mild (<30 mg/day), moderate (30–300 mg/day), and severe (>300 mg/day) albuminuria have a prevalence of hypertension of 42%, 52%, and 79%, respectively. For type 2 diabetic patients, the same categories have a hypertension prevalence of 71%, 90%, and 93% [36].

When albuminuria is found within the first 5 years on new-onset diabetes in the absence of diabetic retinopathy and in the presence of nephrotic syndrome or accelerated loss of kidney function, a biopsy should be considered to rule out other causes of kidney disease other than diabetes.

Evolution of diabetic nephropathy up to this stage is most often accompanied by obesity, hyperuricemia, tobacco use, and noncontrolled hypertension. Treatment of the former entities along with glycemic control may lead to reverse albuminuria and its associated cardiovascular risk.

Overt Diabetic Nephropathy

This phase describes what it is now known as diabetic nephropathy syndrome: decreased GFR, increased proteinuria, and systemic hypertension. This stage's timeline is about 15–20 years after the diagnosis of diabetes mellitus and 30–40% of those who had diabetic renal involvement with progress up to this point. Structural and functional anomalies are irreversible, systemic hypertension is usually present and is the most damaging entity to kidney function, and there is a progressive decline of GFR at an approximate rate of 1 mL/min/month without medical treatment.

End-Stage Renal Failure

Within 25–30 years of diabetes mellitus evolution, end-stage renal disease is expected in those patients who had renal involvement. Clinical picture is not different from any other patient in this stage of kidney disease.

New Findings in the Natural History of Diabetic Nephropathy

The evolution of diabetic nephropathy has now changed. Most patients do not evolve without medical and pharmacological interventions seeking to control progression of disease. The most dramatic change in the natural history described by Mogensen et al. is the possibility to withhold progression of albuminuria from mild to moderate or severe and even when the former and the latter are established and achieve complete remission [39, 40]. Albuminuria evolution has changed since the widespread use of ACE inhibitors and ARBs; further body of knowledge is growing in the field of SGLT-2 receptor antagonists. Different phenotypes of diabetic nephropathy had been postulated, such as the non-albuminuric diabetic nephropathy (Fig. 55.3). However, despite the absence of albuminuria, some patients continue to lose GFR through time. The former evidence has led to new perspectives on the natural history of diabetic nephropathy in the light of comorbidities such as hypertension, obesity, ageing, and pharmacologic treatment. Four different phenotypes have been proposed [41]:

(a) Classical Diabetic Kidney Disease

This group fit into the classical natural history of diabetic kidney disease which resembles Mogensen's work the most, before generalized glucose-lowering and pressure-lowering treatments. Patients develop progressive glomerular hyperfiltration and a linear increment in albuminuria with a linear decline in glomerular filtration rate until kidney failure.

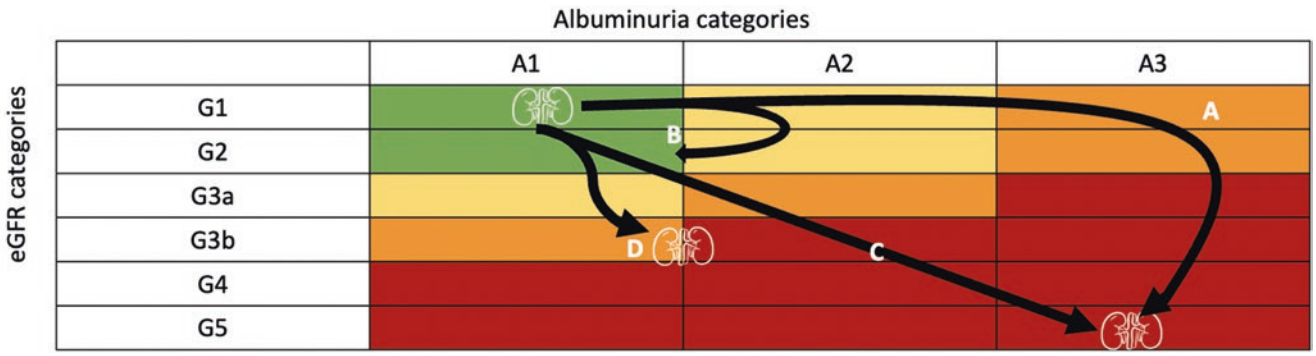

Fig. 55.3 New paradigm of diabetic nephropathy. Diabetic kidney disease trajectories. (**a**) Classic diabetic nephropathy. (**b**) Regression of albuminuria. (**c**) Rapid decliner. (**d**) Non-proteinuria/albuminuric DKD. (Adapted and modified from Oshima M, Shimizi M, Yamanouchi M. Trajectories of kidney function in diabetes: a clinicopathological update. Nat Rev. Neph. 2021)

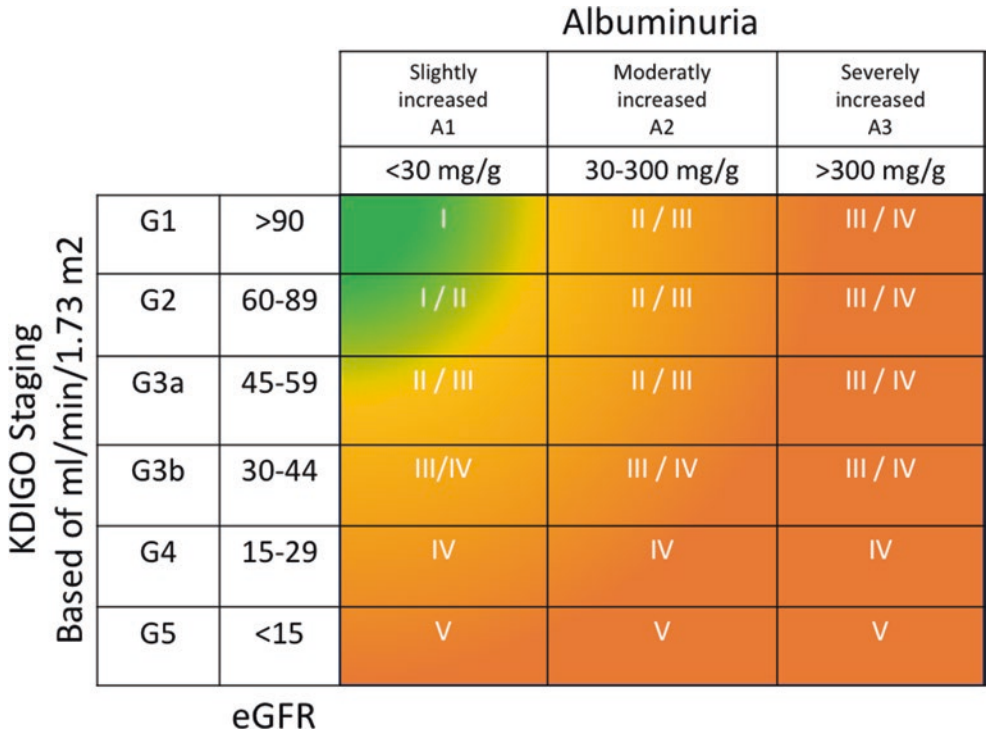

Fig. 55.4 Overlap between KDIGO CKD classification Mogensen's diabetic kidney disease natural history. M = Mogensen's classification stage. G = KDIGO CKD staging. A = Albuminuria. (Adapted and modified: Improving Global Outcomes (KDIGO) CKD Work Group. KDIGO 2012 Clinical practice guideline for the evaluation and management of chronic kidney disease. Kidney inter., Suppl. 2013; 3: 1–150)

(b) Regression of Albuminuria

In the current era of generalized metabolic treatment, it has been shown in different populations that a switch and regression from moderate and severe albuminuria to normoalbuminuria may occur, with improvement of blood pressure and glycemia along with renin-angiotensin-aldosterone blockade and inhibition of sodium-glucose cotransporters. Different studies have shown a lower decline in glomerular filtration rate and lower progression to kidney failure and initiation of dialysis.

(c) Rapid Decliner

A rapid GFR decline is defined as a loss of ≥5 mL/min/1.73 m^2/year regardless of albuminuria degree. It has been hypothesized that this group may correspond to combined entities that coexist in the patient, such as tubulointerstitial diseases or a formerly damaged kidney on top of which DKD develops. Progression to kidney failure is develop in short period of time.

(d) Non-proteinuric/Non-albuminuric

The prevalence of this phenotype is around 20% for DM1 and up to 40% in DM2. Clinical characteristics for this group are female gender, hypertension, smoking, absence of diabetic retinopathy, and pharmacologic treatment with RAAS blockade. Also, a slower progression of GFR loss and kidney failure had been shown.

Natural History and KDIGO Classification

The KDIGO classification is the most widely used and accepted CKD classification. We propose an overlapping figure merging Mogensen's described natural history and KDIGO CKD progression (Fig. 55.4).

Nephropathology

Biopsy Adequacy

As for elemental histopathology recommendations, biopsy core should contain at least 12 full glomeruli. For light microscopy, tissue section must be within 2–3 micrometers thick; two slides must be assigned to H&E, two more for PAS stain, one for Masson trichrome, and one for Jone's silver methenamine. As for direct immunofluorescence, non-fixated tissue is recommended to perform frozen sections and incubate with immunoreactants: IgG, IgA, IgM, C1q, C3c, C4c, fibrinogen, albumin, kappa, and lambda. Finally, a small cortex fraction should be fixed in 2.5% glutaraldehyde for electron microscopy. This last technique is quite useful to characterize and differentiate within nondiabetic lesion on top of diabetic damage.

Histology

According to the Renal Pathology Society [40, 42], diabetic nephropathy is described by light microscopy, through four glomerular stages (Table 55.1); interstitial and vascular affections are also described (Table 55.2).

As for the mentioned stages and findings, we consider the following:

Table 55.1 Glomerular classification of diabetic nephropathy based on light microscopy

Class	Description	Criteria
I	Mild or nonspecific changes and EM-proven GBM thickening	Biopsy does not meet criteria for any other class below GMB in EM is >395 nm in females and > 430 nm in males[a]
IIa	Mild mesangial expansion	Biopsy does not meet criteria for classes III and IV Mild mesangial expansion in >25% of the observed mesangium
IIb	Severe mesangial expansion	Biopsy does not meet criteria for classes III and IV Severe mesangial expansion in >25% of the observed mesangium
III	Nodular sclerosis (Kimmelstiel-Wilson lesion)	Biopsy does not meet criteria for class IV At least one convincing Kimmelstiel-Wilson lesion
IV	Advanced diabetic glomerulosclerosis	Global glomerulosclerosis in >50% of glomeruli Lesion from classes I through III to be present

EM electron microscopy, *GBM* glomerular basal membrane
As described by Tervaert TWC, Mooyaart AL, Amann K, Cohen AH, Cook HT, and Drachenberg CB et al. Pathologic classification of diabetic nephropathy. J Am Soc Nephrol. 2010;21 (4):556–63
aIndividuals to be 9 years old of age or older

Table 55.2 Interstitial and vascular lesions of diabetic nephropathy described by light microcopy

Lesion	Criteria	Score
Interstitial lesion	No IFTA	0
	<25% IFTA	1
	25–50% IFTA	2
	>50% IFTA	3
Interstitial inflammation	Absent	0
	Infiltration only in IFTA	1
	Infiltration outside IFTA	2
Vascular lesions		
Arterial hyalinosis	Absent	0
	A least one area of arteriolar hyalinosis	1
	More than one area of arteriolar hyalinosis	2
Presence of large vessel?	*Yes/no*	
Arteriolosclerosis (score by worst artery)	No intimal thickening	0
	Intimal thickening less than thickness of media	1
	Intimal thickening greater than thickness of media	2

As described by Tervaert TWC, Mooyaart AL, Amann K, Cohen AH, Cook HT, and Drachenberg CB et al. Pathologic classification of diabetic nephropathy. J Am Soc Nephrol. 2010;21 (4):556–63

Stage 1. Early morphologic changes develop within the first 5 years of disease and affect glomerular basal membrane but can only be recognized at EM level. These findings correspond to simultaneous thickening and scarring of GBM, tertiary podocyte process effacement, and some focal podocytopenia. As diabetes continue to evolve, GBM accumulate type IV collagen, laminin, and fibronectin leading to double or triple length of its original width. The former thickening damages filtration barrier by direct endothelial damage and fenestral loss. Fibrin and fibrinogen begin to deposit in the subendothelium. At this point, first light microscopy findings are visible through PAS and Jones' methenamine stains, which reveal the important thickening of GBM. Simultaneously, microaneurysms and membrane remodeling as folding and laminated areas even focally duplicated membranes (Fig. 55.5).

Stage 2. After damage has been established at GMB, as a result of direct AGE effect, mesangium begins to accumulate extracellular matrix and leads to mesangiosclerosis. Early mesangiosclerosis is focal and involves only some glomerular segments; progression leads to global and diffuse mesangium replacement which end up in increased size and hyperlobulation.

Stage 3. Most characteristic diabetic kidney disease histologic findings correspond to this stage. Kimmelstiel-Wilson's nodular lesions are appreciated. These lesions are the result of diffuse mesangiosclerosis and microthrombi within the endothelium of dysfunctional microaneurysms. Microthrombi are constantly and chronically produced and reabsorbed, leading to collagen deposits in a laminated manner which finally generates a typical peripheral acellular nodule in the glomerular tuft. It is also common to find in former microaneurysm areas and foam appearance of endothelial and endocapillary cells. Such findings are known as "insudative lesions," a result of intracapillary pressure that manifests as "subcapsular drops," "fibrotic caps," and areas of hyalinosis, all of which share the same physiopathologic nature (Fig. 55.6).

Stage 4. Global sclerosis, nodular structures, and areas of hyalinosis characterize this stage. When more than 90% of the glomeruli present the mentioned findings, advanced interstitial fibrosis and tubular atrophy (IFTA), along with vascular damage, are common (Fig. 55.7). This is the final stage of cumulative damage and results not only of metabolic injury but also from chronic ischemia after vessels develop nodular hyalinosis, sclerosis, tunica media hypertrophy, and tunica intima fibrotic obliteration.

Nowadays, immunofluorescence and immunohistochemistry are considered as part of routine assessment of kidney biopsy (Fig. 55.8). As previously stated, 5 mm of non-fixed renal cortex is desirable for frozen cuts. If the latter is not feasible, the study can be performed from tissue out of the paraffin block, which even though is useful; it must be pointed out that such technique is less sensitive than frozen cuts without fixation.

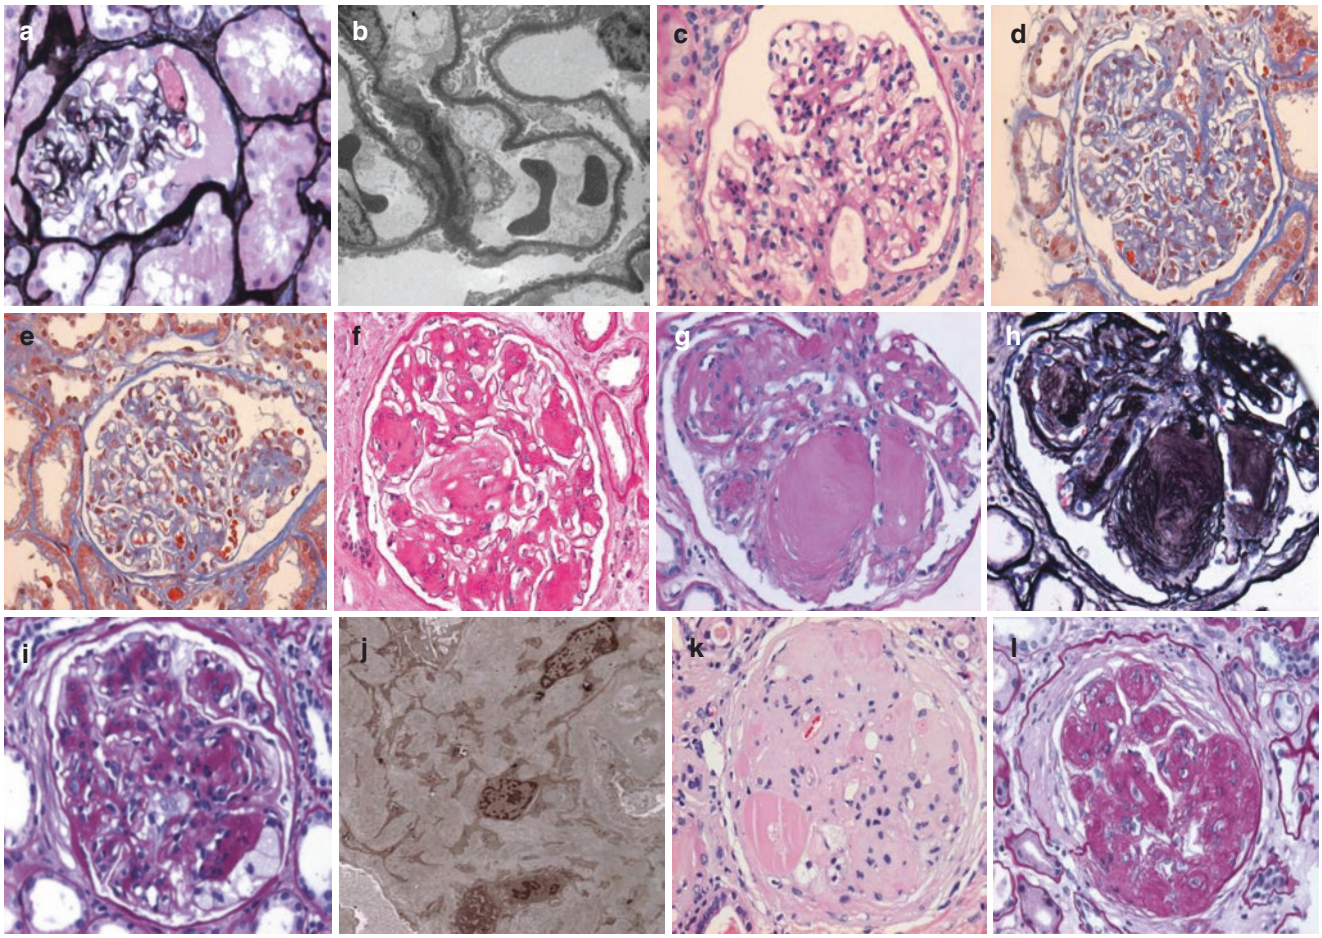

Fig. 55.5 Microphotography showing the different types of diabetic glomerular damage, based on RPS classification. (**a**) Jones Methenamine 40× illustrates a glomeruli with basal membrane irregularities and a microaneurysm. (**b**) Electron microscopy at 2000×, diffuse and homogenous thickening of basal glomerular membrane (RPS Class I). (**c**) PAS 40×, low-moderate expansion of mesangial matrix-generating mesangiosclerosis (Class IIA, RPS). (**d**) Masson's Trichrome 40×, diffuse and homogeneous mesangial thickening, causing glomerular hyperlobulation (Class IIB, RPS). (**e–g**) Microphotography with Masson's Trichrome, PAS [2] and Jones methenamine, respectively. Each at 40×, different stages of acellular collagen forming nodular structures (Class III RPS). (**h**) Residual microaneurysms with endothelial edema within capillary loops, a frequent type of damage in advanced stages of DM. (**i**) Electron microscopy with diffuse collagen deposits within mesangium, characteristic finding in diabetic damage. (**j–l**) H&E and PAS staining, each at 40×, globally sclerosed glomeruli with the presence of hyaline nodules; these findings correspond to DM. When found in most of the glomeruli, it corresponds to Class IV RPS (advanced sclerosis)

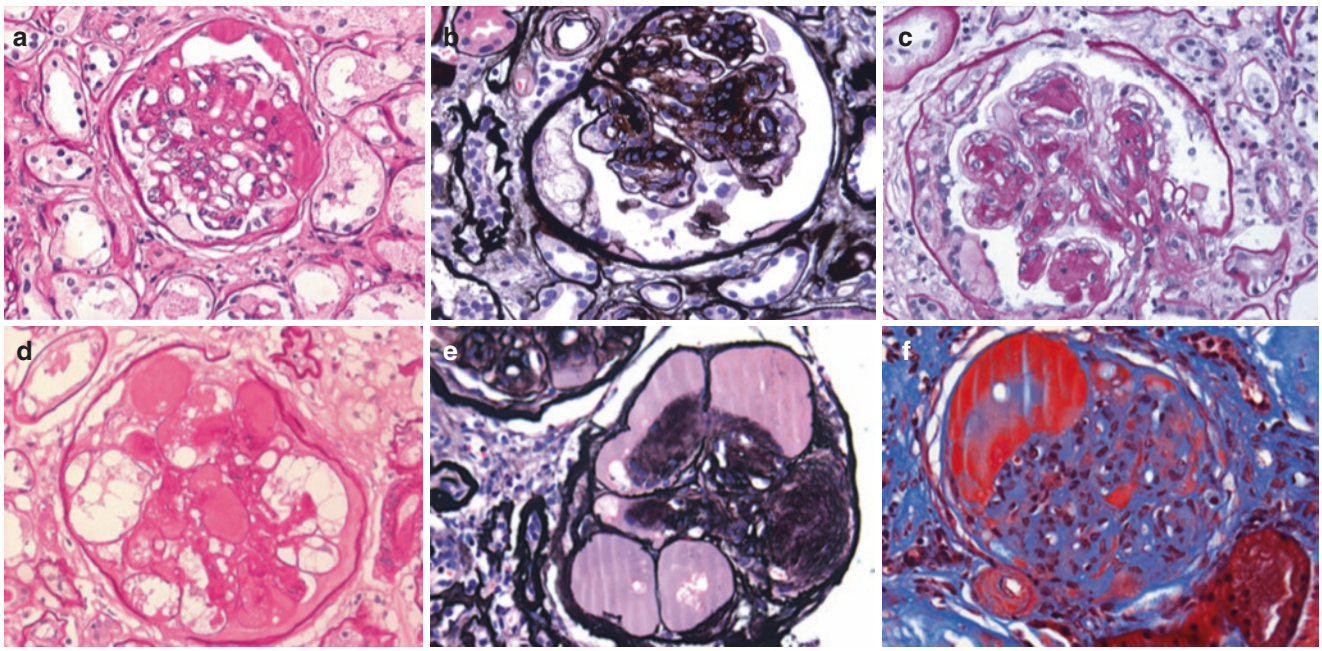

Fig. 55.6 Glomerular insudative lesion. Frequently found in diabetic nephropathy: (**a**) PAS 40×, subcapsular gout, Bowman's capsule-dependent lesion. (**b** and **c**) PAS 40×, fibrous casquet. (**d**–**f**) PAS, Jones methenamine and Masson's Trichrome, respectively. Each at 40× showing glomerular hyalinosis

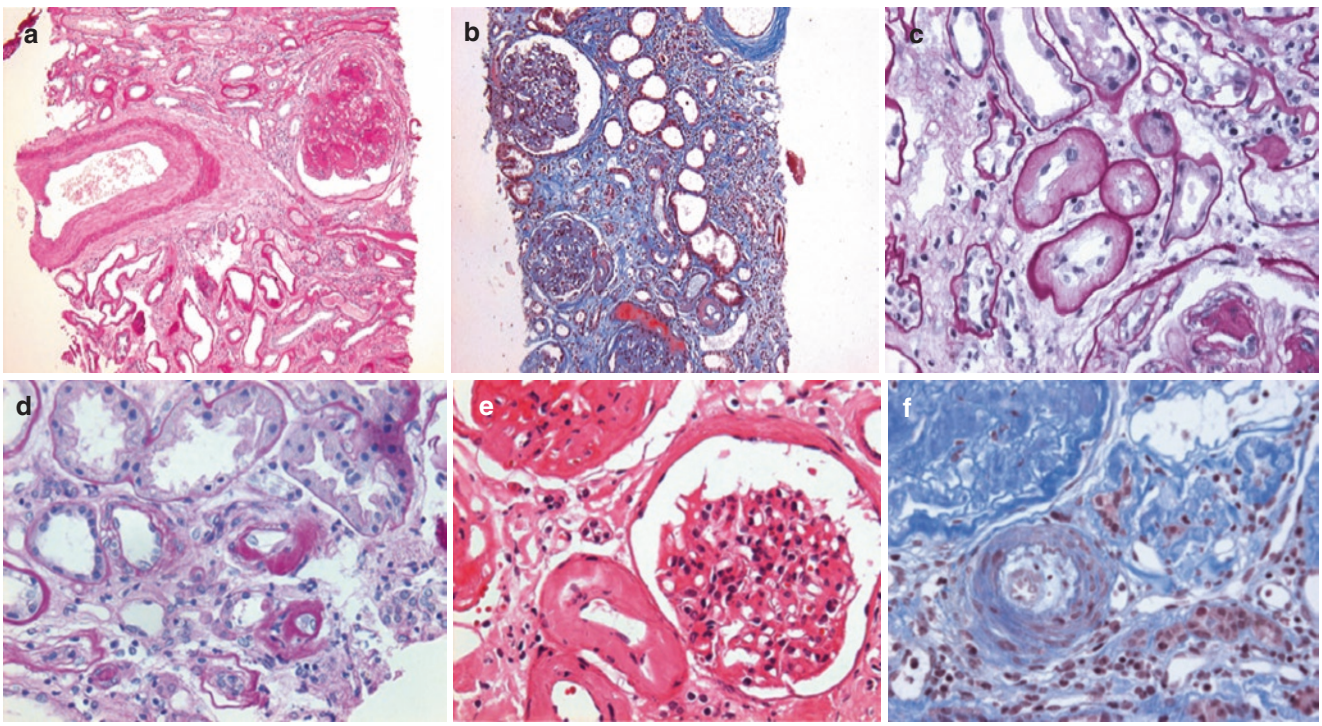

Fig. 55.7 Tubulointerstitial lesions, part of diabetic nephropathy with outmost relevance for renal function prognosis. (**a** and **b**), PAS and Masson's Trichrome 10×, tubulointerstitial fibrosis with loss of tubular "back-to-back" pattern; small caliber arteries present fibrotic damage within arterial intima. (**c**) PAS 40×, lamination and thickening of tubular basal membranes along with atrophic changes. (**d**–**f**) Microvascular lesions in arterioles, PAS, H&E, and Masson's Trichrome, respectively, each at 40×. Advanced arteriolopathy with complete occlusion of vascular lumen. This finding often leads to chronic ischemic glomerular damage and vessel wall hyalinosis, on top of diabetic damage

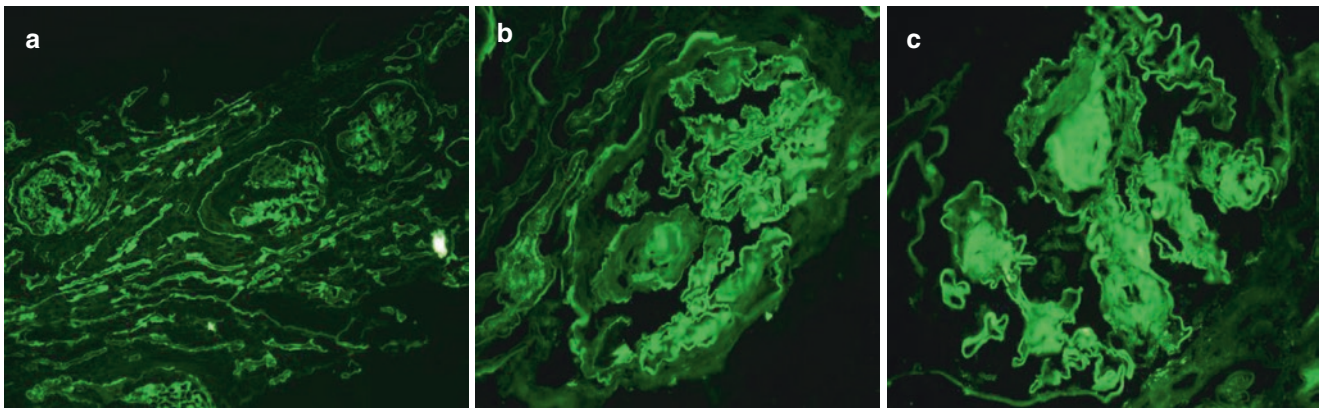

Fig. 55.8 Direct Immunofluorescence in diabetic nephropathy: (**a**–**c**) Albumin 10× and 40× and IgG 40×, respectively. Hyperfiltration generates linear positivity in glomerular and tubular basal membranes. Albumin shows tubular cytoplasmic reabsorption vacuoles

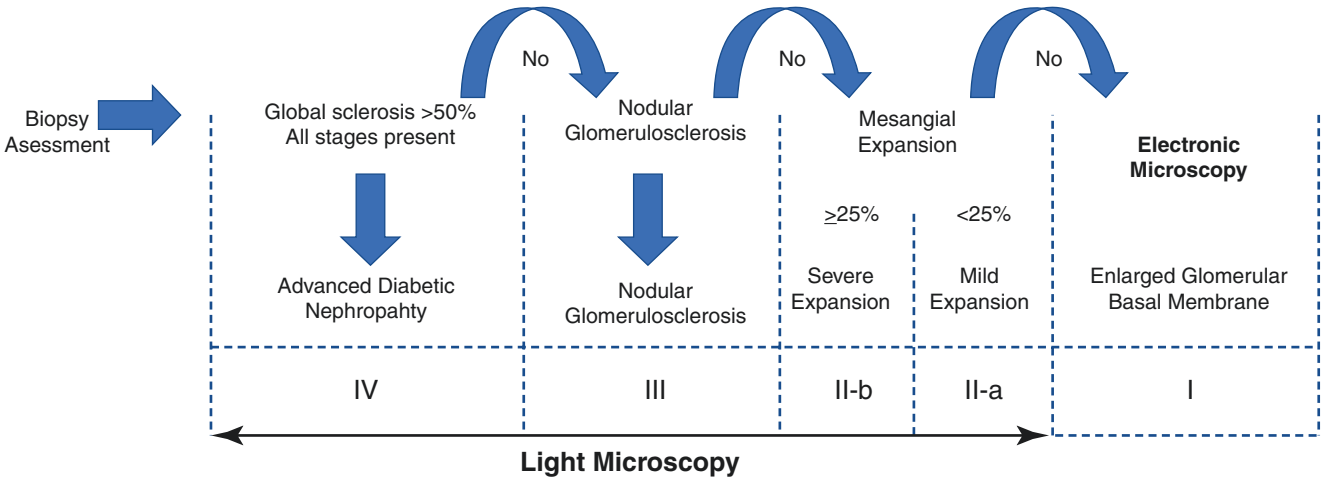

Fig. 55.9 Proposed assessment of kidney biopsy in diabetic nephropathy. (Adapted and modified from as described by Tervaert TWC, Mooyaart AL, Amann K, Cohen AH, Cook HT, and Drachenberg CB et al. Pathologic classification of diabetic nephropathy. J Am Soc Nephrol. 2010;21 (4):556–63)

Tissue out of paraffin block can also be used for indirect immunoperoxidase technique, although with the paramount disadvantage of a less sensitive study.

Diabetic kidney disease continuum implies that histopathologic lesions will not be all at the same stage. A collage of microscopic lesions, from incipient to advanced, will be found. Prevailing histologic findings and the clinical picture ultimately lead to classification, considering an orderly mannered approach by glomerular, interstitial, and vascular findings. It should be emphasized that, being diabetes mellitus such a common entity, it is not uncommon to describe diabetic nephropathy on top of many other nondiabetic entities.

Advanced IFTA is considered the histologic manifestation of end-stage renal disease. As to vessel histology, even though the Renal Pathology Society classification does not make distinction between afferent and efferent arteriolar hyalinosis, it is considered that efferent arteriolar hyalinosis is the most specific vessel finding for diabetic nephropathy, since involvement of the afferent arteriole (afferent arterial hyalinosis) might be present in other entities.

We proposed a flowchart for the evaluation of DKD in kidney biopsy (Fig. 55.9).

It is important to stand out that KDIGO (Kidney Disease: Improving Global Outcomes) 2021 guidelines have proposed the distinction between diabetic nephropathies in which, based on histology, we can affirm such diagnosis. All other cases in which diabetes, albuminuria/proteinuria, and/or diminish glomerular filtration rate are present but without histologic tissue to claim diabetic nephropathy, should be named as diabetic kidney disease (DKD) [43].

Prevention of Diabetic Nephropathy

Avoiding the development of diabetic nephropathy involves treatment of diabetes per se. Glycemic control, antihypertension therapy, and dyslipidemia management are common and comorbid entities that directly impact on the evolution to diabetic nephropathy. However, this is beyond the scope of this chapter, and we will focus specifically on DKD management.

Treatment of Diabetic Nephropathy

Non-pharmacologic Intervention

Salt Intake

Salt intake is associated with increased blood pressure, and therefore, it is considered a risk factor for uncontrolled hypertension and end organ damage with DKD progression. In a systematic review and meta-analysis, by pooling studies with salt reduction in type 1 and type 2 diabetic patients, 13 trials and 254 individuals were included. Mean duration of salt restriction was 1 week for both types of diabetic patients, and median reduction of urinary sodium was 11.9 g/day for type 1 diabetic patients and 7.3 g/day for type 2 diabetic patients. Blood pressure was reduced by −7.11 systolic and −3.13 diastolic mmHg in individuals with type 1 diabetes and −6.90 systolic and −2.87 diastolic mmHg in individuals with type 2 diabetes. The impact of this intervention was considered as effective as the use of one antihypertension medication, and as such, it should be applied to all diabetic patients [44].

Besides salt restriction effect on hypertension, renal and cardiovascular benefits have been described for reduced salt intake in addition to RAAS blockade. The former was described in a pooled analysis of type 2 diabetic patients of RENAAL (Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan) and IDNT (Irbesartan Diabetic Nephropathy Trial) trials. The former analysis included 1177 participants with established DKD assigned to angiotensin receptor blocker therapy, losartan for RENAAL or irbesartan for IDNT populations, or non-RAAS inhibitors (non-RAASi), further stratified according to urine sodium/creatinine ratio into tertiles of <121 mmol/g (<2.78 g of sodium, <6.05 g of salt), 121–153 mmol/g (2.78–3.51 g of sodium, 6.05–7.65 g of salt), and equal or ≥153 mmol/g. Renal outcomes were defined as a composite of doubling serum creatinine from baseline, serum creatinine ≥6.0 mg/dL, and need for chronic dialysis or transplantation. Cardiovascular outcomes were defined as a composite of death, myocardial infarction, stroke, hospitalization for heart failure, or revascularization procedures. Within ARB and RAASi groups, renal outcomes for ARB therapy in the lower tertile of sodium/creatinine urine ratio had a HR 0.57 (95% CI 0.39–0.84) vs. non RAASi in higher tertile with HR 1.37 (95% CI 0.96–1.96), $P < 0.001$. Same groups for cardiovascular outcomes reported HR 0.65 (95% CI 0.43–0.92) versus HR 1.25 (95% CI 0.89–1.75), $P = 0.021$. Significant difference for renal and cardiovascular endpoints disappeared between groups when comparing high urine sodium/creatinine ratio tertiles [45].

The former illustrates sodium restriction which enhances the renal and cardiovascular benefits of angiotensin receptor antagonism on type 2 diabetic population with DKD.

Protein Restriction

Protein overload hastens renal decline by different mechanisms. Pancreas responds to protein ingestion by increasing glucagon secretion; glucagon generates afferent arteriole vasodilation and increases systemic hemodynamics over the glomerulus. Along with the former, filtrated amino acids are reabsorbed by the proximal convoluted tube with sodium and chloride, which reduces the chloride available to the juxtaglomerular apparatus. The latter leads to the absence of tubuloglomerular feedback, further increasing afferent arteriole dilation. Finally, protein overload to the renal parenchyma, in a low renal mass stage, increases profibrotic cytokines, such as transforming growth factor beta-1 and platelet-derived growth factor [46].

Due to the former mentioned mechanisms of action, low protein diet (LPD, 0.6–0.8 g/kg of body weight/day) was proposed as a therapeutic intervention and proved to be effective in animal models along with nondiabetic kidney disease clinical trials [47]. Therefore, recommendation of LPD was extended to DKD by KDIGO (Kidney Disease Improving Global Outcomes) guidelines [47]. Nonetheless, in diabetic kidney disease, evidence is less clear; there are clinical trials and pooled meta-analysis both pro and against LPD as an effective intervention to slow kidney function decline [46, 47]. A definitive evidence-based recommendation cannot be established.

Interesting proposals are being considered such as starting LPD in eGFR higher than 30 mL/min/1.73 m^2 to preserve eGFR in earlier stages and to avoid malnourishment frequently seen in advanced CKD due to protein energy wasting. In addition, it has been proposed that maintaining or increasing caloric intake and switching carbohydrate, protein, and fat proportions could be of further benefit [46–49].

Pharmacologic Interventions

Renin-Angiotensin-Aldosterone System (RAS)

There is a large body of evidence to back up the use of RAS blockade in DKD being the cornerstone of DKD therapy. ACE inhibitors and ARBs have earned this position due to

their positive effect on glomerular filtration preservation, reduction in the development, and progression of proteinuria along with lowering interstitial fibrosis. ACE inhibitors and ARBs are used indistinctly as their effect on the RAS system is directed toward decreasing its activation, even though most of the available evidence for ACE inhibitors is related to type 1 diabetes and for ARBs to type 2 diabetes.

Physiologic explanation of their benefit comes from their effect in systemic and glomerular hemodynamics, by decreasing not only systemic blood pressure but also by decreasing vasoconstriction on efferent arteriole and reducing direct pressure over the glomerulus. The former effect reduces the hyperfiltration phenomenon and clinically translates into GFR preservation and avoidance of proteinuria development, progression, or even regression.

The former was demonstrated in type 1 diabetics in the Collaborative Study Group, where 207 patients received captopril 25 mg three times a day and 202 patients placebo, to a blood pressure goal of ≤140/90 mmHg with a 3-year follow-up. Inclusion criteria corresponded to proteinuria (defined as ≥500 mg per day) and serum creatinine (SCr) of ≤2.5 mg/dL; the primary outcome was doubling of the serum creatinine. By the end of the study, 25 patients in the captopril group and 43 patients in the placebo group had reached the primary outcome, with 48% risk reduction for the captopril group. Subgroup analysis demonstrated that the effect of captopril on outcomes was higher in individuals with increased serum creatinine concentration, 76% for mean SCr 2.0 mg/dL, 55% for mean SCr 1.5 mg/dL, and 17% for 1.0 mg/dL. From the eGFR standpoint, decline in creatinine clearance was 11+/− 21% in captopril group and 17+/−20% in the placebo group ($p = 0.03$) [50].

As for anti-proteinuric effect, a systematic review and meta-analysis that included 646 type 1 diabetic patients (10 clinical trials) with normotensive and moderate increased albuminuria DKD evaluated ACE inhibitor therapy against placebo for this outcome. Reduction in progression to severe albuminuria was reported with an odds ratio of 0.38 (95% CI 0.25–0.57) and regression to low-level albuminuria by 3.07 (95% CI 2.15–4.44). Follow-up at 2 years found 50.5% lower albuminuria in ACE inhibitor-treated patients, compared to placebo ($p < 0.001$) with effect none entirely explained by blood pressure control [51].

In type 2 diabetes, effect of RAS blockade by ARBs also demonstrated reduction in the development and progression of proteinuria along with reduction in GFR decline. The preventing microalbuminuria in type 2 diabetes study (BENEDICT [Bergamo Nephrologic Diabetes Complications Trial]) assessed onset and development of moderately increased albuminuria (primary endpoint) in normoalbuminuric, hypertensive, type 2 diabetic patients. The intervention consisted of a combination of ACEI (trandolapril) and calcium channel blocker (verapamil), either ACEI or calcium channel blocker alone or placebo. Target blood pressure for all participants was 120/80 mmHg, and other antihypertensive medications were allowed to goal. The trial recruited 1204 participants, with a median follow-up of 3.6 years; primary outcome (moderately increased albuminuria) was reached by 5.7% of participants in the combined treatment group, 6.0% in only ACEI group, 11.9% of those receiving calcium channel blocker alone, and in 10% of participant in the placebo group.

In established DKD, a multicentric, randomized, double-blinded, placebo-controlled trial with irbesartan recruited 590 patients with type 2 diabetes and moderately increased albuminuria, assigned groups to placebo, irbesartan 150 mg/day or irbesartan 300 mg/day, with a 2-year follow-up for a primary outcome of severely increased albuminuria or at least 30% increase from baseline. In the intervention arms, 5.2% of patients (10/194) for the 300 mg irbesartan group and 9.7% of patients (9/195) for the 150 mg irbesartan group reached primary outcome, as compared to 14.9% of patients (30/201) in the placebo arm resulting in 70% reduction in albuminuria progression for intervention groups [52]. Regarding GFR, the RENAAL study gathered 1513 patients with type 2 diabetes and randomized to losartan 50 mg, 100 mg, or placebo on top of conventional antihypertensive medication, for a 3.4-year follow-up. Primary outcome was a composite of doubling serum creatinine, and development of end-stage renal disease or death. Secondary outcomes were a composite of morbidity and mortality from cardiovascular causes, proteinuria, and the rate of progression of renal disease. Primary composite was reduced by 16%, double of serum creatinine by 25%, development of end-stage renal disease by 28%, and proteinuria declined by 35% in the losartan groups. There was no effect on mortality [53].

Given the former mentioned data, and many other studies sustaining similar results, double blockade with ACE inhibitor and ARB was explored to obtain more effective results on renal outcomes. The ONTARGET (Ongoing Telmisartan Alone in Combination with Ramipril Global Endpoint Trial) study disregarded the benefit of combined therapy. Such treatment proved increased adverse effects as a composite of need for acute dialysis, double of serum creatinine, and death. The first two endpoints of the composite sustained in individual analysis [54].

Another study to assess the benefit from double blockade in DKD was the Combined Angiotensin Inhibition for the Treatment of Diabetic Nephropathy (VA Nephron-D), which assigned standard baseline therapy of losartan 100 mg per day and randomized participants to lisinopril 10–40 mg per day or placebo. Primary endpoint was eGFR decline, ESRD, and death; secondary endpoint was defined as first occurrence of eGFR decline or ESRD, and safety outcomes were mortality,

hyperkalemia, and acute kidney injury. A total of 1448 type 2 diabetic patients with severely increased albuminuria and an eGFR within 30 and 89.9 mL/min/1.73 m^2 were included and followed for median of 2.2 years. The study was stopped early for significant increased adverse effects in double RAS inhibition groups: hyperkalemia (6.3 events/100 person-years vs. 2.6 events/100 person-years, $p < 0.001$) and acute kidney injury (12.2 vs. 6.7 events/100 person-years, $P < 0.001$) [55].

Aldosterone antagonism has become a valuable tool in the management of chronic kidney disease, for up to 53% of patients on conventional RAS blockade will develop aldosterone escape phenomenon by the end of a 1-year therapy [56]. Compared to ACE inhibitors or ARBs alone, nonselective aldosterone blockade (spironolactone) on top of ACE inhibitors or ARBs significantly reduced 24 h proteinuria [57]. Narrowing to DKD, systematic review and meta-analysis of 7 trials (287 patients) compared ACEI or ARB versus combination therapy of MRA (spironolactone or eplerenone) plus ACEI or ARB. Results showed significantly reduced albuminuria excretion by 69.38% (95% CI -103.53 to −35.22, $p < 0.0001$). As for blood pressure, comparing 296 patients with combined MRA RAS blockade therapy versus 281 patients with RAS blockade alone, significantly decreased systolic and diastolic values were reported, with mean difference − 5.61 (95% CI -9.38 to −1.84, $p = 0.004$) for systolic and − 2.17 (95% CI -4.23 to −0.11, $p = 0.04$) for diastolic blood pressure [57]. In 11 trials pooling within this meta-analysis, GFR did not improve, and as expected, hyperkalemia developed much more (16 studies, 1684 patients) with relative risk of 3.74 (95% CI 2.30–6.09, $p < 00001$) [56].

Summarizing the former evidence, RAS blockade, for which ACEI and ARB have been used interchangeably, is the cornerstone therapy for diabetic kidney disease both in type 1 and 2 diabetes. RAS blocking therapy impacts on the reduction of albuminuria, preservation of GFR, and lowering of fibrotic remodeling. MRA with spironolactone on top of RAS blockade compensates for aldosterone breakthrough, and its major effect is reflected over proteinuria and blood pressure control.

Novel Therapies

Sodium Glucose Transporters

Hyperglycemia induces the proximal convoluted tubule to increase glucose claim, the former is performed in company of sodium, by means of sodium-glucose transporters 1 and 2 (SGLT-1 and SGLT-2, respectively). This leads to a lesser available sodium to be sensed downstream by the macula densa, and as a result, afferent glomerular arteriole is dilated, exposing the glomerulus to direct blood pressure damage while enhancing hyperfiltration phenomenon. Inhibition of sodium-glucose transporters leads to glucosuria and downstream sodium overflow, allowing actual caloric/glucose loss as a desired effect for diabetes treatment in addition to activation of tubule-glomerular feedback.

If we combine RAS blockade with SGLT-2 therapy, we obtain the exact opposite glomerular hemodynamics of diabetic kidney disease pathophysiology. The renal hemodynamics go from dilated afferent and narrowed efferent arterioles, with increased exposure to systemic blood pressure and hyperfiltration on the glomerulus, to a narrow afferent and dilated efferent arteriole, with the opposite effect.

The benefit from the former hypothesis has been tested with positive results in different cardiovascular and renal outcome studies for iSGLT-2. In EMPA-REG OUTCOME trial, type 2 diabetic patients with established cardiovascular disease and eGFR equal or greater than 30 mL/min/1.73 m^2 of BSA were randomly assigned to receive placebo, empagliflozin 10 mg/day, or 25 mg/day for a median duration of treatment of 2.6 years and median observation time of 3.1 years. RAS blockade, by means of ACEI or ARB, was present in 80.7% of study population at baseline. As for renal outcomes, incident or worsening nephropathy (progression to severely increased albuminuria) occurred in 12.7% in empagliflozin groups versus 18.8% in the placebo group, 0.61 (95% CI 0.53–0.70, $P = <0.001$). Doubling of serum creatinine with a decrease of eGFR to ≤45 mL/min/1.73 m^2 BSA was 1.5% versus 2.6% in empagliflozin and placebo, respectively, with a relative risk reduction of 44%. Renal replacement therapy was initiated in 13 of 4687 patients in empagliflozin and 14 of 2333 patients in the placebo group, with a relative risk reduction of 55%. Regarding incident albuminuria, there was no difference between medication and placebo groups. The composite of incident or worsening nephropathy or cardiovascular death had a HR for empagliflozin of 0.61 (95% CI 0.55–0.69, $p < 0.001$) [58].

Estimated GFR lowered during the first 4-week period trial in the empagliflozin arms to a mean of −0.82 ± 0.04 mL/min/1.73 m^2 of BSA for the 25 mg/day and was less evident for the 10 mg/day dose. Estimated GFR remained stable after such period, and mean eGFR annual decline for intervention groups was 0.19 ± 0.11 mL/min/1.73 m^2 BSA compared to 1.67 ± 0.13 mL/min/1.73 m^2 BSA in the placebo group, $p < 0.001$. After cessation of trial medication, empagliflozin groups increased eGFR up to 0.55 ± 0.04 mL/min/1.73 m^2 BSA, making evident the hemodynamic effect of the medication [58].

The Canagliflozin and Cardiovascular Events in Type 2 Diabetes (the CANVAS (Canagliflozin Cardiovascular Assessment Study) Program), another trial for SGLT-2 inhibition, included two sister trials, the CANVAS and CANVAS-R. Both studies were multicentric, double-blinded, randomized, and placebo-controlled. 10,142 DKD participants were assigned to canagliflozin 300 mg/day, 100 mg/day, or placebo for CANVAS and canagliflozin

100 mg/day (with option to increase up to 300 mg/day) or placebo for CANVAS-R. Primary outcome was a composite of death from cardiovascular cause, nonfatal myocardial infarction, and nonfatal stroke. Secondary outcomes were death from any cause, death from cardiovascular cause, progression of albuminuria (30% increase from baseline and category upgrade between normoalbuminuria and moderately or severely increased albuminuria), and another composite of death from cardiovascular cause and hospitalization for heart failure. The mean follow-up was 188.2 weeks. Canagliflozin group had statistically significant less composite of death from cardiovascular cause, nonfatal myocardial infarction, and nonfatal stroke, 26.9 participants per 1000 patient-years versus 31.5 for placebo (HR 0.86, 95% CI 0.75–0.97, $P < 0.001$ non-inferiority and $p = 0.02$ for superiority). Regarding renal outcomes, albuminuria progression was less frequent in intervention groups, 89.4 events per 1000 patient-years versus 128.7 for placebo (HR 0.73, 95% CI 0.67–0.79), along with regression of albuminuria, with 293.4 patients per 1000 patient-years for intervention groups versus 187.5 for placebo (HR 1.70, 95% CI 1.51–1.91). Renal composite of sustained 40% reduction in eGFR, the need for renal replacement therapy, or death from renal causes occurred less in intervention groups, 5.5 in canagliflozin versus 9.0 in placebo per 1000 patient-years (HR 0.60, 95% CI, 0.47–0.77). Death from any cause was not different between canagliflozin and placebo groups [59].

Dapagliflozin and Cardiovascular Outcomes in Type 2 Diabetes (DECLARE-TIMI 58) study randomized patients with type 2 diabetes who have or were at risk for atherosclerotic cardiovascular disease to dapagliflozin or placebo for primary outcomes of major adverse cardiovascular events (MACE) of cardiovascular death, myocardial infarction, or ischemic stroke, and secondary outcomes of renal composite composed of ≥40% decrease in eGFR to less than 60 mL/min/1.73 m^2 of BSA, new end-stage renal disease, death from renal or cardiovascular causes, and death of any cause. A total of 17,160 patients were evaluated, most of which did not have atherosclerotic cardiovascular disease, a primary prevention group of 10,186 patients. Patients were followed for a median of 4.2 years; dapagliflozin was non-inferior to placebo in MACE but did not achieve superiority. Only benefit in a composite of cardiovascular death or hospitalization for heart failure was found, with a 17% relative risk reduction at the expense of lower heart failure events, for there was no difference in cardiovascular events within groups [60].

CREDENCE (Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation). The goal of the trial was to assess the effect of canagliflozin on renal outcomes among patients with type 2 diabetes mellitus (DM2) and chronic kidney disease (CKD). Patients were randomized in a 1:1 fashion to either canagliflozin 100 mg daily ($n = 2202$) or matching placebo ($n = 2199$). Four thousand four-hundred patients were included with a mean follow-up of 2.62 years. The trial stopped early due to overwhelming benefit. The primary outcome of end-stage renal disease (ESRD), doubling of serum creatinine, and renal or cardiovascular (CV) death, for canagliflozin versus placebo, was 43.2 versus 61.2 per 1000 patient-years (P-Y) ($p = 0.00001$): doubling of serum creatinine, 20.7 versus 33.8/1000 P-Y ($p < 0.001$) for canagliflozin versus placebo, and ESRD, 20.4 versus 29.4/1000 P-Y ($p = 0.002$) for canagliflozin versus placebo [61].

DAPA-CKD (Dapagliflozin and Prevention of Adverse Outcomes in Chronic Kidney Disease). The DAPA-CKD trial was a multinational, multicenter, event-driven, randomized, double-blind, parallel-group, placebo-controlled study involving 4304 patients with CKD and eGFR ≥25 mL/min/1.73 m^2, but ≤75 mL/min/1.73 m^2, and a UACR ≥200 mg/g, but ≤5000 mg/g, with or without type 2 diabetes (T2D). As occurred in the CREDENCE trial, the trial was stopped early due to overwhelming efficacy. Over a median of 2.4 years, a primary outcome event occurred in 197 of 2152 participants (9.2%) in the dapagliflozin group and 312 of 2152 participants (14.5%) in the placebo group (hazard ratio, 0.61; 95% confidence interval [CI], 0.51–0.72; $P < 0.001$). The hazard ratio for the composite of a sustained decline in the estimated GFR of at least 50%, end-stage kidney disease, or death from renal causes was 0.56 (95% CI, 0.45–0.68; $P < 0.001$), and the hazard ratio for the composite of death from cardiovascular causes or hospitalization for heart failure was 0.71 (95% CI, 0.55–0.92; $P = 0.009$). For the first time, this trial demonstrated similar efficacy in subjects with and without diabetes [62].

EMPA-KIDNEY (Empagliflozin in Patients with Chronic Kidney Disease) is an ongoing trial to evaluate renal and cardiovascular outcomes in 6600 patients for the use of empagliflozin on CKD profession; different to other trials, EMPA-KIDNEY would include lower eGFR (CKD-EPI eGFR ≥20–<45 mL/min/1.73 m^2 or) and CKD-EPI eGFR ≥45–<90 mL/min/1.73 m^2 and lower urinary albumin/creatinine ratio ≥ 200 mg/g (or protein/creatinine ratio ≥ 300 mg/g) (Clinical Trial NCT03594110).

Considerations as to adverse effects of SGLT-2 inhibitors as a group include an increased risk for euglycemic ketoacidosis, perineum-necrotizing fasciitis, genitourinary tract infections, hypotension, and acute kidney injury. Medication-specific adverse effects have been described, as in canagliflozin-treated patients, increased incidence for bone fracture, and mid foot/toe amputations. Amputations occur more often in patients with lower-extremity peripheral artery disease and/or diabetic foot.

GLP1 Receptor Agonists (GLP1AR)

Cardiovascular outcome trials for GLP1AR in diabetic population have included chronic kidney disease patients. Data from these trials proved a favorable profile for lixisenatide, exenatide, liraglutide, semaglutide, albiglutide, and dulaglutide for decreasing in albuminuria and may have an effect in lowering eGFR decline rate. Meta-analysis of seven GLP1AR cardiovascular risk outcome trials pooled a 17% risk reduction compared to placebo for a renal composite of severely increased albuminuria, eGFR decline, progression to kidney failure, or death from kidney disease.

As for today, there has not been a completed GLP1RA kidney outcome trial. The Effect of Semaglutide Versus Placebo on the Progression of Renal Impairment in Subjects with Type 2 Diabetes and Chronic Kidney Disease (FLOW) trial started on 2019 and is expected to be completed by 2024 [63].

Finerenone

As previously mentioned, MRAs proved reduction in albuminuria for diabetic and nondiabetic CKD. Finerenone (FRN) is a more selective MRA than spironolactone, with more affinity than eplerenone. Finerenone was evaluated for DKD in the ARTS-DN study, a multicenter, randomized, double-blind, placebo-controlled, parallel group, phase 2B trial in which finerenone at different doses (1.25 mg/day, 2.5 mg/day, 5 mg/day, 7.5 mg/day, 10 mg/day, 15 mg/day, 25 mg/day) or placebo was administered to patients with DKD already on RAS blockade. Eligibility criteria were type 2 diabetic patients already on RAS blockade, with at least moderately increased albuminuria, eGFR ≥30 mL/min/1.73 m^2, first visit serum potassium concentration ≤ 4.8 mmol/L, and 4-week or longer stable non-potassium-sparing diuretic use. Endpoints were evaluation of albuminuria reduction at the end of the 90-day period and adverse effects such as hyperkalemia and eGFR reduction. Effect on albuminuria excretion rate (AER) was noticed in an increasing dose-dependent effect starting on finerenone 7.5 mg/day. Placebo-corrected mean ratios of AER, according to dose, were FRN 7.5 mg/day, 0.79 (90% CI 0.68–0.91, $p = 0.004$), FRN 10 mg/day, 0.76 (90% CI 0.65–0.88, $p = 0.001$), FRN 15 mg/day 0.67 (90% CI 0.58–0.77, $p < 0.001$), and FRN 20 mg/day 0.62 (90% CI 0.54–0.72, $p < 0.001$). Hyperkalemia was reported for the 7.5-, 15-, and 20 mg/day groups in 2.1%, 3.2%, and 1.7%, respectively. There was no difference in eGFR decrease rate of ≥30% [64].

This study suggests the potential benefit from finerenone as another MRA with a lesser adverse effect and dose-dependent effect on reducing albuminuria. Nonetheless, it must be noticed that on the trial, 60% of patients had eGFR of 60 mL/min/1.73 m^2 or more, and serum potassium higher than 4.8 mmol/L was considered an exclusion criteria. Hard endpoints such as cardiovascular events, progression to end-stage renal disease, and dialysis requirement are currently being explored; most recent studies in this regard are FIGARO (Facilitated Immunoglobulin Administration Registry and Outcomes Study) and FIDELIO (Finerenone in Reducing Kidney Failure and Disease Progression).

FIGARO was a double-blind, randomized study that explored cardiovascular outcomes for CKD population with type 2 diabetes treated with finerenone. Eligibility criteria required patients to have ACR of 30 to less than 300 mg/g, eGFR of 25–<90 mL/min per 1.73 m^2 (stage 2–4 CKD) or ACR of 30 to less than 5000 mg/g, and eGFR >60 mL/min per 1.73 m^2 (stage 1 or 2 CKD), both groups on top of maximum tolerated RAAS blockade. Primary outcome was time to event composite of death from cardiovascular causes, nonfatal myocardial infarction, nonfatal stroke, or hospitalization for heart failure. Secondary outcome was kidney failure, sustained decrease of ≥40% in eGFR from baseline, or death from renal causes. Randomization was 7437 patients to finerenone of placebo. Finerenone achieved during a 3.4-year median follow-up, 13% relative risk reduction in primary composite (HR 0.87; 95% CI 0.76–0.98, $P = 0.03$), and 13% relative risk reduction for secondary composite (HR 0.87; 95% CI 0.76–1.01) [65].

FIDELIO was a kidney outcome-driven study for finerenone in chronic kidney disease with type 2 diabetic patients. It was a randomized, double-blind, placebo-controlled trial with 1:1 assignment of 5734 patients to finerenone or placebo. Inclusion criteria were a composite of albumin to creatinine ratio (ACR) of 30 to less than 300 mg/g, eGFR of 25–<60 mL/min per 1.73 m^2 and diabetic retinopathy, or ACR of 300–500 mg/g and eGFR of 25–<75 mL/min per 1.73 m^2. All patients are on maximum tolerated dose of RAAS blockade. The primary outcome was a time-to-event composite of kidney failure, sustained decrease of ≥40% in eGFR from baseline, or death from renal causes. Secondary outcomes were death from cardiovascular causes, nonfatal myocardial infarction, nonfatal stroke, and hospitalization for heart failure. Results for finerenone after a 2.6-year of follow-up were a primary outcome relative risk reduction of 18% (HR 0.82, 95% CI 0.73–0.93; $P = 0.001$) and a secondary outcome relative risk reduction of 14% (HR 0.86, 95% CI 0.75–0.99, $P = 0.03$), lowering risks of progression for CKD and cardiovascular events compared to placebo [66].

Conclusions

Diabetic kidney disease remains the main cause of end-stage kidney failure in the world. Although mechanisms of disease are now better understood, the only accepted medical treat-

ment for DKD is RAS inhibition. Despite this treatment, many patients still progress to kidney failure. Double RAS inhibition is no longer recommended based on two randomized trials. Newer agents such as SGLT-2 inhibitors, GLP1 receptor antagonists, and finerenone are novel and promising therapies that have modified the natural history of the disease. There is still lack of sufficient evidence to combine these agents; however, it is possible that targeting different pathways will result in improved outcomes.

Multiple Choice Questions

1. Which of the following structures must become damaged in order to develop albuminuria:
   (a) Distal collecting duct
   (b) **Glicocalix**
   (c) Juxtaglomerular apparatus
   (d) Urea counter current mechanism
2. The following pathways are responsible for the hyperfiltration mechanism:
   (a) Hexosamine pathway
   (b) Metabolic pathway
   (c) **Hemodynamic pathway**
   (d) Autophagy
3. Hyperfiltration develops in diabetic nephropathy by effect of which of the following:
   (a) Afferent arteriole vasoconstriction
   (b) **Efferent arteriole vasoconstriction**
   (c) Juxtaglomerular apparatus dysfunction
   (d) Glomerular basal membrane thickening
4. Nephropathology description of diabetic nephropathy is based on:
   (a) Electron microscopy description
   (b) Immunofluorescence description
   (c) **Light microscopy description**
   (d) Kimmelstiel-Wilson nodules
5. Earliest nephropathologic findings in diabetic nephropathy.
   (a) Mesangial expansion
   (b) Tubular atrophy
   (c) Interstitial fibrosis
   (d) **Glomerular basal membrane thickening**
6. Most effective treatment for established diabetic nephropathy is based on:
   (a) Endothelin receptor blockade
   (b) Protein restriction
   (c) Diuretic use
   (d) **Renin-angiotensin-aldosterone system blockade**
7. SGLT-2 inhibitor treatment produces which of the following hemodynamic effects in the glomerulus:
   (a) **Vasoconstriction of afferent arteriole**
   (b) Vasodilation of afferent arteriole
   (c) Vasodilation of efferent arteriole
   (d) Vasoconstriction of efferent arteriole
8. Mineralocorticoid antagonist therapy should be considered to compensate for which of the following:
   (a) Hyperfiltration phenomenon
   (b) Albuminuria
   (c) **Aldosterone breakthrough**
   (d) Diuretics hypokalemia effect
9. Overt diabetic nephropathy without treatment leads to glomerular filtration rate loss of.
   (a) **1 mL/min month**
   (b) 1 mL/min week
   (c) 1 mL/min year
   (d) 50% of baseline within first 6 months
10. Which of the following findings must be considered to perform kidney biopsy in diabetic patients
    (a) Development of albuminuria within the first 5 years of diabetes diagnosis
    (b) Development of albuminuria in absence of diabetic retinopathy
    (c) Development of nephrotic syndrome
    (d) **All the above**

Peripheral Diabetic Neuropathies

56

Gergely Feher

Introduction

More than 25% of the US population aged ≥65 years has diabetes, and the aging of the overall population is a significant driver of the diabetes epidemic. The epidemic is chiefly of type 2 diabetes and also the associated conditions known as 'diabesity' and 'metabolic syndrome'. In conjunction with genetic susceptibility, particularly in certain ethnic groups, type 2 diabetes is brought on by environmental and behavioural factors such as a sedentary lifestyle, overly rich nutrition and obesity. The prevention of diabetes and control of its micro- and macrovascular complications will require an integrated, international approach if we are to see significant reduction in the huge premature morbidity and mortality it causes [1]. Diabetic neuropathies (DN) encompass a wide range of nerve abnormalities and are common, with prevalence rates reported between 5% and 100% depending on the diagnostic criteria. Diabetic peripheral neuropathy (DPN) is associated with considerable morbidity, increased mortality and diminished quality of life, causing a tremendous economic burden [2]. The duration and severity of hyperglycaemia, presence of dyslipidemia, hypertension and smoking are major risk factors for the development of diabetic polyneuropathy [3]. The different mechanisms involved in different pain sensations are still poorly understood, but there is ample evidence that abnormal discharges from diseased somatosensory neurons are responsible. Spontaneous activity in the peripheral nociceptor system may also trigger central nervous system changes responsible for hyperalgesia and allodynia [1].

Epidemiology

Diabetic peripheral neuropathy (DPN) is a common complication of both type 1 and type 2 diabetes. Despite the different pathophysiologies, there has been a longstanding assumption that the mechanism leading to DPN is shared. Type 2 DM is much more common (90–95%) but has a slightly lower lifetime incidence of neuropathy; the reported prevalence varies between 6 and 51% compared with the 54–59% associated with type 1 DM [4, 5]. The primary risk factor for DPN is hyperglycaemia, but apart from chronic hyperglycaemia, recent studies showed the possible role of large or frequent serum glucose level fluctuations as a possible trigger factor [5]. Whereas treating hyperglycaemia in type 1 DM can significantly reduce the incidence of neuropathy by up to 60–70%, glucose control in type 2 DM has only a marginal 5–7% reduction in the development of neuropathy estimated to affect 30–50% of individuals with diabetes. Many recent studies have implicated cardiovascular risk factors which include age, duration of disease, cigarette smoking, hypertension, elevated triglycerides, higher BMI, alcohol consumption and taller height in the background of DN [1, 4]. Interestingly, between 25% and 62% of patients with idiopathic peripheral neuropathy are reported to have prediabetes, and among individuals with prediabetes, 11–25% are thought to have peripheral neuropathy, and 13–21% have neuropathic pain. Population-based studies suggest a gradient for the prevalence of neuropathy, being highest in patients with manifest diabetes mellitus, followed by individuals with impaired glucose tolerance and then impaired fasting glucose and least in those with normoglycaemia [4].

Pathophysiology

It is generally believed that oxidative stress is the key pathological process inducing nerve damage in diabetes. Oxidative stress, possibly triggered by vascular abnormalities and asso-

ciated microangiopathy in the nerve, is a key pathological process inducing nerve damage in diabetes in humans and experimental models. Diabetes-induced oxidative stress in animal models of in type 1, type 2 and pre-diabetes in sensory neurons and peripheral nerve is demonstrated by increased production of reactive oxygen species (ROS), lipid peroxidation and protein nitrosylation and diminished levels of reduced glutathione and ascorbate. Treatment with antioxidants such as α-lipoic acid, γ-linolenic acid and aldose reductase inhibitors prevents many indices of neuropathy in STZ (streptozotocin)-diabetic rats. The neurons and Schwann cells do initiate protective mechanisms involving upregulation of antioxidant pathways; however, the neurodegenerative outcome is energy failure in the nerve, observed as a decrease in high energy intermediates (e.g. phosphocreatine), impaired axonal transport of proteins and sub-optimal ion pumping [1, 6] (Fig. 56.1).

Polyol pathway hyperactivity: Metabolic disorders are the primary cause of diabetic neuropathy. Hyperglycaemia, induced through decrease of insulin secretion or insulin resistance, is responsible for the enhancement of the polyol pathway activity. The rate-limiting first enzyme of this pathway, aldose reductase, catalyses the formation of sorbitol from glucose, with the oxidation of nicotinamide adenine dinucleotide phosphate (NADPH) to NADP+. Sorbitol is further oxidized to fructose by sorbitol dehydrogenase, which is coupled with the reduction of nicotinamide adenine dinucleotide (NAD+) to NADH. It is described that during hyperglycaemic states, the affinity of aldose reductase for glucose is higher, generating intracellular osmotic stress due to accumulation of sorbitol, since sorbitol does not cross cell membranes. Interesting, the nerve damage following the diabetic state seems not to be due to this osmotic stress since it has been reported insignificant sorbitol concentrations in the nerves of diabetic patients [7]. However, the current accepted hypothesis states that polyol pathway hyperactivity is pathogenic primarily by increasing the turnover of cofactors such as NADPH and NAD+, which leads to a decrease in the reduction and regeneration of glutathione, as well as to an increase of advanced glycation end product (AGE) production and activation of diacylglycerol and protein kinase C (PKC) isoforms. Depletion of glutathione could be the primary cause of oxidative stress and be related to the accumulation of toxic species [8]. In fact, aldose reductase inhibitors are effective in preventing the development of diabetic neuropathy in animal models, but they have demonstrated disappointing results and dose-limiting toxicity in human trials [7] (Figs. 56.1 and 56.2).

Oxidative stress and mitochondria: Hyperglycaemia induces activation of classical pathways like AGE, PKC, hexosamine and polyol pathways to mediate cellular damage [7]. Generation of superoxide from mitochondrial electron transport chain is known to contribute towards hyperglycaemia initiated various etiological pathways. Hyperglycaemia enhances the reducing equivalents to electron transport chain (ETC) and the electrochemical potential across the inner mitochondrial membrane and hence increases superoxide production [7]. Superoxide inhibits glyceraldehyde phosphate dehydrogenase (GAPDH) either directly or indirectly through PARP-mediated NADH+ depletion [10]. Inhibition of GAPDH by ROS leads to accumulation of glycolytic intermediates upstream of this enzyme and redirected to initiate cellular pathways like AGE formation. Once the AGEs are formed, they bind to RAGE and activate many other cru-

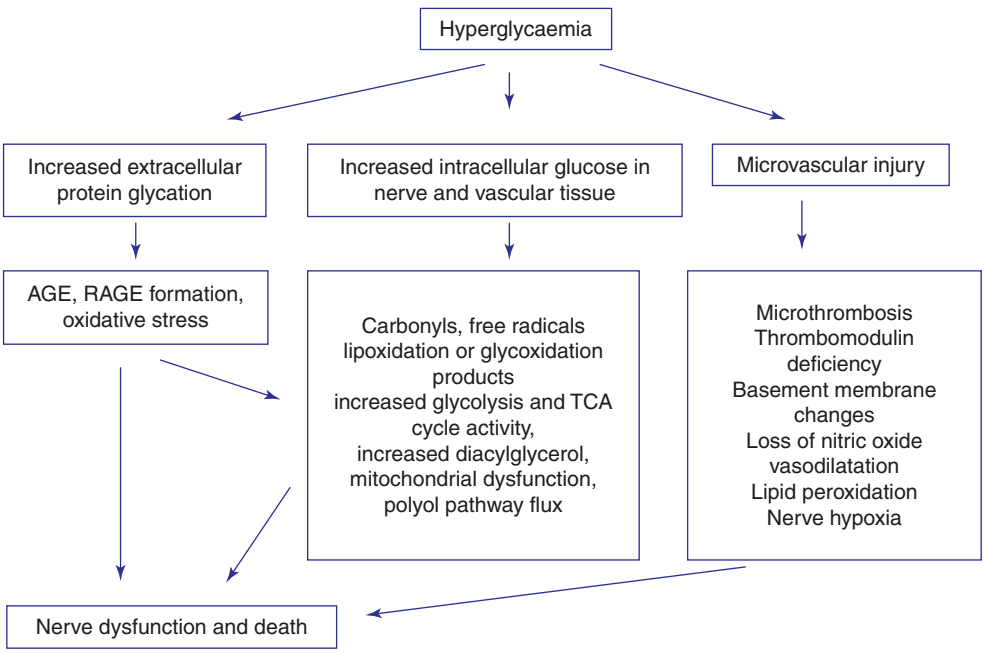

Fig. 56.1 The pathogenesis of diabetic neuropathy (Taken from Deli G et al. Diabetic neuropathies: diagnosis and management. Neuroendocrinology. 2013;98(4):267–80, ref. 1, with permission). *AGE* advanced glycation end product, *RAGE* receptors for AGEs, *TCA* tricarboxylic acid

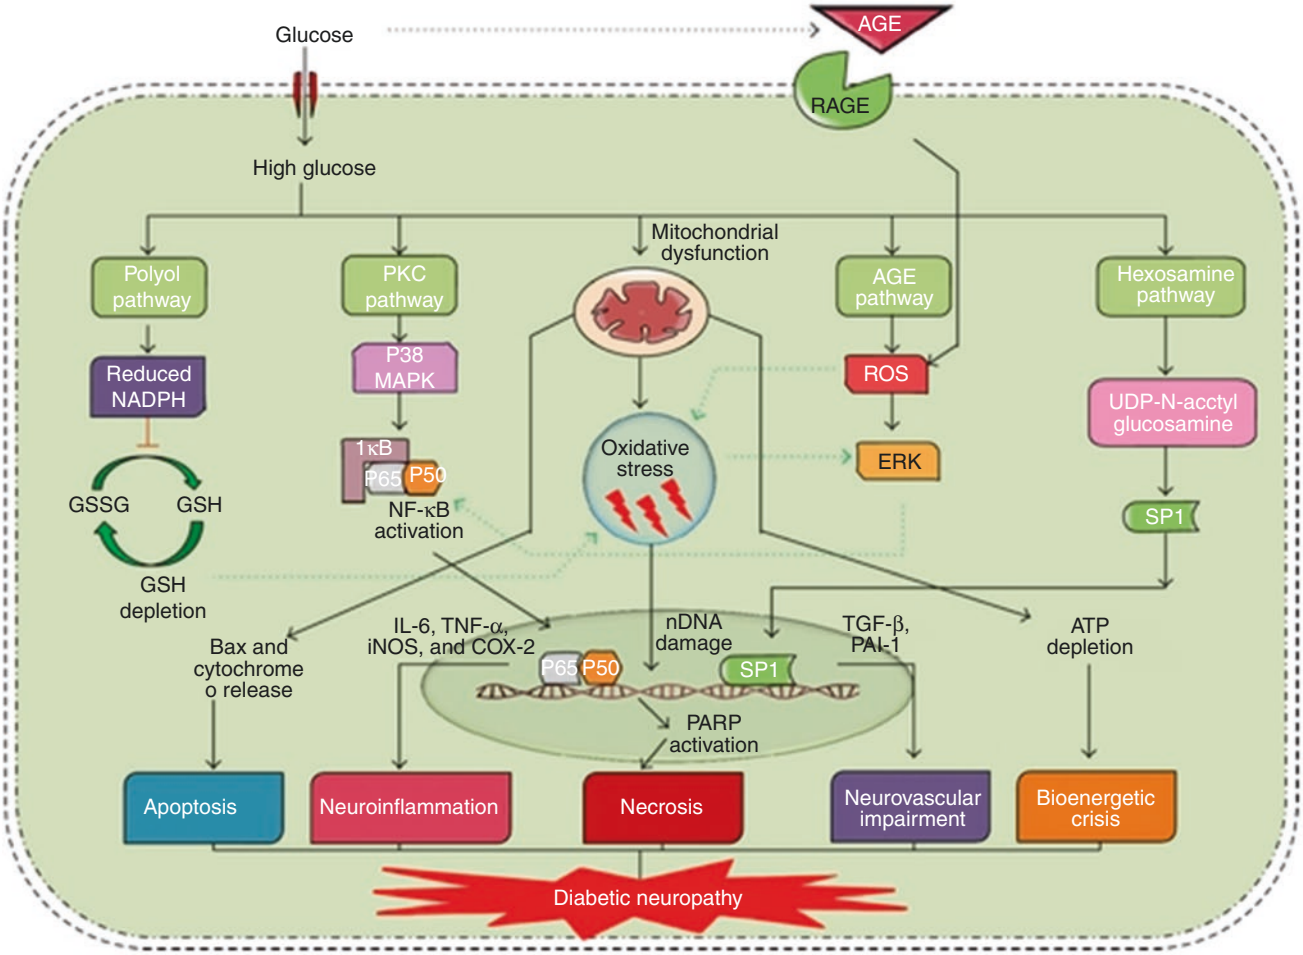

Fig. 56.2 Pathophysiology of diabetic neuropathy. Hyperglycaemia activates numerous metabolic pathways like polyol pathway, protein kinase c (PKC) pathway, advanced glycation end product (AGE) pathway and hexosamine pathway. All these pathways are known to integrate through hyperglycaemia-mediated mitochondrial ROS production. Oxidative stress and these classical pathways in combination activate transcription factors such as nuclear factor kappa enhancer of B cells (NF-κB) and speciality protein-1 (SP-1), resulting in neuroinflammation and vascular impairment. Further, these pathways combined with dysfunctional mitochondria-mediated apoptosis or bioenergetic depletion can lead to neuronal damage leading to DN. Poly-ADP ribose polymerase (PARP)-mediated NADH/ATP depletion can lead to neuronal dysfunction due to failure of various energy-dependent processes in neurons. (ERK, extracellular related kinase; IL-6, interleukin-6; iNOS, inducible nitric oxide synthase; COX-2, cyclooxygenase-2; TGF-β, transforming growth factor-β; and PAI-1, plasminogen activator inhibitor-1) (Taken from Sandireddy R et al. Neuroinflammation and oxidative stress in diabetic neuropathy: futuristic strategies based on these targets. Int J Endocrinol. 2014;2014:674987, ref. 9, with permission)

cial pathways like NF-κB and PARP. PKC pathway is activated through dihydroxyacetone phosphate-mediated diacylglycerol (DAG) activation. Hexosamine pathway is activated through enhanced flux of fructose-6-phosphate and polyol pathway by elevated glucose levels. This, in turn, leads to osmotic stress in the cells which further takes the cell towards necrotic cell death. Enhanced activity of Mn-SOD, a mitochondrial form of superoxide dismutase (SOD) or overexpression of uncoupling proteins (UCP-1) in experimental diabetic animals, prevents the development of vascular complications in the animals and also reduced oxidative stress-mediated neuronal damage. The mechanism for this neuroprotective effect can be the reduction of mitochondrial ROS generation and the clearance of the notorious ROS from the cells. In addition to the above theory, mitochondrial abnormalities and mitochondria-associated oxidative stress stand at a central position in the pathogenesis of diabetic neuropathy. It has been noticed that defects in functioning of ETC chain components compromise ATP production and enhance the generation of free radicals. The free radicals generated causes damage to mitochondrial DNA (mt DNA) and nuclear DNA (nDNA) which in turn aggravates mitochondrial damage. This vicious cycle developed inside mitochondria produces intense oxidative stress and drives the cell towards apoptotic/necrotic death. It is an established fact that diabetes is known to affect the respiratory capacity of ETC

functional complexes and thus alters ATP production (Fig. 56.1). Mainly complex I and complex III are known to be affected, which turns out to be electron leakage centres and thus inflates ROS production [7]. Various experimental observations point towards the critical role of mitotoxicity in the pathophysiology of diabetic neuropathy (Figs. 56.1 and 56.2).

Microvascular changes: DNP is frequently associated with microvascular impairment [1, 7]. In clinical and preclinical studies, it was found that peripheral perfusion is reduced, not only in the nervous tissue but also in the skin, being an important physiological evidence of microvasculature alteration. As a result, nerve ischaemia occurs, caused by raise in wall thickness and hyalinization of the basal lamina of vessels that nurse peripheral nerves, together with luminal reduction. These alterations are caused by plasma protein scape of capillary membrane to endoneurium, promoting swelling and augmented interstitial pressure in the nerves, accompanied by higher capillary pressure, deposition of fibrin and thrombus development. Hyperglycaemia per se can evoke nerve hypoxia, especially in sensory nerves, altering their electrical stability. Apparently controversial data from clinical studies described that diabetic patients suffering from the DNP presented higher levels of intravascular oxygen and augmented blood flow in the lower limbs than painless patients. As a result of nerve ischaemia, both diabetic patients and animals have shown a progressive nerve loss in proximal and distal segments, resulting in reduction of intraepidermal nerve fibre density. Consequently, axonal degeneration and regeneration also occur but more frequently in patients who do not experience pain. Besides axonal retraction and regeneration, another structural modification related to hyperglycaemia is myelin sheath alteration. The observed demyelinization can be related to Schwann cells' altered capacity to support normal myelin sheath [7] (Figs. 56.1 and 56.2).

Nerve excitability: Sensing ongoing spontaneous pain and paroxysmal shooting pain in the absence of any external stimulus is caused by ectopic impulse generation within the nociceptive pathways [1, 10]. The enhanced excitability can result from altered ion channel function, such as an increase in persistent sodium currents. Persistent sodium currents can be reliably estimated using threshold tracking. In peripheral neuropathy, persistent sodium currents usually increase possibly due to overexpression of sodium channels associated with axonal regeneration and could be responsible for ectopic firings. In diabetic neuropathy, the activation of the polyol pathway mediated by an enzyme, aldose reductase, leads to reduced Na(+)/K(+) pump activity and intra-axonal sodium accumulation; sodium currents are reduced presumably due to decreased trans-axonal sodium gradient [1, 10]. In addition to voltage-gated sodium channels, several other ion channels probably undergo alterations after a nerve lesion, such as voltage-gated potassium channels, which might also contribute to changes in membrane excitability of nociceptive nerves [1, 10] (Fig. 56.3).

Nerve injury also induces upregulation of various receptor proteins such as the transient receptor potential V1 (TRPV1), which is activated by heat at about 41 °C [1]. In neuropathic condition, TRPV1 is downregulated on affected/injured fibres but upregulated on uninjured C-fibres, thereby causing spontaneous nerve activity induced by normal body temperature.

Central sensitization: Central sensitization might develop as a consequence of ectopic activity in primary nociceptive afferent fibres, and structural damage within the CNS itself

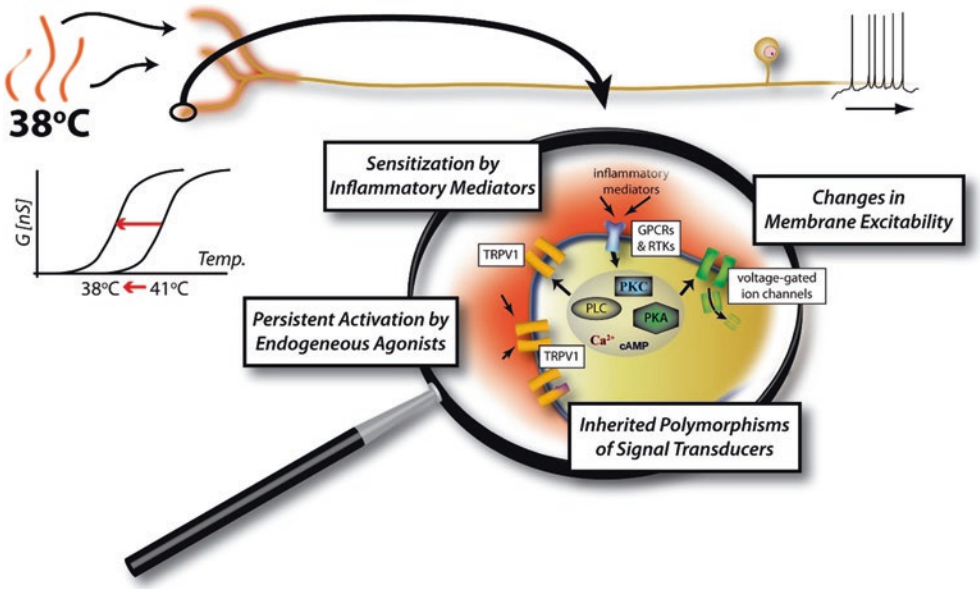

Fig. 56.3 Peripheral sensitization changes in the sensitivity of the peripheral terminals of nociceptors to stimuli can contribute to evoked pain. This can occur through inflammatory mediators sensitizing signal transducer proteins, persistent activation of transducer proteins by endogenous agonists, inherited polymorphisms of transducer proteins or an increase in membrane excitability. (Taken from von Hehn CA et al. Deconstructing the neuropathic pain phenotype to reveal neural mechanisms. Neuron. 2012;73(4):638–52, ref. 11 with permission)

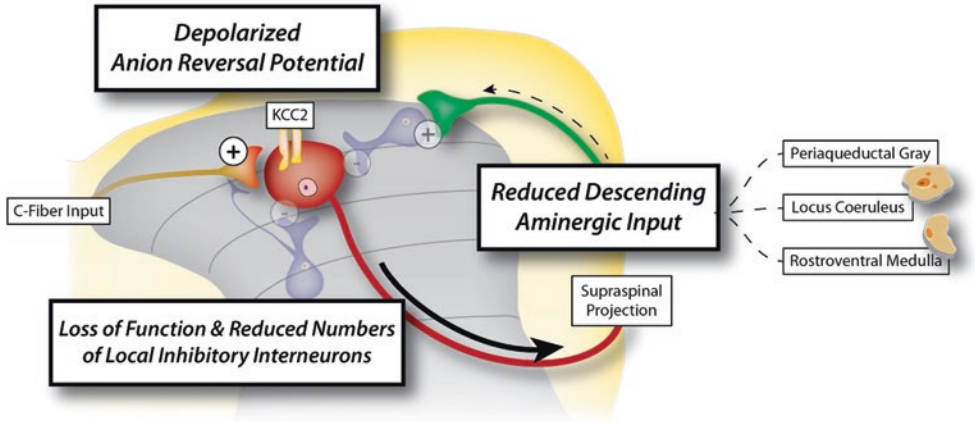

Fig. 56.4 Spinal disinhibition: Excitatory nociceptive signals are enhanced after nerve injury by a reduction in normal inhibitory regulation through a loss of local inhibitory interneurons, a depolarized anion reversal potential and reduced descending inhibition. (Taken from von Hehn CA et al. Deconstructing the neuropathic pain phenotype to reveal neural mechanisms. Neuron. 2012;73(4):638–52, ref. 11 with permission)

might not be necessarily involved. Spinal cord microglia are also strongly activated after nerve injury; the activated microglia not only exhibit increased expression of microglial markers CD 11 b and Iba 1 but also display elevated phosphorylation of p38 mitogen-activated protein kinase. Inhibition of spinal cord p38 has been shown to attenuate neuropathic and postoperative pain, as well as morphine-induced antinociceptive tolerance. Activation of p38 in spinal microglia results in increased synthesis and release of the neurotrophin brain-derived neurotrophic factor and the pro-inflammatory cytokines interleukin-1β, interleukin-6 and tumour necrosis factor-α. Phosphorylation of NMDA and AMPA receptors and expression of voltage-gated sodium channels are also involved both in the spinal cord and supraspinal structures. These mediators can powerfully modulate spinal cord synaptic transmission, leading to increased excitability of dorsal horn neurons, that is, central sensitization, partly via suppressing inhibitory synaptic transmission [1, 7, 10]. Further potent inhibitory neurons, such as descending pathways originating in the brainstem, contribute to modulation of pain processing. Lesions that affect these opioidergic and monoaminergic systems also lead to pain exacerbation via disinhibition [10] (Fig. 56.4).

'Chronic Pain Hurts the Brain'

The pain matrix is composed of several interacting networks. A nociceptive matrix receiving spinothalamic projections (mainly posterior operculoinsular areas) ensures the bodily specificity of pain and is the only one whose destruction entails selective pain deficits. Transition from cortical nociception to conscious pain relies on a second-order network, including posterior parietal, prefrontal and anterior insular areas. Second-order regions are not nociceptive-specific; focal stimulation does not evoke pain, and focal destruction does not produce analgesia, but their joint activation is necessary for conscious perception, attentional modulation and control of vegetative reactions. The ensuing pain experience can still be modified as a function of beliefs, emotions and expectations through activity of third-order areas, including the orbitofrontal and perigenual/limbic networks. The pain we remember results from continuous interaction of these subsystems, and substantial changes in the pain experience can be achieved by acting on each of them. Neuropathic pain (NP) is associated with changes in each of these levels of integration. The most robust abnormality in NP is a functional depression of thalamic activity, reversible with therapeutic manoeuvres and associated with rhythmic neural bursting. Neuropathic allodynia has been associated with enhancement of ipsilateral over contralateral insular activation and lack of reactivity in orbitofrontal/perigenual areas. Although lack of response of perigenual cortices may be an epiphenomenon of chronic pain, the enhancement of ipsilateral activity may reflect disinhibition of ipsilateral spinothalamic pathways due to depression of their contralateral counterpart. This in turn may bias perceptual networks and contribute to the subjective painful experience [12].

In addition to functional changes, morphological alterations at spinal and supraspinal levels have been reported in chronic pain. Neuropathic pain is accompanied by apoptosis of spinal cord cells, sprouting of nerve terminals in somatosensory cortex, grey matter density decrease in PFC associated with reduced cognitive abilities and thalamic atrophy. Morphometric analysis showed that chronic pain particularly in patients with a neuropathic pain component is associated with 5–10% of brain grey matter atrophy in the prefrontal cortex and thalamus. A decrease in grey matter was also

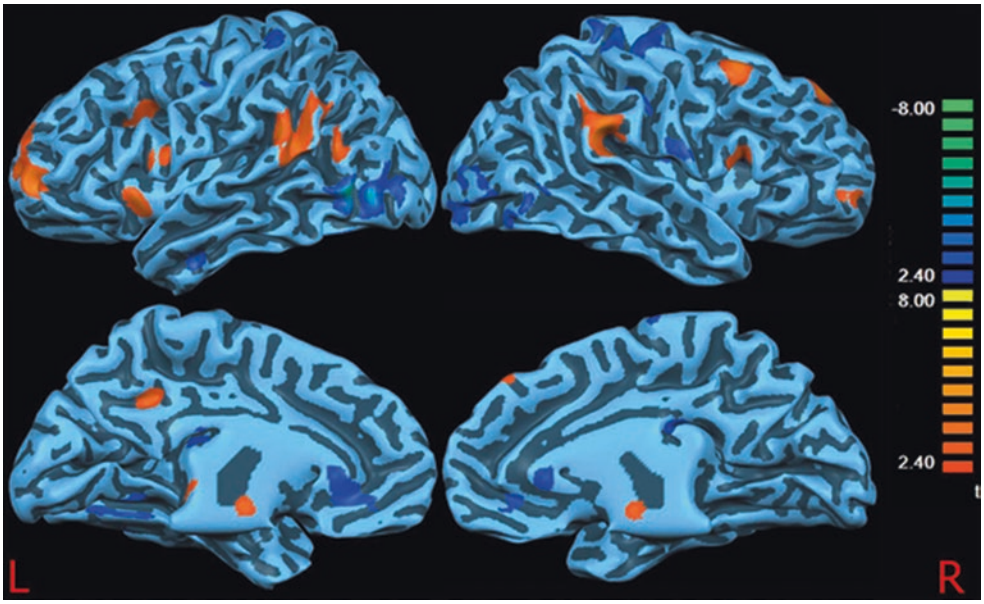

Fig. 56.5 DMN differences between controls and patients. Surface-rendered projection results of a two-sample t-test contrasting the default mode network in the healthy group vs. the pain group. The blue foci indicate the areas that showed significantly less correlational activity in the pain group than in the healthy group. Vice versa the yellow/red foci indicate the areas that showed significantly more correlational activity in the pain group than in the healthy group. (Taken from Cauda F et al. Altered resting state in diabetic neuropathic pain. PLoS One. 2009;4(2):e4542., ref. 13, with permission)

found in brainstem, temporal lobe and somatosensory cortex in addition to PFC in patients with chronic pain; cortical changes were more pronounced in the right hemisphere. It remains to be determined if reduced grey matter density is related exclusively or predominantly to a specific cell population (projection neurons, inhibitory interneurons and microglia) or if different cell types are affected equally. Nerve injury-induced apoptosis in the spinal dorsal horn caused a loss of GABAergic inhibitory interneurons and a decrease in inhibitory synaptic transmission. Microglia was hyperactivated at the spinal level after nerve injury but possibly inhibited in cortical areas in chronic pain [13].

In a revolutionary study by Cauda et al., functional connectivity analyses revealed a cortical network consisting of two anti-correlated patterns: one includes the left fusiform gyrus, the left lingual gyrus, the left inferior temporal gyrus, the right inferior occipital gyrus, the dorsal anterior cingulate cortex bilaterally and the pre- and postcentral gyrus bilaterally, in which its activity is correlated negatively with pain and positively with the controls; the other includes the left precuneus, dorsolateral prefrontal, frontopolar cortex (both bilaterally), right superior frontal gyrus, left inferior frontal gyrus, thalami, both insulae, inferior parietal lobuli, right mammillary body and a small area in the left brainstem, in which its activity is correlated positively with pain and negatively with the controls. Furthermore, a power spectra analysis revealed group differences in the frequency bands wherein the spatial independent component analysis (sICA) signal was decomposed: patients' spectra are shifted towards higher frequencies [14] (Fig. 56.5).

Ever since several studies have confirmed the role of central nervous system impairment. Both somatosensory pathways and cognition-related cerebral areas are involved based on functional MRI studies, which play a role in the complexity in the development of neuropathic pain and its emotional and mental consequences [15, 16]. Altered functional connectivity can also be detected in patients with type 1 diabetes mellitus [17].

Diagnosis

As it has been previously shown, prediabetes can also be associated with neuropathy. Based on the recent ADA (Americans with Disabilities Act) guidelines, diabetes can be diagnosed on the results of HgBA1C, fasting plasma glucose (FPG) or 2 h postprandial glucose (PG) levels. This statement recommended the use of the A1C test to diagnose diabetes, with a threshold of ≥6.5%. The established glucose criteria for the diagnosis of diabetes (FPG ≥ 7 mmol/l or 2h PG ≥ 11.1 mmol/l) remained valid as well [18].

Prediabetes can be defined as having impaired fasting glucose (IFG) (FPG levels 5.6–6.9 mmol/l) or impaired glucose tolerance (IGT) (2h PG values in the oral glucose tolerance test (OGTT) of 7.8–11.0 mmol/l). It should be noted that the World Health Organization (WHO) and a number of other diabetes organizations define the cutoff for IFG at 110 mg/dl (6.1 mmol/l) [1]. Hence, it is reasonable to consider an A1C range of 5.7–6.4% as identifying individuals with high risk for future diabetes, a state that may be referred to as prediabetes [1, 18]. As with glucose measurements, the continuum of risk is curvilinear—as A1C rises, the risk of diabetes rises disproportionately. Accordingly, interventions should be most intensive follow-up particularly vigilant for those with A1Cs above 6.0%, who should be considered to

be at very high risk. Prediabetes is associated with obesity (especially abdominal or visceral obesity), dyslipidemia with high triglycerides and/or low HDL cholesterol and hypertension. The presence of prediabetes should prompt comprehensive screening for cardiovascular risk factors. Standards of lifestyle and medical care can also be found in this guideline [18].

In DPN, sensory deficits usually overshadow motor nerve dysfunction and appear first in the distal portions of the extremities and progress proximally in a 'stocking-glove' distribution with increasing duration or severity of diabetes [1]. In the typical form, the large nerve fibres are damaged later than the small ones [19]. The signs and symptoms of DPN vary depending on fibre type involved, with large fibre disease impairing proprioception and light touch. Small fibre disease impairs pain and temperature perception, leading to paresthesias, dysesthesias and/or neuropathic pain [2] (Table 56.1). Distal weakness occurs only in the most severe cases. Diminished or absent deep tendon reflexes, particularly the Achilles tendon reflex, often indicate mild and otherwise asymptomatic DPN. More advanced asymptomatic neuropathy may first present with late complications such as ulceration or neuroarthropathy (Charcot's joints) of the foot [1, 19].

For diagnosis of DN, bedside examination should include assessment of muscle power, sensations of pinprick, joint position, touch and temperature. Vibration test should be done by tuning fork of a 128 Hz. For touch sensation, mono filament of 1 g is recommended [1]. A number of questionnaires have been developed to help practitioners diagnose neuropathic pain [1, 9, 19]. The DN4 questionnaire is of particular interest, as it can be rapidly completed, is easy to use and has a good diagnostic performance: for a score ≥4/10, it has a sensitivity of 83% and a specificity of 90% for diagnosing neuropathic pain [9, 19]. The main advantage of screening tools is to identify potential patients with NP, particularly by non-specialists. However, these tools fail to identify 10–20% of patients with clinician-diagnosed NP, showing that they cannot replace careful clinical judgement [9] (Table 56.1).

Electrophysiological tests may have no place in the diagnosis of chronic sensorimotor diabetic neuropathy, as they can be normal when only small-diameter fibres are damaged, but are a reliable procedure in the case of mononeuropathies or radiculopathies to exclude any other etiology (demyelinating, toxic polyneuropathies, etc.). Such procedures should be performed only when the clinical presentation is atypical and the diabetic origin uncertain (asymmetrical symptoms or involvement of the upper limbs) [9, 19].

Among laboratory tests, laser-evoked potentials (LEPs) are the best tool for assessing Aδ pathway dysfunction (small-fibre neuropathy) and skin biopsy for assessing neuropathies with distal loss of unmyelinated nerve fibres [1, 9].

Table 56.1 Definition and assessment of negative and positive sensory symptoms and signs in patients with neuropathic pain (Taken from Deli G et al. Diabetic neuropathies: diagnosis and management. Neuroendocrinology. 2013;98(4):267–80, ref. 1, with permission)

Symptom	Sign	Assessment
Negative signs and symptoms		
Hypoesthesia Pallhypesthesia Hypoalgesia Thermohypoesthesia	Reduced sensation To non-painful stimuli To vibration To painful stimuli To cold or warm stimuli	Touch skin with Painter's brush, cotton swab Tuning fork Pinprick Objects of 10 and 45 °C
Spontaneous sensations/pain		
Paraesthesia Paroxysmal pain Superficial pain	Non-painful ongoing sensation Painful, shooting electrical attacks for seconds Painful ongoing sensation	Number per episode Grade intensity (0–10) Threshold for evocation Area in cm^2
Evoked pain		
Mechanical dynamic allodynia Mechanical static allodynia Mechanical punctate or pinprick hyperalgesia Temporal summation Cold allodynia Heat allodynia Mechanical deep somatic allodynia	Normally non-painful stimuli on skin evoke pain Normally non-painful pressure stimuli on skin evoke pain Normally stinging-but-not-painful stimuli evoke pain Repetitive application of identical single noxious stimuli is perceived as increasing pain sensation Normally non-painful cold stimuli evoke pain Normally non-painful heat stimuli evoke pain Normally non-painful pressure on deep somatic tissues evokes pain	Stroking skin with painter's brush etc. Manual gentle mechanical pressure to the skin Manual gentle pricking of the skin Pricking the skin with safety pin at <3 s intervals for 30 s Touch skin with objects of 20 °C Touch skin with objects of 40 °C Manual light pressure at joints or muscle

Forms of Diabetic Neuropathy

Several fairly distinct clinical syndromes of diabetic neuropathy have been delineated: the most common as noted is a distal, symmetrical, primarily sensory polyneuropathy affecting feet and legs in a chronic, slowly progressive manner; the others are acute ophthalmoplegia that affects the third and less often the sixth cranial nerve on one side; acute mononeuropathy of limbs or trunk including a painful thoracolumbar radiculopathy; an acute or subacute painful, asymmetrical, predominantly motor multiple neuropathy affecting the upper lumbar roots and the proximal leg muscles ('diabetic amyotrophy'); a more symmetrical, proximal motor weakness and wasting, usually without pain and with variable sensory loss, pursuing a subacute or chronic course; and an autonomic neuropathy involving bowel, bladder, sweating and circulatory reflexes. These forms of neuropathy often coexist or overlap, particularly the autonomic and distal symmetrical types and the subacute proximal neuropathies (Tables 56.2 and 56.3).

Table 56.2 The main features of different patterns of disabling neuropathies in patients with diabetes (Taken from Deli G et al. Diabetic neuropathies: diagnosis and management. Neuroendocrinology. 2013;98(4):267–80, reference 1, with permission)

	Pains	Distal symmetrical sensory loss	Weakness	Sensory ataxia	Autonomic dysfunction	Progression	CSF protein	Electrophysiological test	Nerve biopsy
Length-dependent polyneuropathy	Frequent in distal limbs	Length dependently predominates on pain and temperature sensations	Minor, distal symmetrical	Rare	Common	Years	Variable	Axonal pattern, distal symmetrical	Massive axonal loss
CIDP in diabetic patients	Occasional	Variable predominates on proprioception	Common, often severe proximal and distal	Common	Uncommon	Weeks or months	Increased	Mixed axonal and demyelinative	Variable axon loss and demyelination
Focal/multifocal diabetic neuropathy	Present in most cases	Variable	Common—asymmetrical—nerve or root territory	Uncommon	Uncommon	Weeks or months	Increased	Axonal pattern, multifocal	Variable

CIDP chronic inflammatory demyelinating polyneuropathy, *CSF* cerebrospinal fluid

Sensorimotor Neuropathy

Distal sensory diabetic polyneuropathy: This is the most common presentation of neuropathy in diabetes, and up to 50% of patients may experience symptoms, most frequently burning pain, electrical or stabbing sensations, paresthesia, hyperesthesia and deep aching pain [1]. These symptoms are generally worse at night and disturb sleep. Together with painful symptoms during the day, this often leads to a reduction in individual's ability to perform daily activities [11].

Examination of the lower limb usually reveals sensory loss of vibration, pressure, pain and temperature perception (mediated by small and large fibres) and absent ankle reflexes [15–17]. Muscle weakness is usually mild, but in some patients, a distal sensory neuropathy is combined with a proximal weakness and wasting [1, 9, 11, 19].

Interestingly, as up to half of the patients may be asymptomatic, a diagnosis may only be made on examination or, in some cases, when the patient presents with a painless foot ulcer [1].

About 10% of diabetic patients experience persistent pain (so-called painful diabetic neuropathy) [11]. Some patients develop predominantly small fibre neuropathy manifesting with pain and paresthesia early in the course of diabetes that may be associated with insulin therapy (insulin neuritis) [8, 20].

Acute diabetic mononeuropathies: Cranial neuropathy in diabetic patients most commonly involve the oculomotor nerve followed by trochlear and facial nerve in order of frequency. Third nerve palsy with pupillary sparing is the hallmark of diabetic oculomotor palsy and is attributed to nerve infarction [8, 9, 11, 19, 21].

Isolated involvement of practically all the major peripheral nerves has been described in diabetes (e.g. carpal tunnel syndrome (CTS) is three times more common in diabetic patients than the normal population and CTS is the second most common neuropathic disease in diabetic patients), but the ones most frequently affected are the femoral, sciatic and peroneal nerves, in that order [22–25]. Rarely is a nerve in the upper extremity affected. In these cases, nerve entrapment seems to be commoner than nerve infarction [8, 9, 11, 19].

The mononeuropathies often emerge during periods of transition in the diabetic illness, for example, after an episode of hyper- or hypoglycaemia, when insulin treatment is initiated or adjusted or when there has been rapid weight loss [1, 8, 9, 11, 19].

Diabetic multiple mononeuropathies and radiculopathies: This category overlaps with the mononeuropathies. A syndrome of painful unilateral or asymmetrical multiple neuropathies tends to occur in older patients with relatively mild or even unrecognized diabetes. Multiple nerves are affected in a random distribution (mononeuritis multiplex). As in mononeuropathy, the onset is abrupt in one nerve and occurs earlier than the other nerves, which are involved sequentially or irregularly. Nerve infarctions occur because of occlusion of vasa nervosum and should be differentiated from systemic vasculitis [8, 9, 11, 19].

Characteristic diabetic syndromes present subacutely with pain followed by weakness, which affect primarily patients with mild diabetes called radiculoplexus neuropathies (Table 56.3). Three main types can occur, alone or in combination, and include diabetic cervical radiculoplexus neuropathy (DCRPN), diabetic thoracic radiculoneuropathy (DTRN) and diabetic lumbosacral radiculoplexus neuropathy (DLRPN) [8, 9, 11, 19].

Diabetic lumbosacral radiculoplexus neuropathy (DLRPN) occurs in approximately 1% of diabetic patients and probably is the form of diabetic neuropathy that causes the most morbidity [25]. It has been variably known by different names, including diabetic amyotrophy, Bruns-Garland syndrome, diabetic mononeuritis multiplex, diabetic polyradiculopathy, proximal diabetic neuropathy and others [1]. Pain, which can be severe, begins in the low back or hip and spreads to the thigh and knee on one side; the discomfort has a deep, aching character with superimposed lancinating jabs, and there is a propensity for pain to be most severe at night. Although pain is initially the worse symptom, weakness and atrophy become the main problem, which are mainly evident in the pelvic girdle and thigh muscles, although the distal muscles of the leg may also be affected [8, 19].

Diabetic thoracic radiculopathies are a rare but important complication of diabetes mellitus. These typically present with severe pain and dysesthesias along the trunk, chest or abdominal wall and often prompt extensive workups for underlying chest or abdominal pathology [1]. They can be symmetric and can involve multiple dermatomes [8, 9, 11, 19]. While DLRPN is a much more familiar branch of the DRPN spectrum, the cervical segment can also be involved, but it is very rare [8].

Insulin neuritis: In a seemingly paradoxical relationship, both poor glucose control and rapid treatment of hyperglycaemia can be associated with an increased risk of neuropathy. A clinically distinct form of neuropathy that deserves mention is treatment-induced neuropathy in diabetes (TIND). This underdiagnosed iatrogenic small-fibre neuropathy is defined as the acute onset of neuropathic pain and/or autonomic dysfunction within eight weeks of a large improvement in glycaemic control specified as a decrease in glycosylated HbA1c of more than 2% points over 3 months [8]. TIND was first recognized soon after the introduction of insulin and named 'insulin neuritis' [1, 8, 20–22]. For many decades, 'insulin neuritis' was considered a rare cause for acute neuropathy. However, recently published data suggest that it is much more common and clinically relevant. It is most common in type 1 diabetes mellitus (DM) treated with

insulin, although rapid glucose correction can occur in both types of diabetes as a result of either insulin or less frequently oral agents. In a study by Gibbons and Freeman, a surprising 10.9% of 954 subjects with diabetes met criteria for TIND, and the risk of developing TIND was associated with the magnitude and rate of HbA1c change [20]. Similar to DPN, the neuropathy of TIND generally follows a length-dependent pattern, but, in contrast, the pain and autonomic symptoms are more extensive and less responsive to opioids. The underlying pathophysiology is poorly understood, although it has been suggested that rapid glycaemic control both with and without insulin leads to hemodynamic changes (arteriovenous shunting) resulting in endoneurial hypoxia of small fibres [8, 20–22].

Diabetes-Associated Chronic Inflammatory Demyelinating Polyneuropathy (CIDP)

Chronic inflammatory demyelinating polyneuropathy (CIDP), as the name implies, is an autoimmune disorder of unknown etiology in two-thirds of the patients; however, in remaining one-third, an etiological cause might be found. Some currently described etiologies include gammopathies including monoclonal gammopathy of undetermined significance (MGUS), multiple myeloma, Castleman's disease and Waldenstrom gammopathy; also, other concurrent disorders like inflammatory bowel disorders, cutaneous melanoma and Hodgkin's lymphoma have been implied [23]. CIDP has typical and atypical phenotypic variants. Only half of CIDP patients have typical CIDP, which exhibits symmetrical sensory and motor symptoms. The remainder has atypical disease, which presents with predominantly focal, sensory, motor, distal or asymmetrical symptoms. Despite increased efforts to identify a biomarker, there is no definitive diagnostic marker for CIDP, and recognition of CIDP is not straightforward in some cases due to its heterogeneous nature [24]. For further details, see the excellent review by Nelligan et al. [25].

Simultaneous occurrence of CIDP and diabetes mellitus (DM) (diabetic CIDP or CIDP-DM) is frequently seen in clinical practice; however, it is ambiguous whether the two disorders are pathogenetically correlated. It is of utmost importance to be familiar with CIDP occurring in diabetics for the reason that contrasting to diabetic polyneuropathy, it may be treatable [23].

There is an increasing body of literature suggesting that the prevalence of CIDP tends to be higher in diabetic patients, especially in those of older age. A recent retrospective health insurance administrative claims database study suggested that the prevalence of CIDP in a nondiabetic population is 6 per 100,000 persons, while the prevalence of CIDP in a patient population with DM is ninefold higher at 54 per 100,000 persons. The association of CIDP with DM remains controversial, as both diseases have increased prevalence in patients over age 50 years. It is a challenge to identify CIDP in a diabetic population due to concomitant axonal damage. Although some patients with CIDP and DM respond to treatment, it is difficult to predict response. Because of the rising prevalence of DM throughout the world, there is a need to differentiate CIDP from DPN accurately [24].

The diagnosis of CIDP relies on a combination of clinical and electrophysiological criteria. A number of criteria have been proposed. The European Federation of Neurological Societies (EFNS)/Peripheral Nerve Society (PNS) guidelines were developed for clinical and research use [26]. The criteria combine clinical features and electrophysiological evidence to define CIDP, with supportive criteria including elevated cerebrospinal fluid (CSF) protein, gadolinium enhancement of nerve roots or plexus on MRI or nerve biopsy findings providing supplemental diagnostic evidence. Electrodiagnostic evidence of peripheral nerve demyelination in motor nerves is required for diagnosis, including distal latency prolongation, reduction of motor conduction velocity, prolongation of F-wave latency and partial motor conduction block, and must be identified in at least two nerves for a diagnosis of 'definite' CIDP. It should be noted that in some cases of pure sensory CIDP where routine motor conduction studies are normal, the EFNS/PNS guidelines may fail to diagnose the condition as CIDP. In these cases, if CIDP is suspected, the proximal region of the peripheral sensory nervous system should be carefully interrogated using sensory-evoked potentials. Although other criteria have been proposed, the EFNS/PNS criteria have good sensitivity and specificity for CIDP diagnosis and are currently the most commonly used [26].

Treatment of Diabetic Neuropathy

In diabetic patients, the risk of DPN and autonomic neuropathy can be reduced with improved blood glucose control, and the improvement of lipid and blood pressure indexes and the avoidance of cigarette smoking and excess alcohol consumption are already recommended for the prevention of other complications of diabetes [1].

Preventive Treatment

Based on the etiology of diabetic neuropathy, several agents have been tested to halt its progression (after the onset of subjective symptoms, only palliative treatments are currently available), thereby improving clinical outcome [23]. A very recent meta-analysis showed that main preventive strategies for DPN are intensive glycaemic control with a target

HbA1c < 6% in patients with type 1 diabetes mellitus and standard control of 7.0–7.9 in patients with type 2 diabetes mellitus, incorporating lifestyle modifications.

An analysis of the literature on experimental peripheral diabetic neuropathy suggests that, to date, all of the pharmacological agents shown to counteract one or several manifestations of painful or insensate neuropathy also have efficacy against nerve conduction velocity deficit [27]. Animal studies using pharmacological and genetic approaches revealed important roles of increased aldose reductase, protein kinase C and poly(ADPribose) polymerase activities, advanced glycation end products and their receptors, oxidative-nitrosative stress, growth factor imbalances and C-peptide deficiency in both painful and insensate neuropathies [27].

Aldose reductase inhibitor treatment was suggested not only improving impaired conduction velocity but also improving a variety of subjective symptoms based on recent studies [24]. These findings may support the hypothesis that the polyol pathway plays a central role in the onset and progress of diabetic neuropathy in human subjects. On the other hand, a Cochrane meta-analysis including 32 trials found no overall significant difference between the treated and control groups (SMD -0.25, 95% CI -0.56 to 0.05), although one subgroup analysis (four trials using tolrestat) is favoured [28]. There was no overall benefit on nerve conduction parameters (27 studies) or foot ulceration (one study). Quality of life was not assessed in any of the studies. While most adverse events were infrequent and minor, three compounds had dose-limiting adverse events that lead to their withdrawal from human use: severe hypersensitivity reactions with sorbinil, elevation of creatinine with zenarestat and alteration of liver function with tolrestat [28]. Interestingly, they may ameliorate cardiac automatic neuropathy especially mild or asymptomatic forms, but it merits further investigations as randomized trials are lacking [29].

Alpha lipoic acid is also a potent antioxidant in experimental models, reported to reduce diabetic microvascular and macrovascular complications in animal models [30]. Four trials (ALADIN I, ALADIN III, SYDNEY, NATHAN II) comprised $n = 1258$ patients (α-lipoic acid $n = 716$; placebo $n = 542$) were included in the first meta-analysis based on the intention-to-treat principle. The results of this meta-analysis provided evidence that treatment with α-lipoic acid (600 mg/day i.v.) over three weeks is safe and significantly improves both positive neuropathic symptoms and neuropathic deficits to a clinically meaningful degree in diabetic patients with symptomatic polyneuropathy [30]. This statement was also included in the ADA guidelines as a Level I, Grade A evidence [1]. On the other hand, this meta-analysis did not fulfil the requirements of the Cochrane Collaboration [30]. In an economical point of view, standard symptomatic treatment seems to be much more cheaper in Europe [1, 30]. The combination of parenteral (600 mg daily for three weeks) and oral therapy (600 mg three times daily for six months) administered over a total of seven months failed to translate into significant improvements [1]. The four-year-follow-up Nathan 1 trial also led to this neutral result [1, 30]. A recent meta-analysis confirmed the abovementioned findings [1, 30]. The current AAN (American Academy of Neurology) and EFNS (European Federation of Neurological Societies) guidelines do not support the use of this drug in neuropathic conditions [1].

Angiotensin-converting enzyme (ACE) or angiotensin receptor blockers (ARB) are widely used in diabetic patient to manage blood pressure and prevent or treat cardiovascular disease and nephropathy. Large-scale studies of the effects of ACE inhibitors or ARBs have not been done, although some small studies and prospective assessments have been performed with positive impact on neuropathy [1].

Symptomatic Treatment: Painful Diabetic Neuropathy

Tricyclic antidepressants (TCA): These are so-called early antidepressant medications. These first-generation medications were effective in the treatment of depression because they enhanced serotonergic or noradrenergic mechanisms or both. They also were the first medication category that proved effective for neuropathic pain in placebo-controlled trials [26]. Unfortunately, the TCAs also blocked histaminic, cholinergic and alpha1-adrenergic receptor sites, and this action brought about unwanted side effects such as weight gain, dry mouth, constipation, drowsiness and dizziness [30]. The cardiovascular effects of TCAs are well characterized and include orthostatic hypotension, slowed cardiac conduction, type 1A antiarrhythmic activity and increased heart rate. Although much of them are temporary and exhibit mild effect, they are generally well tolerated. Based on a Cochrane analysis for diabetic neuropathy, the number needed to treat (NNT) for effectiveness was 1.3 (95% CI 1.2 to 1.5), the number needed to harm (NNH) for minor adverse effects was 6 (95% CI 4.2 to 10.7) and number needed to harm (NNH) for major adverse effects defined as an event leading to withdrawal from a study was 28 (95% CI 17.6–68.9) [31]. Comparison meta-analysis of TCAs and SSRIs showed beneficial safety profiles (but the key effects differed between the drug classes) [1, 31]. On the other hand, their use should be avoided in post-infarct states and in the case of conduction disturbances and cardiac arrhythmias (IA antiarrhythmic effect) [1] (Table 56.3).

Selective serotonin reuptake inhibitors (SSRIs): The SSRIs are increasingly being used to treat a spectrum of depressed patients, including the elderly. As a class, SSRIs have comparable efficacy to TCAs against depression but are generally better tolerated [31]. Despite of their widely use,

there is still limited evidence for the role of classical SSRIs in the treatment of painful diabetic neuropathy [31].

The class of serotonin and norepinephrine reuptake inhibitors (SNRIs) now comprises three medications: venlafaxine, milnacipran and duloxetine. These drugs block the reuptake of both serotonin (5-HT) and norepinephrine with differing selectivity. Whereas milnacipran blocks 5-HT and norepinephrine reuptake with equal affinity, duloxetine has a tenfold selectivity for 5-HT and venlafaxine a 30-fold selectivity for 5-HT. All three SNRIs are efficacious in treating a variety of anxiety disorders [32–34].

Venlafaxine (three studies) has an NNT of 3.1 (95% CI 2.2–5.1). The NNH for minor adverse effects 9.6 (95% CI 3.5 to 13) and the number needed to harm (NNH) for major adverse effects defined as an event leading to withdrawal from a study 16.2 (95% CI 8–436) for venlafaxine [1].

Duloxetine at 60 mg daily was also effective in treating painful diabetic peripheral neuropathy in the short term to 12 weeks with a risk ratio (RR) for 50% pain reduction at 12 weeks of 1.65 (95% confidence interval (CI) 1.34–2.03) and number needed to treat (NNT) 6 (95% CI 5–10) [32–34]. In a side effect analysis, it was generally safe and well tolerated, with the three most commonly reported adverse events which were nausea, somnolence and constipation. Modest changes in glycaemia were associated with duloxetine. Aspartate transaminase/alanine transaminase increases were transient and not considered predictive of more severe outcomes [33, 34] (Table 56.3).

Antiepileptic drugs: Antiepileptic drugs (AEDs) have a long history of effectiveness in the treatment of neuropathic pain, dating back to case studies of the treatment of trigeminal neuralgia with phenytoin in 1942 and carbamazepine in 1962 [1, 35–38]. Since 1993, nine new AEDs (felbamate, gabapentin, pregabalin, lamotrigine, topiramate, tiagabine, levetiracetam, oxcarbazepine and zonisamide) have received Food and Drug Administration (FDA) approval for the adjunctive treatment of partial seizures [35–38]. In addition to providing efficacy against epilepsy, these new AEDs may also be effective in neuropathic pain. For example, spontaneous activity in regenerating small caliber primary afferent nerve fibres may be quelled by sodium channel blockade, and hyperexcitability in dorsal horn spinal neurons may be decreased by the inhibition of glutamate release [35–38].

Gabapentin is an effective agent in the treatment of diabetic neuropathy, the NNT for effective pain was 2.9 (95% CI 2.2 to 4.3) and the NNH for minor harm was 3.7 (95% CI 2.4 to 5.4). Persons taking gabapentin can expect to suffer dizziness (21%), somnolence (16%), peripheral oedema (8%) and gait disturbance (9%). Serious adverse events (4%) were no more common than with placebo [35–38] (Table 56.3).

Pregabalin at doses of 300 mg, 450 mg and 600 mg daily was effective in patients with postherpetic neuralgia, painful diabetic neuropathy, central neuropathic pain and fibromyalgia (19 studies, 7003 participants). Pregabalin at 150 mg daily was generally ineffective [1]. The best (lowest) NNT for each condition for at least 50% pain relief over baseline (substantial benefit) for 600 mg pregabalin daily compared with placebo were 5.0 (4.0–6.6) for painful diabetic neuropathy. With 600 mg pregabalin, daily somnolence typically occurred in 15–25% and dizziness occurred in 27–46%. The proportion of participants reporting at least one adverse event was not affected by dose nor was the number with a serious adverse event, which was not more than with placebo [35–38] (Table 56.3).

The efficacy of valproic acid and lamotrigine is doubtful; they are not recommended routinely [32]. Using the Cochrane criteria, carbamazepine seems to be effective; on the other hand, no trial was longer than 4 weeks, of good reporting quality, using outcomes equivalent to at least moderate clinical benefit. In these circumstances, caution is needed in interpretation, and meaningful comparison with other interventions is not possible [1, 35–38]. The efficacy of topiramate is also neutral in this condition [1, 35–38].

Narcotic agents: Short-term studies provide only equivocal evidence regarding the efficacy of opioids in reducing the intensity of neuropathic pain, whereas intermediate-term studies demonstrate significant efficacy of opioids over placebo, which is likely to be clinically important [39]. The opioids studied were classified as weak (tramadol, propoxyphene, codeine) or strong (morphine, oxycodone) [39]. Weak and strong opioids outperformed placebo for pain and function in all types of neuropathic pain based on the result of a recent meta-analysis [39]. Other drugs produced better functional outcomes than opioids, whereas for pain relief, they were outperformed only by strong opioids. Dropout rates averaged 33% in the opioid groups and 38% in the placebo groups [39]. Among the side effects of opioids, only constipation and nausea were clinically and statistically significant.

Benzodiazepines: Agonists at the benzodiazepine binding site of ionotropic gamma-aminobutyric acid (GABA(A)) receptors are in clinical use such as hypnotics, anxiolytics and anticonvulsants since the early 1960s. Analgesic effects of classical benzodiazepines have occasionally been reported in certain subgroups of patients suffering from chronic pain or after spinal delivery through intrathecal catheters. However, these drugs are generally not considered as analgesics. Recent evidence from genetically modified mice now indicates that agents targeting only a subset of benzodiazepine (GABA(A)) receptors should provide pronounced antihyperalgesic activity against inflammatory and neuropathic pain. Several such compounds have been developed recently, which exhibit significant antihyperalgesia in mice and rats and appear to be devoid of the typical side effects of classical benzodiazepines [40].

Other agents: Local lidocaine and capsaicin cream have been shown to be effective in the treatment of neuropathic

conditions. They are included as potential therapeutic options in the recent AAN guidelines. Acupuncture, but not traditional Chinese herbal medicine, seems to be slightly effective. Transcutaneous electric nerve stimulation (TENS) should also be considered in the treatment of painful diabetic neuropathy [1].

Comparison: In random effect and fixed effect analyses of duloxetine (DLX), pregabalin (PGB) and gabapentin (GBP), all were superior to placebo for all efficacy parameters, with some tolerability trade-offs. Indirect comparison of DLX with PGB found no differences in 24 h pain severity, but significant differences in subjective global improvement, favouring PGB, and in dizziness, favouring DLX, were apparent. Comparing DLX and GBP, there were no statistically significant differences [41]. In three head-to-head trials, there was no difference between gabapentin and tricyclic antidepressants for achieving pain relief (RR 0.99, 95% CI 0.76 to 1.29) [42]. In a recent network meta-analysis, all interventions remained effective in comparison with placebo (mean difference in change of pain from baseline compared with placebo, amitriptyline, -12.58 [95% CI -16.66 to −8.50]; capsaicin, -9.40 [95% CI -13.92 to −4.88]; gabapentin, -10.22 [95% CI -17.25 to −3.19]; and pregabalin, -10.53 [95% CI -14.74 to −6.32] [35–37]. Based on these results, 5% lidocaine medicated plaster was comparable with the previously mentioned medications [43].

The recent ADA guidelines recommend optimization of glucose control to prevent or delay the development of neuropathy in patients with type 1 diabetes and to slow the progression of neuropathy in patients with type 2 diabetes [44]. Pregabalin, duloxetine are gabapentin are the first line of pharmacological treatments for painful diabetic neuropathy [44]. A very recent narrative in-depth review included pregabalin and duloxetine as first-line treatment options (and gabapentin as a reasonable alternative to pregabalin). Second- and third-line drugs were opioids (they are effective but adverse reactions and addiction concerns should be kept in mind) and topical analgesics. Pathogenesis-oriented treatments such as α-lipoic acid and actovegin should be confirmed in more extensive trials [45].

Combination therapy: Unfortunately there are too few controlled studies (complying with modern requirements for EBM) on combination therapy for neuropathic pain (84). Based on pharmacological, and pharmacokinetical profile, SNRIs and TCAs cannot be combined because of the high possibility of serotonin syndrome. TCAs and gabapentin and pregabalin or SNRI in combination with the abovementioned agents are good possibilities. Opioids can be combined with each of these drugs. Based on the recent AAN guidelines, venlafaxine may be added to gabapentin for a better response, and the EFNS guidelines prefer the combination therapy of TCA-gabapentin and gabapentin-opioids [1].

The recently published COMBO-DN multicentre, double-blind, parallel-group study in diabetic peripheral neuropathic pain addressed whether, in patients not responding to standard doses of duloxetine or pregabalin, combining both medications is superior to increasing each drug to its maximum recommended dose [46]. For initial eight-week therapy, either 60 mg/day duloxetine (groups 1 and 2) or 300 mg/day pregabalin (groups 3 and 4) was given. Thereafter, in the eight-week combination/high-dose therapy period, only nonresponders received 120 mg/day duloxetine (group 1), a combination of 60 mg/day duloxetine and 300 mg/day pregabalin (groups 2 and 3) or 600 mg/day pregabalin (group 4). Eight hundred four patients were evaluated for initial therapy and 339 for combination/high-dose therapy. Fifty percent response rates were 52.1% for combination and 39.3% for high-dose monotherapy ($P = 0.068$). In exploratory analyses of the initial eight-week therapy uncorrected for multiple comparisons, 60 mg/day duloxetine was found superior to 300 mg/day pregabalin ($P < 0.001$) [46]. Although not significantly superior to high-dose monotherapy, combination therapy was considered to be effective, safe and well tolerated.

Low-quality evidence raised the possibility of the combination of oxycodone with pregabalin and that of pregabalin with the 5% lidocaine plaster, but future, clear-cut studies are required to drive evidence-based decisions in the clinical setting [47].

Multiple Choice Questions

1. Consequences of peripheral diabetic neuropathy:
   (a) Morbidity
   (b) Discapacity
   (c) Mortality
   (d) Diminished quality of life
   (e) **All of the above**
2. Prevalence of peripheral neuropathy in patients with prediabetes:
   (a) Zero, it is exclusive of patients with diabetes
   (b) 5–10%
   (c) **11–25%**
   (d) 26–40%
   (e) 41–55%
3. Key pathological process inducing nerve damage in diabetes:
   (a) Trauma
   (b) **Oxidative stress**
   (c) Ischaemia
   (d) All of the above
   (e) None of the above
4. Diabetic peripheral neuropathy initially affects:
   (a) One extremity
   (b) Several extremities, asymmetrically
   (c) The proximal portions of the extremities
   (d) **The distal portions of extremities, symmetrically**
   (e) The distal portions of extremities, asymmetrically

5. The percentage of patients with asymptomatic distal sensory diabetic neuropathy is:
   (a) 100%
   (b) 75%
   (c) **50%**
   (d) 25%
   (e) 10%
6. Acute diabetic mononeuropathies are frequently associated:
   (a) With adequate metabolic control
   (b) With viral infections
   (c) With emotional stress
   (d) **With periods of transitions of the disease**
   (e) None of the above
7. Effective doses of pregabalin for the treatment of painful diabetic neuropathy:
   (a) 75 mg/day
   (b) 150 mg/day
   (c) **300 mg/day**
   (d) **450 mg/day**
   (e) **600 mg/day**
8. Traditional benzodiazepines are effective analgesics.
   (a) True
   (b) **False**
9. The evidence regarding the efficacy of opioids in reducing the intensity of neuropathic pain shows that:
   (a) They should be standard therapy.
   (b) They are superior to tricyclic antidepressants.
   (c) They are equally effective to pregabalin.
   (d) **They are only superior to placebo, and the evidence is equivocal**.
   (e) They should not be used.
   (f) They are equally effective to non-steroid anti-inflammatories.
10. In patients with diabetic peripheral pain, the COMBO-DN study showed:
   (a) That combination therapy with duloxetine and pregabalin is superior to high dose monotherapy
   (b) That 300 mg pregabalin is superior to 60 mg duloxetine
   (c) **That 60 mg duloxetine is superior to 300 mg pregabalin**
   (d) That both medications have similar rates of effectiveness and safety
   (e) That doses of duloxetine could be decreased

Victoria Serhiyenko and Alexandr Serhiyenko

Abbreviations

ABPM	Ambulatory blood pressure monitoring
BP	Blood pressure
BRS	Baroreflex sensitivity
CAD	Coronary artery disease
CAN	Cardiac autonomic neuropathy
CARTs	Cardiovascular autonomic reflex tests
CHD	Coronary heart disease
CVD	Cardiovascular diseases
DLP	Dyslipidemia
DM	Diabetes mellitus
GLP1-RA	Glucagon-like peptide 1 receptor agonists
HR	Heart rate
HRT	Heart rate turbulence
HRV	Heart rate variability
LV	Left ventricular
MI	Myocardial infarction
MSNA	Muscle sympathetic nerve activity
OH	Orthostatic hypotension
QTi	QT interval
SGLT2i	Sodium glucose transporter 2 inhibitors
SMI	Silent myocardial ischemia
T1DM	Type 1 diabetes mellitus
T2DM	Type 2 diabetes mellitus
α-LA	α-Lipoic acid
ω-3 PUFA	ω-3 Polyunsaturated fatty acids

Core tip: Cardiac autonomic neuropathy (CAN) is a serious complication of diabetes mellitus that is strongly associated with increased risk of cardiovascular mortality. CAN manifests in a spectrum of things, ranging from resting tachycardia, fixed heart rate arrhythmias, intraoperative cardiovascular instability and orthostatic hypotension to development of "silent" myocardial ischemia, "silent" myocardial infarction.

Diabetic patients should be screened for CAN due to the possibility of reversal of cardiovascular denervation in the early stages of the disease. Cardiovascular reflex tests and Holter-derived time and frequency-domain measurements are frequently used for the diagnosis. Therapeutic approaches are promising and may hinder or reverse the progression of the CAN when initiated during the early stages.

Introduction

Diabetes mellitus (DM) is a global epidemic affecting at least 8.3% of the population and 371 million people worldwide with a significant proportion (50%) remaining undiagnosed. It is estimated that almost one of six people are currently at risk of developing diabetes-related complications [1–4].

The majority of patients with long-term course of DM [mainly type 2 diabetes mellitus (T2DM)] are diagnosed

with coronary heart disease (CHD) due to coronary vessels arterial sclerotic disease. Often the course of CHD is complicated by combination of hypertension, specific kidney arterial involvement, and eyes and lower limbs affection. Metabolic alterations in the myocardium are combined with early coronary atherosclerosis. All these changes in the heart which occur out of prolonged duration of DM among middle age and elderly patients [coronary vessels affection, myocardium changes, diabetic cardiac autonomic neuropathy (CAN), and arterial sclerotic disease] are associated with the term "diabetic heart or diabetic cardiomyopathy" [5, 6].

Cardiac autonomic neuropathy among T2DM patients is characterized by lesion of nerve fibers in the sympathetic and parasympathetic divisions of the autonomic nervous system and is diagnosed unsatisfactorily and may be accompanied by severe orthostatic hypotension (OH), decreased tolerance to the physical loadings, and cause cardiac arrhythmias, ischemia of coronary vessels, *"silent" myocardial infarction (MI)*, "sudden" death syndrome [7–10].

Definition of CAN

Cardiovascular autonomic neuropathy is defined as the impairment of autonomic control of the cardiovascular system in the setting of diabetes after exclusion of other causes [11]. CAN is caused by damage to the autonomic nerve fibers that innervate the heart and blood vessels and leads to abnormalities in cardiovascular dynamics [12]. CAN is usually documented by using several cardiovascular autonomic reflex tests (CARTs) [13–15].

Epidemiology of CAN

CAN is a common chronic complication of type 1 diabetes mellitus (T1DM) and T2DM and is associated with higher morbidity and mortality level among patients with DM. The prevalence of confirmed CAN in unselected people with T1DM and T2DM is around 20%, but figures as high as 65% are reported with increasing age and diabetes duration. Because many studies were hospital based, referral bias cannot be excluded (classes II and III). Clinical correlates or risk markers for CAN are age, diabetes duration, poor glycemic control, microvascular complications (peripheral polyneuropathy, retinopathy, and nephropathy), hypertension, and dyslipoproteinemia (classes I and II). Established risk factors for CAN are glycemic control in T1DM (class I) and a combination of hypertension, dyslipoproteinemia (DLP), obesity, and glycemic control in T2DM (class II) [14, 15].

Screening for CAN should be performed in asymptomatic T2DM at diagnosis and T1DM after 5 years of disease, in particular those at greater risk for CAN due to a history of poor glycemic control [*hemoglobin* A_{1c} (HbA_{1c}) > 7%], or the presence of one major cardiovascular risk factor (among hypertension, DLP, and smoking), or the presence of macro- or microangiopathic complications (level B). CAN screening may be also required in asymptomatic patients for preoperative risk assessment before major surgical procedures (level C) [14–16].

Risk Factors for the Diabetic Cardiac Autonomic Neuropathy

Current data that differentiate CAN in T1DM and in T2DM in terms of risk factors and natural history are summarized in Table 57.1 [17].

Possible factors associated with high mortality and sudden death due to autonomic neuropathy are [5]:

- Silent myocardial ischemia/infarction.
- Cardiorespiratory arrest/increased perioperative and perintubation risk.
- Resting tachycardia.
- Ventricular arrhythmias/prolongation of the QT interval (QTi).
- Hypertension.
- Orthostatic hypotension.

Table 57.1 Cardiac autonomic neuropathy in type 1 and type 2 diabetes mellitus: differences in relation to risk factors and natural history [17]

Diabetes mellitus		
Risk factors	Type 1 diabetes mellitus	Type 2 diabetes mellitus
Age	+	+
Gender (female)	+	–
Obesity	–	+
Hyperinsulinemia	NA	+
Duration of DM	++	++
Smoking	+	+
HbA_{1c}	++	++
Hypertension	++	++
Retinopathy	++	+
Hypertriglyceridemia	+	+
Classical diabetic peripheral neuropathy	++	++
Microalbuminuria	++	++
Dyslipoproteinemia (>LDL and <HDL)	+	(+)
Prevalence at diagnosis of DM	7.7%	5%
Prevalence after 10 years	38%	65%
Prevalence (random)	25%	34%

++ strong association; + moderate association; – not found; (+) controversial; NA not applicable

- Flattening of the nocturnal reduction of blood pressure (BP) and heart rate ("non-dipper" phenomenon).
- Exaggerated BP responses with supine position and exercise.
- Abnormal diastolic/systolic left ventricular function.
- Poor exercise tolerance.
- Impaired cardiovascular responsiveness.
- Heat intolerance due to defective sympathetic thermoregulation.
- Susceptibility to foot ulcers and amputations due to arteriovenous shunting and sudomotor dysfunction.
- Hypoglycemia unawareness.
- Increased risk of severe hypoglycemia.
- Obstructive sleep apnea syndrome.

Pathogenesis of CAN

Diabetic CAN is eventually caused by complex interactions among a number of pathogenic pathways. Hyperglycemia is the leading cause of the initiation of this pathogenic process [12, 18–20]. The pathogenesis of diabetic CAN is multifactorial, including increased mitochondrial production of free radicals due to hyperglycemia-induced oxidative/nitrosative stress. Neuronal activity, mitochondrial function, membrane permeability, and endothelial function are impaired by advanced glycosylation end product formation, polyol aldose reductase signaling, protein kinase C and poly(ADP ribose) polymerase activation, and the alteration of the Na^+/K^+-ATPase pump function. Neuronal apoptotic processes are precipitated by endoplasmic reticulum stress induced by hyperglycemia, along with impaired nerve perfusion, DLP, alterations in redox status, low-grade inflammation, and disturbance in Ca^{2+} balance [21–24].

Classification of Diabetic Cardiac Autonomic Neuropathy [25]

Subclinical phase:

- Decreased heart rate variability.

Early phase:

- Resting tachycardia.

Advanced stage:

- Exercise intolerance.
- Cardiomyopathy with left ventricular dysfunction.
- Orthostatic hypotension.
- Silent myocardial ischemia.

Clinical Impact of CAN

Clinical Manifestations of CAN

Symptomatic manifestations of CAN include sinus tachycardia, exercise intolerance, and orthostatic hypotension. Orthostatic hypotension (OH) was present in 6–32% of diabetic patients depending on diagnostic cutoffs for fall in systolic blood pressure (20 or 30 mmHg) and the diabetic populations studied [15, 26, 27]. Symptoms of orthostatic intolerance were present in 4–18% of diabetic patients [14, 26, 27]. Orthostatic symptoms, such as light-headedness, dizziness, blurred vision, fainting, or pain in the neck or shoulder when standing, may be worse in the early morning, after meals, during a rise in core temperature, during prolonged standing, or with physical activity [28, 29]. Symptoms may be disabling, are often a barrier to an effective antihypertensive treatment, and may lead to falls in the elderly.

A number of other cardiovascular abnormalities were found in association with CAN [30]. These may play a role in excess mortality and morbidity and contribute to the burden associated with CAN (Table 57.2).

Symptoms and signs associated with diabetic CAN are presented in Table 57.3.

Table 57.2 Abnormalities associated with cardiovascular autonomic neuropathy at the level of cardiovascular system and peripheral vascular function [15]

Cardiovascular system	Peripheral vascular function
Perioperative unstability	↑ peripheral blood flow and warm skin
Resting tachycardia	↑ arteriovenous shunting and swollen veins
Loss of reflex heart rate variations	↑ venous pressure
Hypertension	Leg and foot edema
Exercise intolerance	Loss of protective cutaneous vasomotor reflexes
Orthostatic hypotension	Loss of venoarteriolar reflex with microvascular damage
Postprandial hypotension	↑ transcapillary leakage of macromolecules
Silent myocardial ischaemia	↑ medial arterial calcification
Left ventricular dysfunction and hypertrophy	–
QT interval prolongation	–
Impaired baroreflex sensitivity	–
Non-dipping, reverse dipping	–
Sympathovagal imbalance	–
Dysregulation of cerebral circulation	–
↓ sympathetically mediated vasodilation of coronary vessels	–
↑ arterial stiffness	–

Table 57.3 Symptoms and signs associated with diabetic cardiac autonomic neuropathy [20]

Diabetic cardiac autonomic neuropathy	
Resting tachycardia	
Abnormal blood pressure regulation	Nondipping Reverse dipping
Orthostatic hypotension (all with standing)	Light-headedness Weakness Faintness Visual impairment Syncope
Orthostatic tachycardia or bradycardia and chronotropic incompetence (all with standing)	Light-headedness Weakness Faintness Dizziness Visual impairment Syncope
Exercise intolerance	

Morbidity and Mortality in Cardiac Autonomic Neuropathy

CAN is a significant cause of morbidity and mortality associated with a high risk of cardiac arrhythmias and sudden death, possibly related to "silent" myocardial ischemia (SMI). Cardiovascular disease remains the main cause of excess mortality among patients with T1DM and T2DM. Reduced heart rate variability (HRV) as a marker of autonomic dysfunction has been shown to have dire consequences in terms of morbidity (e.g., progression of coronary atherosclerosis) and mortality independent of cardiovascular risk factors in various populations, including those with prediabetes and DM [12, 31]. In T1DM patients, there is a fourfold increase risk of death [31–33]. CAN is significantly associated with overall mortality [7, 12, 15], and in some but not all studies with morbidity, such as SMI, coronary artery disease (CAD), stroke, diabetic nephropathy progression, and perioperative morbidity. In the Detection of Ischemia in Asymptomatic Diabetic Subjects (DIAD) study, a diminished Valsalva heart rate (HR) ratio (a measure of CAN) was strongly associated with SMI, independent of more traditional risk factors including sex, age, hypertension, and smoking [14, 15, 34]. In the European Epidemiology and Prevention of Diabetes (EURODIAB) study, autonomic dysfunction was present in one-third of T1DM patients and was strongly associated with coexisting cardiovascular disease (CVD) after adjustment to age, HbA_{1c}, and duration of diabetes [12]. Results from the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial again confirmed the association of CAN and mortality. These investigators showed that the individuals in this trial with baseline CAN were 1.55–2.14 times as likely to die as individuals without CAN [35]. Furthermore, CAN in the presence of peripheral neuropathy was the highest predictor of CVD mortality. Indeed, combining indexes of autonomic dysfunction have been shown to be associated with the higher risk of mortality [7, 33]. There is also strong evidence, based on studies in patients with T1DM and patients with T2DM with a mean follow-up of 9.2 years, that QT interval (QTi) prolongation is an independent predictor of mortality for all-cause and cardiovascular deaths [7, 30, 33, 36]. Thus, CAN assessment can be used for cardiovascular risk stratification in patients with and without established CVD, as a marker for patients requiring more intensive monitoring during the perioperative period and other physiological stresses and as an indicator for more intensive pharmacotherapeutic and lifestyle management of comorbid conditions. There is definitive evidence for a predictive value of CAN on overall mortality (class I). There is some evidence of a predictive value of CAN on morbidity (class II). Orthostatic hypotension, when due to advanced CAN, is associated with an additional increase in mortality risk over that driven by HRV abnormalities (class III). Some cardiovascular abnormalities, closely linked to CAN, are associated with increased mortality: tachycardia (class II), QTi prolongation (class II), and non-dipping status (class III) [15, 37].

CAN is a risk marker of mortality (level A), as well as a risk marker and likely a risk factor for cardiovascular morbidity (level B), and possibly a progression promoter of diabetic nephropathy (level C). Orthostatic hypotension is associated with a worse prognosis than cardiovagal neuropathy (level C). QTi prolongation has prognostic value in diabetes (level B). Non-dipping status is associated with an adverse cardiovascular prognosis in diabetes (level C). Non-dipping status predicts the progression from micro- and macroalbuminuria to renal failure in T2DM (level C) [15].

CAN Assessment

Methods of CAN assessment in clinical practice include assessment of symptoms and signs, *cardiovascular reflex tests* based on HR and blood pressure (BP), and ambulatory blood pressure monitoring (ABPM).

Assessment of Symptoms

Questionnaires have been developed to investigate orthostatic symptoms and their severity in dysautonomic conditions, although they have not been specifically validated for CAN, and validated translations in different languages are lacking. In the Rochester Diabetic Neuropathy Study, the correlation between the autonomic symptoms and the autonomic deficits was weak in T1DM and absent in T2DM patients [28, 29, 38]. Orthostatic symptoms were poorly related to fall in systolic BP on standing. For their clinical impact, orthostatic symptoms should be looked for regularly together with other dysautonomic symptoms in diabetic patients [15].

Assessment of Signs

Resting tachycardia: While abnormalities in HRV are early findings of CAN, resting tachycardia and a fixed HR are characteristic late findings in diabetic patients with vagal impairment. Resting HR of 90–100 b.p.m. and occasional HR increments up to 130 b.p.m. occur. The highest resting HR have been found in patients with parasympathetic damage, occurring earlier in the course of CAN than sympathetic nerve dysfunction; in those with evidence for combined vagal and sympathetic involvement, the rate returns toward normal but remains elevated. A fixed HR that is unresponsive to moderate exercise, stress, or sleep indicates almost complete cardiac denervation. A blunted HR response to adenosine receptor agonists was described in both patients with DM and patients with metabolic syndrome and attributed to earlier stages of CAN [34, 39]. Higher resting HR (>78 b.p.m.) compared with lower resting HR (<58 b.p.m.) and a rise in HR with time have been shown to be powerful, independent risk predictors for all-cause and CVD mortality in several prospective cohorts [9]. The prognostic value of resting HR is a useful tool for cardiovascular risk stratification and as a therapeutic target in high-risk patients [12, 31, 40].

Exercise intolerance: In diabetic patients without evidence of heart disease, but with asymptomatic cardiac vagal neuropathy, exercise capacity and HR, BP, and cardiac stroke volume responses to exercise were diminished. A further decrease in exercise capacity and BP response was seen in patients with both vagal neuropathy and orthostatic hypotension. It is generally recommended that diabetic patients suspected to have CAN should be tested with a cardiac stress test before undertaking an exercise program. The severity of CAN correlated inversely with maximal HR increase during exercise, suggesting CAN contribution to diminished exercise tolerance [14, 15, 41].

Orthostatic hypotension: Orthostatic hypotension is defined as a fall in BP (i.e., > 20 mmHg or more stringent criteria is >30 mmHg for systolic or >10 mmHg for diastolic BP) in response to postural change, from supine to standing [30, 41]. In patients with diabetes, OH is usually a result of damage to the efferent sympathetic vasomotor fibers, particularly in the splanchnic vasculature [12, 28]. Patients with OH are typically represented with lightheadedness and presyncopal symptoms. Symptoms, such as dizziness, weakness, fatigue, visual blurring, and neck pain, also might be a result of orthostatic hypotension. Many patients, however, remain asymptomatic despite significant falls in BP. Orthostatic symptoms can also be misjudged as hypoglycemia and can be aggravated by a number of drugs, including vasodilators, diuretics, phenothiazines, and particularly tricyclic antidepressants and insulin [30, 31].

QTi prolongation QTi prolongation has been defined as a QTc (corrected QT for heart rate) ≥460 ms in women and ≥450 ms in men, although in most studies less strict criteria were used. The pathogenesis of QTi prolongation is multifactorial and includes imbalance in cardiac sympathetic innervation, intrinsic metabolic and electrolytic myocardial changes, left ventricular (LV) hypertrophy, and CAD, and genetic factors could lead to QTi prolongation [36, 42]. The day-night modulation of the QT/relative risk relation—on 24-h ECG recordings—was altered in CAN patients free of CAD, LV dysfunction, or hypertrophy, with a reversed day-night pattern and an increased nocturnal QT rate dependence. Reversible QTi prolongation may be induced by hyperinsulinemia in healthy subjects, by hyperglycemia, and by acute hypoglycemia in both healthy and diabetic subjects [36, 43]. In T1DM patients, prolonged QTc was shown to occur frequently during overnight hypoglycemia and was associated with cardiac rate/rhythm disturbances. These findings support an arrhythmic basis for the "dead in bed" syndrome and possibly a provocative role of hypoglycemia-induced sympathetic activation in cardiovascular events [14, 44]. In a meta-analysis of 17 studies including 4584 diabetic patients, QTc prolongation (>441 ms) was a specific (86%) albeit insensitive (28%) index of CAN [38].

Impaired HRV: The earliest clinical indicator of CAN is a decrease in HRV. Variability in the instantaneous beat-to-beat HR intervals is a function of sympathetic and parasympathetic activity that regulates the cardiac functional response to the body's level of metabolic activity. In normal individuals, the HR has a high degree of beat-to-beat variability and HRV fluctuates increasing with inspiration and decreasing with expiration. Initially, clinical relevance of HRV was identified through observations that fetal distress is preceded by alterations in beat-to-beat intervals before any appreciable change occurs in HR itself. The serious implications of abnormal HRV became apparent only in the late 1980s, when it was confirmed that HRV was a strong, independent predictor of mortality after acute myocardial infarction [24, 30, 45, 46]

Non-dipping and reverse dipping: At night, health subjects exhibit a predominance of vagal tone and decreased sympathetic tone, associated with reduction in nocturnal BP. In diabetic CAN this pattern is altered, resulting in sympathetic predominance during sleep and subsequent nocturnal hypertension. This is associated with a higher frequency of LV hypertrophy and both fatal and severe nonfatal cardiovascular events in diabetic CAN subjects [14, 24, 38].

Ambulatory blood pressure monitoring is a standard tool in hypertension research and management with regard to diagnostic, prognostic, and therapeutic issues [47]. It allows the assessment of the diurnal BP pattern, which is mainly regulated by sleep-awake changes in the autonomic cardiovascular function. ABPM may be used for research purposes to:

- Evaluate the circadian BP pattern and its abnormalities (e.g., non-dipping, nocturnal hypertension, extreme dipping, morning surge).
- Study its relationship with autonomic dysfunction, sleep disturbances, and kidney function.
- Assess the 24-h BP response to treatment.
- Evaluate the longer term prognostic implications of circadian BP abnormalities.

Non-dipping and reverse-dipping patterns were associated with CAN, which was the major determinant of the circadian variation in blood pressure. Several observations in both diabetic and nondiabetic patients linked non-dipping to a disruption of the circadian variation in sympathovagal activity, i.e., a diminished increase in vagal activity and a sympathetic predominance during the night. The day-night difference in systolic BP was a moderately accurate diagnostic tool for CAN and reverse dipping as a specific (95%)—albeit insensitive (25%)—marker of CAN [15, 38]. In clinical practice, ABPM in the general population is useful for diagnostic purposes and provides unique and additional information for risk stratification with regard to hypertension-related organ damage and cardiovascular events and for the extent of BP response to treatment [24, 38]. The European Society of Hypertension acknowledges that ABPM may improve predictions of cardiovascular risk in hypertensive patients and recommends that 24-h ABPM should be considered in the presence of either noticeable variability of office BP values or a marked discrepancy between office and home BP values and in case of resistance to drug treatment or suspected hypotensive episodes [24, 38]. Thus, in patients with CAN, ABPM may be particularly useful in detecting non-dipping or reverse-dipping conditions, daytime postural BP changes, and postprandial hypotension and in achieving BP control for the whole 24-h period. Conversely, in clinical practice, the presence of reverse dipping in ABPM may suggest the presence of CAN and thus requires CAN testing [15, 38].

"Silent" myocardial ischemia/cardiac denervation syndrome: The presence of both symptomatic and asymptomatic CAD is increased in diabetic patients, and subclinical neuropathy is an important cause of SMI in patients with diabetes. Five of the 12 studies showed a statistically significant increased frequency of SMI in those with CAN compared with those without CAN [15, 38, 48]. "Silent" ischemia in diabetic patients can either result from CAN, from autonomic dysfunction attributable to CAD itself, or from both. The mechanisms of painless myocardial ischemia are, however, complex and not fully understood. Altered pain thresholds, subthreshold by ischemia not sufficient to induce pain, and dysfunction of the afferent cardiac autonomic nerve fibers have all been suggested as possible mechanisms [12, 38]. Features of a MI in patients with CAN are silence, cough, nausea and vomiting, dyspnea, tiredness, and ECG changes. Reduced appreciation for ischemic pain can impair timely recognition of myocardial ischemia or infarction, thereby delaying appropriate therapy. Thus, patients with CAN warrant more careful attention, and cardiovascular autonomic function testing might be an important component in the risk assessment of diabetic patients with CAD [12].

Intraoperative cardiovascular liability Perioperative cardiovascular morbidity and mortality are increased two- to threefold in patients with diabetes. Compared with nondiabetic subjects, diabetic patients undergoing general anesthesia might experience a greater degree of decline in HR and BP during induction of anesthesia and less of an increase after tracheal intubation and extubation. Vasopressor support is required more often in diabetic individuals with CAN than in those without CAN [30, 49]. The normal autonomic response of vasoconstriction and tachycardia does not completely compensate for the vasodilating effects of anesthesia. There is an association between CAN and more severe intraoperative hypothermia that can result in decreased drug metabolism and impaired wound healing. Reduced hypoxic-induced ventilatory drive [30] requires preoperative CAN screening for loss of HRV. Preoperative cardiovascular autonomic screening might provide useful information for anesthesiologists planning the anesthetic management of diabetic patients and identify those at greater risk of intraoperative complications [12, 30].

Thus, resting HR is not a specific sign of CAN (class IV). After exclusion of other causes, OH suggests an advanced CAN that should be confirmed by CARTs (class I). Orthostatic hypotension (class III), QTi prolongation (class II), and reverse dipping on ABPM are specific but insensitive indices of CAN (class III) [12].

In terms of recommendations, it may be advised that the presence of symptoms and/or signs is not a sufficient criterion for CAN diagnosis but should provide the motivation to perform CAN testing to get a definite diagnosis (level B). Screening of orthostatic symptoms is advisable in any diabetic patient (level B). Regardless of the presence of orthostatic symptoms, the OH test is recommended yearly, in particular in patients over the age of 50 and in hypertensive diabetic patients (level B). CAN testing offers a useful tool to identify patients with potentially poor exercise performance and to prevent adverse outcomes when patients are introduced to exercise training programs (level C). Diabetic patients with unexplained tachycardia should undergo CAN testing (level C). Resting HR may be used in clinical practice for cardiovascular risk stratification (level C). QTi prolongation alone is an insufficient measure of CAN but should prompt further testing (level B). QTc may be used for cardiovascular risk stratification (level B).

ABPM should not be routinely employed for the diagnosis of CAN (level C). However, it is a reliable research tool

to explore 24-h BP patterns in different conditions (level B). In the presence of reverse dipping, referral for CAN testing is advisable (level C). ABPM may be useful in patients with CAN to detect non-dipping, to determine risk stratification for cardiovascular mortality and nephropathy progression, and to adjust antihypertensive treatment (level C) [12].

Cardiovascular Autonomic Reflex Tests

Autonomic balance involves complex interactions with several physiological mechanisms that act to maintain heart rate and BP within normal limits. Recent investigations have suggested that autonomic dysfunction (e.g., heightened activity of the sympathetic nervous system and suppressed activity of the parasympathetic nervous system) impairs the ability of the *autonomic nervous system* to regulate the cardiovascular system. Thus, autonomic imbalance might be a key component involved in both the etiology and the clinical course of CVD. What is also emerging is that one needs to distinguish the difference between autonomic imbalance and clear evidence of autonomic neuropathy. Autonomic imbalance produces a number of interesting and trying clinical situations, such as orthostatic tachycardia, orthostatic bradycardia, and OH, and can be responsible for predisposition to arrhythmias and "sudden" death [12, 40]. CARTs assess cardiovascular autonomic function through time-domain HR response to deep breathing, Valsalva maneuver, and postural change, and by measuring the end-organ response, that is, HR and BP changes, although indirect autonomic measures are considered the gold standard in autonomic testing. Heart rate variations during deep breathing, Valsalva maneuver, and lying-to-standing (HR tests) are indices mainly of parasympathetic function, whereas the OH, the BP response to a Valsalva maneuver, and sustained isometric muscular strain provide indices of sympathetic function. These tests are non-invasive, safe, clinically relevant (they correlate with tests of peripheral nervous system function), easy to carry out, sensitive, specific, reproducible, and standardized, and therefore they are considered consolidated, gold standard measures of autonomic function [12].

Diagnostic tests of CAN are summarized in Table 57.4.

Normal, borderline and abnormal values in tests of cardiovascular autonomic function are summarized in Table 57.5**.**

The Toronto Consensus [38] has concluded the following regarding diagnosis of CAN:

- The following CARTs are the gold standard for clinical autonomic testing: HR response to deep breathing, standing and Valsalva maneuver, and BP response to standing (class II evidence).
- These CARTs are sensitive, specific, reproducible, easy to carry out, safe, and standardized (classes II and III).
- The Valsalva maneuver is not advisable in the presence of proliferative retinopathy and when there is an increased risk of retinal hemorrhage (class IV).
- CARTs are subject to a number of confounding or interfering factors (class III).
- Age is the most relevant factor affecting HR tests (class I).
- A definite diagnosis of CAN and CAN staging requires more than one HR test and the OH test (class III).

The main clinical indications of the autonomic reflex tests are the following [15, 17, 38]:

- Diagnosis and staging of CAN in T2DM patients (at diagnosis and annually thereafter).

Table 57.4 Cardiovascular autonomic reflex tests [12]

Test	Technique	Normal response and values
Beat-to-beat HRV	With the patient at rest and supine, heart rate is monitored by ECG while the patient breathes in and out at six breaths per minute, paced by a metronome or similar device	A difference in HR of >15 beats per minute is normal and < 10 beats per minute is abnormal. The lowest normal value for the expiration-to-inspiration ratio of the R-R interval decreases with age: Age 20–24 years, 1.17; 25–29, 1.15; 30–34, 1.13; 35–39, 1.12; 40–44, 1.10; 45–49, 1.08; 50–54, 1.07; 55–59, 1.06; 60–64, 1.04; 65–69, 1.03; and 70–75, 1.02
Heart rate response to standing	During continuous ECG monitoring, the R-R interval is measured at beats 15 and 30 after standing	Normally, a tachycardia is followed by reflex bradycardia. The 30:15 ratio should be >1.03, borderline 1.01–1.03
Heart rate response to the Valsalva maneuver	The subject forcibly exhales into the mouthpiece of a manometer to 40 mmHg for 15 s during ECG monitoring	Healthy subjects develop tachycardia and peripheral vasoconstriction during strain and an overshoot bradycardia and rise in BP with release. The normal ratio of longest R-R to shortest R-R is >1.2, borderline 1.11–1.2
Systolic blood pressure response to standing	Systolic BP is measured in the supine subject. The patient stands, and the systolic BP is measured after 2 min	Normal response is a fall of <10 mmHg, borderline fall is a fall of 10–29 mmHg, and abnormal fall is a decrease of >30 mmHg
Diastolic blood pressure response to isometric exercise	The subject squeezes a handgrip dynamometer to establish a maximum. Grip is then squeezed at 30% maximum for 5 min	The normal response for diastolic BP is a rise of >16 mmHg in the other arm, borderline 11–15 mmHg

Table 57.5 Normal, borderline, and abnormal values in tests of cardiovascular autonomic function [5]

	Normal	Borderline	Abnormal
Tests reflecting mainly parasympathetic function			
Heart rate response to Valsalva maneuvre (Valsalva ratio)	≥1.21	1.11–1.20	≤1.10
Heart rate (R-R interval) variation	≥15 beats/min	11–14 beats/min	≤10 beats/min
During deep breathing (maximum-minimum heart rate) immediate heart rate response to standing (30:15 ratio)	≥1.04	1.01–1.03	≤1.00
Tests reflecting mainly sympathetic function			
Blood pressure response to standing (fall in systolic blood pressure in mmHg)	≤10	11–29	≥30
Blood pressure response to sustained handgrip (increase in diastolic blood pressure	≥16 mmHg	11–15 mmHg	≤10 mmHg

- Diagnosis and staging of CAN in T1DM patients (5 years after diagnosis and annually thereafter).
- Stratification of cardiovascular risk: in pre-operatory testing, pre-physical activity, indication of selective beta-blocker, and suspected silent ischemia.
- Differential diagnosis of other manifestations of CAN (regardless of DM duration): assess whether gastroparesis, erectile dysfunction, OH, dizziness, syncope, or tachycardia in diabetic persons are due to dysautonomia.
- Evaluate the progression of autonomic failure and monitor response to therapy (e.g., continuous infusion of insulin, post-transplants, and use of antioxidants).
- Differential diagnosis of other causes of neuropathy such as autoimmune autonomic neuropathy (chronic inflammatory demyelinating polyneuropathy, celiac disease, amyotrophy) or toxic-infectious neuropathy (alcohol, primary neuritic *Hansen's* disease, human immunodeficiency virus) as well as in cases where the presence of autonomic neuropathy is disproportionate to the sensorimotor neuropathy.

The most sensitive and specific diagnostic tests currently available to evaluate CAN in clinical research are (1) HRV, (2) baroreflex sensitivity (BRS), (3) muscle sympathetic nerve activity (MSNA), (4) plasma catecholamines, and (5) heart sympathetic imaging [50].

Heart Rate Variability

Heart rate is never completely stable. Continuous tonic, phasic, and transient external and internal stimuli of multiple origins affect HR to a variable but measurable extent. Five different mechanisms have been described: (1) sympathetic and parasympathetic efferences to the sinus node; (2) neurohumoral influences (e.g., catecholamines, thyroid hormones), (3) stretch of the sinus node, (4) changes in local temperature; and (5) ionic changes in the sinus node. Under resting conditions, it can be assumed that the short-term HRV is essentially determined by the first and third factors. The sympathetic and parasympathetic stimuli directly influence HR and are responsible for a physiologic variation in the heart rate, or HRV. The HRV can be evaluated in the time and frequency domains [38, 45, 50].

Time-domain measures of the normal R-R intervals include the difference between the longest and shortest R-R intervals, the standard deviation of 5-min average of normal R-R intervals (SDANN), and the root-mean-square of the difference of successive R-R intervals (rMSSD). Longer recordings (e.g., 24-h) allow the calculation of additional indices, as the number of instances per hour in which two consecutive R-R intervals differ by more than 50 ms over 24 h (pNN50). Essentially, all these indices explore the parasympathetic activity.

In the frequency domain, the use of spectral analysis of R-R interval (and other cardiovascular and respiratory signals) allows a precise description of the different fluctuations. The components of the HRV obtained by spectral analysis provide information about both the sympathetic and parasympathetic influences on the heart [38, 50]. Based on studies using acceptable techniques, there is evidence of reduced parasympathetic modulation of HR in diabetes and also reduced modulation of systolic BP in the low-frequency region [38, 51] particularly after sympathetic stimulation in response to tilting or in the microcirculation. As most of the CARTs essentially explore the parasympathetic activity, there is no other simple test of sympathetic activity capable of identifying early (functional or anatomic) autonomic sympathetic abnormality [50]. CARTs are considered the gold standard for CAN testing. Impaired HRV time- and frequency-domain indices have been reported in diabetic patients before CARTs abnormalities arise. However, the few studies that assessed the diagnostic accuracy against the reference standard of CARTs found only fair results. Time- and frequency-domain analysis of 24-h ECG recordings has documented an abnormal nocturnal sympathetic predominance in diabetic patients that was linked to BP non-dipping. In obese patients, weight loss was associated with an improvement in global HRV and in parasympathetic HRV indices [7, 50].

In this way, HRV testing is a clinically relevant measure in addition to CARTs and provides key information about autonomic-parasympathetic and sympathetic-modulation of the cardiovascular system. Analysis of HRV can be done using statistical indices in the time and frequency domains. Time-domain indices of global HRV and total spectral power of HRV represent the index of parasympathetic activity, as well as the HRV spectral power in the high-frequency region, while the relative proportion (not the absolute power) in the low frequencies of HRV provides a relative measure of sym-

pathetic modulation. This interpretation should be made with cautions if respiratory artifacts (slow breaths) cannot be excluded. Application of the technique is critically dependent upon understanding of the underlying physiology, the mathematical analyses used, and the many confounders and possible technical artifacts [46, 50].

In this way, misinterpretation of power spectrum takes place due to irregular respiratory pattern and verbalization during breathing, creating artifactual low frequencies and false "sympathetic overactivity."

Use of the absolute power of R-R interval low-frequency spectral data as evidence of sympathetic activity. In case of very low HRV (2–4% of total variability found in healthy subjects), the interpretation of spectral components is affected by the presence of non-autonomic components in the respiratory range. Other confounding factors (such as drugs) similar as those reported for CARTs [50, 52].

Recommendations [50]

- The best approach to HRV testing involves the analysis of ECG recordings in conjunction with respiration and beat-to-beat BP recordings (level C). When respiration cannot be recorded, breathing rate should be controlled (15 breaths/min) and hyperventilation or slow deep breathing avoided (level B). The subjects must not speak during recordings (level C). The optimal recording time is 4–5 min during well-controlled rest. Longer times (7 min) may be preferable if fast Fourier transform methods are used and if frequent ectopics are to be edited. Long uncontrolled recording times should be avoided (level C). When testing is done under stable conditions, autoregressive or fast Fourier transform methods can be used. When fast changes are to be expected (e.g., during interventions), autoregressive algorithms are preferred or alternatively special time-varying techniques.
- Age-related reference curve should be obtained for the healthy population in the same environment, and using the methodology adopted, construct 95% confidence limits (level B).
- Other recommendations on confounding factors are similar as those reported for CARTs.
- Used with the appropriate methodology, HRV has an increasingly important role in clinical research and therapeutic trials.

During 24-h Recordings

- If the goal is to define the circadian pattern of autonomic activity, long-duration spectra (e.g., 1 h) and autoregressive algorithms are preferable.
- If the goal is to define relatively faster modifications, shorter time windows (e.g., 5 min) are preferable. Special time-varying techniques can provide beat-to-beat autonomic changes.

Heart Rate Turbulence

Another Holter-based technique for evaluating CAN is the HR turbulence (HRT). HRT refers to sinus rhythm cycle length fluctuations following isolated premature ventricular beats. After an initial acceleration, the sinus rate decelerates after a premature ventricular beat. There are two components of HRT, turbulence onset and turbulence slope. A transient vagal inhibition triggers the mentioned initial acceleration in HR as a response to the missed baroreflex afferent input due to hemodynamically ineffective ventricular contraction. The successive deceleration in heart rate is caused by a sympathetically mediated overshoot of arterial pressure through vagal recruitment. HRT evaluation can be used in the risk assessment after acute MI and in the monitoring of disease progression in heart failure and CAN [22, 53]. A turbulence slope of below 3.32 ms/R-R is 97% sensitive and 71% specific for the diagnosis of CAN as detected by the CART in patients with T2DM [22, 54].

Baroreflex Sensitivity

The BRS is an interesting approach as it combines information derived from both HR and blood pressure. The measurement of the cardiac vagal arm BRS can be done with several methods: drugs or physical maneuvers can be applied to modify BP; alternatively, spontaneous blood pressure variations can be used. In all cases, the response in heart rate to the changes in BP is quantified. None of the BRS tests available today—based on drug-induced or physically induced changes in BP, spontaneous BP fluctuations with the sequences technique, or spectral analysis—have shown so far a definite advantage over the others or a clinically relevant difference [50, 55].

Longitudinal studies have demonstrated that BRS has important independent prognostic value in cardiac patients [50, 55] and in diabetic patients. Although some observations in diabetic patients support an early impairment of BRS before CARTs abnormalities, very few studies have evaluated so far the diagnostic accuracy of BRS measures as compared with the reference standard of CARTs with inconsistent results. Thus, no definite conclusion is possible on the diagnostic characteristics for CAN of BRS assessment, in particular on its sensitivity. In patients without CAN, an early stage of functional BRS abnormalities [17, 50] still responsive to lifestyle intervention—physical training or dietary improvement and weight reduction—has been documented.

BRS assessment may warrant use for identifying subjects at risk for CAN and also in clinical trials [50, 56].

In this way, cardiac vagal BRS assessment is an important component of autonomic testing as it combines information derived from both HR and blood pressure. Cardiac vagal BRS is a widely recognized independent prognostic index for cardiovascular mortality and morbidity in the general—mainly cardiac and the diabetic—population (class II). No definite conclusion is possible on the diagnostic characteristics of BRS assessment (classes III–IV). The presence of early abnormalities with respect to CARTs and their reversibility with appropriate treatments warrant the clinical use of BRS in identifying subjects at risk for CAN and to test potential therapeutic approaches (classes II–III). Pharmacological methods allow assessment of BRS across a range of physiologically relevant BP and when used with microneurography measurement of the sympathetic baroreflex. But this invasive technique is limited to research purposes. The methodology of BRS (in particular spontaneous BRS) is simple and fast. All BRS techniques require a dedicated beat-to-beat noninvasive blood pressure monitor. None of the BRS tests today available have shown a definite advantage over the other or a clinically relevant difference (class II) [50].

Fluctuations induced by drifts of the noninvasive blood pressure monitors. Most methods need a large number of arbitrary constraints imposed by the calculations that may affect the results. Respiratory pattern: although BRS measures in general do not need a strict control of respiratory pattern, slow breathing increases BRS and reduces sympathetic efferent drive; therefore, some feedback from respiration is necessary to correctly interpret the results. Age-related reduction in BRS. Other confounding factors (e.g., drugs) are similar as those for CARTs [50].

If the spontaneous approach is adopted, it is suggested to use a battery of methods based on the simplest single 5-min recording procedure (spontaneous BRS) and present the results in terms of a central measure (average or median) (level C) [50]:

- Recording should be performed during spontaneous breathing for 4–5 min, under monitored respiration or during controlled breathing at 15 breaths/min (level C).
- Pre-filtering of the data improves the agreement between methods and provides a more robust estimate of BRS (level C).
- The recording time should be kept between 4 and 5 min of well-controlled rest. Avoid long uncontrolled recording times (level C).
- The subjects must not speak during recordings (level C).
- Age-related reference curves should be obtained from the healthy population of the same environment and for the methodology adopted and construct 95% confidence limits (level B).
- Other recommendations on confounding factors are similar as those reported for CARTs.

Muscle Sympathetic Nerve Activity

Increased resting MSNA and blunted responsiveness to physiological hyperinsulinaemia or glucose ingestion have been described in T2DM having neuroadrenergic autonomic dysfunction and resembles insulin-resistant states and obesity. MSNA abnormalities in these conditions reverse with weight loss [50]. In contrast, T1DM is associated with a significant decrease in the number of bursts by about half [57]. Although reproducibility is similar to nondiabetic subjects, obtaining good-quality recordings is much more difficult in patients with diabetic polyneuropathy than in nondiabetic subjects [50], presumably as a result of a reduction in the conducting sympathetic nerve fibers.

In this way, the MSNA is the only method allowing direct and continuous measurement of sympathetic nerve traffic (class I). MSNA is the only method that can directly assess the sympathetic vascular arm of the arterial or cardiopulmonary baroreflex (class I). Type 1 diabetes appears to be associated with a reduction of MSNA (class IV). In early T2DM, resting MSNA might be increased, possibly due to hyperinsulinemia (class IV). The technique is difficult, invasive, and time-consuming, requires specialized trained operator, and cannot be repeated often in the same subject (class II) [50].

Confounders. BP variation, large inter-individual variations, food intake, age, posture, hypoxia, hydration, exercise, female reproductive hormones, arousal, sleep, mental stress, and ethnicity [50].

Recommendations. MSNA should not be routinely employed for the diagnosis of CAN (level C). MSNA should be employed with standard CARTs or for specific tests aimed at measuring vascular sympathetic modifications (e.g., glycemic clamps) (level C) [50].

Catecholamine Assessment and Cardiovascular Sympathetic Tests

Norepinephrine plasma appearance rate is in principle the biochemical equivalent of MSNA. Norepinephrine plasma appearance rate and clearance have been determined in idiopathic autonomic neuropathy as well as in diabetic CAN. While norepinephrine clearance is low in idiopathic autonomic neuropathy, this was not the case in CAN, and accordingly in diabetic CAN no additional diagnostic power was added by the inclusion of [^{3}H]-norepinephrine kinetic studies [50, 58]. Thus, catecholamine kinetics is an interesting technique which may give more information about catecholamine production and clearance across different regions but

is unsuitable to be used as a diagnostic tool yet. Plasma dihydroxyphenylalanine (DOPA) is not related to sympathetic neuropathy and has a mixed neuronal and non-neuronal origin. Plasma 3,4-dihydroxyphenylglycol (DHPG) may be a more sensitive marker of overall sympathetic innervation than supine plasma norepinephrine [50], and simultaneous measurement of norepinephrine and DHPG yields more information than measurement of either alone. Catecholamine assessment in diabetes showed in general lower than normal responses to postural changes, exercise, hypoglycemia, and CARTs. A subnormal orthostatic increment in plasma norepinephrine is a specific but not sensitive index of baroreflex-sympathoneural failure or sympathetic noradrenergic denervation [50].

Highlights. Clinical investigations including catecholamine determinations have contributed significantly to the understanding of the pathophysiology of CAN (class III). In the diagnostic context, the significance has been less prominent, partly due to the limited inclusion of the essays in clinical evaluations. Plasma catecholamine concentrations can indicate sympathetic noradrenergic and adrenomedullary hormonal system activity. Because levels of catecholamines are extremely responsive to lifestyle factors such as posture, temperature, dietary intake, medications, distress, and comorbidities, the clinical diagnostic value of plasma levels of catecholamines depends importantly on controlling or monitoring these factors (class III). Whole-body plasma norepinephrine and epinephrine respond rather slowly (minutes) to different physiological maneuvres. During turnover studies, different regional norepinephrine and epinephrine activities are "diluted" into a large plasma pool, contributing to blunted responses. Standardization of experimental conditions is to a large extent prohibitive for clinical routine purposes. In general, there is no neurochemical index that specifically assesses cardiac sympathetic innervation or function. This requires measurement of rates of entry of norepinephrine into the venous drainage of the heart, in turn requiring right heart catheterization, measurement of coronary sinus blood flow, and infusion of tracer-labeled norepinephrine [50]

Confounders. Plasma norepinephrine concentrations increase with age. Thus, age matching is mandatory for comparisons. Smoking increases sympathetic nervous activity and catecholamine concentrations; 24 h tobacco abstention is required for comparisons. Posture, emotional stress, and ambient temperature all affect catecholamine concentrations and should thus be standardized [50].

Recommendations. In a number of experimental conditions, plasma catecholamine measurements are mandatory. For clinical routine diagnosis and staging of CAN, the usefulness of plasma catecholamine concentrations is less obvious (level C). Plasma norepinephrine, epinephrine, and DHPG concentrations should be measured when whole-body sympathetic activity is assessed together with other relevant physiological parameters (HR, BP, cardiac output, hormonal and metabolic events) [50].

Heart Sympathetic Imaging and Heart Function Tests

Direct assessment of cardiac sympathetic innervation is possible using radiolabeled catecholamines or sympathomimetic amines that are actively taken up by sympathetic nerve terminals. Although in principle, it is possible to directly assess the integrity of both the parasympathetic as well as the sympathetic nervous system, there has been a paucity of research on parasympathetic imaging of the heart. Cardiac sympathetic neuroimaging, before and after administration of particular pharmacologic probes, can assess specific aspects of neuronal function. This combination has rarely been used [50].

Four tracers have been utilized to visualize the sympathetic nervous innervation of the heart: [^{123}I]-*meta*-iodobenzylguanidine (MIBG), [^{11}C]-*meta*-hydroxyephedrine (HED), 6-[^{18}F] dopamine, and [^{11}C]-epinephrine [32, 50, 59, 60].

The washout rates from the myocardium of [^{11}C]-epinephrine or 6-[^{18}F]-dopamine can give information on vesicular integrity. In subjects with T1DM and CAN, the washout rates of [^{11}C]-epinephrine parallels those of [^{11}C]-HED, suggesting regional differences in vesicular uptake or retention. Causes of defective tracer uptake or increased washout from the heart are a matter of current research [50, 61].

The interpretation of findings using sympathetic neurotransmitter analogues is complicated by the fact that alterations in sympathetic nervous system tone may also affect the retention of these tracers, and this fact is often not considered as an explanation for the clinical findings. In the isolated rat heart model, elevated norepinephrine concentrations in the perfusion increased neuronal HED clearance rates consistent with the concept that neuronal "recycling" of HED can be disrupted by increased synaptic norepinephrine levels. Alternatively at high norepinephrine concentrations, non-neuronal uptake of HED into myocardial cells and impaired retention may be an interfering factor [50].

Additionally, interpretation of early myocardial [^{123}I]-MIBG retention is complicated by increased body mass index and diastolic BP which have been reported to reduce myocardial MIBG uptake. Moreover, difficulties and delays in acquisition of utilizable images can complicate the interpretation of the measurement obtained. The delivery of tracers is critically influenced by myocardial perfusion, so myocardial retention of tracers should be performed with a quantitative analysis of myocardial blood flow. This can be

performed using positron emission tomography in order to derive a myocardial retention index [50, 62]. However, although regional perfusion deficiencies can be excluded using single-photon emission computed tomography, quantitative analysis of regional myocardial perfusion cannot be performed. Additionally, myocardial ischemia or damage is also known to result in cardiac denervation which may occur in the absence of alterations in CARTs [32, 63], whereas CAN is associated with impaired vasodilatory capacity in response to adenosine. Anoxic ischemia severely decreases the efficiency of vesicular sequestration and thus accelerates the loss of radioactivity, giving the false impression of denervation. Left ventricular dysfunction in DM has also been reported to reduce [^{123}I]-MIBG retention and increased washout rate [50].

Highlights. Scintigraphic tracers directly assess the structural integrity of the sympathetic nervous system supply to the heart (class III). [^{123}I]-MIBG scanning and single-photon emission computed tomography are widely used and available at most secondary care institutions; however, MIBG scanning is approved and reimbursed for evaluation of pheochromocytoma and so far not for evaluation of cardiac sympathetic innervation. Most data relate to the evaluation of cardiac sympathetic integrity; few studies evaluate the respiratory system. The relationships of deficits in tracer uptake/washout to sympathetic neuronal integrity and function are poorly understood: current tracers may not be the most optimum. Combined neuroimaging-pharmacologic approaches are required. Scintigraphic data correlates with HRV testing but have greater sensitivity to detect changes in sympathetic neuronal structure and/or function [50, 64] (class III). Scintigraphic data correlate with indices of myocardial perfusion and LV dysfunction in T1DM (class III). Limited studies demonstrate that decreased "uptake" and excessive "washout" of MIBG-derived radioactivity is an adverse prognostic finding in a spectrum of conditions including DM and that scintigraphic data are affected by the quality of glucose control (class III). Cost of scintigraphic studies is considerable [32, 50, 65]

Confounders. Parasympathetic tracers are not yet generally available. [^{11}C]-HED and 6-[^{18}F]-dopamine positron emission tomography have limited availability and are not reimbursed. Damage to the myocardium and LV dysfunction interferes with tracer uptake and washout independently of changes in CARTs. Regional myocardial [^{123}I]-MIBG "uptake" is semi-quantitative and not a clean index of neuronal uptake, which occurs extremely rapidly. [^{123}I]-MIBG retention is affected by body mass index, diastolic BP, and local factors which influence the tracer uptake and retention. Delivery of tracers is critically influenced by myocardial perfusion (myocardial retention of tracers should be performed with quantitative analysis of myocardial blood flow) [50].

The effects of the following on the kinetics of myocardial tracer retention are poorly understood: age (except for 6-[^{18}F]-dopamine), gender, glucose, insulin, DLP, hypertension, and vasoactive agents. Methodology for the assessment of sympathetic integrity is not standardized. Normative values have not been developed [50].

Recommendations [50]

- Scintigraphic studies should not be routinely employed for the diagnosis of CAN and should be utilized in concert with standard CARTs (level C).
- Scintigraphic studies are extremely valuable in the identification of sympathetic noradrenergic denervation as a mechanism of neurogenic orthostatic hypotension (level B).
- [^{123}I]-MIBG single-photon emission computed tomography offers semiquantitative assessment, and [^{11}C]-HED, 6-[^{18}F]-dopamine, and [^{11}C]-epinephrine positron emission tomography offer quantitative assessment of cardiac sympathetic integrity (level B).
- There is no standardized methodology for scintigraphic assessment of cardiac sympathetic integrity, and only limited data on the reproducibility exist (level C).
- Scintigraphic tracer uptake is affected by myocardial perfusion, and tracer retention is affected by available energy for the active neuronal and vesicular uptake transporters (level C).
- The results of scintigraphy should be compared with an appropriate control population (level C).
- Scintigraphic studies offer good sensitivity to detect sympathetic neuronal loss in the heart (level C).
- Scintigraphy is appropriate to explore the effects of sympathetic denervation on cardiac physiology, metabolism, and function (level C).
- Scintigraphy is useful as a marker of cardiac sympathetic denervation in cross-sectional and longitudinal research studies (level C).

Diagnostic Criteria for CAN

No unanimous criteria for diagnosis of CAN have been adapted to date. A single abnormal result among the two or three heart rate tests actually performed was considered a sufficient criterion for early CAN diagnosis. However, the presence of abnormalities in more than one test on several occasions was indicated as preferable for diagnosis [38, 66]. In addition, the presence of two or three abnormal results (two for borderline, three for definite) among the seven autonomic cardiovascular indices (including the five standard CARTs and other time and frequency domain indices of HRV) was recommended as a criterion for CAN diagnosis [67].

The Toronto Consensus established four reasons why the diagnosis of CAN is relevant to clinical practice [38]:

- For diagnosing and staging the different clinical forms of CAN: initial, definite, and advanced or severe.
- For the differential diagnosis of clinical manifestations (e.g., resting tachycardia, OH, and dyspnea upon exercise) and their respective treatment.
- For stratifying the degree of cardiovascular risk and the risk of other diabetic complications (nephropathy, retinopathy, and "silent" myocardial ischemia).
- To adapt the goal of glycated hemoglobin (HbA_{1c}) in each patient: for example, those with severe CAN should have a less aggressive glycemic control due to the risk of asymptomatic hypoglycemia in these patients, while patients with initial stages of CAN should have a more intensive glycemic control.

CARTs are the gold standard clinical tests for cardiovascular autonomic neuropathy [38]. Following the eighth International Symposium on Diabetic Neuropathy in 2010, criteria for diagnosis and staging of CAN are defined in the CAN Subcommittee of the Toronto Consensus Panel statement [23, 38, 68]. Accordingly, only one abnormal CARTs result is sufficient to diagnose possible or early CAN among the seven autonomic function analysis (five CARTs, time-domain and frequency-domain HRV tests), two or three abnormal tests indicate definite or confirmed CAN; and severe/advanced CAN can be indicated by concurrent orthostatic hypotension [23, 38, 68].

Staging of CAN

Ewing et al. proposed a classification based on "early involvement" (one abnormal result on HR test or two borderline results), "definite involvement" (two or more abnormal results on HR tests), and "severe involvement" (presence of OH) [26]. An "autonomic neuropathy score"—obtained by scoring the results of CARTs—has been used with the dual advantage of quantifying the progression of CAN and providing an overall quantitative result [38]. While an abnormal OH test, result generally occurs late in diabetes and subsequent to abnormalities in the HR tests; no chronological order or a markedly different prevalence of abnormalities among the HR tests has been found [38, 67]. Considering progression from an early to an advanced involvement, instead of from parasympathetic to sympathetic neuropathy, would appear to be the most appropriate approach to CAN staging, although OH may on rare occasions precede abnormalities in HR tests [26, 38]. The available information regarding the duration required to progress from an earlier to a later stage of CART impairment is scant, and it is not documented that a progression to OH and symptomatic forms invariably occur in all patients. The combination of CARTs with tests for sudomotor function may provide a more accurate diagnosis of diabetic autonomic neuropathy [38].

Conclusions [38]

- The following CARTs are the gold standard for clinical autonomic testing: HR response to deep breathing, standing, and Valsalva maneuver, and BP response to standing (class II).
- These CARTs are sensitive, specific, reproducible, easy to perform, safe, and standardized (classes II and III).
- The Valsalva maneuver is not advisable in the presence of proliferative retinopathy and when there is an increased risk of retinal hemorrhage (class IV).
- CARTs are subject to a number of confounding or interfering factors (class III). Age is the most relevant factor affecting heart rate tests (class I).
- A definite diagnosis of CAN and CAN staging requires more than one HR test and the OH test (class III).

Recommendations [38]

- Diagnosis of CAN is based on the use of CARTs for HR response to deep breathing, standing, Valsalva maneuver, and for BP response to standing (level A).
- For the diagnosis and monitoring of CAN, more than one HR test and the OH test are required (level B).
- Performance of CARTs should be standardized and the influence of confounding variables minimized (level A).
- Age-related normal ranges of HR tests are strictly required (level A).
- CAN diagnosis and staging: (1) the presence of one abnormal cardiovagal test result identifies the condition of possible or early CAN, to be confirmed over time; (2) at least two abnormal cardiovagal results are required for a definite or confirmed diagnosis of CAN; and (3) the presence of OH in addition to HR test abnormalities identifies severe or advanced CAN (level B).
- CARTs allow CAN staging from early to advanced involvement (level C).
- Progressive stages of CAN are associated with increasingly worse prognosis (level B).

Management of CAN

Clinical effectiveness of CAN diagnosis in clinical forms of CAN and the awareness of CAN for the therapeutic strategy in asymptomatic forms of CAN are presented in Fig. 57.1.

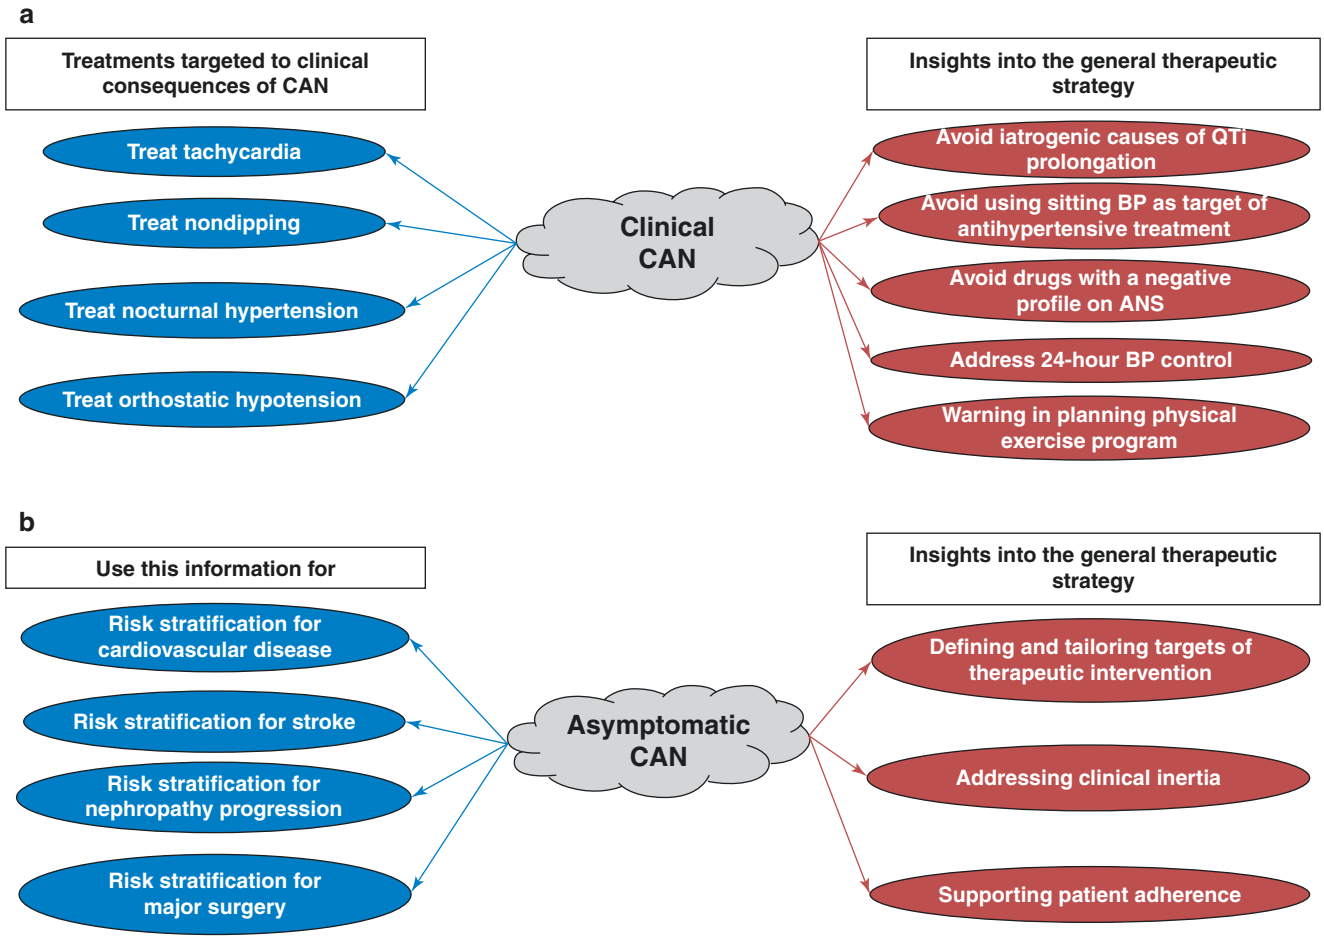

Fig. 57.1 (**a**) Clinical effectiveness of cardiac autonomic neuropathy (CAN) diagnosis in clinical forms of CAN and (**b**) the awareness of CAN for the therapeutic strategy in asymptomatic forms of CAN. *QTi* QT interval, *BP* blood pressure, *ANS* autonomic nervous system. Intensive Glycemic Control and Multifactorial Risk Intervention

Compensation state of T2DM is recognized as a primary goal in the prevention of development and/or progression of CVD [2, 3, 18, 35, 69]. Insulin resistance (IR) is a defining feature in most cases of T2DM and plays a key role in the pathogenesis of myocardial alternations. Obviously, pharmacological agents that are used in the treatment of diabetes should have positive qualities for correction of functional and structural disorders of the cardiovascular system [10, 70]. Theoretically, pharmacological agents that improve insulin sensitivity [metformin, thiazolidinediones (TZD)] appear to be the most appropriate in this regard. It is established that metformin has a positive effect on glucose metabolism; Ca^{2+} concentration in cardiomyocytes, but metformin, unlike TZD, does not show any positive effect on optimization of glucose metabolism in the myocardium [6, 54]. TZD stimulates receptor transcription factors, activated by peroxisome proliferator-activated receptor-γ (PPAR-γ), which improves insulin sensitivity and reduces the level of circulating free fatty acids (FFA). It is likely that TZD, despite the absence of the myocardium PPAR-γ type receptors, improves the functional state of the myocardium by reducing the content of FFA. However, the use of TZD among patients with CVD is limited due to the possibility of fluid retention and/or development of edema [71].

In the Steno 2 study, an intensive multifactorial cardiovascular risk intervention reduced the progression or the development of CAN among T2DM patients with microalbuminuria [72]. However, the beneficial effect of intensive glycemic control on CAN in T2DM has not been specifically proven [14, 19, 73].

Lifestyle Modification

Nutrition and physical activity. Correction of obesity. Limit salt intake to 2–4 g/day. Limit smoking, alcohol, and foods that contain caffeine. It has been established that compliance with recommended lifestyle modifications (exercise, weight loss, etc.) helps improve insulin sensitivity level. Sedentary lifestyle (less than 1000 kcal/week) is accompanied by the risk of mortality three times higher than when living an active lifestyle. Dosed physical activity reduces hyperinsulinemia and encourages the tendency to normalize lipid metabolism in addition to body weight decrease. Physical activity is associated with higher HRV and lower HR, therefore may be a predictor of positive changes in HRV indices [46, 74]. Obtaining the necessary amount of energy combined with physiologic food ration forms the dietary principles. The traditional Mediterranean diet (Greece and Southern Italy) is associated with longevity and/or low mortality due to CVD complications, decrease incidence of T2DM, and low frequency of wide range of chronic diseases, including rheumatoid arthritis, Parkinson's disease, and others [25, 75, 76].

Treatment of Dyslipoproteinemia

For DLP pharmacotherapy using statins, fibrates, bile acid sequestrants, nicotinic acid and its derivatives, products of long-chain ω-3 and ω-6 polyunsaturated fatty acids (PUFA), or as an alternative, their combination with cholesterol absorption inhibitors [54, 77–79].

Statins Statins (along with lifestyle changes) should be prescribed to patients with T2DM aged over 40 where there is at least one of the risk factors for CVD (regardless of basic lipid levels); prescription of statins among patients with T2DM aged under 40 years without diagnosed CVD should be considered when low-density lipoprotein (LDL) cholesterol level exceeds 2.6 mmol/L [78, 80, 81]. Achievement of LDL level in the blood <1.8 mmol/L or reduction by 30–40% compared with initial level (in case of failure to achieve value targets in the course of the prescription of the maximum tolerable dose statin) is suitable for patients at high risk of CVD, particularly patients with T2DM. However, statins are often ineffective when used for treatment of atherogenic DLP as pharmacological agents to achieve reduction in triglycerides (TG) and increase high-density lipoprotein (HDL) cholesterol; statin use (even at high doses) only partially solves the problem of the risk of CVD [80, 82].

Fibrates Fibrates limit the availability of substrates for the synthesis of TG in the liver, encourage lipoprotein lipase effects, increase LDL receptor/ligand interaction, stimulate cholesterol secretion with bile, stimulate reverse cholesterol transport, that is accompanied by reduction of TG and very LDL (VLDL) cholesterol levels, and improve insulin sensitivity. Possible mechanisms that help fibrates improve insulin sensitivity are fibrate binding to receptors that activate PPAR-β enhances fatty acids oxidation in the liver and, consequently, causes increase of insulin sensitivity; fibrates are involved in the regulation of adipokine expression [adiponectin, leptin, tumor necrosis-α (TNF-α), resistin, etc.], accompanied by the increase of insulin sensitivity [83].

Bile acid sequestrants Bile acid sequestrants are safe lipid-lowering medicaments, however often causing gastrointestinal adverse reactions. The second-generation bile acid sequestrants, including colesevelam, bind bile acids with higher affinity and better tolerance. It is used as a supplement to diet therapy and physical activity to reduce the concentration of LDL cholesterol among patients with primary DLP, during monotherapy and/or in combination therapy with statins, and to improve glycemic control among patients with T2DM. In addition, it is important that the bile acid sequestrants reduce the concentration of glucose and HbA_{1c} in the blood (approximately 0.9%) [38, 84] and thus may be useful in the treatment of hypercholesterolemia among patients with T2DM.

Niacin Niacin is the most efficient pharmacological agent for raising HDL cholesterol level and, to a lesser extent, to reduce the concentration of TG and LDL cholesterol. It is reported that the therapeutic effect of prolonged forms of niacin on lipid profile occurs with the medicament intake in the dose range 0.5–2.0 g. A common reason for not using niacin, which significantly affects patient's susception and accurate application, is the problem of "flushing." Current approach to this issue is the use of combined prolonged form of niacin with laropiprant, an inhibitor of prostaglandin D_2 [77].

Long-chain ω-3 PUFAs The use of long-chain ω-3 PUFAs due to their effects on glucose homeostasis and IR (IR reduction in muscle > adipose tissue >> liver) presumably inhibits insulin secretion and delays the development of T2DM) influences the state of lipid metabolism (decrease TG concentrations, presumably increase the concentration of HDL, cholesterol, improve lipid profile among patients with T2DM and DLP), moderately reduces BP, improves endothelial function, reduces the inflammation, and improves antioxidant protection [79, 85–89].

Ezetimibe Ezetimibe is used as a nutrition and exercise supplement to reduce the concentration of LDL cholesterol, total cholesterol (TC), and treatment of homozygous familial hypercholesterolemia. Despite some reservations, ezetimibe remains the medicine of first choice among other pharmacological agents in the absence of target specific level of LDL cholesterol using statin monotherapy [81].

Combined treatment Therapy of first choice for T2DM in case of lipid profile correction is usage of statins to achieve

specific target of LDL cholesterol level <2.6 mmol/L for primary prevention and <1.8 mmol/L for secondary prevention of CVD. Failure to get this target is the indication to combine statins with other lipid-lowering agents of other pharmacological groups. A number of international guidelines as a compulsory component of CVD risk monitoring recommend to control apolipoprotein B level on the first-priority basis [81, 90].

Correction of Metabolic Abnormalities in the Myocardium

Correction of metabolic abnormalities in the myocardium is the basis of pharmacotherapy that aims at optimization of the energy metabolism of the myocardium. Pharmacological impact system includes the following main aspects: use of metabolism regulators; energy-saving solutions; activators of endogenic high-energy compounds and O_2 transportation; inhibitors of metabolic acidosis; membrane's protection (inhibition of lipid peroxidation membranes of cardiomyocytes); and stabilization of lysosomal membranes, neutralization of membranotropic action of humoral agents of lysosomal proteases, and others. Medicaments that enhance cell energy state (means of potential energy supply survival of ischemic myocardium). Deterioration of intracellular reserves of carbohydrates needs to be replenished by use of glycolysis activation measures. The use of macroergic phosphates (ATP, etc.) as a direct energy source is problematic, as the therapeutic effect of ATP in case of ischemia probably has less to do with disposing of its macroergic bonds but more with involving products of catabolism of ATP into energy metabolism of cardiomyocytes [6, 54].

Modulators of metabolism. Insulin resistance affects myocardial function by reducing glucose transportation and oxidation of carbohydrates, enhancing the use of free fatty acids, inhibition of Ca^{2+} transportation in the sarcolemma, violation of the structure, and function of regulatory contractile proteins of myofibrils. In case of DM, the reduction of myocardial energy formation leads to inhibition of glucose oxidation and preferential oxidation of fatty acids in the myocardium and skeletal muscle, which increases sensitivity to myocardial ischemia and leads to significant disturbances of Ca^{2+} homeostasis and deterioration of diastolic and systolic myocardial function. The presence of CAD among patients with diabetes worsens the disease and significantly increases cardiovascular mortality. It is considered that even the initial stages of glycemic profile violations may influence the myocardial metabolism and contribute to the development of cardiomyopathy [91]. It is important that myocardial dysfunction is a suppositive stage of chronic hyperglycemia elaboration. Thus, dysfunction of cells metabolism, rather than systemic hyperglycemia, is the reason for elaboration of cardiac malfunction [54, 76].

Metabolic medicaments. Optimization of myocardial energy metabolism is based on increased myocardial glucose oxidation, which enhances cardiac function and protects myocardial fibers from ischemic and reperfusion injuries. Myocardial use of glucose in case of chronic disease may be improved due to intake of the medicines that can improve fatty acids metabolism and inhibit their oxidation. New therapeutic approach has been implemented after advent of trimetazidine—the first representative of a new class of metabolic agents—inhibitors of 3-ketoacyl coenzyme A thiolase. *Trimetazidine* reduces oxidation of fatty acids; stimulates glucose intake; restores the link between glycolysis and carbohydrate oxidation, which leads to the formation of ATP, reducing O_2 consumption; redirects fatty acids toward phospholipids; and increases cell tolerance to ischemic and reperfusion injuries; increases the oxidation of glucose and the activity of Na^+, K^+-ATPase, and Ca^{2+}-pumps in the sarcoplasmic reticulum. Anti-ischemic properties of trimetazidine do not depend on changes in hemodynamics and are associated with a distinct recovery of mechanical function after ischemia, which makes it recognized as cardyo-cytoprotective agent. Trimetazidine prescription improves glucose metabolism, reduces endothelin-1 among patients with diabetic cardiomyopathy, is accompanied by a significant positive changes in ejection fraction parameters among patients with heart failure, and improves quality of life parameters and NYHA functional class [92]. Another pharmacological agent that facilitates the inhibition of metabolism of fatty acids is *perhexiline.* Perhexiline prescription to patients with heart failure significantly contributes to the improvement of EF, VO_2max, and quality of life. Unfortunately, the clinical use of this medicament is limited because of the risk of hepatotoxicity and peripheral neuropathy [93]. *Ranolazine* is the third antianginal pharmacological agent with a potential of metabolism modificator. However, the following factors do not allow to implement its use: the degree of inhibition of fatty acids metabolism is limited by physiological indicators; ranolazine prescription associates with the possibility of QTi interval prolongation [94].

Limitation of extracellular Ca^{2+} into the cell. Blockers of Ca^{2+}-channels show a protective effect on myocardium in case of ischemia. In terms of correction of cell power, the most pathogenetically efficient option is the use of Ca^{2+} blockers; however they only eliminate secondary dysfunction links of oxidative phosphorylation in mitochondria. Prescription of β-adrenergic receptor blockers for T2DM with CAD and CAN has significant pathogenetic grounds as high sympathetic activity that is followed by CAN, accelerates the development of CVD, and significantly affects prognosis. In addition, several studies demonstrated the ability of β-blockers to reduce the incidence of SMI episodes and improve prognosis among these patients. However, adrenergic receptors and β-blockers negatively affect the

performance of glycemic profile; increase the risk of hypoglycemia, showing a negative effect on blood lipid profile and can provoke acute heart failure. The above-described events occur with prescription of non-selective β-blockers. Selective β-adrenergic receptor blockers, including metoprolol, are free of side effects, including the effectiveness of metoprolol in the treatment of CVD demonstrated in numerous controlled studies. *Metoprolol* has cardioprotective properties; improves prognosis among patients with CAD; and has a fair tolerance in case of prolonged use. Cardioselective β-blockers can also balance the effects of autonomic dysfunction; in particular, by resisting sympathetic stimulation, they can restore parasympathetic–sympathetic balance. However, traditional antianginal agents that affect hemodynamic parameters (β-blockers, Ca^{2+} antagonists, etc.) have lower tolerance among elderly due to the high risk of the interaction of pharmacological agents with a significant incidence of side effects [6, 54].

Total HRV has been shown to be increased and parasympathetic/sympathetic balance improved by angiotensin-converting enzyme (ACE) inhibition in patients with mild autonomic neuropathy through increases in nerve blood flow [52, 66]. Prostaglandin analogs have been shown to be effective through the same mechanism [66, 74]. Cardioselective beta-blockers are considered to have positive effects on autonomic dysfunction. For example, the addition of metoprolol to ramipril therapy in patients with type 1 diabetes resulted in recovery of HRV parameters [11, 95]. Furthermore, bisoprolol improved HRV in heart failure [91]. In a study including individuals with long-term diabetes and diabetic neuropathy, the combination of ACE inhibition and angiotensin-receptor blockade improved autonomic neuropathy [12]. In addition, it was showed that losartan therapy significantly improved HRV in patients with ischemic cardiomyopathy [96]. Similarly, sympathovagal imbalance in heart failure patients was improved following the administration of spironolactone along with enalapril, furosemide, and digoxin [97]. Such evidence reveals that combination therapies appear to provide better results than monotherapies [22, 23].

Medicaments contain micro- and macro-elements, primarily Mg^{2+}. One of the risk factors that can decrease insulin sensitivity is hypomagnesaemia. It is suggested that Mg^{2+} deficiency plays a significant role in increasing the risk of diabetic macro- and microvascular complications and, especially, the risk of CAD [6, 76].

Thrombosis Prevention and Treatment

Platelets obtained from patients with T2DM and tested in vitro are characterized by a real ability to aggregate under the influence of ADP, adrenaline, collagen, arachidonic acid, and thrombin. Aggregation of platelets is significantly increased in the second, irreversible phase, which depends on the transformation of arachidonic acid into labile prostacyclin and thromboxane. Thus, the possibility of ADP receptors of platelet membranes blocking is a pathogenetically justified measure. Prescription of antiplatelet agents, namely acetylsalicylic acid (ASA), clopidogrel, and others, can help prevent blood clots, stenocardia, and development of MI. The active clopidogrel metabolite irreversibly binds to ADP receptor on the platelet membrane, which leads to inhibition of adenylate cyclase, inhibition of ADP-dependent secretion of platelet granules, and inhibition of ADP-dependent process of binding fibrinogen receptor to the platelet membrane, does not affect the expression of receptors directly, blocks myointymal proliferation in case of vascular damage, and unlike ASA does not affect the activity of cyclooxygenase. Effect of clopidogrel and ASA synergy is demonstrated in the study of platelet ex vivo. However, clopidogrel is a more effective pharmacological agent within the frames of the combined risk of MI, stroke, and the syndrome of "sudden death" reduction [54, 98].

Aldose Reductase Inhibitors

*Aldose reductase inhibitors (*ARI) inhibit the *polyol* pathway for *glucose metabolism*, preventing the reduction of the redox potentials. Analysis of the double-blind, placebo-controlled study established that tolrestat contributes to the improvement of independent tests results and vibration sensitivity among patients with symmetric diabetic peripheral neuropathy (DPN). *Zenarestat* prescription for 12 months was accompanied by a dose-dependent change in the spissitude of nerve tissue, increased the velocity of nerve impulses, and improved myocardial systolic function. *Zoporestat and ranirestat*—medicaments of a new generation of ARI group—showed sufficient efficacy in experimental studies [60].

While the use of aldose reductase inhibitors (epalrestat, fidarestat, and AS-3201), which reduce nerve sorbitol, had a positive influence on HRV in patients with mild abnormalities, they were ineffective in advanced CAN patients [54, 66].

Replacement Therapy with the Help of Myoinositol

Several individual clinical trials were conducted for the study of myoinositol efficacy in the treatment of diabetic neuropathy. The results are quite positive; but in the future, clinical double-blind, placebo-controlled trials are needed [99].

Aminoguanidine

Aminoguanidine improves capacity of nerve velocity, increases blood flow, inhibits the formation of advanced glycation end products, and delays the emergence and development of albuminuria. Analysis of controlled trials confirmed quite aminoguanidine high efficiency among patients with diabetic neuropathy, but the development of a number of side effects terminated their application. The use of aminoguanidine derivatives is accompanied by clinical efficacy and lack of adverse side effects [7, 73]. The results are promising, but need further clinical double-blind, placebo-controlled studies.

Neurotrophic Therapy

Inhibition of nerve growth factor (NGF) expression and its receptors suppresses NGF axonal retrograding transport and reduces the activity of small unmyelinated neurons and their neuropeptides, including substance P and gene-linked calcitonin peptide. The use of recombinant human NGF normalizes neuropeptide concentration and prevents the development of sensory neuropathy in the experiment. However, the results of clinical placebo-controlled studies deny the positive impact of recombinant human NGF among patients with diabetic neuropathy [7, 73].

Antineural Autoimmunity Human Immunoglobulin for Intravenous Use

Intravenous human immunoglobulin prescription is recommended for patients with diabetic peripheral neuropathy (DPN), which have signs of antineural autoimmunity symptomes. The side effects include headache, and the main danger could be the development of an anaphylactic reaction; however, it affects mainly patients with deficiency of immunoglobulin A [7, 73].

Endoneural Perfusion Inhibition with the Development of Hypoxia

Experimental and clinical studies have shown benefit in the efficiency of vasodilators when used for improvement of nerve flow velocity, but there is not enough information about the impact of vasodilators on the course of DPN during clinical double-blind placebo-controlled studies. The research results of characteristics that impact the angiotensin-converting enzyme inhibitors on heart rate variability parameters among diabetic patients with CAN appeared to show diametrically opposed results. In particular, prescription of *quinapril* for 3 months was accompanied by statistically significant increased parasympathetic activity, and the use of trandolapril for 12 months did not affect the performance of autonomic myocardial function. However, most of these pharmacological agents have no proven clinical and electrophysiological positive effects and have certain limitations and contraindications [30, 73].

Activation of Free Radical Stress

Considering that one of the major pathogenetic mechanisms of neuropathy is oxidative stress, the need for antioxidants prescription is obvious [100, 101]. Great therapeutic potential is observed in α-lipoic acid (α-LA) and creates pathogenic evidence for the use of this pharmacological agent [100, 101]. Mechanism of α-LA action is not fully developed, but specific attention should be paid to two hypotheses. First, α-LA phenomenon causes dose-dependent proliferation of neuroblastoma cultured cells. Changes in the membrane fluidity that are mediated through sulfhydryl groups α-LA are considered to cause this effect. This is confirmed by the following results of several studies, including experimental neuropathy induced by acrylamide, followed by a significant inhibition of proliferation of the above phenomenon; overlay and/or progression of experimental distal neuropathy, mainly caused by a decrease of content of substances in axons containing sulfhydryl groups (e.g., glutathione); α-LA in vivo and in vitro enhances spontaneous processes of expansion and improvement of the structural and functional nerve terminals membranes state; and prescription of α-LA stimulates the regeneration of nerve terminals in case of the partial denervation, as well as experimental hexacarbon neuropathy. Second, and the most probable mechanism, is the ability of α-LA to function as a radical binder (cleaner) [54, 67, 102].

Vitamins with Antioxidant Properties [a Liposoluble Vitamin B_1 (Benfotiamine)], Combined Medications

There are enough experimental and clinical results of studies that suggest that the hyperinsulinemia, IR, and chronic hyperglycemia in T2DM have a negative impact on the metabolism of thiamine particularly due to the inhibition of the functional state of the thiamine transporter-1 and thiamine transporter-2, responsible for the reabsorption of vitamin in the proximal tubules of the kidneys; and transketolase (TK) activity, which can lead to the congestion of intermediates in the initial stages of glycolysis [glyceraldehyde-3-phosphate (GA3P), fructose-6-phosphate (F6P), and dihydroxyacetone-phosphate]. Congestion of intermediates in case of chronic hyperglycemia increases the production of

free radicals in the mitochondria, followed by inhibition of glyceraldehyde-3-phosphate dehydrogenase (GAPDH). Increased concentrations of GA3P, F6P, and GAPDH can initiate induced hyperglycemia, metabolic fates that favor the overlay of vascular injury, including activation of proteinkinase-C, accumulation of advanced glycation end products (AGEs), hexosamine biosynthetic fates activation, and dicarbonyl compounds. Activation with dicarbonyl compounds is followed by further stimulation of the AGEs formation, which is also associated with functional impaired and structural state of cardiomyocytes [59, 103, 104].

It is clear that the correction of thiamin deficiency must be performed using exogenous vitamin B_1 or benfotiamine (monophosphate S-benzoyl-thiamine, high-bioavailable liposoluble vitamin B_1 derivatives). Results of experimental and clinical studies suggest a positive effect of benfotiamine prescription on prevention of diabetic vascular disease progression. Benfotiamine broad therapeutic potential has a good efficiency on medications containing soluble thiamine derivatives for the purpose of regulating the activity of free radical processes, correction of endothelial dysfunction in case of CVD, and stabilization of clinical and antioxidant effects [105].

Benfotiamine can promote neuronal and vascular deficiency correction through the participation of nitrogen oxide processes, which have a significant therapeutic potential for the treatment of CVD. The use of thiamine and α-LA combination has a great significance in the treatment of diabetic angio-neuropathy. In particular, it demonstrated that prescription of benfotiamine and α-LA to patients with T1DM was followed by normalization of hyperglycemia and for 4 weeks it promoted the normalization of prostacyclin synthase suppressed by diabetes and increase of TK activity in monocytes in two to three times [105–107].

Fatty Acids Metabolism Disorders (γ-Linolenic Acid, Acetyl L-Carnitine)

Vasoactive prostanoids, metabolites and dihomo-γ-linolenic acid (DGLA), including prostaglandins and other eicosanoids, are necessary for the physiological behavior of nerve conductivity and blood flow. The results of double-blind, placebo-controlled studies showed that prescription of DGLA to patients with DPN is followed by positive dynamics in clinical course, as well as increase in the speed of nerve conductivity. L-carnitine's main function is to strengthen the metabolism of fatty acids, but there is experimental evidence of L-carnitine's ability to activate glucose metabolism. It is believed that T2DM is characterized by malfunction of L-carnitine exchange in the mitochondria. The results of several studies showed that prescription of L-carnitine helps to improve energy supplies and LV function. It is established that propionyl-L-carnitine improves the functional status, used as glucose energy oxidation in the rat's affected myocardium (despite the increased level of fatty acids). Nutrition of diabetic mice with obesity with L-carnitine addition increases the level of acyl-carnitine in the blood, muscle, liver, and adipose tissue and increases levels of pyruvate dehydrogenase activity in the muscles; prescription of zinc–carnitine mixture reduces hyperglycemia and improves glucose tolerance. L-carnitine infusion with the help of hyperinsulinemic-euglycemic clamp improves glucose profile control and reduces the concentration of circulating lipids. L-carnitine prescription for 3 or 6 months for newly diagnosed patients with T2DM with lipid metabolism disorders is followed by a statistically significant decrease in lipoprotein(a) [Lp(a)] levels. The results of double-blind, placebo-controlled studies among patients with verified hyperLP(a) established that L-carnitine (2 g/day) encouraged a significant decrease in the concentration of Lp(a) levels; L-carnitine incorporation into nutrition of patients with newly diagnosed T2DM is followed by similar changes; and combined L-carnitine with simvastatin (20 mg/day) treatment is much more efficient in decreasing the concentration of lipids, including TG and Lp(a) than statin monotherapy. Thus, L-carnitine can be used as one of the components for lipid-modifying therapy among patients with T2DM [108, 109].

ω-3 PUFAs Medications

A fundamentally new approach to assessing the biological role of eicosapentaenoic (EPA) and docosahexaenoic acid (DHA) is associated with long-term epidemiological studies results among Inuits, which established a small percentage of CVD. The Greenlandic Inuits were observed to have an increased bleeding duration, lower levels of TC, TG, and VLDL-cholesterol; and a significant increase in TC lipid membranes of EPA and DHA contents, arachidonic acid concentration reduction, and linoleic acid. For the first time, these results allowed to express a reasonable assumption about the protective effect of DHA and especially EPA from the damaging effects on the internal vessel wall capable of inducing experiment CAD—a phenomenon of TC activation—and high blood viscosity, enhanced the cyclic endoperoxide synthase, including prostaglandin H_2, thromboxane A_2 (TXA_2) activation of endothelial cell proliferation, hypercholesterolemia, and hypertriglyceridemia. Prescription of EPA and DHA is followed by a decrease in the "rigidity" of red blood cells, which is obviously associated with labilization of erythrocyte plasmalemma based on rapid and intensive incorporation of long-chain ω-3 PUFAs phospholipids into membrane and decreased synthesis of vasoconstrictor active ingredients [79].

The ability of exogenous EPA and DHA to incorporate phospholipid blood cell membranes and membrane phospholipids of endothelial cells blood vessels affects the fundamental plasmalemma properties and receptor function for the perception and processing of extracellular information. Accumulating long-chain polyenes acids labilizes plasmalemma, changing the microviscosity of its lipid matrix, which causes the transformation of the basic plasmalemma properties: permeability, generation of biopotentials, and ions transit. Changes in the lipid environment of receptor structures affects their functional activity and enzyme systems control in the cell, which primarily relates to the corpuscular adenylate cyclase, whose function is related to the metabolism of phospholipids [87, 110].

Analysis of experimental and clinical studies proves that ω-3 PUFA inhibit the absorption of cholesterol in the intestine and its synthesis in the liver, lead to increased clearance of lipoproteins in the blood, prevent the development of IR in experimental diabetes, decrease level of BP, dose-dependently prevent the development of diabetes, improve the sensitivity of platelets to ADP and collagen, contribute to positive changes in the parameters of coagulation and endothelial cells migration, and inhibit the proliferation of smooth muscle cells. However, the studies aimed to investigate the features of ω-3 PUFA in T2DM are numerically small, and obtained results do not always testify to their effectiveness [88, 89, 111]. In particular, the results of the ORIGIN trial demonstrated that administration of 1 g ω-3 PUFAs did not reduce the rate of death caused by cardiovascular reasons or their outcomes during a period of 6 years among patients with dysglycemia and additional cardiovascular risk factors. In this trial, the dose of ω-3 PUFA was not chosen on the basis of any estimate of its effect on TG levels; nevertheless, a significant reduction in the TG level was shown. However, this study did not apply to treatment of CAN, and it was decided to continue the study for a few more years [85]. In the same time, American Diabetes Association (ADA, 2005) recommended the prescription of α-LA and ω-3 PUFAs in algorithms of DPN treatment [66] and in ADA recommendations (2014) and results of some trials: prescription of ω-3 PUFAs in DLP treatment among patients with T2DM and cardiovascular diseases [1, 88].

Symptomatic Treatment of Orthostatic Hypotension

Orthostatic hypotension syndrome is manifested by dizziness and possibility of loss of consciousness. Hypovolemia and sympathoadrenal disorders are the most common characteristic features among patients with DM and orthostatic hypotension. Orthostatic hypotension among most diabetic patients progresses asymptomatically and, therefore, does not require correction. However, in severe cases, it is key traumatic factor [38, 112].

Treatment of OH is required only when symptomatic with the therapeutic goal to minimize postural symptoms rather than to restore normotension. The first step encompasses non-pharmacological measures with the attempt to (1) identify other causes of OH, e.g., volume depletion, and avoid, when possible, drugs exacerbating postural symptoms, such as psychotropic drugs, diuretics, and α-adrenoreceptor antagonists; (2) educate patients regarding behavioral strategies such as gradual staged movements with postural change, mild isotonic exercise, head-up bed position during sleep, physical counter-maneuvres (e.g., leg-crossing, stooping, squatting, and tensing muscles), use of portable folding chairs, increased fluid and salt intake if not contraindicated, drinking water rapidly, and avoidance of large meals rich in carbohydrates; and (3) use of elastic garment over the legs and abdomen. If symptoms persist despite these measures, a pharmacological treatment should be considered [38].

Treatment of symptomatic postural hypotension among patients with CAN is very complicated because of the need to achieve a balance between changes in BP in the vertical and horizontal position. The increase of peripheral venous inflow is achieved through the use of elastic tightening body linen. It is inappropriate to prescribe psychotropic and diuretic drugs and eliminate the possibility of electrolyte disorders and/or reduce the fluid volume [38].

The peripheral selective α_1-adrenergic agonist *midodrine* is a first-line drug that exerts a pressor effect through both arteriolar constriction and venoconstriction of the capacitance vessels. The dosing should be individually tailored (up to two to four times 10 mg/day, with the first dose taken before arising and use avoided several hours before planned recumbency particularly in patients with documented supine hypertension). Adverse events are pilomotor reactions, pruritus, supine hypertension, bradycardia, gastrointestinal symptoms, and urinary retention. *Midodrine* is the only medication approved by the Food and Drug Administration for the treatment of symptomatic orthostatic hypotension [38].

The *9-α-fluorohydrocortisone* is first-choice drug that acts through sodium retention, a direct constricting effect on partially denervated vessels, and an increase in the water content of the vessel wall leading to a reduced distensibility. Possible adverse effects include supine hypertension, hypokalemia, congestive heart failure, and peripheral edema. The initial dose should be 0.05–0.1 mg daily with individual titration to 0.1–0.3 mg daily [38, 112].

Erythropoietin was proposed to increase standing blood pressure via several mechanisms: (1) increasing red cell mass and central blood volume, (2) correcting the anemia frequently associated with severe CAN, and (3) neurohumoral effects on the vascular wall and vascular tone regulation. It can be administered in diabetic patients with hemoglobin levels under 11 g/dL subcutaneously or intravenously at doses between 25 and 75 U/kg three times/week with an hemoglobin target of 12 g/dL followed by lower maintenance doses [38, 112].

Other possible treatments include (1) *desmopressin acetate*, a vasopressin analogue useful to correct nocturnal polyuria and morning orthostatic hypotension; (2) *somatostatin analogues* aimed at inhibiting the release of vasoactive gastrointestinal peptides, enhancing cardiac output, and increasing forearm and splanchnic vascular resistance, with severe cases of hypertension as possible adverse events in diabetic patients; (3) *caffeine* and (4) *acarbose*, both useful in attenuating postprandial hypotension in autonomic failure [38, 112, 113].

While pharmacological treatments, such as midodrine, clonidine, octreotide, fludrocortisone acetate, erythropoietin, nonselective beta-blockers and pyridostigmine bromide appear promising, all have mild to severe side effects, including hypertension [22, 35].

New Glucose-Lowering Medications and Autonomic Nervous System

Sodium Glucose Transporter 2 Inhibitors (SGLT2i)

It would be of interest to understand whether some of the positive effects on the cardiovascular system of these drugs are mediated by interaction with the autonomic nervous system in the kidney or directly in the central nervous system. However, clinical trials with SGLT2i using ABPM do not confirm to a preferential lowering effect on nocturnal versus daytime systolic BP, despite the diuretic and natriuretic effect of these drugs and the dipping restoration found with SGLT2i in rat models of obesity and metabolic syndrome [14, 114].

Glucagon-like Peptide 1 Receptor Agonists (GLP1-RA)

Experimental findings in mice and rats document that the central and peripheral administration of a glucagon-like peptide 1 receptor agonist (GLP1-RA) increased heart rate, reduced frequency-domain indices of HRV, and increased sympathetic activity [14, 115].

However, it should be noted that the GLP1-RA effects on heart rate and the autonomic nervous system need to be reconciled with the favorable cardiovascular outcomes in clinical trials of at least some GLP1-RAs (liraglutide, semaglutide, exenatide ER) [14].

The Toronto Consensus Panel on Diabetic Neuropathy concluded the following in relation to CAN treatment [38]:

- Intensive diabetes therapy retards the development of CAN in T1DM (level A).
- Intensive multifactorial cardiovascular risk intervention retards the development and progression of CAN in T2DM (level B).
- Lifestyle intervention might improve HRV in prediabetes (level B) and diabetes (level B).
- Symptomatic orthostatic hypotension might be improved by non-pharmacological measures (level B) and by midodrine (level A) and/or fludrocortisone (level B).

The recommendations from the Toronto Consensus Panel on Diabetic Neuropathy are as follows:

Diabetes therapy in patients with type 1 and type 2 diabetes should consider the individual risk profile and comorbidities (class I).

Lifestyle intervention should be offered as a basic preventive measure (class I).

Given the limited evidence from very few large-scale randomized clinical trials, recommendations cannot be given for pharmacological and non-pharmacological treatments of CAN.

Drugs that might reduce HRV should be avoided in patients with CAN (class III).

Resting tachycardia associated with CAN can be treated with cardioselective beta-blockers (class I).

The first therapeutic approach in symptomatic orthostatic hypotension should consider the exclusion of drugs exacerbating orthostatic hypotension, correction of volume depletion (class I), and other non-pharmacological measures (class IIa).

Pharmacotherapy of symptomatic orthostatic hypotension should include midodrine (class I) or fludrocortisones or a combination of both in non responders to monotherapy (class IIa).

Because of the limited evidence, the potential risk of any pharmacological treatment should be thoroughly weighed against its possible benefit (class I).

CARTs should be used as end points in prospective observational and clinical trials.

Concluding Remarks

Cardiac autonomic neuropathy is a serious complication of diabetes mellitus that is strongly associated with increased risk of cardiovascular mortality.

Screening for CAN must be performed to asymptomatic patients with type 2 diabetes at diagnosis and type 1 diabetic patients after 5 years of disease, in particular those (but not only) at greater risk for CAN.

Diagnosis of CAN is based on the use of CARTs, which are considered as the gold standard for clinical autonomic testing: the presence of one abnormal cardiovagal test result identifies the condition of possible or early CAN, to be confirmed over time; (2) at least two abnormal cardiovagal results are required for a definite or confirmed diagnosis of CAN; and (3) the presence of OH in addition to HR test abnormalities identifies severe or advanced CAN.

Lifestyle intervention is a basic preventive measure and may improve HRV. Intensive diabetes therapy retards the development of CAN in type 1 diabetes and intensive multifactorial cardiovascular risk intervention retards the development and progression of CAN in type 2 diabetes. Resting tachycardia by CAN can be treated with cardioselective β-blockers. Pharmacotherapy of symptomatic orthostatic hypotension should include midodrine or fludrocortisone or a combination of both in nonresponders to monotherapy.

The promising methods include research and use of tools that increase blood flow through the vasa vasorum, including butaprost (prostacyclin analogue), TXA_2 blockers, and drugs that contribute into strengthening and/or normalization of Na^+, K^+-ATPase (cilostazol, a potential phosphodiesterase inhibitor), α-LA, DGLA, and ω-3 PUFAs and the simultaneous prescription of α-LA, ω-3 PUFAs, and DGLA [8, 20, 30, 67, 95]. In addition, the combination of α-LA, ω-3 PUFAs, DGLA, and ARI is the most rational pathogenetically justified use.

Multiple Choice Questions

1. At what timepoint screening for CAN must be performed?
   (a) Asymptomatic patients with T2DM at diagnosis and patient with T1DM after 5 years of disease.
   (b) Asymptomatic patients with T2DM after 5 years of disease and type 1 diabetic patients at diagnosis.
   (c) Only patients with clinical signs of CAN.
   (d) Only patients with the history of poor glycemic control.
   (e) Screening for CAN shouldn't be performed.
2. Which risk factors are known for the development of CAN?
   (a) Diabetes duration.
   (b) Poor glycemic control.
   (c) Microvascular complications.
   (d) Combination of hypertension, dyslipidemia and obesity.
   (e) All listed above.
3. What method is considered as a gold standard for CAN diagnosis?
   (a) CARTs.
   (b) Orthostatic hypotension.
   (c) QTc prolongation on ECG.
   (d) Reverse dipping on ABPM.
   (e) Resting tachycardia by physical assessment.
4. What result based on the use of CARTs could confirm definite CAN?
   (a) At least two abnormal results of cardiovascular tests/or two for borderline, and three for definite.
   (b) At least three abnormal results of cardiovascular tests/or three for borderline, and four for definite.
   (c) At least one abnormal result of cardiovascular tests/or two for borderline.
   (d) At least four abnormal results of cardiovascular tests.
   (e) Orthostatic hypotension.
5. What signs are needed to undergo CAN testing?
   (a) Orthostatic hypotension.
   (b) Resting tachycardia.
   (c) QTc prolongation.
   (d) Reverse dipping by ABPMA.
   (e) All of above.
6. List a definition that is true for CAN management and prevention.
   (a) Lifestyle intervention is a basic preventive measure.
   (b) Resting tachycardia can be treated with cardioselective β-blockers.
   (c) Intensive diabetes therapy retards the development of CAN in type 1 diabetes mellitus, and intensive multifactorial cardiovascular risk intervention retards the development and progression of CAN in type 2 diabetes.
   (d) Symptomatic orthostatic hypotension should be treated with midodrine or fludrocortisone or a combination of both in nonresponders to monotherapy.
   (e) All answers are correct.
7. Patient complains (suffers) from tachycardia and exercise intolerance. After examination anemia was diagnosed. Despite this, patient was directed to CAN testing, and CARTs were performed. Results: the deep breathing test-borderline, all others normal. Check the correct answer.

(a) Possible early CAN.
(b) Definite confirmed CAN.
(c) Severe advanced CAN.
(d) Symptomatic CAN.
(e) Insufficient information for CAN diagnosis.

8. By performing the screening of orthostatic symptoms to asymptomatic type 2 diabetic patient, a fall in systolic blood pressure of 30 mmHg and diastolic of 11 mmHg was found. The patient didn't have any other specific conditions that could lead to orthostatic hypotension. Patient was referred for CAN screening and CARTs were performed: three heart rate test abnormalities were found. What stage of CAN patient suffers from?
   (a) Possible early CAN.
   (b) Definite confirmed CAN.
   (c) Severe advanced CAN.
   (d) Symptomatic CAN.
   (e) CAN is excluded.
9. Patient with newly diagnosed type 2 diabetes mellitus and arterial hypertension had undergone ABPM test. It is also known that patient suffers from obesity and dyslipidemia. The results had shown the presence of reverse dipping. Should this patient be referred for CAN testing?
   (a) Of course patient should be referred.
   (b) CAN testing is inappropriate.
   (c) Yes, he should but in 5 years.
   (d) Just if he has clinical signs of CAN.
   (e) Yes, but after the normalization of blood pressure profile.
10. Which drugs should include pharmacotherapy of symptomatic orthostatic hypotension by CAN?
   (a) Midodrine and/or fludrocortisone.
   (b) Erythropoetin.
   (c) Desmopressin acetate.
   (d) Somatostatin analogues.
   (e) Nonselective β-blockers.

Correct Answers

1. (a) Asymptomatic patients with T2DM at diagnosis and patient with T1DM after 5 years of disease

   According to the Consensus of the CAN Subcommittee of the Toronto Consensus Panel on Diabetic Neuropathy, screening for CAN must be performed to asymptomatic patients with type 2 diabetes at diagnosis and type 1 diabetic patients after 5 years of disease, in particular those (but not only) at greater risk for CAN (level B). Screening for CAN may be also required for preoperative risk assessment before major surgical procedure (level C).
2. (e) All listed above

Risk markers for CAN are age, diabetes duration, poor glycemic control, microvascular complications (nephropathy, peripheral polyneuropathy, retinopathy), hypertension, and dyslipidemia (classes I and II). For type 1 diabetic patients, the established risk factors for CAN development is poor glycemic control (class I), and for type 2 is the combination of hypertension, dyslipidemia, obesity, and poor glycemic control (class II).

3. (a) CARTs

   Resting tachycardia may reflect diabetic autonomic dysfunction, but it also can reflect sympathetic hyperactivity and/or vagal impairment by some cardiovascular diseases, low physical activity, anemia, and other conditions. Orthostatic hypotension suggests advanced CAN that should be confirmed by CARTs (class I) but after exclusion of other pathophysiological conditions (hypovolemia, deconditioning, influence of some drugs). QTc could be prolonged due to imbalance in cardiac sympathetic innervation, intrinsic metabolic and electrolytic changes, CAD, and genetic factors. Non-dipping and reverse dipping patterns are associated with CAN, as by this conditions, vagal activity is impaired with sympathetic predominance during the night and disrupted circadian variation. So resting heart rate is not a specific sign of CAN (class IV), orthostatic hypotension (class III), QTc prolongation (class II), and reverse dipping on ABPM (class III) are specific but insensitive indices for CAN and requires CAN testing. Diagnosis of CAN is based on the use of CARTs, which are considered as the gold standard for clinical autonomic testing: heart rate response to deep breathing (standing), Valsalva maneuver, blood pressure response to standing (class II, level A).
4. (a) At least two abnormal results of cardiovascular tests/or two for borderline and three for definite

   According to the Consensus of the CAN Subcommittee of the Toronto Consensus Panel on Diabetic Neuropathy, for the definite or confirmed diagnosis of CAN is required the presence of at least two abnormal cardiovagal test results/or two for borderline, three for definite.
5. (e) All above

   According to the Consensus of the CAN Subcommittee of the Toronto Consensus Panel on Diabetic Neuropathy, all of the listened above clinical findings can alert on the presence of CAN. Especially, orthostatic hypotension suggests an advanced CAN that should be confirmed by CARTs (class I); resting tachycardia is not a specific sign of CAN (class IV), but patients with unexplained tachycardia should undergo CAN testing (level C). Qtc prolongation (class II) alone, as a reverse dipping on ABPM (class III) are an insufficient measure of CAN, but should be sign to referral for CAN testing (level B and C accordingly).
6. (e) All answers are correct

   According to the existing data, all definitions are correct. Lifestyle intervention is a basic preventive measure

(class I) and may improve HRV (level B). Resting tachycardia by CAN can be treated with cardioselective β-blockers (class I). Intensive diabetes therapy retards the development of CAN in type 1 diabetes (level A) and intensive multifactorial cardiovascular risk intervention retards the development and progression of CAN in type 2 diabetes (level B). Pharmacotherapy of symptomatic orthostatic hypotension should include midodrine (class I, level A) or fludrocortisone (level B) or a combination of both in non-responders to monotherapy (class II A).

7. (e) Insufficient information for CAN diagnosis

   Patient complaints could be explained by anemia. The presence of one abnormal cardiovagal test result identifies the condition of possible or early CAN that should be confirmed over time (level B). As the result was on borderline it is insufficient for CAN diagnosis. So, patient should undergo CAN testing after treatment of anemia.

8. (c) Severe advances CAN

   According to the Consensus of the CAN Subcommittee of the Toronto Consensus Panel on Diabetic Neuropathy, after exclusion of other causes, orthostatic hypotension suggests an advanced CAN that should be confirmed by CARTs (class I); the presence of orthostatic hypotension in addition to abnormal heart rate test (two or more) identifies severe or advanced CAN.

9. (a) Of course patient should be referred

   This patient should be referred to CAN diagnostic tests. There are several reasons to perform screening for CAN: (1) he has established risk factors for CAN development, combination of hypertension, dyslipidemia, and obesity in type 2 diabetes mellitus (class II); (2) diabetes mellitus type 2 is newly diagnosed (level B); and (3) In the presence of reverse dipping referral for CAN testing is advisable (level C).

10. (a) Midodrine and/or fludrocortisone.

    Pharmacotherapy of symptomatic orthostatic hypotension should include midodrine (class I) or fludrocortisones or a combination of both in nonresponders to monotherapy (class IIa).

    The first-line medication by orthostatic hypotension is the peripheral selective α_1-adrenergetic agonist midodrine (class I, level A). The dosing regimen should be individually tailored (the usual starting dose is 2.5 mg three times daily, most patients are controlled at or below 30 mg per day given in three or four (up to six) divided doses, but a total daily dose of 30 mg should not be exceeded. Fludrocortisone could be the first-choice drug that acts through sodium retention, a direct constricting effect on partially denervated vessels and an increase in the water content of the vessel wall leading to a reduced distensibility. In nonresponders to monotherapy, the combination of midodrine and fludrocortisone should be prescribed.

Glossary

Cardiac autonomic neuropathy Cardiac autonomic neuropathy chronic complication of diabetes mellitus is defined as the impairment of autonomic control of the cardiovascular system in the setting of diabetes after exclusion of other causes and is usually documented by using several cardiovascular autonomic reflex tests.

Cardiovascular autonomic reflex tests Cardiovascular autonomic reflex tests these tests are considered the gold standard in autonomic testing. Heart rate variations during deep breathing, Valsalva maneuver, and lying-to-standing (HR tests) are indices mainly of parasympathetic function; whereas the orthostatic hypotension, the blood pressure response to a Valsalva maneuver, and sustained isometric muscular strain provide indices of sympathetic function.

Orthostatic hypotension Orthostatic hypotension is defined as a fall in BP (i.e., >20 mmHg or more stringent criteria is >30 mmHg for systolic or >10 mmHg for diastolic BP) in response to postural change, from supine to standing.

Non-dipping status Non-dipping status a fall in average sleeping blood pressure <10% from baseline.

Reverse dipping Reverse dipping nocturnal hypertension.

Autonomic Visceral Neuropathy and Gastrointestinal Disorders

58

Anne Mohr Drewes, Christina Brock, and Asbjørn Mohr Drewes

Chapter Objectives

- The autonomic nervous system consists of the enteric, parasympathetic, and sympathetic nerve systems. In the early stages of autonomic neuropathy, the vagal nerve seems to be the most vulnerable consequently compromising its function.
- Autonomic neuropathy is one of the most burdensome symptoms in patients with diabetes mellitus. It is, however, frequently under-diagnosed.
- In patients with longstanding diabetes, up to 40% suffer from gastrointestinal symptoms.
- Symptoms induced by visceral neuropathy cover the entire gastrointestinal tract and includes nausea and vomiting, bloating, early satiety, diarrhoea, and constipation.
- Both hyperglycaemic and hypoglycaemic episodes coalesce to form a cumulative indirect cascade which initiates and maintains neuro-inflammation in diabetic autonomic neuropathy.

Introduction

The brain–gut axis is a bidirectional nexus of the sensory input from the gastrointestinal (GI) tract and efferent pathways, which is involved in secretion of digestive hormones, homeostatic regulation, and gut motility. This axis comprises among other the autonomic nervous system (ANS), comprising the enteric nervous system (ENS), parasympathetic and sympathetic branches, which have a delicate regulatory interaction. Therefore, the ANS has an essential role, and any dysfunction leads to impaired mediation of visceral regulation. Consequently, damage to the ANS such as development of diabetic autonomic neuropathy (DAN) is one of the most burdensome complications to diabetes, yet frequently underdiagnosed. These complications cause symptoms in the GI tract such as nausea, vomiting, diarrhoea, and constipation, see Fig. 58.1. It is difficult to diagnose DAN, but it may be defined as impaired functions of the involved nerves controlling the involuntary body functions such as the cardiovascular, urinary, pulmonary, and digestive systems [1]. Cardiac autonomic neuropathy is a measureable impaired regulation of the heart function, leading to dysrhythmias, such as atrial fibrillation, tachycardia, and even cardiac arrest [2]. Patients with cardiac autonomic neuropathy develop an impaired adaptability of the heart rate, assessed as reduced heart rate variability [3], see Chap. 59 for further elaboration. In this chapter, we focus on autonomic gastrointestinal neuropathy in patients with diabetes, explaining the underlying pathophysiology and the symptomatology in the GI tract.

Diabetic autonomic neuropathy could be defined as impaired functions of nerves controlling involuntary body functions.

Neuropathy in Diabetes Mellitus

Neuropathy can objectively be demonstrated in 40–50% of who are diagnosed with diabetes for >20 years [4]. Recent research found evidence that in patients with long-term type 1 diabetes and polyneuropathies, there was prolonged neuronal transmission and altered neuronal brain responses at all levels of the neuraxis. The increased central conduction time was associated with diminished parasympathetic tone. This confirms that diabetes induced neuronal impairment at all levels, involving autonomic, central, and peripheral nerves [5]. It has been shown that structural changes in endoneuronal capillary morphology and vascular reactivity exist prior to neuropathy in patients with type 2 diabetes [6]. Furthermore, such endoneuronal hypoxia was associated with reductions in nerve conduction velocities. The pathophysiology underlying these findings is however complex and multifactorial and includes neuronal changes within Schwann cells, axons, and the microvascular compartment [7]. In addition, several biochemical mechanisms triggered by hyperglycaemia or hypoglycaemia also leads to neuropathy, which will be elaborated in this chapter, see Fig. 58.2.

The ENS innervates the gastrointestinal tract, gallbladder, and pancreas with motorneurons, sensory neurons, and interneurons. ENS controls the fluid transport between the gut and its lumen, local blood flow, as well as the gut motility. These functions are maintained as the ENS receive and integrate the incoming information leading to efferent transmission, which regulate the digestive system from the brainstem. Thus, there is a close connection to the central nervous system (CNS) in order to balance physiological demands. Due to the enormous amount of neurones that correspond closely to the number in CNS, the ENS is recognized as the second brain [8, 9]. All these neurones and their interconnections are vulnerable to DAN [10].

The neuronal tissue in the brain might undergo changes as well [11, 12]. Animals where diabetes has been induced showed changes in the CNS. Furthermore, functional brain imaging and electroencephalographic recordings in patients with diabetes confirm functional and structural brain changes [3]. The imaging studies demonstrated mainly microstructural changes in brain areas involved in visceral sensory processing in patients with diabetes and GI symptoms. The encephalographic studies indicated that altered insular processing of sensory stimuli could be the key player in symptom generation. In particular, one study found that the deeper the insular electrical source was located, the more GI symptoms the patients experienced [13]. Another study found that GI symptoms and beat-to-beat interval (as a proxi of autonomic tone) were correlated to reorganization in the opercular cortex. Furthermore, the shift in operculo-cingulate networks was related to decreased quality of life in the patients [14]. These studies with electroencephalography were often conducted in combination with quantitative sensory testing and mostly it was found that stimulation of the GI organs induced hyposensitivity. This is in line with patients suffering from somatic diabetic neuropathy where pain and other sensations typically are associated with hypo-

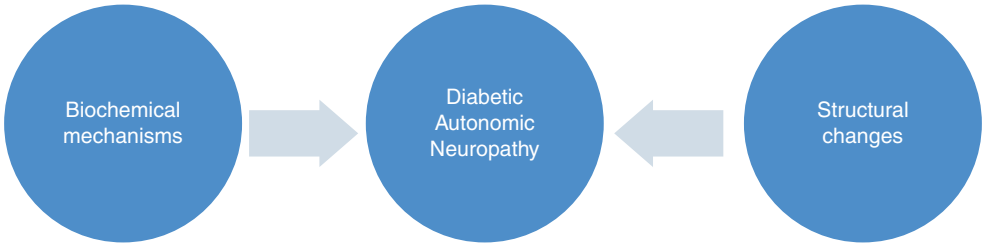

Fig. 58.2 Structural changes and biochemical mechanism triggered by hyperglycaemia or hypoglycaemia may induce visceral neuropathy

algesia to stimulation of the skin. The imaging findings and electrophysiological changes within the brain were associated with GI symptoms in patients with diabetes, therefore they might represent a biomarker for disease severity and hence be a new therapeutic target for neuromodulation or pharmacological therapy [3]. In Fig. 58.3, a conceptual model illustrating the different nerve pathways that may contribute to the GI symptoms in DM is shown.

In the early stages of DAN, alterations in the ENS are masked and difficult to detect. However, the vagal nerve due to its length and widespread appearance is most vulnerable to impaired function, and thus most work regarding DAN characterizes the vagal function [15]. The vagal nerve is the longest of the cranial nerves, and among other functions, it transmits signals from the gut wall receptors, sensitive to chemical and mechanical stimuli, controlling gut motility, secretion, and feeding behaviour [16]. Patients with diabetes and GI symptoms experience gastric retention and a delay in transit with segmentation of barium column within the small intestine, which was similar to changes found in patients with vagotomy [17, 18]. It has been shown in animal studies that the presence of glucose-responsive neurons have been identified in the CNS which may alter the vagal efferent activity [18]. Therefore, the systemic changes in blood glucose experienced in both hyper- and hypoglycaemic episodes might have a direct effect on the parasympathetic tone. Increased blood glucose level increases the level of oxidative stress and pro-inflammatory cytokines involved in neuroinflammation. Recent studies have shown that both electrical and pharmacological stimulation of the vagal nerve reduces the level of pro-inflammatory cytokines in both healthy, experimental inflammatory and auto-immune diseases [19, 20]. Hence, enhanced vagal tone might activate the cholinergic anti-inflammatory reflex and may have the potential to modulate the immune system [21, 22]. Therefore, it is plausible that enhanced vagal activity might have a protective function on diabetes-induced neuroinflammation. Taken together, the multifaceted mechanisms linked to ENS and ANS explain the variety of symptoms underlying DAN [23].

In experimental models of diabetes, reduced levels of neurotrophic support, including insulin-like growth factor and nerve growth factor, have been found. These findings have implicated reduced endoneuronal blood flow and thereby causing neuronal damage. The consequence of such

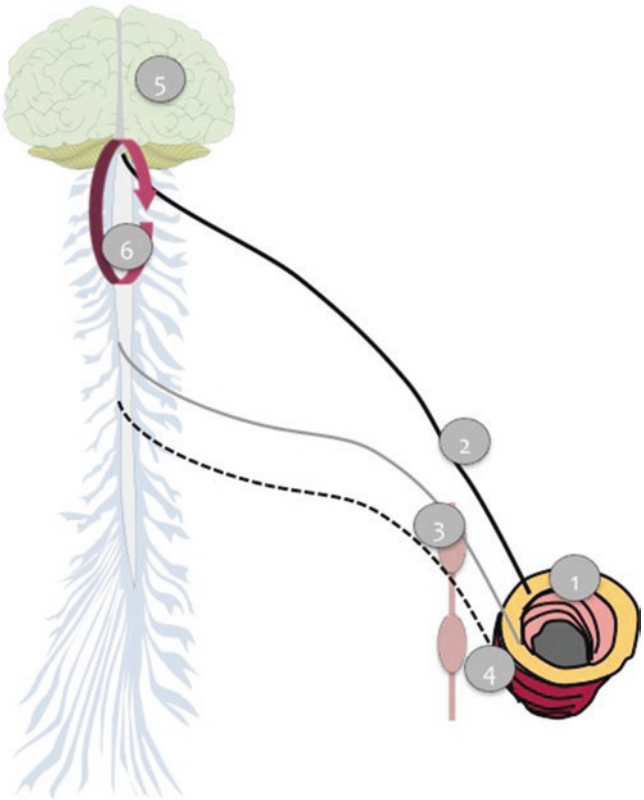

Fig. 58.3 Nerve pathways and mechanisms that may contribute to gastrointestinal symptoms in patients with diabetes mellitus: (1) Biochemical, vascular and degenerative changes in the enteric nervous system; Autonomic neuropathy that may affect (2) the vagal nerve (black line) and (3) sympathetic pathways (grey line) and indirectly modulate sensations from the gut; (4) Affection of visceral (and somatic in case the peritoneum is involved) afferents (dotted line) mediating sensations such as pain; (5) Structural and functional changes in the brain (and spinal cord), together with (6) affection of spino-bulbo-spinal loops

impairment in blood flow also leads to alteration of the nitric oxide metabolism and the Na^+/K^+ ATP-ase activity [24]. Furthermore, animal studies indicated that a changed Na+/K+ pump function may occur as a result of C-peptide deficiency. This may cause shunting glucose through the polyol pathway leading to increased levels of sorbitol and alteration of nerve excitability recovery cycle, which ultimately leads to neuronal damage [25, 26]. A last mechanism to mention is nerve damage through complement activation, as it has been reported in several peripheral neuropathies [27, 28]. A study

on chronic peripheral neuropathy in children found a cell surface deficiency of the protein CD59, which is a complement regulatory protein. Furthermore, sural nerve biopsies from patients with diabetes have shown presence of activated complement proteins and membrane attack complex neoantigen [27]. Complement activation might be a potential new area to investigate when explaining autonomic neuropathy.

The Hyperglycaemia Hypothesis

Consequences of hyperglycaemia are increased intracellular glucose level and cellular toxicity. This glucotoxicity alters cell function in different ways causing increased level of diacylglycerol (which in turn activates protein kinase C) and synthesis of polyols and hexosamines that accumulate intracellularly [29–31]. These metabolic pathways are summarized in Fig. 58.4 and is shortly explained in the following:

A minor branch of glycolysis is the hexosamine biosynthesis pathway, where fructose-6-phosphate converts to glucosamine-6-phosphate, which is a rate-limited enzyme. Hexosamine accumulate intracellular causing oxidative stress. Second, another intracellular metabolic pathway is the polyol. When the polyol pathway is activated, it may cause reduction of Na^+/K^+ -ATPase activity and osmotic damage and intracellular oxidative stress [32]. Third, increase in diacylglycerol and protein kinase C pathways is believed to increase the activity of cytosolic phospholipase A2 and produce prostaglandin E_2, as well as other pro-inflammatory mediators, which inhibit cellular (Na^+/K^+) ATPase [33, 34].

The exact mechanism by which these pathways lead to altered cell function is not fully understood, but taken together they coalesce to induce oxidative stress [35]. In the mitochondria, levels of free radicals, such as nitrogen species and superoxide rise. However, the ability to gather free radicals is reduced because of a reduction of the proton donor nicotinamide-adenine-dinucleotide [30]. Additionally, this mechanism may activate an enzyme, poly(ADP-ribose) polymerase, of great importance to deoxyribonucleic acid repair, and this activation may cause break-up of the deoxyribonucleic acid strands. The consequence of this mechanism is critically level of adenosine triphosphate in, e.g. Schwann cells, possibly leading to neuronal death [34].

When superoxide level rises, an inhibition of the key enzyme in glycolysis (glyceraldehyde-3-phosphate dehydrogenase) is manifest, resulting in enhanced activity in the involved biochemical pathways including further production of polyols, hexosamines, poly(ADP-ribose) polymerase, and advanced glycation end products, and thereby closing the loop of a vicious cycle [35]. For further reading, the following references are recommended: [36–38].

It has been found that the hyperglycaemia theory may be more valid for patients with type 1 than type 2 diabetes. Additionally, a Cochrane review found that improved glucose control prolongs the onset of peripheral sensorimotor neuropathy in type 1 DM, whereas it only had a modest, non-significant relative risk reduction in patients with type 2 DM after a follow-up period of 4 years. Contrarily, when the follow-up period was 15 years for the same cohort, the effect of increased glucose control showed significant risk reduction [39–41]. Even though these studies were conducted on peripheral axons, similar mechanisms are likely present in other nerve tissues, such as the ANS.

Finally the formation of advanced glycation end-products contribute to the intracellular non-enzymatic glycation of proteins, in which the extracellular matrix interacts with various receptors and possibly leads to pro-inflammatory gene expression that further amplifies the process [38].

The Influence of Severe Hypoglycaemia

Prolonged and severe hypoglycaemia may result in increased release of excitatory amino acids, which may cause uncontrolled triggering calcium influx. This again activates proteolytic enzymes that are known to cause neuronal damage [41]. Furthermore, hypoglycaemic levels of glucose may be counter-regulated through hormones inducing an acute rise in blood viscosity and haematocrit levels, which influences capillary blood flow especially when structural changes of the metabolic pathways and vessel of the neurons are already present [42].

Taken together, the biochemical pathways induced by hyperglycaemia and consequences of hypoglycaemia coalesce to form a cumulative indirect cascade that can initiate and summate neuro-inflammation, as is observed in DAN.

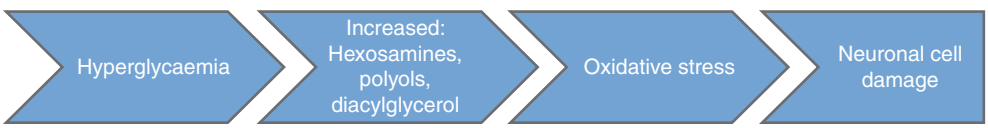

Fig. 58.4 Hyperglycaemia induces an increased level of hexosamines, polyols, and diacylglycerol within the cell, which may cause oxidative stress inducing cell damage

Gastrointestinal Disorders in Patients with Diabetes

Diabetic neuropathy may induce gastrointestinal symptoms, which will be elaborated in the following section (see Table 58.1). In several studies, patients with diabetes have reported more symptoms originating from the GI tract in comparison to people without diabetes [43–45]. Up to 20% of patients with diabetes have diarrhoea and up to 60% suffered from constipation [17, 44]. One study reported that long-term type 1 DM was accompanied by increased frequency of upper GI symptoms [46, 47]. On the other hand, another study found the prevalence of upper gastrointestinal symptoms, abdominal pain, and constipation was not significantly increased [48]. The prevalence of these symptoms varied which could have different explanations. However, due to lack of consensus, the assessment of GI symptoms varies, and thus to ensure consistency between study sites, it has been suggested to use the Diabetes Bowel Symptom Questionnaire in future epidemiological and clinical studies [49]. These disorders are difficult to treat which is why a multidisciplinary team including gastroenterologists, diabetologists, nurses, dieticians, surgeons, psychologist, and other health professionals should work together to help the patient. One main goal should be to prevent further progression by tight glycaemic control and then to ease symptoms which will be elaborated briefly in the following sections [50].

Gastrointestinal Reflux Disease

Patients with diabetes often suffer from nausea and vomiting [51]. One reason may be autonomic neuropathy-induced gastro-oesophageal reflux disease (GORD), where gastric content into the oesophagus causing complications or symptoms. Symptoms include heartburn and regurgitation. Clinical findings in GORD may also include laryngitis, chronic cough, and bronchospasm [52]. GORD could be seen in patients with DAN due to a hyperglycaemia-induced lower oesophageal sphincter pressure and increased amount of transient lower oesophageal sphincter relaxations. Furthermore, studies report that impaired relaxation of the gastric fundus might cause early satiety and dyspeptic symptoms that also influence the symptom pattern in GORD [53].

Table 58.1 Possible diabetic neuropathy-induced gastrointestinal symptoms

Diabetic neuropathy-induced symptoms
Nausea
Vomiting
Reflux
Gastroparesis
Bloating
Constipation
Diarrhoea

Patients experiencing reflux should in many cases undergo endoscopy possibly accompanied by biopsy. Acidic and non-acidic content in the oesophagus can be assessed with pH impedance monitoring, and the swallowing and sphincter functions can be investigated with oesophageal high-resolution manometry, which is especially relevant in diabetic patients where neuropathy is suspected.

Reflux treatment is individual and determined by severity and progress. First, it is important to avoid provoking factors such as large meals, coffee, and alcohol. Symptoms caused by reflux can be treated with proton-pump inhibitors, but occasionally antacids, H_2 blockers, or foaming agents are used. However, symptoms such as nausea and vomiting are mainly controlled from the brain; therefore, it is mandatory to consider dysfunction of the CNS when other causes are ruled out [3]. It is expected that the alterations in the CNS system persist even long after the primary cause (if any) is ruled out.

Gastroparesis

The most common cause of gastroparesis is diabetes, and of all cases of gastroparesis, about one-third originates from diabetes-induced gastroparesis [54, 55]. The cumulative incidence for gastroparesis is approximately 5% for patients with type 1 DM and 1% for type 2 DM [56]. Even though gastroparesis proceeds the presence of delayed gastric emptying, most research have focused on this topic, as it is present in 30–50% with long-lasting diabetes [57]. The typical patient experiencing symptomatic gastroparesis has a long history of insulin-dependent diabetes and poor glycaemic control lasting for several years. In some cases, recent onset of gastroparesis is the only diabetic complication experienced by the patient. Other symptoms may include nausea, vomiting, bloating, early satiety, and epigastric pain [58]. Furthermore, gastroparesis predisposes for small intestinal dysfunction in up to 80% of those presented with clinical symptoms, which may lead to small intestinal bacterial overgrowth or interaction between host and gut microbiota [59]. One study investigating the microbiome in patients with type 1 diabetes even indicated that the patients had a decreased diversity, reduced stability, and more classified members in their microbiome compared with healthy controls [60]. Bacterial overgrowth as well as transit problems and constipation can secondarily cause abdominal pain [61].

The detailed anamnesis is crucial when diagnosing a patient with gastroparesis, and the use of validated questionnaires, such as the PAGI-SYM, are used to assess the patient reported symptoms from which the Gastroparesis Cardinal

Symptom Index can be calculated [62]. To investigate a gastroparetic patient, gastroscopy is often needed to rule out differential diagnosis such as celiac disease, ulcers, and cancer. If symptoms resemble those seen after truncal vagotomy (mild gastric dilation, poor to no peristalsis, residual gastric secretions despite a prolonged fast, atonic duodenal bulb, and open pylorus), then the diagnosis is straightforward. However, a proportion of these patients have no gastroscopic abnormalities [17, 63]. In such cases, motility investigations such as scintigraphy or radiopague markers are needed [64]. Scintigraphy is in most laboratories the "gold standard" to assess gastric emptying time, where retention of a meal labelled with ^{99m}Tc sulfur colloid is compared to normal reference values [57]. Recently, the wireless motility capsule (such as the SmartPill), which consist of a portable receiver, a wireless transmitting capsule, and displaying software has been taken into use. Following consumption of a standard meal, the participant swallows the capsule, which samples and transmits pressure, pH, and temperature data, from which segmental transit times (including gastric emptying time) can be derived [65, 66]. Alternative tests to asses gastric emptying include breath tests which measures the non-radioactive isotope ^{13}C labelled digestible substance and measure the metabolized isotope in the breath, emptying of radiopaque markers from the stomach by use of fluoroscopy, ultrasonography, ultrasound, and the paracetamol absorption test which is valid for gastric emptying of liquid meals [57, 64, 67–70].

The treatment of gastroparesis is challenging, but patients should be encouraged to focus on glycaemic control. The antiemetic drug metoclopramide has shown control of symptoms in 30–60% of patients and domperidone has shown effective in up to 60% of cases [71]. However, it must be underlined that there is no association between symptom improvement and changes in gastric motility following treatment with prokinetics [72]. Furthermore, most prokinetics are limited to short-term use due to the risk of irreversible tardive dyskinesia and cardiovascular side effects. Furthermore, symptoms can be diminished by use of pharmacological agent that increases motility such as erythromycin or (off label) prucalopride. New molecular targets are currently identified, and relamorelin, a synthetic ghrelin analogue, has shown promising results accelerating gastric emptying [73]. Endoscopic procedures such as botulinum toxin injections and myomectomy of the pylorus are also promising [61]. Constipation—if present—should also be adequately treated as it may give "upstream" motility disorders.

Another important aspect is nonpharmacological treatment with dietary consulting to improve glycaemic control [61]. In theory, patients with concomitant functional disorders or bloating may benefit from Low Fermentable Oligo-, Di-, and Mono-saccharides and Polyols diet (low-FODMAP) [74]. It is a dietary intervention under investigation in dysmotility disorders, which is why it might benefit selected diabetic patients with neuropathy-induced dysmotility [75]. Avoidance of these carbohydrates should be global, and it is important to recognize that ingestions of FODMAPs are not the cause of the disease, but limited intake may represent an opportunity to reduce the patient symptoms [74]. Another dietary intervention has been studied by Olausson EA et al. [76]. In this study, patients with diabetes mellitus and gastroparesis were to eat a small particle diet. They found that patients on this diet improved in key symptoms such as nausea and vomiting. Furthermore, gastric electrical stimulation has been approved by the US Food and Drug Administration to alleviate symptoms in gastroparesis. The underlying mechanisms are debated and a growing body of evidence points toward alteration of the sympatico–vagal balance rather than enhancing gastric motility [77]. Nonetheless, the procedure has shown to decrease both symptom frequency and severity [78]. A potentially new method is stimulation of the vagal nerve during the skin together with deep breathing. This has been shown to increase gastric contractions in healthy volunteers [79], and currently a study is undergoing to explore this method in patients with diabetes [80].

Diarrhoea

Diarrhoea is observed in up to 20% of patients. The diarrhoea can be present as episodic, loose stool consistency, and periods with normal bowel function alternating with constipation [17, 59]. The cause of idiopathic diabetic diarrhoea is not known; however, the most recognized explanation is shifted sympatico–vagal balance as both sympathectomy and truncal vagotomy can cause diarrhoea. It may be caused by rapid transit or slow transit together with bacterial overgrowth [59, 81]. Even though autonomic neuropathy often induce prolonged transit times, it may also indirectly cause diabetic diarrhoea [17]. Furthermore, a study found that long-standing diabetes was associated with a decrease in number of interstitial cells of Cajac as well as decreased inhibitory innervation and an increase in excitatory innervation causing diarrhoea [82].

Abnormal and dis-coordinated motility of the small bowel may also lead to small intestinal bacterial overgrowth, which potentially also causes diarrhoea [83]. Third, faecal incontinence due to *anorectal dysfunction* can be present due to a weakened internal anal sphincter and lowered rectal sensory threshold [84]. Finally, as insulin is a trophic hormone for the acinar and ductal cells in pancreas, *pancreatic exocrine insufficiency* must be considered, especially when steatorrhoea is found, and as a parallel, patients with pancreatitis may have demolished the visceral nerves [85]. Appropriate test with pancreatic enzyme therapy or pancreatic function test is recommended.

Diagnosis of neuropathy-induced diarrhoea serves to exclude differential diagnosis that can lead to chronic watery diarrhoea, for example microscopic colitis or irritable bowel syndrome. If differential diagnosis can be excluded, the diagnosis idiopathic diabetic diarrhoea can be made (non-specific radiological findings and clinical symptoms) [17].

In order to treat patients with severe and long-lasting diabetic neuropathy-induced diarrhoea, there are six important targets: (1) hydration, nutrient deficiency, and correction of electrolyte deficiencies, (2) fibre supplementation which might be helpful in some cases, however it may also worsen gastroparesis, (3) symptomatic treatment with, e.g. codeine or loperamide as antidiarrheal medication by prolonging transit time and reduction of peristalsis, (4) treatment of underlying causes such as bacterial overgrowth with probiotics/antibiotics, (5) enzyme supplementation in case of exocrine pancreas insufficiency [71], and (6) glycaemic control in order to reverse underlying mechanisms [86].

Constipation

Motility disorders, more specifically reduced colonic transit time due to dysfunction of the ENS and ANS leads to constipation [53, 87]. A study investigating the prevalence of constipation in diabetics showed that 60% reported constipation and thus it is the most commonly reported symptom. Furthermore, the same study reported that 76% of the patients suffered from at least one GI symptom [17]. Furthermore, reduced bowel motility may result in specific constipation that occasionally leads to overflow incontinence that influences the clinical picture [71]. Of note, 80% of patients with diabetic diarrhoea also suffered from periods with constipation.

Constipation can be evaluated with radiopaque markers, scintigraphy, or different capsules as mentioned above and recently reviewed in [65]. In patients with functional gastrointestinal disorders, a reduction in caecal and colonic contractility, as well as bloating and distension was associated with excessive fermentation in the caecum assessed as a higher pH-drop across the iliocaecal junction [88]. A recent study found that patients with type 1 diabetes had prolonged small bowel transit, colonic transit, gastric emptying, and whole-gut transit time compared with healthy controls. Furthermore, prolonged colonic transit time in association with an increased fall in pH across the ileocecal junction was found [66]. Similar findings were shown in a recent paper where the wireless motility capsule was used to show panenteric prolongation of gastrointestinal transit times and a more acidic caecal pH, which may represent heightened caecal fermentation in diabetics [66].

Constipation could be due to alterations in the microbiota—or vice versa—however the exact mechanism on how alterations in microbiota influences the colonic motility. One study indicates that the breakdown of short chain fatty acids induces acidic milieu and thus modifies motility rhythm in the hindgut [89]. In support of this, animals who received antibiotics were shown to modulate their gut microbiota, which consequently improved their glucose tolerance and sensitivity to insulin [90]. Similar mechanisms are plausible in humans but need to be investigated in further detail.

Constipation may be treated conservatively with regular exercise, increased intake of dietary fibres, and focus on hydration. A non-pharmacological vibrating capsule has reduced constipation by improving peristaltic waves in the large intestine, however further studies are needed. Medical interventions may include bulk fibres or laxatives. In patients with slow-transit constipation, it is preferred to use osmotic laxatives compared to fibre supplementation and bulking agents. As the latter stimulates the intestines to absorb excessive amounts of fluid from the body. Frequently, osmotic active drugs are also used in combination with enemas. The reader is referred to [50, 61, 91].

In chronic constipation due to autonomic neuropathy and slow transit newer drugs such as prucalopride, a selective 5-HT receptor agonist may prove to be useful as it enhances colonic transit. Furthermore, lubiprostone stimulates secretion of electrolyte secretion and colonic water through activating of type 2 chloride channels in enterocytes. Another plausible target in the future is altering the composition of the microbiota through dietary alterations or faecal transplantation.

Diagnosis of Diabetic Autonomous Neuropathy

The clinician should ideally investigate the GI symptoms as described in section "Gastrointestinal Disorders in Patients with Diabetes" of this chapter. Additionally when gut symptoms arise in patients with diabetes, autonomic neuropathy should always be suspected, especially if the patient also suffers from distal symmetric polyneuropathy. Conventional measures of the autonomic function are indirect methods that rely on cardiovascular reflexes. However, the detection of early and subtle abnormalities in the parasympathetic system remains controversial, as the methods are relatively insensitive to sympathetic deficits [1, 92]. Classically, the ANS function has been correlated to recordings of the peroneal nerve [1, 93]. However, these methods are unspecific, invasive, and time consuming, which could explain why the most popular and the most utilised is time domain derived parameters of Heart Rate Variability or sudomotor reflex testing. One way to measure real-time brainstem vagal efferent activity known as cardiac vagal tone is with the neuroscope. A non-invasive measurement using ECG electrodes to

detect phase shift in the beat-to-beat RR interval, which is described in detail elsewhere [94]. Another method in the future may be to measure potential biomarkers such as N-acetylaspartate with magnetic resonance imaging, which have been found to be reduced in patients with type 1 diabetes and central neuronal dysfunction or loss [95]. However, diagnosing DAN remains complicated as there is poor association between autonomic function testing and experienced GI symptoms [1].

There is no consensus regarding the optimal test parameters [96–98], and the shortcomings of each methods and their interpretation is responsible for the lack of formal diagnosing of DAN. Thus, such diagnosis is frequently delayed, the causes of which are most certainly multifactorial but arguably includes the non-specificity of presenting symptoms, the lack of clinician appreciation, and the limited availability of specialised diagnostic services. Nevertheless, diagnosis of DAN is important as it has a pivotal role in the pathophysiology of a number of diabetes-induced complications.

Concluding Remarks

Manifest DAN is one of the most burdensome symptoms, yet frequently under-diagnosed. The autonomic neuropathy induces symptoms such as nausea, vomiting, bloating, early satiety, diarrhoea, and constipation, which undoubtedly compromise the quality of life in these patients. The frequently presence of GI symptoms in patients with diabetes should make the clinician focus on DAN. Conservative and symptomatic treatment should accompany the suspicion of DAN, and if possible, the underlying cause should be treated. Ideally, treatment should be individualised as the symptom complex differs between patients. New emerging therapies are in pipeline and future research will undoubtedly result in improvement of the armamentarium clinicians have available for treatment of the severe complications associated with DAN.

Multiple Choice Questions

1. The autonomic nervous system comprises.
   (a) The sympathetic, parasympathetic branch.
   (b) **The enteric nervous system, parasympathetic, and sympathetic branches.**
   (c) The sympathetic branch.
   (d) The parasympathetic and enteric nervous system.
   (e) The brain, the so-called second brain "the enteric nervous system" and the sympathetic branch.
2. In patients with longstanding diabetes up to how many percentage of the patients suffer from GI symptoms such as nausea and vomiting.
   (a) 10%
   (b) 12%
   (c) 20%
   (d) 25%
   (e) **40%**
3. Which part of the gastrointestinal tract can be affected by visceral neuropathy?
   (a) The upper GI tract.
   (b) The lower GI tract.
   (c) The bowel.
   (d) Only the anorectal part of the GI tract.
   (e) **It is possible that the neuropathy cover the entire gastrointestinal tract causing symptoms such as nausea and vomiting, bloating, early satiety, diarrhoea, and constipation.**
4. In order to treat patients with reflux which statement is most correct?
   (a) The only treatment is avoiding provoking factors such as large meals.
   (b) The only treatment is medical including combinations of antacids and proton pump inhibitors.
   (c) **First, it is important to avoid provoking factors such as large meals, coffee, and alcohol. Symptoms caused by reflux can be treated with antacids, H_2 blockers, proton pump inhibitors, or foaming agents.**
   (d) Constipation treatment should be the first option.
   (e) Currently no treatment exists.
5. The typical patient experiencing symptomatic gastroparesis is?
   (a) A newly diagnosed type 1 diabetic.
   (b) **A patient with a long history of insulin-dependent diabetes and poor glycaemic control lasting for several years.**
   (c) A diabetic with extreme alcohol abuse.
   (d) A newly diagnosed type 2 diabetic.
   (e) A patient with a long history of well-controlled diabetes.
6. Hypoglycaemia has been shown to cause cell damage, but how?
   (a) It increases levels of NO in the entire body.
   (b) Unhealthy levels of calcium leaves the cell.
   (c) Reduction in release of excitatory amino acids protecting the cell.
   (d) **Increased release of excitatory amino acids, which may cause uncontrolled triggering calcium influx. This again activates proteolytic enzymes that are known to cause neuronal damage.**
   (e) The production of reactive oxygen species is limited.

7. In order to treat patients with diabetes and diarrhoea, which statement is most correct?
   (a) **Hydration, nutrient deficiency and correction of electrolyte, antidiarrheal medication to prolonging transit time and reduce peristalsis, as well as reducing faecal volume in order to control symptoms, treatment of the underlying cause.**
   (b) Antidiarrheal medication for 1 week.
   (c) Hydration, nutrient deficiency and correction of electrolyte, and treatment of underlying cause such as bacterial overgrowth which should be treated with antibiotics.
   (d) Hydration, nutrient deficiency and correction of electrolyte, and treatment of underlying cause such as anorectal dysfunction.
   (e) Surgery of the intestines.
8. Which of the following statements about the pathophysiological explanation behind visceral neuropathy is most correct?
   (a) Hyperglycaemia is the only main player in inducing oxidative stress.
   (b) Hypoglycaemia is the only main player in pro-inflammatory mechanism.
   (c) Hyperglycaemia and hypoglycaemia are the only main players in inducing neuronal damage.
   (d) **Peripheral and autonomic neurons, as well as their interconnections, are particularly vulnerable to hyperglycaemia. It is obvious that any increase in glucose is associated with increased risk of injury to the organ including neuropathy.**
   (e) Hyperlipidaemia is main player alone to induce oxidative stress and pro-inflammatory mechanisms.
9. The measurements of GI symptoms have varied in many studies. What should researcher be aware of in future studies?
   (a) Every patient with gut symptoms should be offered an upper endoscopy locating symptoms.
   (b) Every patient with gut symptoms should be offered an upper endoscopy as well as a colonoscopy to investigate the entire gastrointestinal tract.
   (c) **In future epidemiological and clinical studies, the Diabetes Bowel Symptom Questionnaire is suggested as a consistent method to measure GI symptoms.**
   (d) A computed tomography scan of the body should be conducted in order to cover every symptom in patients with diabetes.
   (e) The variation is unavoidable and must be accepted.
10. When should autonomic neuropathy be suspected in patient with diabetes?
   (a) When newly diagnosed.
   (b) When the patients asks about it without symptoms.
   (c) **When gut symptoms arise, especially if the patient also suffers from distal symmetric polyneuropathy.**
   (d) When changing medicine.
   (e) Always.

Urologic Complications in Patients with Diabetes

59

Ivan Mauricio Schroeder-Ugalde,
Karen Yhadira Sanchez-Lastra, and Angel Enrique Garcia-Cortes

Introduction

Diabetes Mellitus (DM) is a group of metabolic diseases associated with high glucose levels that cause systemic long-term damage, dysfunction, and failure of several tissues [1]. Among the consequences of this chronic hyperglycemic state, patients with DM suffer several urologic complications that involve endothelial and neural damage all along the genitourinary tract with significant economical and quality-of-life costs.

The worldwide incidence of urologic complications associated with DM is increasing because of the high incidence of obesity in the entire world [2]. The effect of obesity in our society is growing at a worrying rate, and it is associated with an increasing risk of noninsulin-dependent diabetes. Clinicians have the opportunity to prevent, diagnose, and change the evolution of these urologic complications among patients with diabetes by maintaining a proper weight [3].

Diabetes has been associated with an earlier presentation and increased severity of urologic complications [4]. DM leads to nerve function disturbance, loss of innervation of neuromuscular nerve terminals, abnormal immune response, and altered sympathetic/parasympathetic innervation [5]. Therefore, peripheral accumulations of fat in the abdominal region of patients with diabetes has been associated to an increased risk of urologic complications such as urinary incontinence, erectile dysfunction, benign prostatic hyperplasia, urinary tract infections, and possibly with cancer [3].

Bladder Dysfunction (BD) and Cystopathy

Generally, the beginning of bladder lesions of diabetes is not very evident, and they are not recognized until the disease is in the most advanced stages. Between 20 and 50% of all diabetic patients are affected, although some studies raise this figure to 88% of cases. No correlation has been observed between the type and duration of diabetes or the age of the patients, although it was shown that 80% of cases with a neurogenic diabetic bladder have lesions in other organs (kidney, eye, penis, arteries, etc.). (Campbell-Walsh 12 ed).

Bladder dysfunction or dysfunction in the bladder outflow tract attributed to any alteration of the nervous system. Some bladder symptoms that occur in patients with diabetes mellitus are known as diabetic bladder dysfunction or diabetic cystopathy, which include lower urinary tract symptoms (LUTS) characterized by increased postvoid residual volume due to inadequate emptying of the bladder, resulting in increased bladder capacity, worsened by reduced sensation and contraction of the bladder [6].

The cornerstone for evaluation is the questioning of urologic history, sexuality, bowel behavior, and neurologic history. Within the specific urological history, we must take into account the onset of symptoms, relief after urination, the beginning and end of urination, if there is presence of interruption of urination, mode and type of urination, enuresis and a strict record is essential in a urination diary.

Almost half of patients with DM suffer from different degrees of bladder dysfunction (74% men and 59.26% women), which causes an increase in postvoid residual urine and urinary incontinence, causing infections, bladder stones, or eventually kidney damage [7]. In men, bladder disorders are made worse by the enlargement of the prostate associated with age.

In Mexico, approximately 12% of the population suffers from type 2 diabetes mellitus, so the prevalence of bladder dysfunction due to this cause is common in the urological delivery, it is important to know how to detect it and refer it in time to the urology specialist to its timely treatment.

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_59

Obese and diabetic women are expected to have more pelvic floor disorders, such as stress urinary incontinence and overactive bladder [4] that could be related to increased abdominal pressure from the abdominal panniculus that exerts pressure unwanted over the pelvic organs, uterus, bladder, urethral sphincters and vagina [3], peripheral neuropathy, and loss of bladder support. Insulin treatment in women with diabetes mellitus increases the risk of urge incontinence, compared to women treated with metformin, which has no effect on incontinence [8, 9].

Bladder hypersensitivity is reported as the most common finding, ranging from 39% to 61% in patients with diabetes mellitus, in numerous clinical studies [6]. Furthermore, an important predictor of bladder dysfunction is the presence of peripheral neuropathy, renal disease, and the association of metabolic syndrome [4].

Pathophysiology

During the early stages of diabetic cystopathy, there is an increase in the storage capacity of the bladder, which affects its compliance or ability to adapt to pressure as the bladder fills [10]. Several mechanisms have been described that induce abnormalities in bladder function at the detrusor muscle level, including changes in intracellular connections and excitability, muscarinic receptor density, genetic traits, and changes in intracellular signaling. All of these contributing factors result in decreased contractility and increased postvoid residual volume. Compensatory bladder hypertrophy results in increased bladder instability that decreases its contraction force due to collagen deposits, rendering detrusor muscle tension ineffective [10]. Another theory is the associated increase in diuresis due to the hyperglycemic state resulting in neural and endothelial damage, which collectively can lead to detrusor muscle hypertrophy in an attempt to adapt to these changes. On the other hand, abnormalities in calcium and potassium cell wall channels increase detrusor muscle activity and increase hyperactivity [11]. Furthermore, rabbit models have shown that overexpression of aldose reductase and increased lipid peroxidation products result in decreased detrusor contractility [12].

Another problem that influences bladder hypertrophy could be an increase in oxidative stress, associated with greater damage to the bladder muscles [13] or induced by a deficiency in axonal transport of neural growth factor (NGF). Bladder tissue remodeling is also associated with downregulation of tissue growth factor (TGF) and collagen mRNA levels, which induce an increase in elastin synthesis. These factors can result in an increase in bladder compliance in patients with diabetes associated with a reduction in collagen synthesis [14].

Neuronal control of bladder function consists of an interaction between autonomic sympathetic and parasympathetic, somatic afferent and efferent pathways. Patients with diabetic cystopathy have somatic and autonomic neuropathy. In addition, cells subjected to long periods of exposure to hyperglycemia suffer an accumulation of oxidative stress products, which cause axonal degeneration and nerve damage, decrease nerve conduction, trigger diabetic cystophaty, and erectile dysfunction [15]. In addition, decreased bladder filling sensation, caused by nerve damage, can cause excessive distention and increased hypocontractility of the bladder wall in diabetic patients. Diabetic cystopathy also involves neuropathic changes, produced by hyperexcitability of the urethral afferent reflex, leading to external urethral sphincter dysfunction and reduced urethral smooth muscle relaxation with obstruction to urine outflow.

Long-standing diabetes also affects the peristaltic function of the ureters by interfering with ureteral muscle cells and nerve function, causing upper urinary tract dysfunction, urine stasis, and eventually kidney stone formation [5]. The voiding reflex is a neural stimulus controlled by the M2 and M3 receptors. Patients with diabetes have a greater number of muscarinic receptors in the urothelium that increase sensory nerve activity and modify detrusor contraction, causing greater bladder dysfunction and urinary stasis [11].

Clinical Manifestations

In the early stages of the diabetic bladder, compensatory changes maintain the ability to maintain a normal diuresis. In later stages, decreased voiding pressure and increased urethral obstruction lead to larger volumes of postvoid residual urine, producing a wide variety of symptoms ranging from urgency to urinate and incontinence (a sensation urinary leakage) (40% to 80% risk) to the most severe expression of overflow incontinence (in which the bladder empties due to excess residual urine without patient control) [16].

Diabetic patients can complain of lower urinary tract symptoms, including urgency, difficulty in initiating, maintaining and ending urination, inadequate voiding or sensation of residual urine, frequent urination during the day and night, slow or decreased urinary flow of different severity levels. Consequently, voiding reflexes appear to be diminished or inactive, causing a progressive asymptomatic increase in bladder capacity, which can eventually cause urinary retention, bladder stone formation, diverticula, infection, upper urinary tract dilation, and kidney damage. . In contrast, diabetic bladder dysfunction can also present as overactive bladder syndrome with corresponding frequent day and night bladder emptying, urgency, and lower urinary tract symptoms. Hypersensitivity and hypercontractility of the bladder are more common than hypocontractility [6].

Diabetic cystopathy and bladder dysfunction are common in long-standing diabetic patients. They can be asymptomatic or manifest a wide spectrum of clinical symptoms, ranging from voiding discomfort due to overactive bladder and urge incontinence due to decreased bladder sensation, to overflow incontinence and acute urinary retention [4]. Bladder symptoms can be divided into irritating and obstructive. Irritant symptoms involve the overexcited detrusor muscle, causing urgency, polyakiuria, nocturia, and urge incontinence, known as overactive bladder syndrome. Obstructive symptoms include decreased size and strength of voiding flow, terminal dribbling, decreased sensation of a full bladder, and high postvoid residual urine. Obstructive symptoms are related to a pseudo-obstructive bladder, represent the last phase of visceral diabetic neuropathy, and are associated with a low urine flow that can be demonstrated with uroflowmetry, high postvoid residual and urodynamic studies, which show a hypotonic bladder in cystometry caused by a myogenic alteration of the microvasculature and neuronal cells. [10, 17].

Diagnosis

The approach to the study of diabetic cystopathy depends on the individual patients symptoms, severity, renal function, and impact on quality of life. In patients with symptoms of bladder dysfunction, physicians should take a detailed history including the International Male Prostate Symptom Score, physical examination with neurological reflex and rectal examination, presence of pelvic organ prolapse, followed by tests of laboratory to evaluate kidney function (serum creatinine), infections (urine test), and clinical chemistry. Similarly, a sexual history, the presence of genital or sexual dysfunction, the sensation in the genital area, specific to the man (erection, orgasm and ejaculation) and specific to the woman (dyspareunia and orgasm), within the habits bowel movements, presence of fecal incontinence, urgency, rectal sensation, stool pattern, and the onset of this complication. In the neurological history, if you have a congenital or acquired condition, mental status, neurological symptoms, spasticity, or autonomic dysreflexia.

The diagnosis of diabetic neurogenic bladder is based on the performance of a complete urodynamic study (flowmetry, cystometry, electromgraphy, and urethral pressure profiles). The most common findings of the final stages of the disease are the loss of voiding sensation with significant increase of bladder capacity and decreased detrusor contraction (areflexia) with low voiding flow and presence of residual postvoiding urine. The picture must be differentiated from infravesical urinary obstruction, which is achieved with a pressure/flow study. Urodynamic evaluation is an essential component of the examination, although it is not indicated in all cases. It includes cystometrogram, simultaneous flow and pressure studies, sphincter electromyography, and postvoid residue measurement [6]. It is recommended that the patient has to carry out a voiding diary prior to the urodynamic study. Diabetic women have significantly higher nocturia scores on lower urinary tract symptom questionnaires, with weaker urinary flows, reduced voiding volumes, increased residual urine volumes, and lower peak flow rates by uroflowmetry [4].

Treatment

The first step in managing any type of diabetes complications is blood glucose control. The treatment of diabetic cystopathy depends on the severity of the symptoms, but in the early stages, it is basically conservative and, in case of complications, they should be treated accordingly [18]. The treatment of diabetic neurogenic bladder resides in the treatment of symptoms, the prevention of urinary infection, the maintenance of renal function, and continence with an adequate bladder emptying. However, there is no cure for the disease. When there is an unstable bladder, the use of anticholinergics is of great help to improve symptoms (Campbell-Walsh 12 ed). In patients who complain of urgency, different types of first-line therapy are available to control detrusor overactivity, including oral muscarinic drugs, and more uroselective anticholinergics with fewer adverse effects (oxybutynin, tolterodine, darifenacin, or solifenacin). A recently approved β3 adrenergic agonist (mirabegron) that increases urine storage capacity, by direct relaxation of detrusor smooth muscle, can be used to provide rapid relief of symptoms [19, 20]. Infiltration of the detrusor muscle with botulinum toxin has been shown to decrease urge incontinence. A surgical approach could be offered in severe cases of unresolved urge incontinence with selective muscarinic anticholinergics, including bladder denervation, myomectomy, and bladder augmentation with ileal cystoplasty. All of them are associated with the risk of increased postvoid volume, urinary tract infection, kidney damage, and stone formation [18].

In men with additional bladder outlet obstruction associated with an enlarged prostate, initial treatment includes the use of alpha blockers such as terazosin, tamsulosin, and alfuzosin. In advanced stages, transurethral resection of the prostate could be considered.

In cases of failure to empty the bladder, frequent clean intermittent catheterization is the best option to avoid permanent use of indwelling catheters, due to the risk of increased infection rate, lower urinary tract lithiasis, and squamous cell carcinoma of the bladder [21].

All these measures are always carried out to protect kidney function, since, by increasing bladder pressure, due to the increase in urinary volume and the lack of accommodation of the bladder, they can cause a deterioration in kidney

function and worsen the damage per se. That is what diabetes mellitus does to the kidneys (Campbell-Walsh 12ed.). Similarly, within the objectives of treatment, they are to avoid urinary tract infection, achieve or maintain urinary continence, preserve the ability to urinate, and improve the quality of life of the patient.

Benign Prostatic Hyperplasia (BPH) and Urethral Obstruction

Benign prostatic hyperplasia (BPH) is an age-related phenomenon that affects up to 50% of men aged 60–69 years and almost 90% at age 90 [22]. DM is frequently associated with BPH due to the same age of incidence [23]. BPH has been largely associated to metabolic disorders including diabetes, metabolic syndrome, obesity, and hypertension. Preclinical and clinical studies have shown that increased plasma insulin levels are positive independent predictors of BPH, as well as high fasting glucose level and hyperlipidemia; all of them have shown a positive correlation to the progression of BPH [24–26].

Pathophysiology

Several theories have been proposed in the pathogenesis of BPH. The most convincing however is that prolonged chronic ischemia and repeated ischemia-reperfusion injury in the bladder could generate oxidative stress, which increases sympathetic nerve activity and vascular damage, further hypoxia of the bladder and prostate, abnormal cell proliferation, in addition to an increase of lower urinary tract symptoms [22]. Endothelial dysfunction and nitric oxide (NO) deficiency are among the most important factors in the development of diabetic complications, affecting the lower urinary tract as well. Relaxation of the urethral sphincter is partially affected by NO, which in turn causes outflow obstruction and hyper-excitability of afferent neurons associated with progression of diabetes [27]. All these factors, in addition to the increased risk of overactive bladder in diabetic patients are closely related to peripheral nerve irritation [28]. Another possible explanation for the presence of BPH in diabetic patients involves insulin-like growth factor (IGF). Beta cells of patients with Type 2 diabetes secrete higher concentrations of insulin; the resulting hyperinsulinemia stimulates IGF synthesis. Activation of the prostate IGF receptors may also cause prostate growth [29, 30] which could be explained because of homology of insulin and IGF receptors [31] and cross-activity to insulin action [32].

The pathogenesis of BPH is multi-factorial and characterized by basal cell hypertrophy, secretory alterations of luminal cells, infiltration of lymphocytes with production of pro-inflammatory cytokines, stromal proliferation, diminished apoptosis, trans-differentiation and extracellular matrix production, abnormal autonomous innervation, and modification of the neuroendocrine cell function among others [22]. Disturbances in fatty acid metabolism are also influential in the progression of BPH, including inflammation, oxidative stress, peroxidation of lipids and accumulation of 8-hydroxy-2′-deoxyguanosine, and increased androgen synthesis [33].

Clinical Manifestations

Initially, patients with BPH complain of symptoms of LUTS (which already mentioned includes nocturia, frequency, urgency, weakened stream, hesitancy, intermittency, straining, and a sense of incomplete emptying) [34]. Progressive evolution toward complications in the urinary tract is more important than symptoms related to micturition. They are significant and include bleeding, lithiasis, renal insufficiency, and infections [35], but the most serious and painful manifestation is acute urinary retention, the inability to urinate, characterized by intense pain in the pelvis [36].

Diagnosis

Evaluation of BPH in diabetic patients includes a detailed medical history, including LUTS questions, severity, and influence in their quality of life. The American Urological Association Symptoms Index (AUA-SI) is a questionnaire that allows physicians to quantify symptoms at diagnosis and over time in response to treatment. Digital rectal examination should be included in the physical examination. PSA (Prostate-specific antigen), urinalysis, and frequency/volume chart may be filled, as well as uroflowmetry, post void residual ultrasound, and renal ultrasound in order to diagnose complications [34].

Treatment

To avoid complications, effective and conservative drug treatment for BPH is currently available. Patients with a small prostate are routinely treated with alpha-1 blocker monotherapy as first-line therapy, either with nonselective blockers such as doxazosin and terazosin or uroselective blockers such as tamsulosin, alfuzosin, and silodosin. All of them have similar effectiveness but diverse side-effect profiles. Characteristic side effects include postural hypoten-

sion, dizziness, rhinitis, asthenia, sexual dysfunction, and abnormal ejaculation. Storage and voiding symptoms improve briefly after initiation of treatment. Alpha-1 blockers do not prevent BPH progression. For that reason, prostate volume and symptom progression should be monitored during the follow-up of the patient [34, 37].

Patients with a small prostate associated to voiding symptoms, the diagnosis of overactive bladder should be considered and treated as previously mentioned with anticholinergics, keeping in mind the need to monitor by dynamic bladder ultrasound the possibility of urinary retention, even though the risk is low.

In patients with enlarged prostate (over 30–40gr), the use alpha-1 blockers in combination with an alpha 5 reductase inhibitor (finasteride or dutasteride) that block the conversion of dehidrotestosterone from testosterone is highly recommended, in order to diminishing the prostate volume at long term with a faster effect on the relaxation of the bladder neck. In case of failure with all these therapies, the surgical approach is the next option. Transurethral resection of the prostate is the gold standard, but newer techniques such as bipolar resection, and the use of laser vaporization, botox infiltration, cryotherapy and high intensity focused ultrasound among others, represent less invasive approaches than open adenomectomy [36, 37].

Sexual Dysfunction

Men and women with diabetes are affected by sexual dysfunctions, which are defined as the inability to achieve or maintain an adequate sexual response to complete a sexual encounter or intercourse resulting in a satisfactory orgasmic sensation. Sexual dysfunctions include disorders of libido, ejaculatory problems, orgasmic abnormalities, and erectile dysfunction. The reported prevalence of sexual dysfunction in men with type 2 diabetes is up to 46%. Sexual dysfunction in women is harder to diagnose but it has been proposed that its prevalence in type 1 diabetes is 71% and 42% in females with type 2 diabetes [38, 39].

Almost half of nonsexually active men and women with type 2 diabetes report that their sexual life do not fulfills their sexual needs, suggesting that they are more concerned and even more distressed than sexually active patients. Commonly, women argue that lack of sexual activity is related to a number of reasons, including lack of interest, physical problems that make it difficult or unpleasant, absence of partner, or having a partner with physical limitations [40].

Sexual dysfunctions involve a group of alterations that affect significantly the quality of life of these patients and include reduced desire, decreased arousal, orgasmic abnormalities, and painful intercourse [41].

Leading risk factors that further affect diabetic men and women include age, length of diabetes [40] co-medications, obstetric history, neurogenic and vascular complications, and infections among others.

Erectile Dysfunction (ED)

It is defined as a long term, consistent, or recurrent inability to attain and/or maintain penile erection sufficient for sexual satisfaction. It is the third most frequent complication of diabetes and considered as one of the most significant complaints affecting quality of life [42]. Manifestations usually appear after 10 to 12 years after the onset of diabetes, because of diabetic endothelial and neural damage associated with persistent high serum glucose levels [43].

The WHO Global Report on Diabetes states that the number of people with diabetes has risen from 108 million in 1980 to 422 million in 2014 and that the global prevalence among adults has risen from 4.7% to 8.5% over the same period. The overall prevalence of erectile dysfunction in diabetes is 59.1%, but significantly different across countries, South America 74.6%, Oceania and Africa 71.3%, and lowest amongst North American studies with 34.5% . Diabetic male patients generally have a greater prevalence and an earlier onset of erectile dysfunction than men without diabetes and it appears 10–15 years earlier in diabetic than in nondiabetic men. Erectile dysfunction in diabetics is directly associated with poor glycemic control as well as greater duration and severity of diabetes [44]. Moreover, it has been demonstrated that ED is an early sign of cardiovascular events, particularly coronary heart disease. Prevention of cardiovascular disease through screening and management of cardiovascular risk factors in men with ED is very important [45].

Pathophysiology

The aetiology of ED in diabetes is considered to be multifactorial, pathophysiologic changes associated with diabetes can broadly be classified as vasculopathy, neuropathy, hypogonadism, and local pathological factors.

Men with erectile dysfunction that have macrovascular disease have diminished vasodilating responses causing less relaxation of the vascular smooth muscle tissue because of changes in the vessel that predispose to subsequent atherosclerosis, plaque formation, thrombosis leading to occlusive macrovascular disease, and microvascular disease due to deficient production of nitrate oxide in nonadrenergic noncholinergic neurons and in the endothelium [46]. These

abnormalities are associated with important accumulation of advanced glycation products, altered expression of arginase, a competitor of the NO synthase for its substrate L-arginine [47, 48]. All of these abnormalities cause a tendency toward vasoconstriction, such as that caused by phenilephrine and endothelin-1, resulting in lack of vasodilatation and inadequate penile erection.

Numerous mechanisms play important roles in the pathophysiology of erectile dysfunction in diabetic males, one of them is the polyol pathway, which forms sorbitol by action of the enzyme aldose reductase. Sorbitol accumulates inside the cells, causing diminished myo-inositol levels (a precursor of the phosphatidylinositol), required for the adequate functioning of the Na-K ATPase pump. Increased sorbitol concentrations additionally produce progressive peripheral nerve damage [49].

Regarding vascular component, endothelial damage is a central issue in ED, because in comparison with healthy males, diabetic male patients have a diminished arterial inflow, which has been observed microscopically with reduced diameter and deficient morphology of the vascular wall [50]. Contraction of cavernosal smooth muscle cells is also affected by hyperglycemia, which results in an increased forced response to vasoconstrictors. This could be partially explained because of sensitization in protein kinase C and Rho A-Rho kinase Ca^{2+} pathways, which may cause a tendency toward a flaccid stage and modify the responses to NO [51]. All of these mechanisms are further compromised by other factors that impact erectile function including apoptosis or atrophy of the cavernous smooth muscle, due to diminished expression of blc2, intracellular release of Ca^{2+}, increased connective tissue proliferation due to tumor growth factor beta causing fibrosis, and a deficient response to NO in the cavernous and sinusoidal artery, with a decrease in neuronal and endothelial levels of NO synthetase. In brief, there are several components that take place in the endothelial and neural damage in the periphery and central nervous system, which globally impact on ED in patients with DM.

Diabetes is associated with peripheral and autonomic neuropathy and both of these can contribute to ED. The mechanism for ED is due to the reduced or absent parasympathetic activity needed for relaxation of the smooth muscle of the corpus cavernosum, which is produced by the decrease of norepinephrine levels as well as an increase in acectylcholine, resulting in increased NO synthase (NOS) activity, which releases NO.

Other factor is Hypogonadism, associated with type 2 diabetes. One study reported that 20% of diabetic men with ED had frank hypogonadism with a total testosterone level below 8 nmol/L and 31% had borderline low total testosterone levels between 8 and 12 nmol/L. The mechanism of hypogonadism in diabetes is incompletely understood. Hypogonadism is also associated with obesity and advancing age, common factors in type 2 diabetes.

Diagnosis

The International Questionnaire for Erectile Function helps to determine the degree of erectile dysfunction and evaluate the progression or response to medical treatment, one of the questionnaires is the International Index of Erectile Function (IIEF) and its short form, IIEF5 (also known as SHIM: Sexual Health Inventory for Men). The erectile function domain of IIEF and SHIM has been validated to assess the presence and the severity grade of ED. In the erectile function domain of IIEF, men scoring ≤25 are classified as having ED and those scoring >25 are considered not to have ED, with a sensitivity of 97% and specificity of 88%. The SHIM scale, those who score ≤ 21 are considered to have ED and those scoring >21 are considered not to have ED and sensitivity 98% and specificity of 88%.

In certain cases, in which a more precise evaluation of vascular flows is needed, an echo Doppler could be performed to determine cavernous artery flux and morphology. In selected cases, other studies to determine the degree of damage of myelinated pudendal somatosensory fibers and unmyelinated fibers can be done. Additional studies include assessment of nocturnal penile tumescence and electrostimulation. Most of these studies, however, are more commonly used in research protocols than in everyday clinical practice [52].

Treatment

Approximately 20% of patients with ED received pharmacological treatment, for that reason, clinicians should broadly evaluate sexuality among DM patients, trying to improve the sexual activity of patients and consequently their quality of life [40]. Glycemic control is an important factor, a decrease in or maintenance of hemoglobin A1c below 7.0% were significantly associated with a change on IIEF-5.

The first line of treatment are oral medications (phosphodiesterase 5 inhibitors), followed by intracavernosal injection (alprostadil), and finally penile prosthesis.

The daily use of phosphodiesterase 5 inhibitors can improve not only sexual function but also diminishes urinary tract symptoms associated with prostate enlargement. Meta-analysis has confirmed that phosphodiesterase 5 inhibitors are effective treatments of ED in patients with diabetes [53].

Sildenafil citrate, tadalafil, udenafil, and vardenafil hydrochloride are the oral agents for the treatment of erectile dysfunction. All PDE5 inhibitors are less efficacious in

diabetic men. They all share the same mechanism of action, which involves the hydrolysis of guanosine monophosphate to guanosine 5′-monophosphate, diminishing it, causing an increase in the relaxation of the cavernosal smooth muscle mediated by NO, increasing the blood flow into the corpus cavernosum, and causing penile erection [54]. Vardenafil and sildenafil are more effective on an empty stomach and start working after 30 min, with peak action at 1 h and a window of action of 4–6 h. Tadalafil has a long half life with a therapeutic window of 36–48 h, which may aid spontaneity.

Common side effects of phosphodiesterase 5 inhibitors are headache, dyspepsia, bluish eye sight, and facial flushing; lumbar musculoskeletal pain has been found in patients receiving tadalafil and mirodenafil [53]. Phosphodiesterase type 5 inhibitors are contraindicated in those who are on nitrates, because of the potential for a dramatic fall in blood pressure.

Vacuum erection devices cause blood flow to be directed into the penis, and when a satisfactory erection is obtained, a compressive device is applied at the base of the penis in order to prevent blood return and lose the erection. Side effects include cold penis due to noncirculating blood, loss or diminished sensation due to nerve compression, and the uncomfortable process to obtain the erection using the device [55]. External support devices that hold the flaccid penis to allow penetration have been designed, but the use of these instruments has not gained acceptance among patients and their partners.

Another medical option is intraurethral suppositories of prostaglandin E-1 which are injected into the urethra. In men with diabetes, their reported efficiency rate to achieve satisfactory intercourse is 60%, although in clinical practice, they have not proved to be as effective [56, 57]. Injections of prostaglandin E-1 directly into the corpus cavernosum have a direct effect on blood vessels, causing immediate penile erections, with a reported response rate above 83% [58]. Main limitations include the need of injection prior to the sexual encounter, its impact on the spontaneity of sexual intercourse, and adverse effects including penile pain, hematomas, infection, fibrosis and priapism, prolonged and painful erections [59].

Patients not responding to medical therapy, unsatisfied with side effects or patients who prefer a permanent solution should consider a penile prosthesis implant (PPI). PPI improves flaccidity and rigidity, male satisfaction and correlates positively with satisfaction of the sexual partner. The rate of complications related to penile implantation is lower than 5%; they may be catastrophic however and include misplacement, migration, perforation, and a low risk of infection (less than 1.8%) using antibiotic prophylaxis, antibiotic impregnation, or hydrophobic-coated prosthesis [60].

Urinary Tract Infections

Urinary tract infection (UTI) is the most common infection among patients with diabetes mellitus [7, 8], with estimates of diabetics suffering from UTI reaching 10% of patients visiting hospitals [61].

The worldwide prevalence of urinary tract infections (UTI) is around 150 million persons per year [62]. DM patients have a higher incidence of infections in general, and UTI are not the exception. In a cohort of over 6000 patients with diabetes mellitus enrolled into 10 clinical trials of diabetes therapies, the incidence of urinary infection was 91.5/1000 person/years for women and 28.2/11,000 for men. [63]. In the Dutch National Survey of General Practice, patients with Type 1 diabetes mellitus were1.96 times more likely to experience urinary infection and with Type 2 diabetes 1.24 times more likely. [64]. In a recent study of a cohort of 460 hospitalized participants, the overall prevalence of UTI was 27.39% among diabetic patients and 17.83% among nondiabetic participants, with a higher prevalence in ages between 40 and 49 and a higher prevalence between women (43%) in comparison with men (13.8%) [61]. The high prevalence of UTI recorded among the age group 40–49 years could be due to increased rate of sexual activity in this age group. Metabolic abnormalities and long-term complications including neuropathy and nephropathy are presumed to be determinants of increased infectious morbidity [65].

The variety of UTI patients with diabetes ranges from asymptomatic bacteriuria to cystitis, pyelonephritis, renal abscess, xantogranulomatouse pyelonephritis to severe urosepsis [66]. DM is also associated with severe cutaneous infections of the genitals such as Fournier's gangrene.

Asymptomatic bacteriuria is more prevalent in women, due to the anatomical length of the urethra, and it is closer to the warm, moist, vulvar, and perianal areas that are commonly colonized by enteric bacteria [66]. Asymptomatic bacteriuria occurs in 8–26% of diabetic women, a prevalence estimated to be 2–3 times higher than nondiabetic women [67].

DM female patients frequently suffer bacterial cystitis with higher prevalence of both asymptomatic bacteriuria and symptomatic UTI added to recurrent complications, compared to healthy women [62]. Bacterial cystitis is frequently suffered by diabetic patients; it is more common in women than in men, especially in those with type 2 DM. Diabetic women have a higher prevalence of asymptomatic bacteriuria than healthy women, and they have a greater tendency for developing symptomatic UTI and recurrent complications with higher incidence of more serious complications [68, 69]. For women with diabetes and asymptomatic bacteriuria, those with type 2 diabetes have an increased risk for pyelonephritis and subsequent impairment of renal function [68, 69].

Type 2 DM is more than a risk factor for community acquired UTI and is a high predisposition for healthcare associated UTI, such as catheter-associated UTI, postrenal transplant recurrent UTI, and catheter-associated UTI [66]. Hospitalization due to pyelonephritis occurs more frequently in diabetic patients, and they are at higher risk of developing acute pyelonephritis, which could progress to renal abscess, pyelitis or emphysematous cystitis or pyelonephritis, and bacteriemia [66, 70]. In a Canadian report, diabetic women were 6–15 times more frequently hospitalized for acute pyelonephritis and diabetic men 3.4–17 times [71].

A retrospective analysis found that diabetes mellitus was one of four variables independently associated with a poor outcome (clinical or bacteriological failure or relapse) of therapy for acute pyelonephritis. Other evidence supporting increased severity of infection is an increased frequency of bacteremia, more prolonged duration of fever, and increased mortality (12.5% with diabetes and 2.5% without) in older patients with diabetes. Over 90% of episodes of emphysematous pyelonephritis cases occur in persons with diabetes and 67% of episodes of emphysematous csystitis [72]. Other clinical manifestations that are unique or strongly associated with diabetes include abscess formation and renal papillary necrosis.

Pathophysiology

The development of UTI in women is preceded by colonization of the vaginal and periurethral epithelium by the infecting organism. Ascension to the bladder may then ensue E. coli causes the overwhelming majority of UTIs. Normal host defense mechanisms usually prevent entry to or persistence of bacteria within the urinary tract. The growth rate of bacteria and fungi in urine is stimulated by glycosuria [73]. In addition, higher renal parenchymal glucose levels create a favorable atmosphere for multiplication of many microorganisms [66]. A reduction of urinary Tamm Horsfall glycoprotein (THP) excretion which correlates with reduction of renal mass is consistently observed in diabetic nephropathy. Glycation of THP in patients with diabetes or renal diseases also reduces the capacity of THP to inhibit bacterial adherence to human uroepithelium [74].

Bacterial attachment to the uroepithelium is the necessary initiating event permitting bacterial persistence. Uropathogenic *E. coli* are specialized for success in the urinary tract, elaborating virulence determinants such as adhesins (type 1, P and S fimbriae, and afimbrial adhesin), which bind to specific molecules in the uroepithelium, such as glycosphingolipids and uroplakins [75]. A recent study examined the ability of three representative clinical isolates of uropathogenic *E. coli* to adhere to uroepithelial cells collected from urine of women with and without diabetes. Uropathogenic *E. coli* expressing type 1 fimbriae were twice as adherent to cells from women with diabetes as compared with cells collected from the women without diabetes.

Local urinary cytokines regulate host defence against urinary tract infections. DM results in abnormalities in the host immune defense system that may result in higher risk of developing infection. Immunologic impairments such as defective migration and phagocytes alterations of chemotaxis in polymorphonuclear leukocytes are common in DM patients [76]. A potential risk factor for urinary tract infection is polymorphonuclear leukocyte dysfunction in a high-glucose state. Significantly lower urinary IL-8- and Il-6-concentrations are found in diabetic women compared with nondiabetic controls, and these lower levels correlate with lower urinary leukocyte counts [68, 69]. One recent study shows that monocytes from women with type 1 diabetes produced lower amounts of proinflammatory cytokines upon stimulation with lipolysaccharide, women with diabetes who developed bacteriuria also produced lower urinary IL-6 concentrations, as compared with specimens from bacteriuric control subjects without diabetes [68, 69]. Diminished neutrophil responses, lower levels of cytokines and leukocytes facilitate adhesion of microorganisms to uroepithelial cells and the development of infections [77].

General host factors associated with risk of infection in patients with diabetes include age, metabolic control, duration of diabetes mellitus, microvascular complications, urinary incontinence, and cerebrovascular disease or dementia. The only risk factor associated with acute cistitis in premenopausal women with Type 1 diabetes was sexual activity. Previously suggested as possible risk factors, duration of diabetes or elevated HBA1c levels have not been shown to increase the risk of urinary tract infections in recent studies [68, 69].

The increased frequency of UTI in patients with diabetes might be associated to nerve damage caused by hyperglycemia, affecting the capacity of bladder to sense the presence of urine and leading to stagnation of urine for a long time, or inadequate bladder emptying due to ineffective detrusor contraction, increasing the probability of infections [62]. Over 50% of men and women with diabetes have bladder dysfunction which may impair voiding and facilitate infection. Urinary incontinence is consistently associated with urinary tract infection in diabetic women, but this association is not likely causative. Bladder dysfunction occurs in 26–86% of diabetic women depending on age, extent of neuropathy, and duration of diabetic disease. The possibility that voiding disorders are contributing to UTI should be considered in all diabetic patients.

Also of importance is the fact that many diabetic patients are infected with non-Escherichia coli species, in particular Klebsiella, other gram-negative rods, enterococci, and group B streptococci. Additionally, urinary infections with Candida

Albicans occur commonly in diabetic women but infrequently in other women.

Clinical Manifestations

UTI in DM patients can be the origin of severe complications that can end up in sepsis, organ failure, and death. Therefore, it is important to be vigilant of the usual clinical manifestations such as urinary urgency, frequency, bad urine odor, pain, dysuria, tenesmus, incomplete emptying and incontinence for lower UTI; and costovertebral angle pain or tenderness, fever, chills for upper UTI [66]. Diabetic patients generally present with symptoms similar to nondiabetic patients, but clinical signs may be altered in some patients with peripheral or autonomic neuropathy. Patients with diabetes are more likely to have more severe presentations of pyelonephritis including fever bacteremia and bilateral renal involvement. Less frequent presentations of urinary infection which occur most often in patients with diabetes include emphysematous cystitis or pyelonephritis, ureteral obstruction secondary to papillary necrosis, and renal or perinephric abscesses.

Diagnosis

Frequent and early screening for UTI should be performed in DM patients with suggestive symptoms, in order to establish the appropriate early treatment and to avoid complications.

As soon as the clinical diagnosis of UTI is suspected, a midstream urine sample must be examined, looking for the presence of leukocytes (more than 10 leukocytes/mm^3) or a positive dipstick leukocyte esterase test to detect pyuria. Microscopic or macroscopic hematuria is sometimes observed [66] associated to positive nitrites and the presence of bacteriuria. A urine specimen for culture should be obtained prior to initiating antimicrobial therapy for every diabetic patient presenting with pyelonephritis or complicated urinary tract infection. Women with symptoms consistent with acute cystitis and who do not have diabetic nephropathy or other long-term complications, particularly if they have a prior history of recurrent acute cystitis, do not usually require a urine culture. However, these women should also have a urine specimen for culture if this is a recurrent episode within 1 month of treatment, if empiric therapy has failed, or if there has been recent antimicrobial treatment so resistant organisms are more likely.

Pyuria is a universal accompaniment of symptomatic urinary tract infection. Thus, the presence of pyuria, by itself, is not useful for diagnosis of urinary tract infection or to differentiate asymptomatic and symptomatic infection. The absence of pyuria, however, is useful to exclude urinary tract infection in patients with questionable symptoms.

A diagnosis of bacteriuria is made when >105 cfu/ml of an organism is isolated from a voided urine specimen. Despite the fact that Escherichia coli is the most frequent bacteria in patients with urinary tract infections, unusual, multidrug resistant and aggressive pathogens are more prevalent in DM patients, including Klebsiella, gram negative rods, enterococci, group B streptococci, Pseudomonas and Proteus mirabilis [78]. Type 2 DM is a risk factor for fungal UTI, such as candida, these patients are more predisposed to be infected by resistant pathogens, including extended-spectrum β-lactamase-positive Enterobacteriaceae, fluoroquinolone-resistant Uropathogens, carbapenem-resistant Enterobacteriaceae, and vancomycin-resistant Enterococci [66].

The increased frequency of serious complications of urinary tract infection in patients with diabetes requires a low threshold for obtaining diagnostic imaging. Ultrasound scanning is safer, less costly, and easier to perform. These methods allowed detection of calculi, obstruction, and incomplete bladder emptying. Computerized tomography (CT) is now accepted as the most sensitive imaging modality for diagnosis and follow-up of abnormalities potentially associated with urinary tract infections. An enhanced CT scan is preferred, but contrast media should be used with caution in patients with diabetes mellitus or with renal disease.

Treatment

Treatment of urinary tract infection in patients with diabetes is generally similar to nondiabetic patients. Key factors to consider include whether the patient is asymptomatic or symptomatic, whether infection is localized to the bladder or kidney, and renal function. Glycemic control is helpful in the control of (UTI) [62].

Assuming that asymptomatic bacteriuria is more common and that the consequences more deleterious among women with diabetes, the question as to whether to attempt to eradicate it is of considerable relevance. In a randomized controlled trial of type 1 and type 2 diabetic women with asymptomatic bacteriuria, women were randomized to treatment with antimicrobials or no treatment for episodes of asymptomatic bacteriuria >3 years. Importantly, the study demonstrated that screening and treatment episodes of asymptomatic bacteriuria had no impact on overall occurrence of symptomatic urinary tract infections or hospitalizations [79]. Therefore there are no short- or long-term benefits for treatment of asymptomatic bacteriuria in women with diabetes mellitus. Asymptomatic bacteriuria by itself is not associated with an increased rate of progression to renal impairment or other long-term complications in patients with diabetes [80].

Acute cystitis in women with good glucose control and without long-term complications should be managed as uncomplicated urinary infection, usually with short-term antimicrobial therapy [81]. However, patients with pyelonephritis and severe systemic symptoms including nausea and vomiting or hemodynamic instability should be hospitalized for initial parenteral antibiotic therapy.

The choice of initial empiric antimicrobial therapy should consider current treatment guidelines, the patient's metabolic status and tolerance, the clinical presentation, and known or suspected local or institutional susceptibility of uropathogens (Table 59.1). The use of trimethoprim, cotrimoxazole, or nitrofurantoin is considered as the standard regimen of antibiotic therapy [82]. Broad spectrum cephalosporins and fluoroquinolones are the drugs of choice for pyelonephritis. However, alternate regimens such as the carbapenems meropenem, ertapenem or doripenem or betalactam/beta lactamase inhibitors such as piperacillin/ tazobactam or ampicillin/sulbactam may be appropriate if antimicrobial resistance is a concern. For patients who present with severe sepsis or septic shock, broad spectrum antimicrobial therapy to provide maximal coverage for resistant organisms should be initiated pending urine culture results. Antimicrobials with nephrotoxic side effects, e.g., aminoglycosides should be used with caution in patients with renal insufficiency. Nitrofurantoin should be avoided in renal failure as drug metabolites accumulate and may cause peripheral neuropathy [83]. There are studies reporting higher frequency of extended spectrum beta-lactamase producing E. coli and Klebsiella pneumonia in diabetic patients. However, these studies didn't report whether diabetes was an independent risk factor for increased resistance [84].

Table 59.1 Recommendations for antimicrobial therapy in uncomplicated cystitis in patients with diabetes mellitus

Antimicrobial	Regimen	Duration
First-line		
Fosfoycin trometamol	3000 mg	Single dose
Nitrofurantoin	50–100 mg orally 3–4 times a day	5 days
Nitrofurantoin monohydrate/ macrocrystals	100 mg twice a day	5 days
Trimethoprim/ sulfamethoxasole	800/160 mg orally every 12 h	3 days
Alternatives		
Ciprofloxacin	250–500 mg orally every 12 h	3 days
Levofloxacin	250–500 mg every 12 h	3 days
Norfloxacin	400 mg orally every 12 h	3 days
Ofloxacin	200 mg orally every 12 h	3 days
Cephalexin	500 mg 4 times daily	7 days
Axetil cefuroxime	500 mg twice daily	7 days
Cefpodoxime proxetil	100 mg orally every 12 h	3 days
Cefixime	400 mg daily	3 days

Among women with type 1 diabetes, sexual activity has been identified as the most important risk factor for the development of urinary tract infections, similar to women without diabetes. Continuous or postcoital prophylaxis with low-dose antimicrobial agents and intermittent self-treatment with antimicrobials are the recommended strategies to prevent recurrent urinary tract infections in women without diabetes which also could be useful in women with diabetes [85].

Recurrent infection in young women without long-term complications of diabetes is managed as acute uncomplicated cystitis, including antimicrobial therapy given as long-term low dose or post intercourse prophylaxis for women with very frequent recurrence. For patients with complicated infection, it is essential to identify and correct any known urologic abnormalities and to optimize voiding, including use of intermittent catheterization where appropriate.

Conclusions

Patients with diabetes are highly susceptible to urologic complications. They may be serious, life threatening, and affect quality of life. The underlying mechanisms determining the increased risk and severity of infection are not fully described, but alterations in specific components of the host response, metabolic abnormalities, and long-term complications of diabetes likely contribute. It is important to take into account these comorbidities in the management of diabetes and to understand their pathogenesis to prevent systemic dissemination. Many patients with diabetes accept these comorbidities are part of their disease but clinicians should be aware, interrogate, and screen for these complications in order to indicate the adequate treatment. Controlled clinical trials of therapy comparing patients with and without diabetes mellitus or diabetic patients stratified by adequacy of control and complications will be necessary to improve management of this common and important problem.

Multiple Choice Questions

1. Urologic complications in people with diabetes are associated to:
   (a) Nerve function disturbances
   (b) Loss of innervations of neuromuscular terminals
   (c) Abnormal immune responses
   (d) Altered sympathetic/parasympathetic innervations
   (e) **All of the above**
2. Peripheral accumulations of fat in the abdominal region of DM patients have been associated to an increased risk of urologic complications including:

(a) **Urinary incontinence**
(b) **Erectile dysfunction**
(c) **Benign prostatic hyperplasia**
(d) **Urinary tract infections**
(e) **Cancer**

3. Diabetic cystopathy is characterized by:
(a) **Urinary incontinence**
(b) **Increased post voiding residual volume**
(c) **Urinary tract infection**
(d) All of the above
(e) None of the above

4. Bladder symptoms of diabetic cystopathy include:
(a) **Polyakiuria**
(b) Decreasing caliber and strength of the voiding flow
(c) Terminal dribbling
(d) **Urgency incontinence**
(e) High postvoid residual urine

5. Infiltration of the detrusor muscle can be achieved with:
(a) Oxybutynin
(b) Solifenacin
(c) **Botulinum toxin**
(d) Darifenacin
(e) Tolterodine

6. Positive predictive predictors of benign prostatic hyperplasia:
(a) Urinary tract infection
(b) Plasma insulin levels
(c) Dysuria
(d) **Urinary urgency**
(e) Fasting blood glucose

7. Patients with benign prostatic hypertrophy and enlarged prostate should be treated with:
(a) Nonselective alpha-1 blockers
(b) Selective alpha-1 blockers
(c) Alpha reductase inhibitors
(d) **Alpha-1 blockers combined with 5 alpha reductase inhibitors**
(e) Surgical management is the only option

8. The reported prevalence of sexual dysfunction in men with type 2 diabetes:
(a) 18%
(b) 37%
(c) **46%**
(d) 53%
(e) 71%

9. The reported prevalence of sexual dysfunction in women with type 1 diabetes:
(a) 18%
(b) 37%
(c) 46%
(d) 53%
(e) **71%**

10. Erectile dysfunction:
(a) is a minor complaint of men with diabetes
(b) has not been quantified
(c) is usually present at diagnosis
(d) **is the third most common chronic complication and the most significantly affecting quality of life**
(e) is common but less relevant regarding quality of life

Musculoskeletal Complications of Diabetes Mellitus

60

Deep Dutta, Rajiv Singla, Meha Sharma, Aarti Sharma, and Sanjay Kalra

Introduction

Musculoskeletal complications of diabetes are a diverse set of disorders which are associated with significant impairment of the quality of life in affected patients. Lack of awareness amongst patients and also perhaps amongst the caregivers contributes to increased morbidity due to this complications amongst patient with diabetes.

In contrast to the extensively studied microvascular and macrovascular complications of DM, data and evidence on the musculoskeletal complications of Diabetes Mellitus (DM) is largely derived from observational studies. Pathogenic mechanisms for many of these conditions are yet to be fully elucidated. An important aspect of the musculoskeletal complication of DM is that their occurrence is not limited to individuals with diabetes. Such conditions are also known to occur in a diverse set of non-diabetes disorders. The only exception to this rule is perhaps the diabetic muscle infarction (DMI)/ myonecrosis, which is believed to occur exclusively amongst patients with DM [1].

In a study from Kerala, the prevalence of rheumatologic and musculoskeletal disorders was observed to be very common in patients with diabetes having a prevalence of 42.58% in a cohort of 310 individuals. With the exponential increase in the burden of diabetes, especially in India, the burden of patients with musculoskeletal complication of diabetes is also going to increase manifold. Some of the unique challenges with type-2 diabetes in India is the nearly two decade earlier onset in Indians as compared to rest of the globe, a greater insulin resistance, systemic inflammation, a more severe beta cell impairment, greater central adiposity, increased body fat percentage, and a more rapid progression from prediabetes to diabetes [2]. Duration as well as severity of diabetes has been often linked with increased occurrence and severity of the musculo-skeletal complication of diabetes. In this chapter, a review of the major musculoskeletal complications of diabetes has been done, highlighting their pathophysiology, treatment modalities, and outcomes (Table 60.1).

Musculoskeletal manifestations can be divided largely into three categories:

- Bone effects of diabetes
- Muscle effects of diabetes
- Joint and connective tissue effects of diabetes

Table 60.1 Musculoskeletal involvement in diabetes mellitus

Conditions occurring more frequently in DM
• Shoulder capsulitis
• Limited joint mobility
• Dupuytren's disease
• Stenosing flexor tenosynovitis (trigger finger)
• Neuropathic charcot arthropathy
• Calcific shoulder periarthritis
• Carpal tunnel syndrome
Conditions unique to DM
• Diabetic muscle infarction
Condition sharing risk factors of DM and metabolic syndrome
• Diffuse idiopathic skeletal hyperostosis
• Crystal-induced arthritis
• Osteoarthritis
Miscellaneous
• Bone health and osteoporosis

Bone Effects of Diabetes: Bone Density and Fracture Risk

Effect of diabetes on bone health is quite complex and interesting. Effect varies with type of diabetes and with site of skeletal system. Both type 1 and type 2 diabetes are associated with poor bone health and increased fracture rate, but their effect on bone mineral density varies. Type 1 diabetes is associated with decreased bone density in majority of studies done. Uncontrolled type 1 diabetes may, in fact, prevent an adolescent from acquiring peak bone mass. When assessed in midlife, most of the studies show, bone mineral density to be decreased. Low body mass index, lower lean mass contributes to lower BMD in patients with T1DM. Different studies have consistently shown that fracture risk is increased by around two times, at lumber spine, hip, and distal radius in patients with type-1 diabetes. Major pathophysiologic factor responsible for decreased bone density in type 1 diabetes is lack of insulin that, otherwise, acts as an anabolic agent for bone. Raised blood glucose in uncontrolled diabetes also deteriorates bone quality by formation of non-enzymic glycated collagen cross-links which are much weaker than, usually formed, enzymic pyrilodine cross-links. Another important factor predisposing to poor bone health in this population is low body mass index. Only measure, which is effective, for prevention and recovery is adequate glycaemic control as that would signify normal blood glucose levels with optimum insulin therapy [3].

Situation in type 2 diabetes is much more complex as these patients often have associated hyperinsulinism. Bone mineral density in type 2 diabetes can vary from low to normal to some patients even increased, depending on the disease state and the clinical scenario. Raised BMI in obese type-2 DM patients has a trophic effect on BMD. However, it must be highlighted that even in patients with normal to increased BMI in T2DM, the fracture rates has been consistently demonstrated to be increased in T2DM. This can be attributed to the poor bone quality in such patients, secondary to glycation of bone matrix secondary to persistent hyperglycaemia in patients with T2DM. The authors have observed in a cohort of type-2 diabetes patients that is the lean mass, which has the maximum impact on bone health in diabetes. A greater lean mass leads to a greater dynamic loading of the bones, which has a trophic effect on bone health and density. Sarcopenia due to any cause is associated with low bone density in diabetes.

Apart from weakening the bone, accumulation of advanced glycosylation end-products (AGEs) in the organic bone matrix by nonenzymatic glycation interfere with normal osteoblast development, function, and attachment to the collagen matrix. In type 2 diabetes, differential effect at trabecular and cortical sites has also been noted with preservation of trabecular bone and loss of cortical bone mass. There are clinical studies which show that in T2DM, most of the fractures occur at sites that are rich in cortical bone. Risk factors other than bone density also need to be kept in mind in patients with diabetes, most notable being microvascular complication (esp. neuropathy and retinopathy), macrovascular complications, and muscle weakness.

Smoking, use of glucocorticoids, associated inflammatory diseases like inflammatory arthropathy all are associated with poorer bone mineral density and bone health in diabetes. Bone health is often a neglected aspect of diabetes management. It would a good clinical practice from the clinician's point of view to avoid medications which are associated with impaired bone health in patients of diabetes with established low bone mineral density. Pioglitazone and SGLT2 inhibitors have been linked to adverse bone mineral outcomes in diabetes. Pioglitazone (thiazolidinediones) inhibits bone formation directly, by diverting mesenchymal stem cell precursors from the osteoblast to the adipocyte lineage. SGLT2 inhibitors use has been linked to increased phosphate reabsorption from the kidneys. Increased phosphate reabsorption and increased circulating phosphorous leads to secondary hyperparathyroidism, increased circulating levels of phosphatonins, all of which have an adverse impact on bone mineral density. The high prevalence of vitamin-D deficiency also contributes to impaired bone mineral health and peak bone mass in adulthood.

Muscle Effects of Diabetes

Muscles are a major user of insulin-mediated glucose uptake. In face of insulin resistance in type 2, proteomics studies have revealed weakened metabolic flexibility, i.e. difficulty in switching between glucose metabolism and fatty acid utilization with preferential oxidative-to-glycolytic shift. There is altered mitochondrial function, reduced lipid oxidation, increased cellular stress response, and enhanced detoxification mechanisms. All these metabolic change result in changes in contractile proteins and altered cytoskeletal proteins and also fatigue and tiredness.

Acute and chronic neuropathies associated with diabetes can lead to muscle atrophy and weakness. For example, carpal tunnel syndrome (discussed in sections ahead) can lead to atrophy of hand muscles, and distal polyneuropathy can lead to loss of small muscles of foot. Primary diseases of muscles seen in diabetics include diabetic myonecrosis and amyotrophy.

Diabetic Myonecrosis

Spontaneous infarction of muscle in diabetic patients is a rare but well-known entity. Approximately 200 cases have been reported in literature so far. The pathophysiology for diabetic myonecrosis has not been fully elucidated, but it is proposed to be ischemic in nature without any obvious athero-embolism or vascular occlusion of any major artery. It is more commonly seen in patients who are dependent on insulin and already have underlying microvascular complications.

Clinically, the disease has slight male preponderance and patient usually present with a disabling and constant pain involving quadriceps muscles. Other areas which can be involved in minority of cases include calf muscles, upper limb, and neck muscles. There may be an apparent swelling at site of involvement. Asymmetry is a hallmark of this disease. Bilateral involvement occurs in one-third of patients. Blood investigation reveals raised levels of ESR and CRP, while creatine kinase may be raised or normal during early or late stage of presentation, respectively. Leucocyte count and temperature are normal and helps in differentiation from infective pathology. Sonography reveals diffuse or focal muscle edema and is invaluable in ruling out deep vein thrombosis or major arterial thrombosis. Magnetic resonance imaging is investigation of choice in such cases and the involved muscle shows hyperintensity on T2-weighted sequences and addition of contrast differentiates non-enhancing infarcted muscle from surrounding inflammation or edema. Additional findings on MRI can be subcutaneous edema, subfascial fluid, and loss of the normal fatty intramuscular septa. Biopsy is not generally indicated, but reveals muscle edema and infarction along with evidence of microangiopathy.

Disease generally resolves on its own by 6–12 weeks. Rest and pain relief are mainstay of therapy. But as there is evidence of microangiopathy and association with other microvascular complications, antiplatelets are generally advised. Constant vigil, however, is required as some of the cases can be complicated by compartment syndrome. Moreover, recurrence rate is very high and half of the cases would have recurrence. The mean mortality rate associated with DMI is 10% within 2 years of initial diagnosis, predominantly as a result of macrovascular complications.

Diabetic Amyotrophy

Amyotrophy or diabetic lumbosacral plexopathy has overlapping clinical presentation with diabetic myonecrosis. But, amyotrophy occurs predominantly in type 2 patients who are fairly controlled or has recently been diagnosed. It also present with acute onset proximal leg pain followed by muscle weakness. Disease is usually unilateral at onset, but bilateral involvement eventually occurs in majority of patients. About one-third of patients may have distal onset of disease. This condition is also associated with distal and proximal sensory loss. New onset autonomic symptoms may occur in up to half of the patients and more than 80% patients would report loss of at least 10% body weight. Rarely, muscles of upper limb and thorax can be involved.

Underlying pathophysiology is not clear (e.g., ischemic, metabolic and/or inflammatory), though there is general consensus that ischemic injury due to non-systemic microvasculitis is most likely cause. Electrodiagnostic studies, in presence of typical features, are sufficient to clinch the diagnosis. Abnormalities are localized to lumbosacral plexus and peripheral nerves of lower limb. HIV and cytomegalovirus can cause similar disease with same electrodiagnostic findings. Inflammatory myopathies such as polymyositis and dermatomyositis should always be ruled out. Associated classical cutaneous manifestations makes easy for dermatomyositis to be ruled out. Polymyositis is classically associated with elevated levels of creatine-phosphokinase (CPK) in the blood which is not seen in amyotrophy.

Disease usually runs a self-limited course with spontaneous resolution but some residual problem remains in large majority in form of either weakness or persistent pain. Course of disease can run over months. Treatment is only symptomatic. No evidence exists to favour treatment with steroids, immunosuppressants, or immunoglobulins.

Joint and Connective Tissue Effects of Diabetes

Joint and connective tissue diseases are more common in people with diabetes (Table 60.2). There is no single mechanism that has been shown to account for the development of joint and connective tissue effects of diabetes, viz. limited joint mobility (LJM), shoulder adhesive capsulitis, stenosing flexor tenosynovitis, and Dupuytren's contracture amongst

Table 60.2 Prevalence of joint and connective tissue diseases in people with and without diabetes

Musculoskeletal disorder	With diabetes (%)	Without diabetes (%)
Shoulder capsulitis	11–30	2–10
Limited joint mobility	8–50	0–26
Dupuytren's disease	20–63	5–10
Carpal tunnel syndrome	11–16	2–5
Stenosing flexor tenosynovitis	10–12	<1
Diffuse idiopathic skeletal hyperostosis	13–50	2–15

others. However, the shared cause of these conditions seems to involve abnormal connective tissue deposition around joints, in tendon sheaths, and in the palmar fascia, respectively.

Accumulation of advanced glycation end products (AGEs) with cross-linking of collagen and other macromolecules has been proposed as a potential pathogenetic mechanism. It is likely that poorer glycaemic control over time with resulting AGE formation influences the development of hand and shoulder problems amongst patients with DM.

Adhesive Capsulitis of the Shoulder (Frozen Shoulder Syndrome, Shoulder Periarthritis) Enter Box 60.1

Box 60.1 Adhesive Capsulitis of Shoulder

Painful progressive restriction of shoulder motion
30 months: Average duration of symptoms
10–29% prevalence amongst diabetics
Treatment: Analgesics, physiotherapy, intra-articular corticosteroid injection, arthroscopic capsular release

The prevalence of adhesive capsulitis is 11–29% in patients with T2DM, as compared to only 2–3% in healthy euglycaemic individuals. Risk factors for adhesive capsulitis include older age, increased duration of diabetes, history of myocardial infarction, presence of peripheral neuropathy and nephropathy. Adhesive capsulitis usually presents as painful progressive restriction of range of shoulder movement, especially on abduction and external rotation. Its natural history can be divided into three phases: pain, stiffness, and recovery. The length of the recovery phase depends on the duration of the stiffness phase, with symptoms lasting for an average of 30 months. Adhesive capsulitis can involve any of the large joints in diabetes. Frozen shoulder syndrome is perhaps the most common type of adhesive capsulitis (Table 60.2). Shoulder adhesive capsulitis is more likely to develop in older individuals with either type of DM and in those with longer duration of disease amongst patients with type 1 DM, history of myocardial infarction, associated nephropathy, and/or neuropathy [4].

Analgesics physical therapy and intra-articular corticosteroid injection are first-line therapy during the initial painful phase of shoulder adhesive capsulitis. Intra-articular injection, early in the course of the disease, has been linked to improved outcomes and better mobility in the long run. It must be highlighted that oral corticosteroids have limited role and should be routinely used in patients with adhesive capsulitis. Oral glucocorticoids are not associated with improved mobility outcomes in the long run and additionally they adversely affect glycaemic control. Intensive physiotherapy including stretching and mobilization also has a key role in improving clinical outcomes. Arthroscopic capsular release has been an effective treatment modality for refractory shoulder adhesive capsulitis in a few patients. Radiographic-guided hydro-dilation and manipulation under anesthesia have been tried in refractory patients with mixed long-term outcomes.

Limited Joint Mobility (Diabetic Cheiro-Arthropathy) Enter Box 60.2

Box 60.2 Limited Joint Mobility

Collagen disease seen only in diabetes
Prevalence 8–50%
Stiff hands with thick, tight, and waxy skin
Asymptomatic
Harbinger of microvascular disease

Limited joint mobility (LJM) also known as ‘diabetic cheiro-arthropathy’ is characterized by stiff hands. The skin is markedly thick, tight, and waxy especially on the dorsal aspects of the hands which are usually, symmetrically affected: mimicking scleroderma.

Patients with LJM have limited extension of the metacarpophalangeal, proximal interphalangeal, and distal interphalangeal joints, usually beginning in the ulnar digits and spreading radially. Screening for LJM can be done by physical examination. The prayer (preachers) sign involves the patient holding the hands opposed to one another vertically with elbows flexed and wrists extended. A positive sign is observed by an inability of the patient to completely approximate the palmar surface of the digits.

In the table top sign, the patient places the palms flat on a hard surface with the digits spread. Normally, the entire palmar surface of the digits should contact the table. If the test is positive, the digits and palm will not lie flat. Both these tests can also be positive with Dupuytren’s contracture. The prayer sign is also useful for staging of LJM as follows:

Stage 0: normal findings on prayer sign examination.
Stage 1: involvement of one or two interphalangeal joints bilaterally.
Stage 2: Inability to approximate three or more interphalangeal joints bilaterally.
Stage 3: Hand deformity at rest.

The prevalence of LJM in diabetes varies from 8% to 50%. The frequency of LJM in diabetics increases with

increasing diabetes duration. The importance of LJM can be highlighted by the fact that its presence is an indicator for other associated more grave microvascular and macrovascular complications of diabetes. An association with microvascular complications (retinopathy, microalbuminuria) has been shown, both in Type 1 and in Type 2 diabetes. LJM increases the risk for microvascular disease in Type 1 diabetes. There is an 83% risk for microvascular complications after 16 years of diabetes in the presence of LJM, compared with a 25% risk in the absence of LJM. Patients with LJM may be at higher risk for foot ulceration because of concomitant limited joint mobility at the hallux.

Treatment of LJM is not very satisfactory. Physiotherapy to increase the range of motion in the hand joints is fundamental. This involves active and passive mobilization and use of corrective splints. Glucocorticoids injection of flexor tendon sheaths leads to resolution of finger contractures in every two out of three patients with LJM. At a more practical level, optimization of glycaemic control is believed to be vital for the management of LJM.

Dupuytren Contracture (DD)

DD is a progressive fibro-proliferative disorder resulting in abnormal scar-like tissue in the palmar fascia leading to irreversible, permanent, painless, and progressive contracture of the involved digits. DD is commonly bilateral, and 'Dupuytren-like' fibrotic tissue can occur on the dorsum of the hand over the knuckles (Garrod's pads), feet (Lederhose's disease), and penis (Peyronie's disease). The ring finger is the most frequently involved, followed by the little finger, and then middle finger; the index finger and thumb are rarely involved.

The incidence of DD also increases with concurrent patient clinical conditions or factors such as diabetes, smoking, chronic alcoholism, seizures, and infection. Microvascular changes in smokers may play a role. Hand examination also reveals palpable palmar nodule or nodules.

The prevalence of DC in diabetes ranges between 20% and 63%, considerably higher than amongst nondiabetic subjects (13%). DC in diabetic subjects is associated with diabetes duration, long-term poor metabolic control, and presence of microvascular complications. LJM and DC may coexist in the same patient [5].

DD must be distinguished from several other conditions that affect the hand, including trigger finger, stenosing tenosynovitis, a ganglion cyst, or a soft-tissue mass. Unlike DC, trigger finger typically involves pain with flexion followed by the inability to extend the affected digit. Stenosing tenosynovitis may be distinguished from DD by pain and a history of overuse or trauma. A small, movable nodule that is tender to palpation at the metacarpophalangeal joint is likely a ganglion cyst. Treatment of DC involves optimized glycaemic control and physiotherapy. Topical steroid injection and surgery are reserved for the more severe cases. Surgery yields satisfactory results.

Calciphylaxis

Calciphylaxis is a form of small vessel vasculitis. It has been reported in patients with renal failure as well as diabetes. Clinically, they present as small tender areas on the skin, initially red in color, which then become subcutaneous nodules, leading to poorly healing necrotizing skin ulcers. Key to treatment is to ensure a good glycaemic control and analgesics for pain relief.

Stenosing Flexor Tenosynovitis (Trigger Finger)

Stenosing flexor tenosynovitis typically presents with locking (or 'triggering') of fingers in flexion, extension, or both, most commonly involving the thumb, middle, and ring fingers. At clinical examination, locking is reproducible on active or passive finger flexion. Moreover, a nodule is palpable at the base of affected finger. The prevalence of stenosing flexor tenosynovitis ranges between 5% and 36% amongst patients with type 1 and 2 DM, as compared with 2% in the general population. Compared with nondiabetics, patients with DM are more likely to have multiple fingers involved simultaneously by stenosing flexor tenosynovitis [6].

In diabetic subjects, it is associated with diabetes duration, long-term poor metabolic control, and presence of microvascular complications. Additionally, it has been suggested as an indicator of glucose dysmetabolism that should prompt glucose measurement and oral glucose tolerance test in the general population. Treatment of stenosing flexor tenosynovitis includes modification of activities to avoid triggering of digits, nonsteroidal anti-inflammatory drug therapy, splinting, corticosteroid injection into the tendon sheath, and surgical release. Corticosteroid injections into the tendon sheath has been especially found to be beneficial in patients with disease duration of less than 6 months and having nodular type of disease. In these patients, the success rate of a single injection is as high as 96%.

Calcific Shoulder Periarthritis (Tendinitis)

Calcific tendinitis is a painful condition most commonly affecting the shoulder in which calcium hydroxyapatite crystals deposit predominantly in periarticular areas. In the

shoulder, these crystals may also deposit within the tendons of the rotator cuff. The incidence of calcific shoulder periarthritis is increased amongst patients with DM. Calcific tendinitis may coexist with adhesive capsulitis in the shoulder.

Carpal Tunnel Syndrome (CTS)

Carpal Tunnel Syndrome is a common compression neuropathy of the median nerve associated with many conditions including diabetes. Classically, these patients present with the wasting of the muscles of the thenar eminence (abductor pollicis brevis, extensor pollicis longus, and extensor policis brevis). The typical presentation is hand paresthesia involving the median nerve distribution. Paresthesia and pains are usually exacerbated in the night. Apart from diabetes, CTS is also associated with rheumatoid arthritis, pregnancy, and obesity. Diabetes may induce structural alterations of tendon, increase obesity, and produce metabolic abnormalities that result in proliferation or fibrosis of the connective tissues surrounding the nerve. Transforming growth factor-beta has a key role in the pathogenesis of CTS. Increased TGFb is seen in TGF which is associated with increased localized inflammation and collagen deposition. The prevalence of CTS in diabetes has been reported at 11–25%, and it is more common in women. Conversely, 5–8% of patients with carpal tunnel syndrome may have diabetes. Two classic signs, Tinel's sign and Palen's test, are very helpful in establishing the diagnosis. A positive Tinel's sign refers to the elicitation of paresthesia and/or pain in the hand (mainly thenar and thumb area) by tapping over the median nerve on the volar aspect of the wrist. Palen's test is positive if similar symptoms are produced when the patient flexes both wrists completely and opposes the dorsal surfaces of the hands to each other.

Management focuses on analgesics and splints, while topical steroid injection and surgery may be indicated in more severe cases. Endoscopic tendon release procedures are increasingly being used in CTS to relieve the median nerve from compression, with good clinical outcomes. Recent studies have suggested that a single dose of ultrasound-guided perineural platelet-rich plasma (PRP) injection can provide therapeutic effect for at least 1 year post injection [7].

Reflex Sympathetic Dystrophy

Also known as algodystrophy, Sudeck's atrophy, and chronic regional pain syndrome type 1, this disorder is characterized by pain, swelling, trophic changes, and vasomotor disturbances with impaired mobility of the body part involved. The development of the condition is usually preceded by a trauma, which may range from trivial injury to a surgery or a fracture. Apart from diabetes, reflex sympathetic dystrophy is also seen in hyperthyroidism, hyperparathyroidism, and type IV hyperlipidemia. A large variety of treatment options have been used in reflex sympathetic dystrophy ranging from analgesics, physiotherapy, intravenous bisphosphonates, calcitonin, oral corticosteroids, and sympathetic ganglion blocks. Clinical outcomes are usually good. In rare patients, it may lead to contractures.

Diffuse Idiopathic Skeletal Hyperostosis (DISH), Forestier's Disease

Diffuse idiopathic skeletal hyperostosis (DISH) is a condition characterized by ossification of spinal ligaments associated with large bridging osteophytes between vertebral bodies. Obesity, hyperlipidemia, hyperuricemia, hypertension, hyperinsulinemia, and diabetes are thought to be associated with DISH.

The diagnosis of DISH is based on radiologic features. Radiographic criteria for the diagnosis of DISH include the presence of 'flowing' osteophytes along the anterolateral aspects of at least four contiguous vertebral bodies, the preservation of intervertebral disk spaces, and the absence of changes of degenerative spondylosis or spondyloarthropathy. Analgesics, heat application, exercise, and local corticosteroid injections have been used to treat patients with DISH. Targeted spine strengthening exercise and posture training program reduced kyphometer measured, but not radiographic-measured kyphosis in people with DISH [8].

Crystal-Induced Arthritis and Gout

Calcific tendinitis is clearly associated with diabetes. Similar calcific processes certainly occur in blood vessels of diabetic patients as well as in spinal ligaments in DISH. Metabolic changes, consequent to chronic high glucose and insulin levels, may produce important changes in connective tissues that might predispose to pathologic calcification.

Gout is an inflammatory arthropathy characterized by increased deposition of mono-sodium urate crystals in the joint. Gout is more common in Caucasians where it effects 1–2% of the population. Risk factors for gout include hyperuricemia, male sex, renal impairment, alcohol use, and increased consumption of meat. Insulin resistance, which is very common is type-2 diabetes, is associated with decreased uric acid excretion and hence is associated with hyperuricemia. Serum urate concentration and gout is strongly associated with central adiposity and insulin resistance. Few meta-analysis have showed that the prevalence of gout in type-2 diabetes may be as high as 25%. It must be highlighted

that amongst the anti-hypertension medicines and anti-lipid medication, losartan and fenofibrate have urate-lowering effects. Hence, special consideration should be given to these drugs when type-2 diabetes patients with hyperuricemia/gout is planned to be put on hypertension or lipid medications. Mycophenolate mofetil therapy with pegloticase and anakinra are new upcoming therapies for refractory gout [9, 10].

Osteoarthritis

Osteoarthritis is the most common form of arthritis in adults and as such would frequently co-occur with diabetes by chance alone. Clear clinical evidence that diabetes predisposes to premature or severe osteoarthritis is lacking. The fact that obesity is a common risk factor for both osteoarthritis and diabetes makes epidemiologic studies difficult. Peripheral neuropathy may also adversely affect joints and increase the risk of advanced, aggressive forms of osteoarthritis. There seems to be propensity for diabetic patients to have more severe pain and radiographic changes both preoperatively and postoperatively, an increased risk of deep tissue infection as well as an increased revision rate compared with nondiabetic controls. Whether insulin resistance worsens or not when therapeutic doses of oral glucosamine are used to treat osteoarthritis remains controversial. Intra-articular injections of autologous fat with or without platelet rich plasma is a new upcoming therapy for severe osteoarthritis [11].

Charcot Arthritis

Charcot's arthropathy is a form of destrictive arthritis. It is seen in diabetes usually as an association with peripheral neuropathy. It is a debilitating condition observed in 0.4% of patients with diabetes and is associated with limb deformity, gait instability, ulcers and may lead to limb amputation also. Four different stages of Charcot arthropathy have been described. In the earliest stage (Stage 0), the patient usually complains of pain in the joint. The join may or may not have swelling. X-rays of the joint are normal at this stage. MRI is the most sensitive tool for diagnosis at this stage where it can pick up marrow edema, subchondral cysts, and microfractures. In Stage 1, the X-rays of the joint now start showing varying degrees of osteolysis, bone fragmentation, and architectural destruction. Stages 0 and 1 are the clinically active stages of the disease characterized by joint pain swelling, redness, and localized increase in skin temperature. In stage 2, the clinical signs of local inflammation usually resolves, coalescence starts which may be visible on joint X-rays. Stage 3 is known as the reconstructive stage, where fusion or ankylosis of the bones occur. Stages 0 and 1 usually last up to 6 months whereas stages 2 and 3 last up to 24 months.

Charcot's arthropathy most commonly involves the foot. Altered architecture of the foot as a result of the deformity leads to abnormal foot pressure distributions, leading to increased risk of foot ulcers at the high pressure points. Tarsometatarsal followed by the mid-tarsal joint involvements are the two most common types of Charcot arthropathy. After foot, knees, elbows, and the shoulder joints are most commonly affected by Charcot's arthropathy.

The pathogenesis of Charcot's arthropathy is yet to be fully elucidated. Localized joint inflammation and osteoclast activation is central to the pathogenesis of Charcot arthropathy. Increased local levels of tumor necrosis factor alpha, interleukins (IL-1, IL6), RANK ligand have been documented in Charcot arthropathies. Abnormal weight bearing due to diabetic neuropathy leads to small microtrauma to the foot, which leads to foot inflammation and hyperemia which sets up a vicious cycle of joint inflammation and damage resulting to Charcot arthropathy.

The most important aspect of managing Charcot arthropathy, especially in the acute stage is joint immobilization, and absolute cessation of weight bearing. Nonweight bearing total contact cast (TCC) is the treatment of choice for managing Charcot foot. This leads to significant reduction in joint inflammation and reduces the risk of deformity also. Bisphosphonates (pamidronate, alendronate, zoledronate) have been demonstrated to be useful in reducing joint inflammation and hastening recovery in patients with Charcot arthropathy, both in observational studies as well as randomized controlled trials. Small studies have also showed the beneficial effects of RANK ligand inhibitors (denosumab) in the management of Charcot arthropathy. Surgery has no role in the management of Charcot arthropathy in the active stage. Surgery has a role in inactive or burnt out stage of the disease, where it helps in joint stabilization, and helps improving the pressure distribution of the joint, which would help in preventing ulcers. Therapeutic footwears have an important role in improving foot pressure distribution in patients with Charcot's foot, help in healing of foot ulcers, and also providing limited mobility to the patients.

Diabetic Foot

One of the most devastating complications of diabetes is diabetic foot. Foot problems in diabetes occur due to combination of abnormalities affecting vascularity, peripheral nerves, skin and musculoskeletal system.

Foot problems in diabetes can be largely divided into infective and noninfective complications.

Charcot's foot is characterized by destruction of small foot joints and complete disorganization of anatomy of foot. Neuropathy is the main contributor in this condition with both peripheral and autonomic neuropathy playing

significant roles. Peripheral neuropathy makes the insensate foot take repeated trauma and also to transmit pressure in not-so-optimal way. This creates false pressure points and puts undue stress on small joints of foot. Autonomic neuropathy, on the other hand, impairs regulation of blood flow to foot and thus exposing bones of foot to excessive bone loss during periods of increased blood flow. Charcot foot is great danger to health of any diabetic as this condition cannot be reversed and puts patient at grave risk of foot ulcer and infections. It can present early on, as an acute inflammatory process which is frequently mistaken for gout, osteomyelitis or injury, and then develops into chronic arthritis with severe deformities. It is always a clinical challenge to differentiate between Charcot foot and osteomyelitis. Systemic signs of infection (fever, leucocytosis), breach in skin of foot, positive probe test and positive labeled leucocyte scan favor a diagnosis of osteomyelitis. MRI and Tc bone scan have also been used to differentiate between them.

Proper foot care education to patient to avoid further deterioration and to prevent ulcers is of paramount importance. Non-weight bearing and immobilization of the affected limb have been the mainstays of therapy. Bisphosphonates have also been reported to be useful for the acute phase of Charcot arthropathy.

A detailed discussion of ulceration and infective complications of foot in diabetes is beyond the scope of this chapter. However, general principles for wound care remain the same. There are two ways in which diabetic foot is at disadvantage. One, diabetic foot is more predisposed to trauma. Any skeletal abnormality in foot in patient with diabetes predisposes them to increased risk of trauma because of sensory loss. Diabetic patients with minor trauma to foot are more likely to ignore because of lack of pain. Insensate foot also alters proprioception and thus makes these patients more prone to falls and major trauma while walking. Moreover, neuropathy further contributes to deformity of foot, e.g. atrophy of mid-foot muscles causes clawing. Associated autonomic neuropathy results in dry skin and more risk of fissures. Second, altered blood supply to foot, due to vasculopathy, makes these trauma and infection difficult to heal. Moreover, delivery of antibiotics is also hampered. And because of this reason, patient vasculature is a must for a normal foot in diabetics. In the presence of vascular adequacy, even if minor wounds are sustained they would heal with basic care.

The main goal should be prevention of diabetic foot ulcers. In this regard, at-home foot skin temperature monitoring is a great way to predict sites of increased risk of foot ulcer. At-home foot temperature monitoring significantly reduces incidence of diabetic foot ulcer recurrence at or adjacent to measurement sites over usual care, only if the participants reduce ambulatory activity when hotspots are found or when aiming to prevent ulcers at any foot site [12].

Conclusion

Musculoskeletal complications of diabetes hence are a large number of diverse set of disorders. In contrast to other complications of diabetes, a good clinical eye has a key role in the diagnosis of these disorders. Many a times, these complications are missed in a busy clinic practice, as most of these complications are not severe and life threatening, although lack of their diagnosis and timely treatment may lead to significant morbidity in the patients.

Multiple Choice Questions

1. Anti-diabetic medications linked with adverse impact on bone health include:
   (a) Sulfonylureas
   (b) Insulin
   (c) **SGLT-2 inhibitors**
   (d) DPP-4 inhibitors
   (e) **Glitazones**
2. All of the following are true regarding diabetic myonecrosis except:
   (a) Painful
   (b) ESR is raised
   (c) Spontaneously resolving.
   (d) **Recurrence rates are low**
   (e) Asymmetrical
3. All of the following are true regarding diabetic amyotrophy except:
   (a) Asymmetrical
   (b) Predominantly motor involvement and muscle wasting.
   (c) Spontaneously resolving.
   (d) **Definitive role of immunosuppresive and glucocorticoids in management**
   (e) **Sensory involvement is absent**
4. Most commonly involved joints in adhesive capsulitis in patients with diabetes:
   (a) Knee
   (b) **Shoulder**
   (c) Hips
   (d) Elbow
   (e) Metacarpophalangeal
5. Carpel tunnel syndrome leads to wasting of the following small muscles of the hand except:
   (a) abductor pollicis brevis
   (b) **abductor policis longus**
   (c) extensor pollicis brevis
   (d) extensor policis longus
   (e) **Opponens pollicis**
6. Carpel tunnel syndrome is due to the involvement of the following nerve:
   (a) Ulnar nerve
   (b) **Median nerve**

(c) Radial nerve
(d) Cutaneous nerve of the forearm
(e) Superficial peroneal nerve

7. Antihypertensive medications with uric acid lowering effects include.
   (a) amlodipine
   (b) ramipril
   (c) lisinopril
   (d) olmesartan
   (e) **losartan**
8. Anti-lipid medication with uric acid lowering properties
   (a) **Fibrates**
   (b) statins
   (c) bile acid binding resins
   (d) PCSK9 inhibitors
   (e) Ezetimibe
9. Medications acting on bone metabolism found to be beneficial in Charcot's arthropathy include:
   (a) teriparatide
   (b) **bisphosphonates**
   (c) calcitonin
   (d) **denosumab**
   (e) saracatanib
10. The pathogenesis of Charcot's arthropathy involves all except:
   (a) increased inflammatory cytokines
   (b) increased osteoclast activation
   (c) **decreased RANK-L expression**
   (d) **increased osteoblast activation**
   (e) increased local hyperemia.

Diabetes and the Skin

61

Justine Mestdagh, Sterre Blanche Laura Koster, Jeffrey Damman, and Hok Bing Thio

Chapter Objectives/Key Features

- There are several skin manifestations in diabetes mellitus, some of them occur frequently.
- Some of these are specific for Type 1 diabetes mellitus, others for Type 2 and some occur in both.
- Medications used to treat diabetes mellitus may also cause skin adverse effects.

Introduction

Many diabetes mellitus patients develop skin manifestations during the course of the disease and children are no exception [1, 2]. Prevalence rates range from 30 to 80% [2, 3]. However, we should keep in mind that diabetes is a highly prevalent disease and therefore should remain critical toward studies trying to determine a direct relationship without being aware of possible confounding factors. The skin is a large organ of the human body and is directly visible to the outside world. Because of this, patients tend to care a lot about their skin, sometimes more than clinicians realize [4].

Skin manifestations of diabetes mellitus are diverse and range from cosmetic concerns to severe conditions more frequently seen in long-standing disease. Recognizing these is a rewarding clinical skill to master, since some of them may be important diagnostic clues as well as markers of advanced disease [5]. Some diabetes-related skin defects can be a port of entry for later infections. Several medications can affect the skin shortly after intake. Some skin manifestations are more specific for diabetes than others. Besides evaluating the skin for establishing a diagnosis of diabetes, it can also be a help for evaluating treatment success, study results, and glucose levels.

Pathogenesis

Pathogenesis of skin involvement in diabetes mellitus can be seen as a collaborative, cumulative phenomenon of biochemical, vascular, neurological, immune-mediated and metabolic changes with longstanding hyperglycemia as its key pathogenic player. Diabetics with hemoglobin A1c values <8 mmol/ml tend to have less cutaneous involvement than those with hemoglobin A1c values >8 mmol/ml [2].

Increased oxidative stress and chronic high levels of circulating glucose lead to a non enzymatical chemical reaction between glucose and proteins, lipids and nucleic acids. The chemical reactions between amino acids and the carbonyl group of glucose are called Maillard reaction. First reversible Schiff's bases are formed followed by the conversion to stable products. Finishing transforming chemical reaction leads to the formation of advanced glycation end products (AGE) which bind to specific receptor on many cell surfaces initiating numerous intracellular signaling cascades leading to diabetic complications [6]. Due to formation of AGE and oxidative stress, vascular damages appear [7]. Neuropathy leads to hypo- or even anhidrosis, vascular dilation causing erythema and hyposensation. Vascular and neurological changes are responsible for loss of sensation, impaired blood supply, and failure of homeostatic regulatory mechanism in end organs such as the skin.

Today, skin autofluorescence (SAF) can be measured easily by a quick, non-invasive method. The SAF serves then as

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_61

a quantitative parameter of the cutaneous AGE which in turn can be used to predict and early detection of diabetic vascular complications [8].

Hyperglycemia increases the flux through to pyolol- and hexosamine pathways with activation of protein kinase C, NFkappa b, mitogen-activated protein kinase (MAPK), and others [9]. Consequently, this leads to endothelial proliferation and basement membrane thickening with deposition of periodic acid-Schiff stain positive (PAS+) material with narrowing of arterioles, capillaries, and venules.

Keratinocyte function is frequently altered which leads to an impaired epidermal barrier function and delayed wound healing. [10–12] Decreased hydration might play a role. pH values of the skin are higher than in non-diabetic patients leading to an increase in bacterial colonization.

Skin Manifestations of Diabetes Mellitus

Certain skin manifestations are specific for Type 1 diabetes mellitus, others for Type 2 and some occur in both. In the following text, diseases appear in alphabetical order. Whether they occur predominantly in Type 1 diabetes mellitus, 2, or both will be mentioned.

Acanthosis Nigricans

Acanthosis nigricans (Fig. 61.1) consists of velvety hyperpigmented plaques in the intertriginous areas of the skin. Frequently skin tags are found within these lesions. Most patients are asymptomatic although maceration, malodor, and discomfort have been reported. It is the most frequent skin condition in diabetes, almost all Type 2 diabetic patients develop acanthosis nigricans to a certain extent. It is more frequently seen in Hispanics and native as well as African Americans; men and women are equally affected. Besides diabetes, acanthosis nigricans can also appear in obese individuals, patients with insulin resistance (both independently associated) and less frequently in patients with acromegaly, Cushing syndrome, and leprechaunism. It is sometimes observed in malignancies (especially those of the stomach) and associated with certain medications, for example, nicotinic acid, corticosteroids, and rarely repetitive insulin injections. Lastly, it can appear in healthy individuals as well [13, 14].

Histopathology of the affected skin (Fig. 61.2) reveals hyperkeratosis, papillomatosis, mild acanthosis, and sometimes hyperpigmentation of the basal layer. There is usually no dermal inflammation. The hyperkeratosis causes the darkened aspect and papillomatosis causes accentuation of skin markings. High levels of circulating insulin bind the tyrosine

Fig. 61.1 Acanthosis nigricans

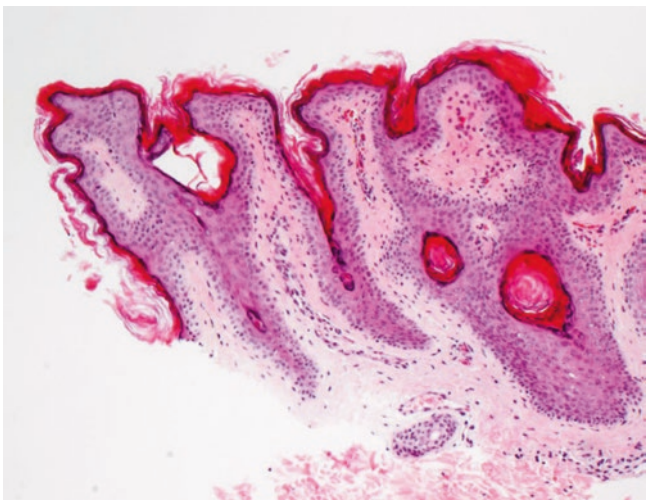

Fig. 61.2 Acanthosis nigricans. Acanthosis nigricans: the lesion shows hyperkeratosis and papillomatosis usually without dermal inflammation.

kinase growth factor receptors (e.g., insulin-like growth factor 1receptor) on fibroblasts and keratinocytes. This stimulates these cells to grow, causing the typical skin manifestations.

People with extensive acanthosis nigricans seem to have higher fasting plasma insulin levels [15, 16].

Weight reduction, exercise, and if necessary, glucose lowering treatment in combination with lipid lowering drugs may reduce insulin resistance and improve acanthosis nigricans. If patients experience discomfort, ointments containing salicylic acid, urea, lactic acid, or retinoids may reduce the hyperkeratotic lesions. Systemic retinoids have been used in severe cases. Recurrence is often seen after discontinuation of therapy.

Acrochordon

Acrochordon (Figs. 61.3 and 61.4), also called fibroma molle, fibroepithelial polyp, or skin tag is a soft pedunculated flesh colored papule in the axillae, neck, eyelids, and in the inframammary region. Patients are asymptomatic apart from possible cosmetic concerns and rarely experience pain or irritation when the fibroma contains nerve endings.

There is a slight female predisposition and its prevalence increases with age. The association between acrochordon and obesity is well established, but they are also an independent marker for diabetes, especially Type 2 [17]. Skin tags have been detected in 23% of diabetic patients compared to 8% in a healthy control group. Though there is some controversy regarding the total amount of skin tags per individual and the associated risk of diabetes, current literature seems to show that the higher the number, the higher the risk for diabetes mellitus. Patients with over 30 skin tags are especially at risk. A positive correlation has also been found between the total number of skin tags and mean fasting plasma glucose [18, 19] making skin tags an even more sensitive cutaneous marker for diabetes than acanthosis nigricans. Clinicians should be aware of this association when taking note of multiple acrochordons. As mentioned earlier, high levels of circulating insulin stimulate keratinocytes to grow, which could help explain the higher prevalence of skin tags in diabetics. Treatment is not necessary, but if patients want them to be removed, they can be excised. Electrodessication and cryotherapy are two valid alternatives.

Fig. 61.3 Acrochordon in the right axilla

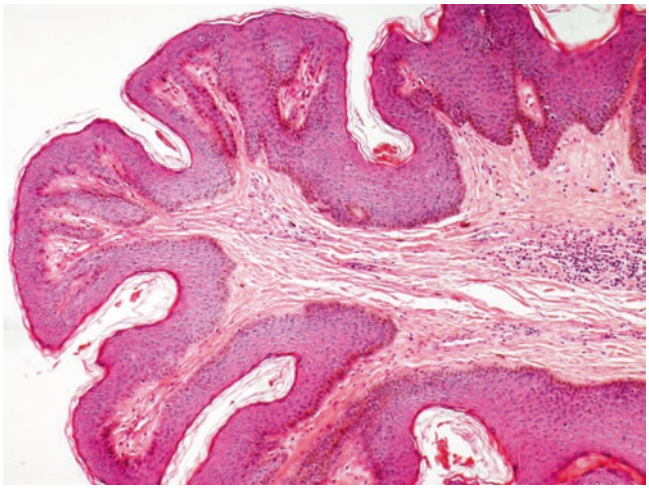

Fig. 61.4 Acrochordon. Acrochordon or fibroepithelial polyp: the papules show a fibrovascular core covered by epidermis showing hyperplasia sometimes resembling seborrheic keratosis. The stroma often shows loosely arranged collagen, an increased number of blood vessel and (in larger lesions) fat cells

Acquired Perforating Dermatosis

Acquired perforating dermatosis (Fig. 61.5) presents with scaly highly pruritic follicular hyperkeratotic dome-shaped papules and nodules, often with central umbilication or a central keratotic plug on the extensor surfaces of the lower extremities and in some cases also on the face, trunk, and dorsal area of the hands.

This chronic disease is rare but more frequently seen in Afro-Americans with diabetes (both Type 1 and 2) and chronic kidney disease or hemodialysis (as high as 10%). However, it can also occur in diabetics with normal kidney function [20–22].

Skin conditions to be included in the differential diagnosis are prurigo nodularis, folliculitis, arthropod bites, multiple keratoacanthomas, psoriasis vulgaris, and lichen planus. Pathologic examination (Figs. 61.6 and 61.7) shows a hyperplastic invaginating epidermis containing parakeratosis, degenerated connective tissue and cellular debris, following the transepidermal elimination of dermal collagen and elastin.

Fig. 61.5 Acquired perforating dermatosis

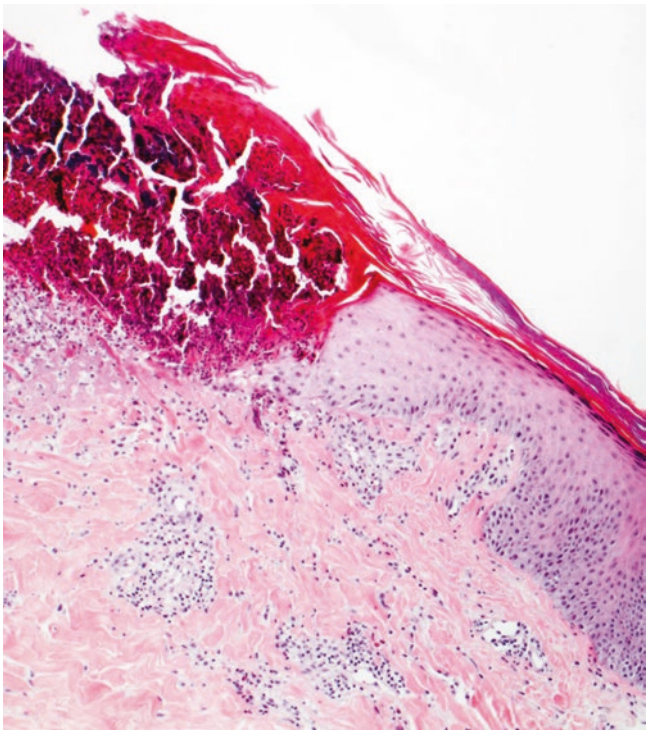

Fig. 61.6 Acquired perforating dermatosis. The lesion shows an invaginating epidermis containing a parakeratotic plug with degenerated connective tissue fibers and cellular debris

The cause is probably a multifactorial interplay between glycation of collagen, Koebner phenomenon, microvasculopathy, and inflammatory reaction to altered dermal collagen or deposition of substances which are not removed by dialysis. It is unclear whether the abnormality appears

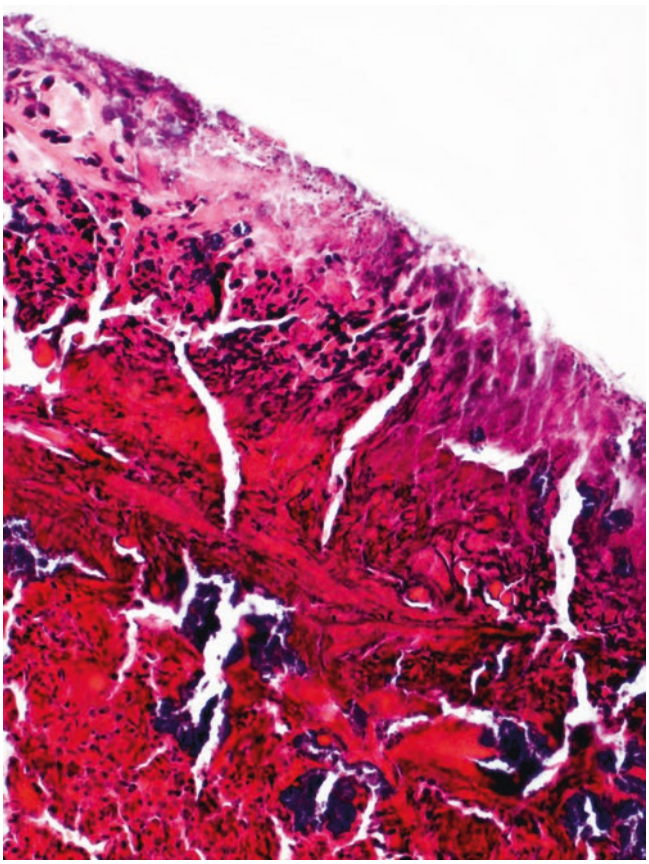

Fig. 61.7 Acquired perforating dermatosis. The lesion shows an invaginating epidermis containing a parakeratotic plug with degenerated connective tissue fibers and cellular debris

first in the dermis or epidermis, pruritus is probably rather the cause of these changes than the effect. Acquired perforating dermatosis is difficult to treat. Treating the pruritus is the main goal. Coexisting disease should be treated according to current standards though dialysis does not improve the disease course. Topical glucocorticoids, antihistamines, topical and systemic retinoids, doxycycline, allopurinol, cryotherapy, and phototherapy are all used for symptom relief.

Bullosis Diabeticorum

Patients suffering from bullosis diabeticorum present with uni- to bilateral spontaneous tense non-inflammatory bullae on normal appearing skin of the dorsolateral sides of the lower extremities and sometimes of the hands. Though it is thought to be a distinct marker for diabetes, it is the rarest skin manifestation in diabetes occurring in 0.5% of all diabetic patients. No large population studies have confirmed this so its frequency might be higher. It does occur more in men with longstanding poorly controlled Type 1 diabetes mellitus with peripheral neuropathy [23, 24].

There are three known subtypes. In the first, "classic" type, the cleavage level of the bullae is intraepidermal [25], the fluid in these bullae is clear and sterile and the surrounding epidermis shows spongiosis. There is no pain. These bullae resolve spontaneously without scars in a few weeks but recurrence is possible. Histopathological examination shows a subepidermal blister with early re-epithelialization. The second type consists of bullae filled with hemorrhagic fluid. The cleavage level lies below the dermoepidermal junction. Healing comes with scarring and atrophy. The third type appears on tanned skin, and its cleavage level lies within the lamina lucida of the dermoepidermal junction. Healing leaves no scars. The differential diagnosis of bullosis diabeticorum includes primary autoimmune blistering such as pemphigus, bullous pemphigoid, erythema multiforme, epidermolysis bullosa acquisita, and porphyria cutanea tarda. Immunofluorescence tests are negative. Bullosis diabeticorum is associated with high blood glucose levels but venous pressure elevation may also play a role. Microangiopathic vessels offer less blood to the skin which then becomes more prone to acantholysis, and thus blister formation. Other possible causes are autoimmune phenomena, exposure to UV light, and alterations in calcium and magnesium levels [23, 26, 27]. Spontaneous resolution is seen within 2 to 5 weeks [28]. No treatment is needed besides the prevention of complications, e.g., chronic ulcers and bacterial infections. In cases of major discomfort, aspiration can be considered. Nevertheless, recurrence of bullae is frequent.

Diabetic Cheiroarthropathy (Diabetic Stiff Hand or Limited Joint Mobility Syndrome)

People with diabetic cheiroarthropathy have a thickened waxy skin and bilateral limited joint mobility of the hands and fingers leading to flexion contractures (e.g., Dupuytren's disease). This process starts at the fifth digit and progresses radially. It can extend to the wrists, elbows, ankles, knees, toes, and cervicothoracic spine. Clinical examination can reveal a prayer sign, which is the inability to approximate the palmar surfaces of the hands and fingers. Some patients have Huntley papules, which are multiple tiny papules grouped on the dorsal sides of the fingers or periungally. On histologic examination, a hyperkeratotic epidermis and dermal papillary hypertrophy is noticed. Up to 30% of diabetics have diabetic cheiroarthropahty. Incidence increases with disease duration but not with diabetes control. Although it is more common in patients with Type 1 and Type 2 diabetes mellitus than in other individuals, the disease can occur in people without diabetes. If presenting in diabetic patients, it is a predictor of other complications (especially retinopathy and nephropathy). In children with Type 1 diabetes, it is the earliest clinically apparent long-term complication [1].

Differences in the collagen household of the skin such as increased glycosylation of collagen lead to irreversible crosslinking of collagen and other proteins and decreased collagen degradation. Other possible contributing factors are microangiopathy, neuropathy [29, 30], and accumulation of AGE which, after binding their receptors, would stimulate inflammatory and fibrogenic growth factor receptors and cytokines via protein kinase C.

Diabetic cheiroarthropathy is not yet treatable but control of diabetes and physiotherapy are likely to be helpful. Phototherapy, radiotherapy, prostacyclin, penicillin, ciclosporin, factor XIII, and sorbinol have been applied without spectacular results. Research in animals is currently underway, investigating drugs blocking the protein crosslinking or blocking interactions between AGE and their receptors in the early stages of the disease.

Diabetic Dermopathy

Lesions of diabetic dermopathy or so-called shin spots are dynamic, various stages can present in the same patient at the same time. They are usually asymmetrical, 0.5 to 1 cm large red to brown hyperpigmentated spots ranging from atrophic macules to plaques. Plaques are more frequently recognized. These appear bilateral on the extensor parts of the legs but can rarely occur elsewhere and are usually asymptomatic. It is one of the most common skin manifestations in diabetes (Type 1 and 2) with a prevalence of up to 70%, although it is rare in children [1]. It is more frequent in men aged 50 and over and patients with poorly controlled diabetes. Although the association is strong, it is not entirely specific for diabetes mellitus since 20% on nondiabetic people have similar lesions [3]. Patients presenting with this dermopathy should be screened for diabetes especially if they present with four or more shin spots because they are thought to represent postinflammatory hyperpigmentation and cutaneous atrophy in the setting of poor vascular supply and microtrauma [31].

Shin spots may precede abnormal glucose metabolism but may also be a marker for microangiopathic complications such as retinopathy, nephropathy, and neuropathy, as well as macroangiopathic complications, especially coronary artery disease [32, 33]. Differential diagnosis with dermatophytosis should be made. Diabetic dermopathy should be a clinical diagnosis, and there is no need for skin biopsy. If performed, a specific histopathologic findings are seen such as hyperpigmentation of the epidermal basal layer, hemosiderin and melanin in the dermis, and thickening of the arteriolar basement membrane. There is no effective treatment but some lesions resolve spontaneously in 18–24 months on average though atrophic hypopigmented scars are seen afterward. Infection prevention can be indicated and new lesions may always arise.

Disseminated Granuloma Annulare

Granuloma annulare (Fig. 61.8) is a rare benign inflammatory disease. The main efflorescences are erythematous papules which slowly expand centrifugally and resolve centrally to reveal annular plaques with superficial scaling. The back of the hands and arms are usually affected. Patients are usually asymptomatic but can experience pruritus. The disease can occur at any age but is mostly seen in children and adolescents. Multiple subtypes exist. Its relation to diabetes has been the subject of many discussions over the years and now only the disseminated form is believed to be associated with diabetes and even this correlation is only based on retrospective studies and currently no case control studies are available [34, 35]. Generalized granuloma annulare can also be seen in malignancies, thyroid dysfunction, hepatitis B, C and HIV infections [36–40]. Histology reveals a granulomatous reaction pattern showing palisading of histiocytes (and sometimes giant cells) and lymphocytes surrounding an area of necrobiotic/collagenolytic collagen (complete type) (Fig. 61.9). The necrobiotic areas show deposition of mucin. The incomplete type shows interstitial inflammation with histiocytes (sometimes admixed with giant cells) and lymphocytes and also mucin deposition can be found (incomplete/interstitial form). Pathologists sometimes have difficulties differentiating this disease from necrobiosis lipoidica because both present with infiltrating palisaded histiocytes and collagen degeneration in the dermis. In the disseminated form, inflammation may be mild and the areas of inflammation are often found in the papillary dermis as seen in lichen nitidus. Also, necrobiosis and mucin deposition might be less profound. Not only pathologists have a hard time differentiating these diseases, they are also clinically resembling and might even coexist. Some authors suggest that generalized granuloma annulare is an early phase of necrobiosis lipoidica, [41] although in the former no epidermal atrophy or yellow discoloration is seen.

Fig. 61.8 Disseminated granuloma annulare

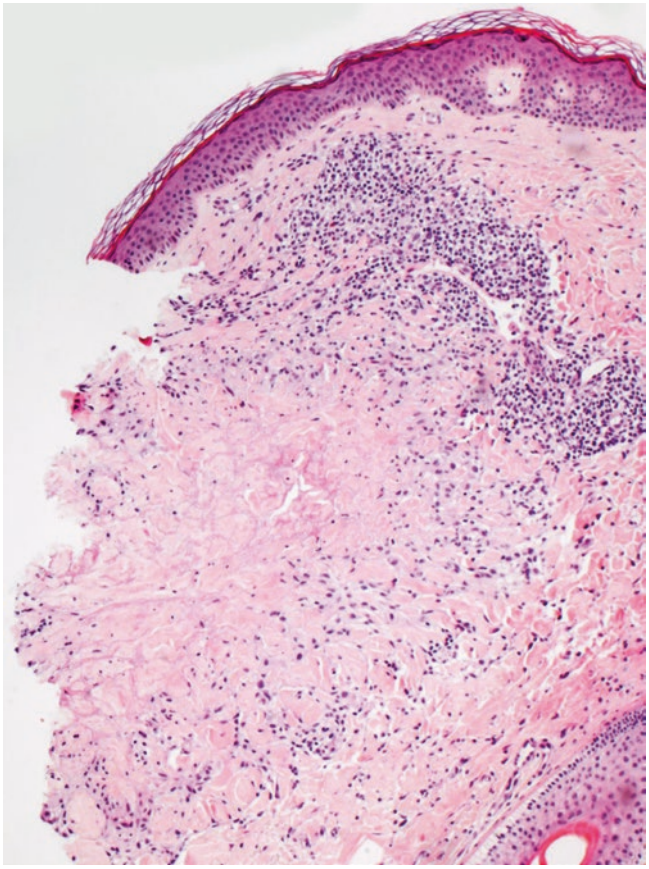

Fig. 61.9 Disseminated granuloma annulare. Areas of necrobiosis are surrounded by palisading histiocytes and lymphocytic inflammation. Although the histopathological features can be identical to classical granuloma annulare, disseminated granuloma annulare often shows a mild infiltrate located in the papillary dermis.

In contrast to localized forms, generalized granuloma annulare only rarely resolves spontaneously. A protracted and relapsing course is usually seen with often therapy-resistant lesions. Many different types of treatment have been used including cryotherapy, topical, intralesional or systemic corticosteroids, phototherapy (UVA1 and PUVA), chlorambucil, pentoxifylline, cyclosporine, fumaric acid ester derivatives, potassium iodide, niacinamide, etanercept, infliximab, adalimumab, efalizumab, hydroxychloroquine, and dapsone.

Eruptive Xanthomas

Eruptive xanthomas are small (1–2 mm) yellow papules with erythematous border appearing in weeks to months, mostly asymptomatic but sometimes tender. They appear most frequently on the extensor surfaces of the limbs and the buttocks. Lesions often occur as a result of Koebner phenomenon on pressure sites. The yellow discoloration is due to foamy

macrophages in the dermal inflammatory infiltrate of lymphocytes and neutrophils. They are associated with elevated eruptive triglycerides in the blood of patients with poorly controlled diabetes (especially Type 2), in familial hypertriglyceridemia and in patients using excessive amounts of alcohol. Insulin stimulates the activity of lipoprotein lipase and plays a role in the metabolism of triglycerides. This leads to a decreased clearance of very low density lipoproteins and chylomicrons. This can be aggravated further by polyphagia caused by glycosuria [42, 43]. Clinicians should be aware of a significantly elevated risk of pancreatitis [44]. Only 0.1% of patients with diabetes will develop eruptive xanthomas. The main treatment objective is controlling the hypertriglyceridemia and to be aware of other problems related to this condition. Control of diabetes and hyperlipidemia leads to swift disappearance of the xanthomas. Local therapeutic options are application of trichloroacetic acid, excision, curettage, and CO_2 laser therapy.

Infections

Recurrent skin infections may be the presenting feature of diabetes. Bacterial and fungal infections appear more frequently, more severe, and atypical. Skin infections occur in 20–50% of diabetic patients, more frequently in Type 2 and are associated with poor glycemic control. Patients with well-controlled diabetes are not at higher risk of infections. Viral infection on the contrary are not more frequent. For further details, we refer to Chap. 66 on infections.

Lichen Planus

Lichen planus (Fig. 61.10) is a chronic inflammatory disease of the skin, mucous membranes, scalp, and nails. Lesions are pruritic and present as flat-topped polygonal violaceous papules. Wickham striae can be visible on oral mucosa only and consist of a fine reticular network of white arborizing lines but lichen planus can also affect genital mucosa. Four Ps (pruritic, purple, polygonal, and papules or plaques) can be used as a mnemonic. The exact pathogenesis of lichen planus is not clear but it has been postulated to be a T-cell-mediated autoimmune process, resulting in damage of keratinocytes [45–47]. Microscopic examination of a skin specimen reveals specific changes consisting of a lichenoid lymphocytic infiltrate with liquefactive degeneration (Fig. 61.11). Half of the patients with lichen planus have impaired glucose metabolism and approximately 25% suffer from diabetes. The reverse relationship has been examined much less, and the association is still controversial. Prevalence ranges from 0.9 to 1.4% in the general population vs. 2 to 4% in patients with either Type 1 or 2 diabetes [48–50]. Although the disease is usually self-limiting, patients are frequently treated. Topical corticosteroids should be tried first. If necessary other options include oral corticosteroids, oral retinoids, cyclosporine, and phototherapy which have all shown efficacy.

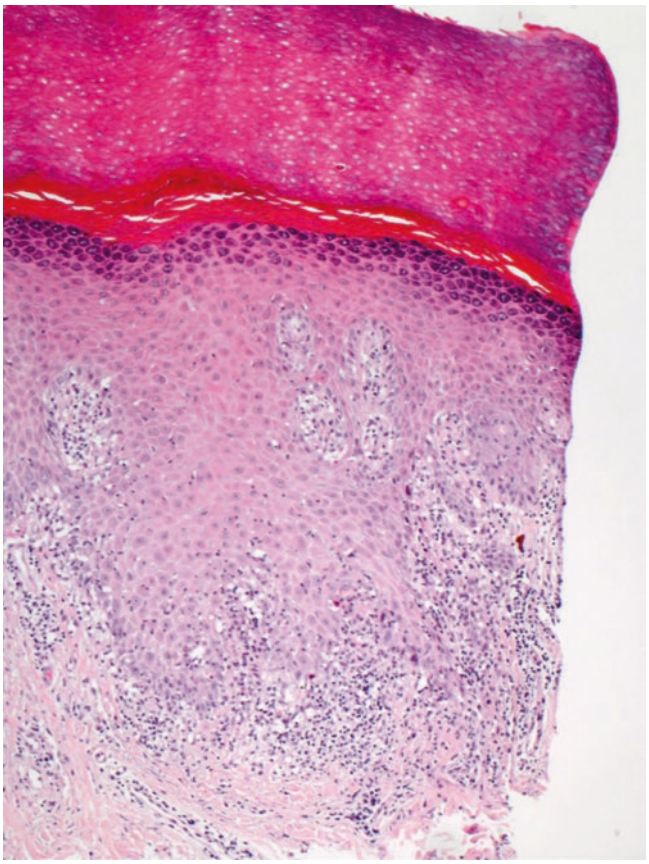

Fig. 61.10 Lichen planus. The lesion shows hyperkeratosis, acanthosis, and a lichenoid interface dermatitis with scattered apoptotic cells along the basement membrane

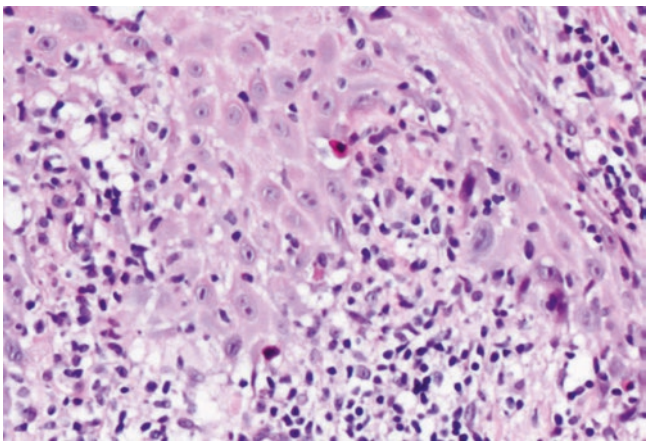

Fig. 61.11 Lichen planus. An interface dermatitis is noted with scattered apoptotic keratinocytes along the basal layer

Necrobiosis Lipoidica

Necrobiosis lipoidica (Fig. 61.12) is a chronic inflammatory skin disorder of collagen degeneration with a granulomatous response, thickening of the blood vessel walls and fat deposition [51]. A small clinical study determined that patients with necrobiosis lipoidica had a higher proportion of natural antibodies against such as actin, myosin, keratin, desmin when compared to patients with Type 1 diabetes mellitus and healthy control subjects [52, 53]. The disease is typically seen in patients in the third to fourth decade. Normally patients are asymptomatic though pain and pruritus can occur. Necrobiosis lipoidica starts with bilateral non-scaling red papules mostly seen on the pretibial regions though other regions can be involved. Red-brown rims may indicate disease activity. There is a centrifugal spreading pattern. Red papules slowly turn into atrophic lesions with central yellow discoloration possibly due to underlying dermal fibrosis and lipid excess in the dermis or due to the formation of advanced glycation end products, especially 2-(2-furoyl)-4[5]-(2-furanyl)-1H-imidazole which has a yellow hue. Telangiectasia can be seen through the translucent plaque. In advanced disease, large plaques can be seen and 35% of the lesions show ulceration. It should be known that chronic ulceration is a risk factor for the development of squamous cell carcinomas. Necrobiosis lipoidica is generally recognized in association with diabetes mellitus, however, the precise biological association remains unclear. In addition, quite recently necreobiosis lipoidica also has been associated with obesity, hypertension, dyslipidemia, and thyroidal disorder [54, 55]. The prevalence of necrobiosis lipoidica ranges from 0.3 to 1.2% in all diabetics to 2 to 3% in the insulin-dependent subtype. Even higher percentages in female patients have been reported. Necrobiosis lipoidica is thought to be the best recognized skin-associated disease of diabetes although it is rare. Prevalence ranges from 0.3 to 1.2% of all diabetics to 2 to 3% in the insulin-dependent subtype and even higher rates in female patients. Patients with Type 1 diabetes develop the disease earlier than those with Type 2 diabetes. Diabetes usually proceeds with the onset of necrobiosis lipoidica by 10 years although simultaneous and reverse patterns can be seen [56]. The association is less strong if the skin disease presents on other body parts than the legs. Whether the severity of diabetes and the activity of necrobiosis lipoidica are correlated is still uncertain. Its presence is worth mentioning given the higher prevalence of retino- and nephropathy. Histology shows a dermal infiltrate which usually affects the entire thickness of the dermis. The infiltrate tends to be horizontally orientated showing intervening layers of granulomatous inflammation and horizontal layers of necrobiosis (sandwich), in areas showing palisading of histiocytes surrounding necrobiosis. The deep dermis often shows admixture with lymphocytes and plasmacells (Fig. 61.13). Whether microangiopathy, neuropathy, trauma, immunoglobulin deposition causing vasculitis or a combination of these forms the origin of the collagen matrix destruction is still under discussion. Necrobiosis lipoidica is very

Fig. 61.12 Necrobiosis lipoidica

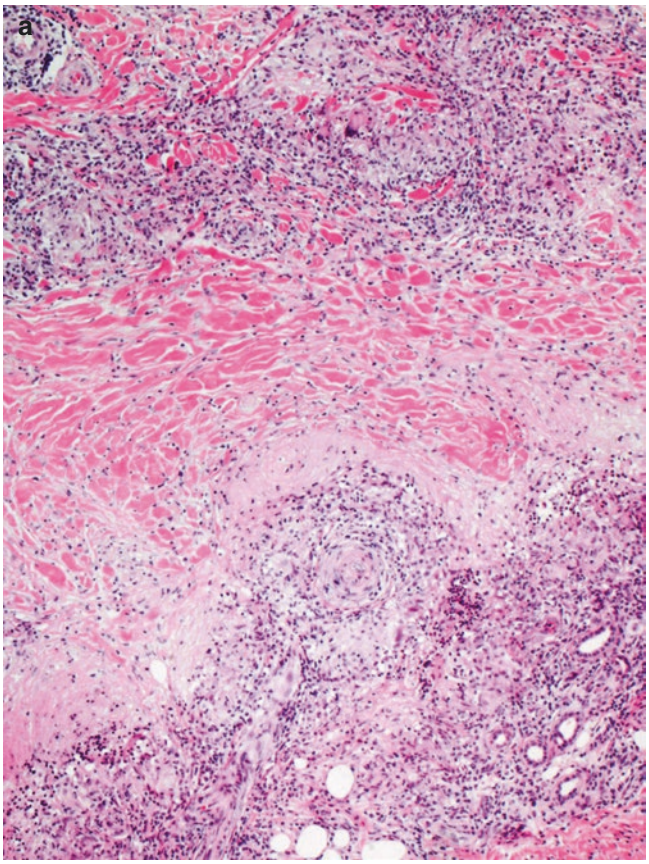

Fig. 61.13 Necrobios lipoidica. The infiltrate shows horizontal "sandwich" layering of (**a**) granulomatous inflammation and necrobiosis (**b**) and fibrosis. The deep dermis often shows a surrounding lymphocytic infiltrate admixed with plasmacells (**c**).

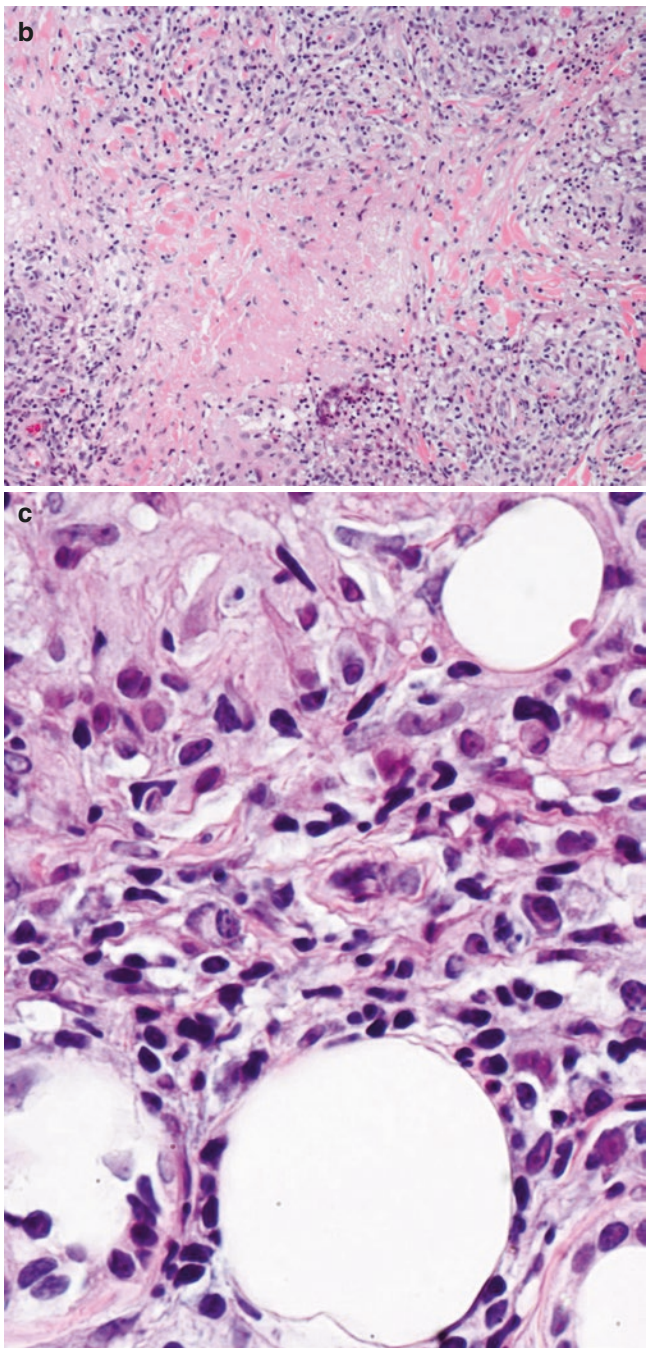

Fig. 61.13 (continued)

hard to treat, but sometimes slow healing occurs. No positive effect of glycemic control has been demonstrated so far [57, 58]. Topical steroids (if necessary under occlusion) are a therapeutic option but can also worsen the atrophy. If an active border is seen, intralesional steroids may be of help. Topical calcineurin inhibitors and compression therapy might be effective. Systemic treatment is possible with chloroquine, fumaric acid ester derivatives, mycophenolate mofetil, cyclosporine, anti-TNF alpha, and psoralen with ultraviolet A radiation (PUVA). Lesions tend to relapse with therapy cessation. Spontaneous resolution is seen in 13–19% of patients after 6 to 12 years [42].

Fig. 61.14 Psoriasis vulgaris

Psoriasis Vulgaris

Psoriasis (Fig. 61.14) is a chronic immune-mediated inflammatory disease of the skin. Patients present with erythematous scaly papules and plaques occurring most frequently in areas of friction [53]. It is common; the prevalence worldwide is estimated to be 1–3% [59]. Association between these two diseases has been made but up until now no consensus was made. Patients with diabetes may present with a more edematous inflammatory course of psoriasis as well as more therapy-resistant psoriasis [60]. Treatment consists of topical (e.g., calcipotriol, corticosteroids, and tacrolimus) or systemic immunomodelators, as well as UV light [53].

Pruritus, Xerosis Cutis, and Keratosis Pilaris

Xerosis cutis, xeroderma, or dry skin is one of the earliest and most frequent skin signs in diabetes, found in almost half the diabetic population. Dry mucous membranes, for example laryngitis scleroticans sicca can be observed as well. Xerosis can be demonstrated in diabetics by measuring transipedermal water loss and high frequency conductance of the forearm [54]. We should keep in mind that both xerosis cutis and diabetes mellitus are very common. The presence of xerosis cutis increases the risk of complications, including infection and ulceration [53]. Pruritus is the main complaint patients present with. In atopic patients, the prevalence of xerosis cutis is higher.

Xerosis cutis is believed to result from sympathetic and sensory neuropathy and also vasculopathy. Sweat gland dysfunction starts with thermoregulatory dysfunction of the extremities and later on the entire body (global anhidrosis), although the reverse can occur (e.g., postprandial gustatory sweating on the face, neck, and chest). Chronic generalized pruritus can be a sign of undiagnosed diabetes as well as truncal pruritus, burning feet syndrome, pruritus vulvae, and anogenital pruritus although the latter may be secondary to candidiasis or streptococci infection. Clinicians should keep in mind that underlying illness and drug reactions also cause pruritus. Regular use of emollients helps to prevent this skin problem.

Keratosis pilaris consists of rough follicular papules and variable erythema on the extensor surfaces of the extremities and sometimes on the face, buttocks, and trunk. It flares up in wintertime. 11.7% of children with Type 1 diabetes have keratosis pilaris but it is very common in non-diabetic patients as well. Xerosis cutis certainly plays a role in this disease. Treatment is difficult and not strictly necessary but emollients as well as keratolytic agents, retinoids, and topical corticosteroids of low potency can be helpful.

Rubeosis Faciei—Palmar Erythema and Periungual Telangiectasia

Acral erythema is an erysipelas-like erythema of the hands (especially the thenar and hypothenar region) and feet and has a mostly patchy distribution due to microangiopathy [61]. It differs from physiological erythema caused by warmth, emotional state, hand elevation, and external pressure in its distribution and aspect of the erythema.

Rubeosis faciei is a relatively common chronic flushed appearance of the face, neck, and upper extremities. It is more easily to notice in Fitzpatrick skin types one and two.

These two asymptomatic skin signs both result from small vessel occlusive disease with compensatory hyperemia of superficial blood vessels or from decreased vascular tone. Described prevalence in patients with Type 1 and 2 diabetes range from less than 10% to over 60% [62–65]. This might be due to confounding factors such as Fitzpatrick skin type [66], severity of disease, and inpatient status. It is associated with vessel engorgement which contributes to visual impairment in diabetics. The erythema (Fig. 61.15) is directly related to disease duration. Improvement is seen with adequate control of blood sugar levels but these phenomena flare up with concomitant use of vasodilating therapies or vasodilators such as caffeine and alcohol.

Periungual telangiectasia are clinically visible dilated capillary veins due to loss of capillary loops and dilation of other surrounding capillaries. It is seen in 40–50% of all patients with diabetes. It can also be seen in connective tissue diseases such as scleredema and dermatomyositis. It is highly likely that nail folds show erythema and that cuticles are ragged (this should not be confused with paronychia caused by infection). Some patients are asymptomatic while others experience discomfort in their fingertips. No treatment is necessary [53].

Fig. 61.15 Erythema

Different skin types are divided based on skin color and response to ultraviolet irradiation.

Skin Thickening and Scleredema Diabeticorum

Skin thickening and scleredema diabeticorum are associated with long-term disease progression and diabetic neuropathy ($P < 0.05$) [67] and is a cutaneous marker for other microvascular complications.

There are three subtypes of skin thickening. In the first subtype, there is a benign asymptomatic thickening which is only measurable with ultrasonography. This type is seen in nearly 25% of all diabetic patients. The second type of skin thickening is clinically noticeable. Phenotypes range from Huntley papules to diabetic hand syndrome in 8 to 50% of diabetic patients [68, 69]. The initial complaints in diabetic hand syndrome consist of stiffness and progresses to limited joint mobility and possibly Dupuytren contracture (caused by shortening of skin anchoring ligaments).

Scleredema diabeticorum is a rare asymptomatic diffuse ill-defined erythematous induration of the upper back and neck possibly extending to the deltoid and lumbar region. Acral regions are spared. The skin can have a peau d'orange aspect. Reduced elasticity of the skin can result in reduced joint mobility, and thus stiffness frequently coexists. Two-and-a- half to 14% of patients with diabetes suffer from this condition. Men and obese patients with long lasting Type 2 diabetes are at higher risk. Pathology reports show an unaf-

fected epidermis and a homogenous thickened dermis with activated fibroblasts and enlarged collagen bundles separated by mucin deposition. It is important to take a full thickness excisional biopsy. An excess of blood glucose leads to collagen synthesis by fibroblasts and retarded collagen degradation and glycosaminoglycan depositions. Scleredema is also seen in rheumatoid arthritis, hyperparathyroidism, Sjögren's syndrome, and seldom in IgG paraproteinemia or malignancy.

Scleredema diabeticorum and classic scleredema are clinically difficult to distinguish but appear to have distinct light and electron microscopic features [70]. Scleredema diabeticorum does not improve with glycemic control although this measure is believed to be an important preventive tool. Treatment is often difficult and includes UVA (psoralen UVA as well as UVA1) and systemic therapy such as oral corticosteroids, cyclosporine, cyclophosphamide. In severe cases, radiotherapy could give some relief [71–74].

Ulcers

see Chap. 65, foot complications.

Vitiligo

In vitiligo (Fig. 61.16), depigmented maculae are seen which are slowly progressive. The extent of affected skin ranges from localized to generalized and even universal and is mostly seen on the face, hands, and genitals. Histopathology shows the absence of melanocytes in the basal layer after Melan A staining (Figs. 61.17 and 61.18). It is possible that some melanocytes are seen around the hair follicles. The depigmentation is the result of immune mediated melanocyte loss or function loss, and tyrosinase is the main antigen recognized. One in three patients has a positive family history of vitiligo. One to 7% of insulin-dependent diabetics suffers from vitiligo [2] compared to a 0.2 to 1% prevalence in the global population making it the most common depigmenting disorder [5]. Due to the high number of Type 2 diabetics, these patients will be seen more often with vitiligo,

Fig. 61.16 Vitiligo

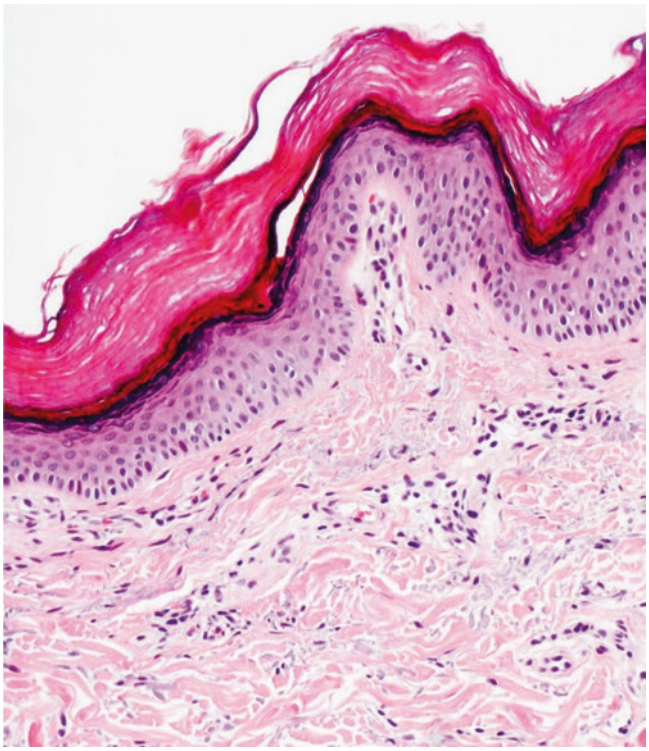

Fig. 61.17 Vitiligo. Absence of melanocytes (HE stain)

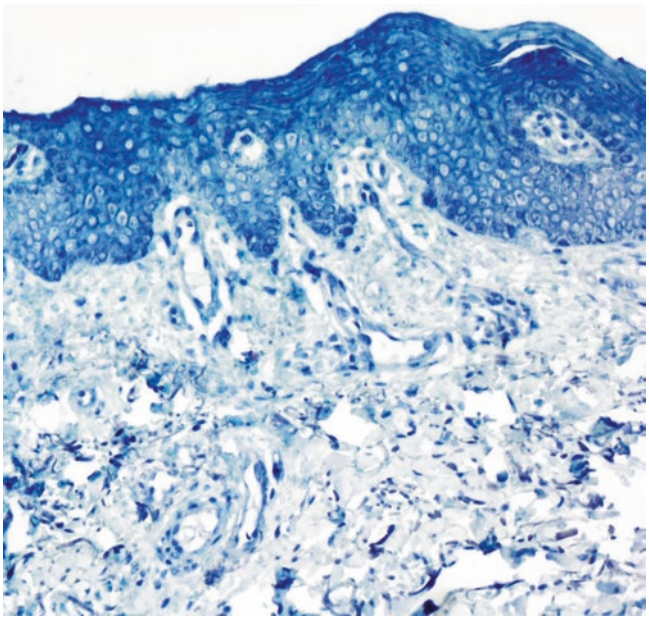

Fig. 61.18 Vitiligo. Absence of melanocytes (Melan A stain)

though it is relatively more prevalent in Type 1 diabetes. The combination of Type 1 diabetes and vitiligo is suggestive for polyglandular autoimmune syndrome. This is a rare immune-mediated endocrinopathy with at least two affected endocrine glands. In these cases, vitiligo is often more difficult to treat. Patients should avoid sun exposure. Topical corticosteroids of high potency can give satisfying results if applied early on (with or without narrow-band ultraviolet B). Topical calcineurin inhibitors have shown some benefit. PUVA and 8-methoxypsoralen lotion can be used as well. In generalized vitiligo, treatment with ultraviolet B light may be an option as well. Camouflage therapy is an option if patients have cosmetic concerns.

Yellow Skin

The yellow skin of some diabetic patients consists of an orange to yellow discoloration of the skin, most obvious on the palms and soles. The sclerae are spared in contrast to patients suffering from jaundice. Yellow nails (Fig. 61.19) affects up to 40% of diabetic patients, especially the elderly. The yellow color is best visible at the distal part of the nails, and these discolored nails have a slower growth rate and appear more curved due to poor vascularization of the nail matrix. Differential diagnosis includes physiological processes in the elderly, onychomycosis, yellow nail syndrome, yellow nails due to lymphedema or respiratory tract disease [75].

The relationship of both discolorations to diabetes mellitus is questionable. Some believe that diabetic patients are exposed to higher levels of carotene in their diet rich of fruits and vegetables, which together with an impaired hepatic conversion leads to carotenemia and thus yellow discoloration of skin and nails. Differential diagnosis of carotenemia includes jaundice hypothyroidism, hypogonadism, hypopituitarism, bulimia and anorexia nervosa [13].

Another possibility is the formation of advanced glycation end products, especially 2-(2-furoyl)-4[5]-(2-furanyl)-1H-imidazole, which has a yellow hue as mentioned earlier. There is currently no treatment available.

Mucormycosis

Mucormycosis is a rare opportunistic fungal infection, with a high mortality rate, caused by fungal species belonging to the order Mucorales (class Zygomycetes). Mucormycosis occurs in immunocompromised patients. Risk factors include poorly controlled diabetes mellitus, end-stage renal disease, hematologic malignancies, and solid organ transplantation. It can affect various organs, including sinuses, nose, eyes, brain, intestine, lungs, and skin. Clinical presentation depends on the anatomical site of involvement, which is associated with the predisposing medical condition. Diabetes mellitus, for example, was found to be correlated with rhinocerebral mucormycosis [76]. In the skin, it presents as an indurated plaque which rapidly evolves into a necrotic ulcer. The diagnosis can be confirmed by histological evalution; broad non-septate hyphae can be observed in blood vessels (Fig. 61.20).

Whilst mucormycosis is prevalent globally, the disease is most common in India [77]. Lately, higher infection rates have been reported worldwide in COVID-19 patients [78, 79]. The exact incidence and prevalence remain unknown. Treatment of mucormycosis is difficult, as mucorales are naturally resistant to most antifungals. Amphotericin B and surgical debridement or excision are the most effective options [78].

Fig. 61.19 Yellow nails

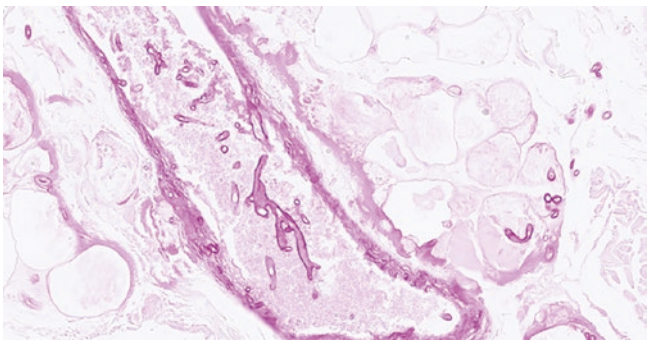

Fig. 61.20 Mucormycosis: Broad non-septate hyphae in a vascular lumen and wall. PAS+ stain

Necrotising Fasciitis

Necrotising fasciitis is a bacterial infection, localised in any of the layers within the soft tissue compartment (dermis, subcutaneous fat tissue, superficial fascia, deep fascia, or muscle). It is a rapidly progressive disease with a high mortality rate. Early recognition, surgical treatment (amputation, fasciotomy, and debridement of necrotic tissue), plus intravenous antibiotic therapy, and hemodynamic support are the most important factors effecting survival rate [80, 81]. Patients usually present with pain disproportionate to clinical signs, which may include erythema with poorly defined edges, oedema, and bullae. At a later stage, purpura and necrotic tissue may be present. Furthermore, patients can present with signs of sepsis, such as hypotension, tachycardia, and fever [81, 82]. Microscopically an extensive diffuse neutrophilic infiltrate can be seen in the subcutaneous fat tissue (Fig. 61.21a, b). However, necrotising fasciitis is a clinical diagnosis.

Necrotising fasciitis may result from any skin damage (i.e., minor trauma, skin biopsy, laceration, insect bite, needle puncture [particularly intravenous drug use], chronic ulcer, herpes zoster, surgical wound, skin abscess). Diabetes mellitus is the most common co-morbidity associated with necrotising fasciitis. A possible explanation why patients with diabetes are more prone to necrotizing fasciitis is that peripheral sensory polyneuropathy increases susceptibility to minor trauma. Next to this, tissue hypoxia caused by vasculopathy and the underlying immunodeficiency in diabetic patients may ease out bacterial colonization [83]. Other predisposing factors include use of immunosuppressants, malnutrition, and peripheral arterial disease [3]. COVID-19 can be an aggravating factor [84].

COVID-19, the Skin, and Diabetes

COVID-19, caused by the novel coronavirus SARS-CoV-2, is most notorious for causing respiratory pathology. However, multiple extrapulmonary manifestations have been described, among which is skin manifestations. Erythematous rash, chil-

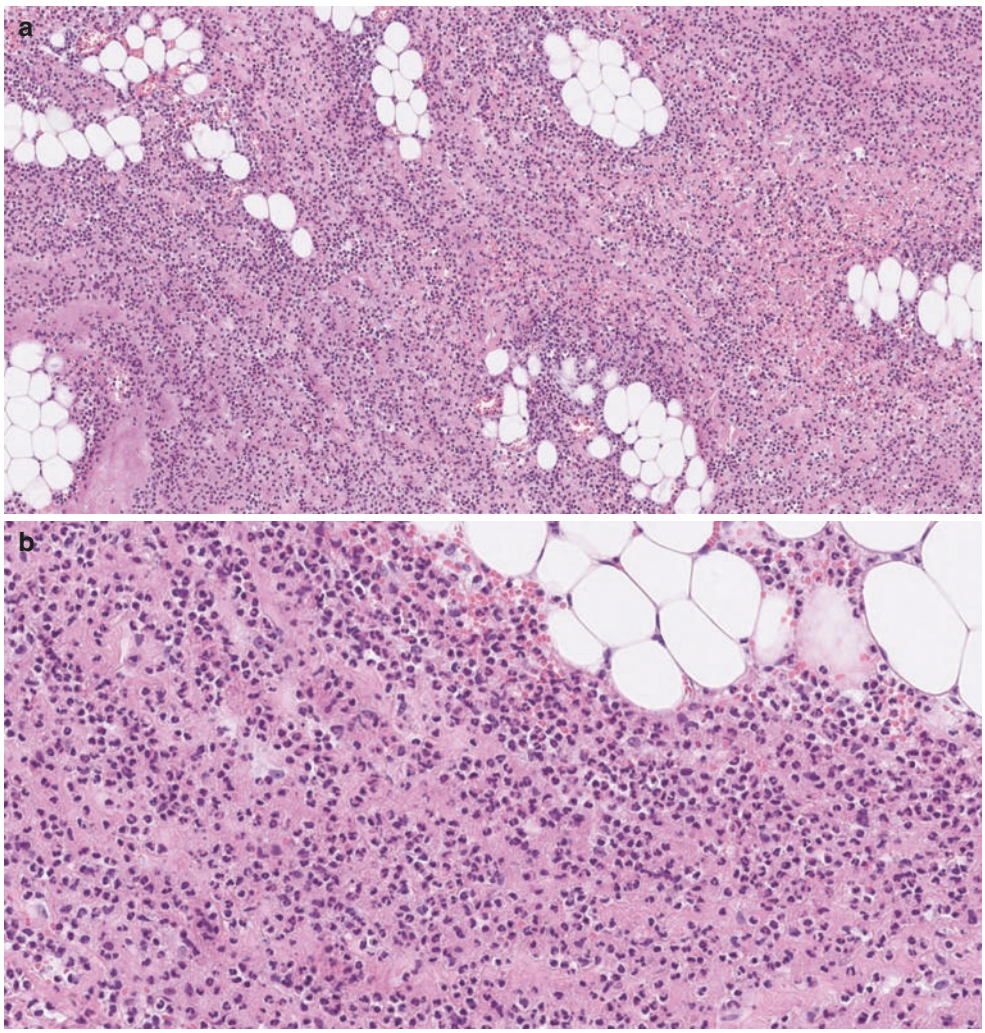

Fig. 61.21 (**a**) (Magnification 10×)—necrotising fasciitis: An extensive and almost pure diffuse neutrophilic infiltrate in the subcutaneous fat. (**b**) (Magnification 40×)—necrotising fasciitis: An extensive and almost pure diffuse neutrophilic infiltrate in the subcutaneous fat

blain-like lesions, and urticarial lesions were most commonly reported [85, 86]. Other manifestations include exanthema in various forms (morbilliform/maculopapular/papulovesicular), livedoid/necrotic lesions, and purpura/petechiae. The skin lesions were often accompanied by pruritus and were mostly self-resolving [83–87]. SARS-CoV-2 enters the human cells via the angiotensin-converting enzyme 2 (ACE2) receptor, which is expressed in various organs, including the skin. Especially, keratinocytes in the epidermis show a high expression of ACE2, which can explain the presence of cutaneous manifestations in COVID-19 patients [85, 88].

Diabetes mellitus is one of the comorbidities associated with COVID-19, and diabetic patients are at risk of developing a more severe disease manifestation. Hyperglycemia and ketosis, as a result of deterioration in pancreatic β-cell function and apoptosis, caused by elevated cytokine levels, are mechanisms that may account for the more severe disease course. Next to this, the presence of ACE2 receptors in the pancreas might contribute to insulin deficiency and hyperglycemia. Consequently, COVID-19 can be associated with deterioration of skin manifestations of diabetes mellitus [88, 89].

Side Effects of Medication

Side Effects of Insulin

Insulin Lipodystrophy.

Atrophy and hypertrophy of the skin might both occur although they are less frequently seen since the use of more pure insulins and synthetic analogues. Hypertrophy used to be present in two-thirds of insulin-dependent patients, but this number has been reduced to 1 to 2 %. It is characterized by a localized hypertrophy of subcutaneous fat. In these hypertrophic areas, insulin absorption is delayed; therefore, patients should rotate the injection site. Hypertrophy resolves spontaneously.

Atrophy at the insulin injection sites is due to an immunological reaction including IgM, IgE, and C3 in dermal blood vessels initiating a signal cascade that inhibits adipocyte differentiation [90]. Duration of exposure and depot formation play a role in the onset of atrophy. Substitution with fast acting insulin has been suggested as therapy [3]. It is unknown why women are more likely to develop atrophy and why men suffer from lipohypertrophy more often.

Continuous subcutaneous insulin infusion with the latest types of infusion materials does not frequently induce local infections, although allergy to tape and certain tubing constituents can be seen.

Allergic reactions to insulin are seen in approximately 2.4% of insulin-dependent diabetics. They can be classified into four categories (immediate local, generalized, delayed, and biphasic). Immediate local reactions range from erythema to urticaria and are assumed to be IgE mediated. Peak intensity is reached in 15–30 min and resolves within an hour. The immediate local reaction may progress to generalized erythema and urticaria. Anaphylaxis is rare. Delayed forms (4–24 h after injection appearing 2 weeks after the start with insulin therapy [3, 11]) present most frequently with itchy nodules at the injection site. Biphasic reactions are rare and consist of a combination of an immediate and a delayed local reaction in patients with symptoms resembling serum sickness. Treatment with topical corticosteroids is almost always successful.

Oral Hypoglycemic Medication

A wide range of quit frequently appearing cutaneous drug reactions to oral antidiabetic agents have been described ranging from pruritus, photosensitivity, allergic reactions, erythema multiforme, erythema nodosum, urticarial and pruritus to lichenoid, and morbilliform eruptions.

- Sulphonylurea has the most skin-related side effects, as approximately 1 to 5% of patients develop cutaneous reactions within 2 months of treatment. Maculopapular eruptions are the most common. Other cutaneous side effects include erythema, urticaria, erythema multiforme, exfoliative dermatitis, erythema nodusum, pemphigus vulgaris, psoriasiform, and lichenoid drug eruptions. Most sulfonylureas can induce photosensitivity. Even with a negative patch test, oral antidiabetic therapies should be switched.
- Approximately 20 % develop an alcohol flush with symptoms of redness, warmth, headache, tachycardia, and seldom dyspnea within 15 min after alcohol consumption and disappearing within the hour. Second- generation sulphonylureas present with less cutaneous side effects.
- Meglinitinides or glinides rarely cause cutaneous reactions (<0.01%). If present, they usually consist of pruritus, rash, urticarial, or generalized reactions such as anaphylaxic shock.
- Biguanides such as metformin cause cutaneous side effects ranging from psoriasiform drug eruptions and leucocytoclastic vasculitis to phototoxic reactions and erythema multiforme.
- Thiazolidinediones glitazones can seldom cause edema.
- Dipeptidyl peptidase IV inhibitors give dose-dependent necrotic skin lesions in monkeys. Increased rates of angioedema are noted only if they are used together with ace inhibitors due to inhibition of the degradation of bradykinin and substance P. Case reports show severe skin reactions such as bullous pemphigoid, Stevens–Johnson syndrome and toxic epidermal necrosis.

– Alpha glucosidase inhibitors-like acarbose have been responsible for acute generalized exanthematous pustulosis and erythema multiforme.
– Injection of Glucagon-like-peptide-1 receptor agonist (or incretinomimetics) can cause local granulomatous reactions (e.g., eosinophilic sclerosing lipogranulomas).

Concluding Remarks

The skin is often involved in diabetes mellitus as well as in side effects of medications used to treat diabetes. Some of those skin diseases are more specific for diabetes than others and some are more frequent in Type 1, others in Type 2 or both types of diabetes mellitus.

The intensity ranges from mild to severe. Recognizing these skin conditions may be of great value since they can be the presenting symptom in diabetes mellitus, port of entry for infection, or sign of advanced disease.

Multiple Choice Questions

1. Which statement is false?
   A. **A Circa 10% of all patients with diabetes mellitus develop skin manifestations.**
      False, 30–80% of all patients with diabetes mellitus develop skin manifestations.
   B. Patients care a lot about the appearance of their skin.
   C. Disseminated granuloma annulare can be observed in diabetes mellitus patients, malignancies, thyroid dysfunction, hepatitis B, C, and HIV infections.
   D. Skin manifestations of diabetes mellitus can be present before the diagnosis of diabetes mellitus.
   E. Some of the skin manifestations of diabetes mellitus are linked to neuropathy and angiopathy.
2. What is true about acanthosis nigricans?
   A. Acanthosis nigricans can only occur in patients with diabetes mellitus.
   B. Acanthosis nigricans is highly disabling.
   C. **Acanthosis nigricans occurs in the intertriginous areas.**
      Correct, especially in the neck, armpits, and groins.
   D. After treatment no recurrence is possible.
   E. It occurs more often in the Caucasian race.
3. Acquired perforating dermatosis is (Fig. 60.22).
   A. easy to treat.
   B. a frequently appearing dermatosis.
   C. is most frequently seen on the flexor areas of the lower extremities.
   D. **a highly pruritic skin disease.**

Correct. It presents with scaly highly pruritic follicular hyperkeratotic papules and nodules.

   E. more frequently seen in Caucasian people.
4. Which statement about bullosis diabeticorum is false?
   A. There are three known subtypes.
   B. **all subtypes heal without scarring.**
      False, the cleavage level of the second subtype lies below the dermoepidermal junction so healing leaves scars.
   C. It occurs more frequently in men with longstanding poorly controlled Type 1 diabetes.
   D. No treatment is needed.
   E. Primary autoimmune blistering should be excluded.
5. Diabetic dermopathy is.
   A. **a synonym for shin spots.**
      Correct, these are asymmetric red to brown hyperpigmentated spots.
   B. a synonym for diabetic stiff hands.
   C. no reason to screen for diabetes mellitus.
   D. a skin manifestation that never preceeds to diabetes mellitus.
   E. a unilateral appearing dermatosis.
6. Which statement concerning eruptive xanthomas is false?
   A. A Patients with eruptive xanthomas are usually asymptomatic.
   B. There is a correlation with elevated blood triglycerides.
   C. There is an elevated risk of pancreatitis.
   D. **Systemic treatment is indicated.**
      False, the main treatment objective is controlling the hypertriglyceridemia. Local therapeutics can be used.
   E. 10% of all diabetes mellitus patients develop eruptive xanthomas.
7. Which statement on granuloma annulare is false?
   A. Granuloma annulare is a rare benign inflammatory disease.
   B. This disease usually occurs on the hands and arms.
   C. **All forms occur more frequently in patients with diabetes mellitus.**
      False, only the disseminated form occurs more frequently in diabetes mellitus patients.
   D. It is sometimes histopathologically difficult to distinguish from necrobiosis lipoidica.
   E. Multiple subtypes exist.
8. Which statement on lichen planus is true?
   A. Lichen planus is a chronic inflammatory disease due to overactivity of the B cells.
   B. Lichen planus only occurs on the oral mucous membrane.
   C. The relationship to diabetes mellitus is completely clear.
   D. Lichen planus only occurs on the skin.
   E. **Four Ps can be used as a mnemonic.**

Correct, it stands for pruritic, purple, polygonal, papules, or plaques.

9. What is true about necrobiosis lipoidica?
   A. **A It is important to diagnose.**
      Correct, prevalence of retinopathy and nephropathy is higher in this subgroup of patients.
   B. Never preceeds to diabetes mellitus.
   C. Occurs in the first and second decade.
   D. This skin condition never heals.
   E. This skin condition is easy to treat.
10. Which statement on vitiligo is false?
   A. Patients with vitiligo should avoid sun exposure.
   B. After melan A staining, no melanocytes are observed on histopathological examination.
   C. **It occurs more often in Type 2 diabetes.**
      False, vitiligo occurs more frequently in Type 1 diabetes. Both are auto-immune diseases.
   D. Ultraviolet B light may be of help in the treatment of this disease.
   E. Topical corticosteroids and calcineurin inhibitors are used in the treatment of vitiligo.

Glossary

Atrophy A loss of tissue from the epidermis, dermis, or subcutaneous tissues. There may be fine wrinkling and increased translucency if the process is superficial.

Erythema Redness of the skin produced by vascular congestion or increased perfusion.

Koebner phenomenon The onset of new inflammatory skin lesions after minor trauma such as scratching.

Macula A circumscribed alteration in the color of the skin.

Nodule A solid mass in the skin, which can be observed as an elevation or can be palpated. It is more than 0.5 cm in diameter. It may involve epidermis and dermis, dermis and subcutis, or subcutis alone. It may consist of fluid, other extracellular material (e.g., amyloid), inflammatory, or neoplastic cells.

Papule A circumscribed palpable elevation, less than 0.5 cm in diameter. By careful examination it is often possible to determine whether the thickening involves predominantly the epidermis or the dermis and what type of pathological process is concerned. The only distinction between a papule and a nodule is the size, and this is artificial; some lesions characteristically occur at the smaller size of a papule, whereas others typically enlarge from a papule to become a nodule. Recording a finite size is more useful.

Plaque An elevated area of skin, usually defined as 2 cm or more in diameter. It may be formed by the extension or coalescence of either papules or nodules as in psoriasis and granuloma annulare, respectively. Small plaque is sometimes used for such lesions 0.5–2 cm in diameter.

Sclerosis Diffuse or circumscribed induration of the subcutaneous tissues. It may also involve the dermis, when the overlying epidermis may be atrophic. It is characteristically seen in scleroderma, but may occur as a sequel to or in association with many different processes.

Ulcer A loss of dermis and epidermis, often with loss of the underlying tissues.

Vesicles and bullae Visible accumulation of fluid within or beneath the epidermis. Vesicles are small (less than 0.5 cm in diameter) and often grouped. Bullae, which may be of any size over 0.5 cm, should be subdivided as multilocular (due to coalesced vesicles, typically in eczema) or unilocular [91]

Foot Complications

62

Lawrence B. Harkless, Jarrod Shapiro,
and Joel Rodriguez-Saldana

Introduction

Patient C was a 50-year-old diabetic male truck driver. He presented to the emergency department with a red, hot, painful, swollen right foot and lower leg. There were no open lesions with unilateral edema and diffuse erythema. A venous duplex ultrasound was negative for deep venous thrombosis. Laboratory data showed no leukocytosis. The patient was admitted, placed on broad spectrum I.V. antibiotics, and discharged three days later. He returned to the emergency department 3 days after discharge with the same complaint of persistent redness and swelling. A second venous ultrasound was negative for thrombosis, and he was discharged home with a new oral antibiotic and a referral to the podiatry clinic. After a 2 week delay in obtaining an appointment, the patient noted his right foot had changed shape and was flatter in the arch than the contralateral foot. The deformity progressed to ulceration requiring surgical intervention. This unfortunate outcome in which the correct diagnosis of acute Charcot neuroarthropathy was missed resulted in considerable patient morbidity and increased healthcare utilization.

Diabetic foot complications are serious events in the lives of patients with diabetes. Historically, pedal complications were underappreciated by the general medical community; however, international efforts have improved the recognition of this very serious problem. All health professionals involved with diabetic patients should be well informed about the potential complications of diabetic foot syndrome. This chapter will discuss diabetic foot complications with an emphasis on a conceptual framework of the epidemiology, risk, and wound-healing concepts underlying these complications. A detailed discussion of diabetic foot ulcerations, infections (including skin and soft tissue structure infections and osteomyelitis), Charcot neuroarthropathy, and the role of targeted partial foot amputations will provide healthcare professionals with an understanding of this detrimental disease.

Diabetes is highly common with an estimated 194 million diabetics worldwide [1]. It has also been estimated that 344 million people will be diabetic by 2030 [1]. Of this number of affected people, 15% will develop a diabetic foot ulcer at some time [2], which corresponds to 2% to 6% of diabetics yearly with an estimated 6.9 million that will be affected in 2030 [2]. Diabetes has a significant and often catastrophic effect on patients' lives with global health implications. It is estimated that diabetic patients overall have a 15% risk of lower limb amputation [3]. Of this number, 85% are preceded by an ulcer [2]. Patients who develop an ulcer have a 34% risk of developing another wound within 1 year of healing the index ulcer and a 70% chance at 5 years [4].

Patients often fair poorly with the onset of foot ulceration. Diabetic foot ulcers that progress to lower limb amputation set off a catastrophic chain of events with a 50% risk of contralateral foot ulceration and a 50% rate of contralateral limb amputation within 2 to 5 years [5]. Mortality rates are significantly worsened when considering diabetic foot complications. Five-year mortality rates are 45%, 18%, and 55% for patients with neuropathic, neuroischemic, and ischemic ulcerations, respectively [6]. Limb amputations have similarly dismal survival outcomes. Mayfield et al. reviewed Veterans Affairs discharge documents of 5180 patients who underwent some type of lower limb amputation. They found a 56% 5-year mortality rate after transtibial and 70% mortality after transfemoral amputation [7]. Hoffman et al. found similar poor prognoses after major limb amputation with 1,3,5, and 10-year survival rates of 78%, 61%, 44%, and 19%, respectively [8].

The addition of Charcot neuroarthropathy worsens yet the prognosis of these patients. Sohn et al. found a 59% incidence of foot ulceration in those with Charcot foot (538 of

911 patients). Of these, 66% were treated for foot ulcer at the time of Charcot diagnosis [9]. They also found the relative risk of amputation for patients with foot ulcer and Charcot was 12 times higher than those with Charcot alone [9].

The cost of diabetic foot complications may also be catastrophic. Ramsey et al. retrospectively reviewed 8905 patients from a health maintenance organization and found the cost for a 40- to 65-year-old diabetic male with a new foot ulcer in 1999 was $27,987 over a 2-year period [2]. With inflation, this corresponds in 2016 to $40,003 [10].

These figures demand a specific set of conclusions. The first is that the majority of diabetic foot ulcers and major limb amputations are preventable. When they occur, a foot ulcer greatly increases the risk of further complications such as soft tissue and bone infection and must be treated aggressively. Third, limb amputation is preceded by foot ulceration that becomes secondarily infected with limb amputation as the end result. Finally, the costs associated with diabetic foot complications are extraordinary and place a very large burden on the world's healthcare system.

This has led some to consider how diabetic foot complications compare with other diseases. Armstrong, et al. compared the 5-year mortality rates of neuropathic ulcers and amputations with various types of cancer [6]. They found 5-year mortality rates of neuropathic ulcers and amputations to be equivalent to colon cancer and worse than Hodgkin's disease, breast cancer, and prostate cancer (Fig. 62.1). This has prompted the concept of *malignant diabetes* in which diabetic foot complications are markers for a diabetic process that has advanced to a severity equivalent to (and sometimes worse than) cancer (courtesy Jeff Robbins, DPM, personal communication).

With this background in mind, it is possible to consider a conceptual pathological framework for diabetic foot complications with an emphasis on healing concepts, risk assessment, and psychosocial aspects that play an important role in this process.

At a macroscopic level, the continuum of diabetic foot ulceration to infection to amputation is clearly understood. The hyperglycemic process leads to peripheral neuropathy (discussed below) and loss of large and small sensory fibers. This loss of protective sensation reduces or eliminates the capacity to sense low-grade repetitive or single high-grade traumatic pressures to specific aspects of the foot. Low-grade microtrauma is mediated by the presence of structural deformity or limited joint motion [11, 12] (Fig. 62.2). As pressures continue to wear away epidermis, deeper layers become exposed creating the neuropathic ulcer. If the ulcer remains exposed, the likelihood to become colonized with opportunistic skin flora with contamination cellulitis and infection is high. Chronic or acute infection may lead to osteomyelitis of the nearby bone with possible amputation.

Treating pedal complications successfully requires an understanding of the normal wound-healing process. Aberrant healing associated with diabetic foot complications is discussed later in this chapter. Initial wound healing begins with the hemostatic inflammatory phase, mediated by neutrophils, which diminish in number after the first 24 h and replaced with macrophages and lymphocytes. The proliferative repair phase occurs between several days after injury to the first few weeks,

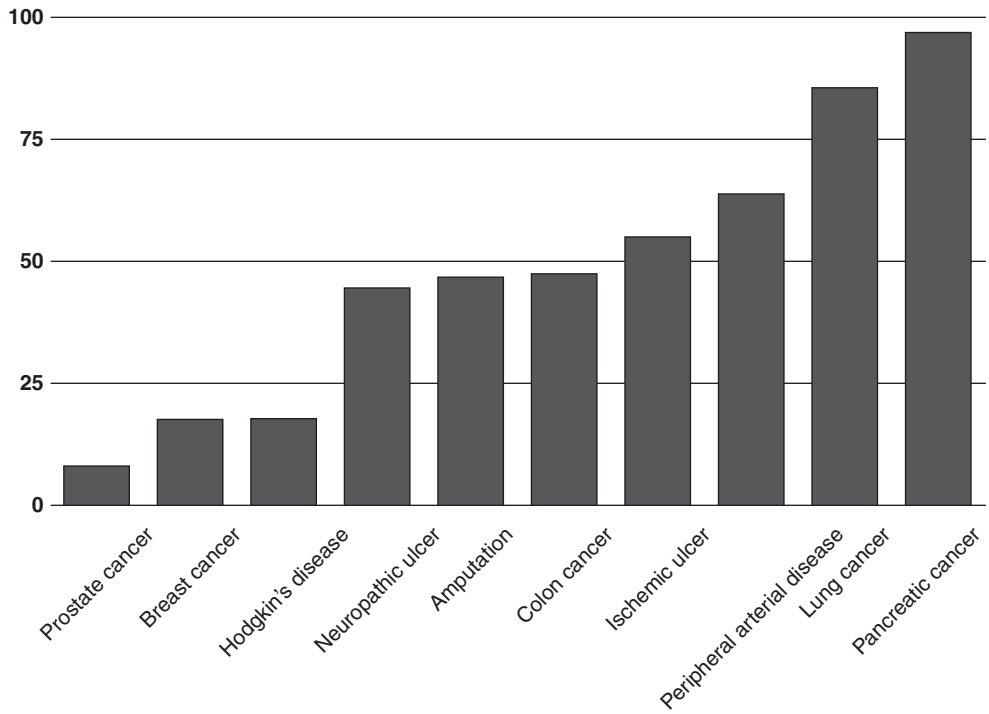

Fig. 62.1 Five-year mortality percentages comparing neuropathic ulceration and amputation with other common malignant diseases (Armstrong et al. with permission)

Fig. 62.2 Preulcerative digital erythema due to chronic repetitive low-grade pressures caused by hammertoe deformity

with steadily increasing fibroblasts and endothelial cells. It is at this stage that the typical diabetic foot ulcer healing process stalls. The final phase, remodeling, occurs after several weeks with type 1 collagen replacing the prior epidermal type III collagen, leaving a healed skin surface with approximately 80% of its original tensile strength [13]. During the proliferative phase, three mechanisms occur: connective tissue deposition (described above), contraction (mediated by myofibroblasts), and epithelialization [13]. Each of these phases is mediated by various cytokines and cell signaling pathways. Successfully, healing diabetic foot ulcers will heal by a variable combination of these three methods.

Peripheral vascular disease has a profound effect on the assessment, treatment, and prognosis of diabetic foot complications. Diabetics with peripheral arterial disease (PAD) are at significantly greater risk for poor outcomes. Jude et al. examined the relationship between diabetes and PAD severity and outcomes by examining the lower-extremity angiograms and medical records of 58 patients with diabetes and 78 without. The results of their analysis depicted that patients with diabetes had greater PAD severity in the profunda femoris and all arterial segments below the knee ($P \leq 0.02$). Furthermore, diabetes was associated with a risk for amputation that was five times greater than that for nondiabetic patients (41.4% vs 11.5%, odds ratio [OR] 5.4, $P < 0.0001$) and mortality that was double for nondiabetic patients (51.7% vs. 25.6%, OR 3.1, $P = 0.002$) [14].

When considering the risk spectrum of peripheral arterial disease in the diabetic patient, it is efficacious to consider an organized approach using the patient's medical history. Harkless and Holmes created a vascular risk spectrum from patient historical data [15]. Table 62.1 lists the pertinent components of this risk spectrum. The clinician obtains the appropriate history, including the listed components, and

Table 62.1 Vascular risk spectrum

Risk Type	Historical Component
Macrovascular disease	CAD, CVA/TIA, intermittent claudication
Microvascular disease	Retinopathy, nephropathy, neuropathy
Functional microvascular disease	Gastroparesis, impotence
Metabolic syndrome	Impaired glucose tolerance(IGT) pre diabetes, insulin resistance(IR), HTN, hyperlipidemia, obesity smoking
Family history	History of DM and complications

determines a low, medium, or high risk for the presence of peripheral arterial disease. This system has not been validated but provides the clinician with a basis in which to understand the presence of PAD and order further testing.

Each of the risk components described above cumulatively increases the risk for peripheral arterial disease and an increased chance of poor outcomes when combined with other complications such as neuropathic ulceration, Charcot arthropathy, or infection. The UKPDS trial found for each 1% increase in glycosylated hemoglobin, there was a 28% increase in peripheral arterial disease at 6 years after diagnosis. Additionally, each 10-mmHg increase in systolic blood pressure increased the risk by 25%, and smoking, prior diagnosis of coronary artery disease, and dyslipidemia were also independent risk factors for PAD [16].

The significance of this vascular risk spectrum is compounded by the concept of metabolic memory in which diabetes complications persist and progress after glycemic control is established. The converse of this, in which intensive glycemic control has a prolonged protective effect despite later reversion to conventional therapy, was termed the "legacy effect" after the UKPDS trial [17]. Increasing research evidence demonstrates that microvascular complications such as retinopathy and nephropathy in diabetics may be mediated by epigenetic DNA methylation, thus modifying gene expression [18]. The presence of advanced glycation end products (via cross-linking and irreversibly altering protein function) and oxidative stress (through creation of reactive oxygen species and subsequent tissue damage) have also been implicated [19, 20]. Experimental evidence for this process was noted during the Diabetes Control and Complications Trial (DCCT) [21] in which a continued retinopathy effect was noted in the conventional treatment group despite later enrollment and intensive glycemic treatment during the EDIC trial [22]. This process may be logically extrapolated from retinopathy and nephropathy to peripheral neuropathy since these three complications are intimately linked. Further research needs to delineate the mechanisms and biological effects of metabolic memory as they pertain to peripheral neuropathy and diabetic foot complications.

Diabetic pedal complications are made more challenging by patient psychosocial aspects. Nonadherence to medical instruction is highly common in this population with significant lower extremity effects. Armstrong et al. performed a prospective study of 20 diabetic patients with plantar ulcers. They placed a pedometer on the hip and in a removable cast boot and tracked ambulatory activity. Only 28% of walking activities at home were performed while wearing the removable cast boot, and the highest utilizers were the boot only 60% of the time [23]. In a similar study, patients were prescribed prescription shoes with a pedometer to track usage to prevent ulceration. Eighty-five percent of patients wore the shoes outside the home, but only 15% wore them when inside the home, which correlated with more steps per day out of the shoes [24]. Additionally, other studies have demonstrated improved ulcer healing outcomes when protocols were utilized that eliminated the chance of noncompliance [25–28].

Charcot Neuroarthropathy

Charcot neuroarthropathy is a well-documented but poorly understood catastrophic imbalanced inflammatory reaction that occurs most often in the diabetic population in developed countries. This disorder was originally described in patients with tertiary neurosyphilis and knee joint destruction and has generally poor outcomes if not recognized early and treated properly [29–31].

Charcot arthopathy appears clinically as a mild to moderately painful joint destructive disease, but at the molecular level, it has been hypothesized as due to an imbalance in pro-inflammatory cytokines responsible for bone growth regulation [32]. Jeffcoate et al. offer the most current description of this disorder as being initiated by an insult to the foot or ankle which then stimulates osteoclast formation by activating nuclear transcription factor **κ**B (NF-**κ**B) which leads to a significant osteoclastic and lytic process with subsequent bone destruction. This molecule is itself activated by receptor activator of NF-**κ**B ligand (RANKL) and has been implicated as an etiologic factor of blood vessel tunica media calcification [33]. Further research will help elucidate this process and will likely lead to medications that will reduce the effects of this devastating disease.

Clinically, Charcot arthropathy presents in two forms [32] acute and [33] chronic. In the acute phase, the affected foot or ankle presents most commonly with moderate to severe edema, erythema, calor, and variable pain. Patients will present a variable history with or without a known traumatic episode. Due to peripheral neuropathy with loss of sensation, diabetic patients may feel limited pain in comparison to a fully sensate person and may have no recollection of trauma. A low-grade chronic trauma or a more significant injury may be the inciting event.

Charcot arthropathy in which no ulcerations are present create a diagnostic dilemma. One must consider the broad differential diagnosis of an erythematous, edematous foot, including acute gouty arthropathy, cellulitis, osteomyelitis, occult or overt trauma, and deep venous thrombosis. This clinical dilemma may be difficult for the physician to sort out and is best handled with emergent referral of a lower extremity specialist. The index of suspicion for each of these differentials may be lowered with appropriate laboratory and imaging studies. However, one must maintain a high index of suspicion for osteomyelitis in a patient with this presentation. Cellulitis and osteomyelitis may be ruled out based on the understanding that the vast majority of foot infections occur via contiguous spread infection (skin surface bacteria entering the deeper tissues through a breach in the skin) rather than hematogenously. Hematogenous spread osteomyelitis in the diabetic foot is an extremely rare occurrence. However, we have seen several patients with bacteremia seed a Charcot joint. A search of the literature demonstrates no case studies of hematogenous spread osteomyelitis to the diabetic foot. This may be due in part to the smaller number of long bones in the foot and lack of open growth plates as is found in the more common pediatric hematogenous osteomyelitis of the tibia and femur. In cases where there is ulceration with Charcot changes, ruling out osteomyelitis becomes much more difficult.

A careful physical examination should be undertaken, looking for any open lesions in the typically edematous, erythematous foot with warmth and variable pain to palpation [30]. Early stages may show no morphological changes to foot structure, however later in the disease, after joint destruction has occurred, the classic rocker-bottom foot is easily witnessed (Figs. 62.3, 62.4, and 62.5). Charcot arthropathy may occur at any joint of the foot and ankle;

Fig. 62.3 Acute Charcot left foot. Note the edema and subtle erythema. The left foot was warmer than the right. Radiographs at this stage were negative for joint destruction or dislocation

Fig. 62.4 Classic rocker bottom foot deformity secondary to Charcot midfoot collapse. Radiograph of same patient demonstrating Lisfranc and naviculocuneiform collapse

however, the tarsometatarsal joint is most commonly involved. Though slightly less common, ankle Charcot is potentially devastating in its poor outcomes [29].

Temperature differences have been shown to assist with diagnosis of Charcot arthropathy and monitor resolution of the acute phase. A greater than 2 °C temperature difference using an infrared dermal thermometer is helpful in diagnosing acute Charcot and in monitoring progression out of the acute and into the coalescence phase [34, 35]. Thermometry should be used 15 min after cast and dressings are removed, and the thermometer should be accurate to ±0.1 °C [36].

Laboratory studies are often inconclusive with either a demonstrable leukocytosis and elevated nonspecific inflammatory markers, such as erythrocyte sedimentary rate (ESR) and C-reactive protein (CRP), or these values may also be found to be in the normal reference range [34, 37]. It has been shown that the acute local inflammation is dissociated from the systemic inflammatory response in these patients [34], and this lack of a systemic response may help providers in differentiating this disorder from infection. Other laboratory values may demonstrate elevations in glycemic indicators and renal dysfunction. No definitive validated laboratory markers for the specific diagnosis of Charcot neuroarthropathy exist outside of limited research studies.

Typical imaging studies begin with foot and/or ankle radiographs depending on the suspected joint involvement. During the earliest stages of Charcot, radiographs may demonstrate no abnormal findings other than increased soft tissue density and volume. Later stages will be clearly evident on plain film radiographs with joint destruction, fragmentation, dislocation (during the development phase) and progressive sclerosis, ankylosis, and rounding of bone fragments (during the coalescence and remodeling phases) (Figs. 62.6 and 62.7).

Charcot neuroarthopathy of the foot progresses through four primary stages that blend intimately making it difficult to determine if a patient has progressed to the next stage. The modified Eichenholtz classification [38, 39] is most commonly used to stage the disorder. Stage 0 is the most acute (inflammatory) stage with the classic "red, hot, and swollen" appearance. Radiographs are the most often utilized initial imaging modality [40] and commonly show no joint destructive changes in the earliest stage. Stage 1 is the development phase, which also appears as a foot with warmth, erythema, and variable edema. Radiographs may show early mild destruction and joint diastasis. Stage 2 is the coalescence phase in which the inflammatory process subsides with clinical normalization and radiographic changes that appear more chronic in nature with sclerosis of prior lucent bone and a blunting or smoothed appearance to bony fragments. The final third stage is termed remodeling which demonstrates a more chronic appearance similar to stage 2. The timeline of each of these stages vary.

An anatomic classification has also been proposed by Sanders and Frykberg [41]. They defined the location of the Charcot destruction coupled with the frequency of complications as follows:

Pattern I: Forefoot = 15%.
Pattern II: Tarsometatarsal joint = 40%.
Pattern III: Naviculo-cuneiform, Talo-navicular, Calcaneo-cuboid joints = 30%.
Pattern IV: Ankle and/or subtalar joint = 10%.
Pattern V: Calcaneus = 5%.

Other imaging modalities, though useful for other pathologic entities, do not provide significant diagnostic assistance. Computed tomography may assist with diagnosing early nondisplaced fractures [40]. Magnetic resonance imaging (MRI) in most cases is not necessary and may in fact create a diagnostic dilemma. Joint fragmentation, fracture, and bone marrow edema involving multiple joints, the typical Charcot appearance on MRI, may be difficult to differentiate from osteomyelitis, acute exacerbations of chronic osteoarthritis, or gouty arthropathy. In situations where ulceration is present, radiologists will be unable to rule out osteomyelitis. Bone scintigraphy should be avoided due to its lack of specificity [42]. Any inflammatory condition may appear as increased radiotracer uptake, even on delayed phases and white blood cell labeled studies. The reader is cautioned to take careful

Fig. 62.5 Chronic Charcot of the right midfoot with collapse and rocker bottom appearance. Note the medial arch ulceration due to increased focal plantar pressures

consideration of the results for all advanced imaging studies for the diagnosis of Charcot neuroarthropathy.

Treatment of the Charcot foot varies based on the acuity of the presentation. Acute Charcot arthropathy management consists of stabilization of any comorbid disorders such as establishing appropriate glycemic control, hydration, and intravenous antimicrobials if infection is suspected. Additionally, local wound care is important if ulceration is identified concurrently with arthropathy. Sharp debridement removes bacterial contamination, while most wound care must

Fig. 62.6 Acute Charcot arthropathy involving the midtarsal and subtalar joints

Fig. 62.7 Late development early coalescent Charcot arthropathy involving the Lisfranc and intercuneiform joints

be established. In cases of abscess formation, operative incision and drainage, and, rarely, amputation may be necessary.

The cornerstone of treatment for acute Charcot neuroarthropathy is protected offweighting with total contact casting. The patient must remain completely nonweightbearing on the affected limb using any manner that will guarantee patient adherence. This may be accomplished via crutches, roller cart, or wheelchair depending on patient psychosocial capabilities and available resources.

Fig. 62.8 Total contact cast for treatment of acute Charcot neuroarthropathy

Clinicians should be aware of the protracted time frame for the acute phase to transition into the coalescent phase where protected weightbearing is possible. Sinacore studied 30 subjects with 35 acute onset presentations of Charcot of the foot and ankle. The midfoot was most commonly involved (46 patients), followed by the hindfoot (23 patients), forefoot (20 patients), and ankle (11 patients). All patients were treated with total contact casting, and the healing endpoint was defined as discontinuation of the necessity for TCC as determined by the treating physician. In 100% of cases, the average healing time was 86 ± 45 days [43]. Providers may take from this a rule-of-thumb of 1 to 2 months for transitioning out of the acute Charcot phase.

Total contact casting (TCC) (Fig. 62.8) is a modified method of below the knee cast that involves applying minimal under-cast padding to the extremity and using a cast that conforms to the shape of the leg and foot. This device attempts to maintain the shape of the foot during the acute destructive process of Charcot. The patient should be maintained in the TCC until the acute phase of destruction has resolved with cast changes weekly at first until the initial edema resolves. The TCC requires considerable training to appropriately apply, and if placed incorrectly may result in abrasions, ulcerations, and an increased potential for limb amputation. This device should be applied only by trained specialists. Pinzur et al. found patients were able to safely bear weight in a TCC with biweekly changes lasting an average of 5.8 weeks. Patients were considered safe for transition into prescription shoes at an average of 12 weeks [44]. In the emergency department, an appropriate alternative is to apply a removable cast walker to the patient with instructions not to remove (Fig. 62.9).

Charcot arthropathy involving the ankle joint is somewhat different in outcomes compared with pedal joints and often involves a surgical approach. Schon et al. found an improved overall outcome of this disorder when treated surgically as opposed to nonsurgically with casting and bracing. They found a greater loss of correction with nonsurgical care and improved success rates with surgical intervention [45].

The effect of bisphosphonate therapy for the treatment of acute Charcot arthropathy has revealed conflicting and controversial results. Jude et al. in 2001 randomized 39 patients with acute Charcot to either a single intravenous dose of pamidronate 90 mg or placebo (saline) in a double blind manner. Patients were then followed for 12 months during which skin temperature, bone-specific alkaline phosphatase, and deoxypyridinoline crosslinks were measured. Patients given the pamidronate were observed to have an initial reduction in bone turnover as compared with placebo with similar levels at the end of the study [46]. This was the first study to examine a potentially definitive treatment for Charcot arthropathy. Subsequently, several studies examined the outcomes of bisphosphonate therapy on acute Charcot with one study finding increased time to clinical resolution with zoledronic acid and possibly extending the time to resolution [47].

Fig. 62.9 Removable cast walker as an alternative to total contact casting

Significant methodological flaws in this body of research demonstrate low experimental numbers, various treatment methods (e.g., intravenous versus oral formulations and different experimental drugs), and lack of long-term follow-up [48, 49]. Two systematic reviews have stated that skin temperature and inflammatory markers decrease with bisphosphonate therapy, but studies have failed to demonstrate improved clinical outcomes and might even prolong the resolution phase [50, 51]. Due to the lack of long-term outcomes and questionable results, we currently recommend against the use of bisphosphonates for acute Charcot neuroarthropathy.

Currently, the joint destruction and subsequent deformity of Charcot are irreversible. Thus, long-term care consists of shoe gear modifications, sometimes requiring custom shoes, custom foot orthoses, and regular serial observation by a foot specialist. Some physicians prefer to place these patients into a Charcot Restraint Orthotic Walker (CROW), which is a custom molded below knee brace that attempts to redistribute plantar pressures (Fig. 62.10). The primary goal is prevention of ulceration and amputation.

In certain situations, surgical intervention may be necessary, including demonstrated instability, preulcerative callus formation, and ulceration. Surgical options are beyond the scope of this chapter but generally include tendoachilles lengthening to reduce forefoot pressures, ostectomy procedures to reduce bony prominence, realignment arthrodesis to create a more functionally stable and plantigrade foot, and limb amputation. Each of these reconstructive procedures should be considered salvage methods in an attempt to avoid amputation.

Outcomes for patients with Charcot arthropathy of the foot vary. When considering the risk of amputation, it is clear that patients with mild joint destruction and minimal to no subsequent deformity are at relatively low risk. Sohn et al. retrospectively reviewed a Veterans' Affairs national cohort of 911 patients with incident Charcot arthropathy and 15,117 patients with diabetic foot ulcers (without amputations). They found the overall amputation rate for patients with Charcot was not significantly different from the overall diabetic population with foot ulcers. However, patients with both Charcot and the

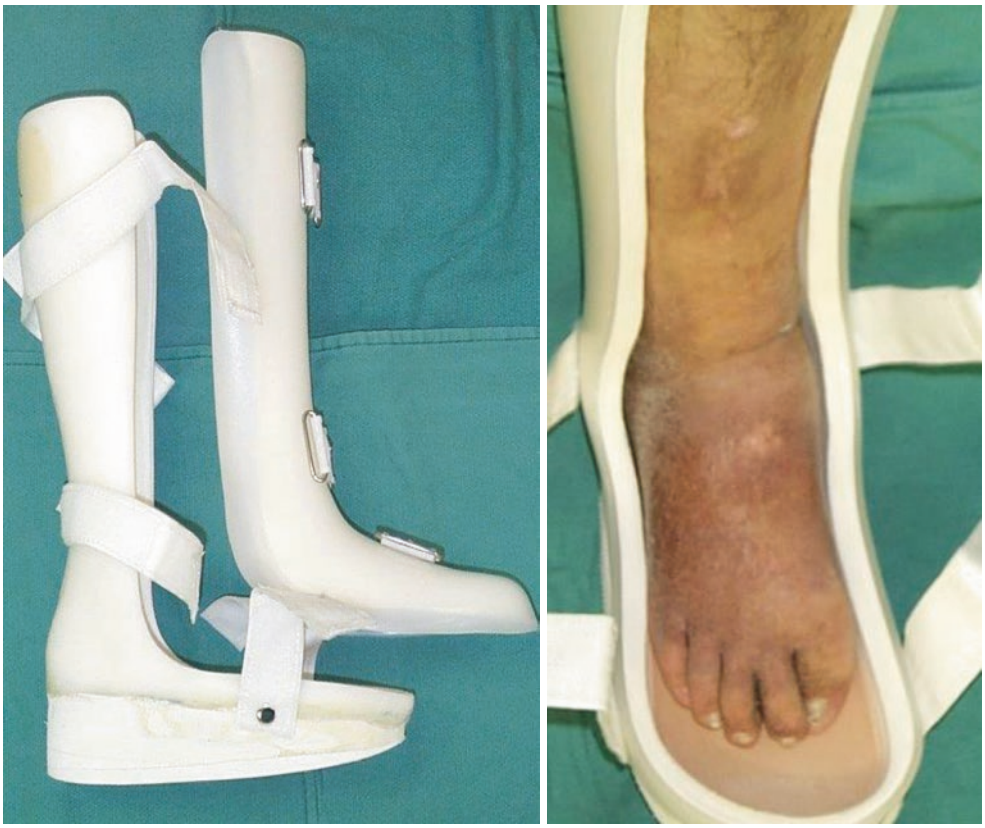

Fig. 62.10 Custom-made Charcot Restraint Orthotic Walker (CROW) for offweighting the Charcot foot

presence of a foot ulcer were 12 times more likely to undergo a limb amputation, and patients with ulcer alone were 7 times more likely to undergo a limb amputation than those with Charcot alone [9]. This demonstrates that Charcot alone does not increase the risk of amputation, but when coupled with a foot ulcer, the risks are much higher.

When considering mortality, the risk profile is different. Sohn et al. examined a cohort of 1050 patients with Charcot arthropathy and compared them to diabetic patients with foot ulcer and those with diabetes alone. During a 5-year follow-up, they found 18.8% of patients with diabetes alone died, 37.0% with foot ulcer died, and 28.3% of the Charcot patients died. These researchers found the presence of Charcot independently and significantly increased the mortality rate of these patients [52].

These findings show that Charcot arthropathy is a complex and serious disease with a high rate of complications and potential morbidity and mortality. Physicians should maintain a very high index of suspicion in any diabetic patient with an acute presentation of erythema, edema, warmth, and new onset pain, despite the presence or absence of ulceration. A low threshold for acute splinting or casting with strict nonweightbearing protocols is the best current treatment to prevent long-term deformity and complications. Further research will be necessary to better elucidate the etiology and treatment of Charcot arthropathy.

Foot Amputation

Amputation is often the final stage of a long process, and in the diabetic this may often be considered a failure of prior care. However, a modified view of this concept may be appropriate to better understand the role of amputations in the foot. As discussed in the introduction to this chapter, major limb amputation (transtibial and transfemoral levels) has significant associated morbidity and mortality in the diabetic population. This may be observed through several lenses. First, these patients already have significant comorbidities, including advanced cardiovascular disease, among others.

Additionally, major limb amputation leads to a greater energy expenditure during walking. Waters et al. performed a seminal study in 1976 in which they compared several gait parameters in patients with above knee, below knee, and Symes ankle disarticulation amputations to a control group of normal subjects. They found improved gait velocity, cadence, stride length, oxygen uptake, maximum aerobic activity, and heart rate in patients with the more distal amputations [53]. Similarly, Gailey et al. compared transtibial amputee oxygen consumption, heart rate, and self-selected walking speed with a non-amputee control group. They also found increased metabolic costs in the amputee group. However, when stratifying the ampu-

tee group by length of amputation, they found a significant improvement in these parameters with increased amputation stump length [54].

However, it has been shown that length of the residual limb also correlates with mortality. There are no studies that show amputation itself leads directly to increased mortality. This correlation is likely complex and may be hypothesized as a population with significant comorbidities, especially cardiovascular, with the additional physiologic stressor of the amputation (increased energy expenditure and decreased ambulatory capability) accelerating the rate of development of the already present comorbidities.

Several research studies although have demonstrated improved mortality when comparing partial foot amputations to major limb amputations [55–57]. Table 62.2 shows a synthesis of studies that compared mortality by level of amputation: digital, below knee, and above knee levels. As shown, the 1 and 5 year mortality trends are decreased in favor of those that involve only the forefoot as compared with the leg.

With this general trend toward improved outcomes with more distal amputations, it is important to strongly consider partial foot amputations as significant tools to help patients maintain an active life and potentially improved life expectancy.

It is the intention of this section to provide clinicians with general information about the options available for pedal amputations. Interested surgeons should refer to other textbooks for procedure specifics. A variety of pedal amputations exist, all of which spare the remaining portions of the foot with variable success, most of which prevent major limb amputation.

The choice of which amputation to perform is highly patient-specific and depends on therapy goals, reason for amputation (cellulitis, abscess, gas gangrene, osteomyelitis, malignancy, or gangrene secondary to peripheral arterial disease). A detailed work-up must be performed including obtaining an appropriate history, physical, and laboratory and imaging data. Additionally, the preoperative functional status and psychosocial history must be evaluated to appreciate the anticipated postoperative level of function.

Table 62.2 Mortality percentages by level of lower limb amputation demonstrating improvements with increasingly distal amputations [55–57]

Amputation level	30 day mortality %	1 year mortality %	5 year mortality %
Toe	1.7	6.6	46
TMA	2.7	8.5	45
BKA	7.0	25.5	56
AKA	11.1	49.4	70

Peripheral arterial disease is a major risk factor for failure of partial foot amputations [58]. Patients with peripheral arterial disease should undergo a comprehensive evaluation with noninvasive vascular testing, angiography, and consultation with a vascular surgeon. Revascularization should be performed before amputation unless an acute infection necessitates incision and drainage with debridement. It is sometimes necessary to stage the definitive amputation after emergent debridement and subsequent revascularization. Very little evidence is available to assist caregivers in determining the best timing of amputation after revascularization.

Caselli et al. attempted to answer this question by retrospectively reviewing 23 diabetic patients with ischemic foot ulcers who underwent successful transluminal percutaneous angioplasty (PTA) and 20 patients who underwent unsuccessful PTA. They used transcutaneous oxygen pressure measurement ($TcPO_2$) on the dorsal surface of the foot before and after PTA at 1, 7, 14, 21, and 28 days postoperative as a marker of improved perfusion. In the successful revascularization group, $TcPO_2$ measurements progressively improved and peaked at 4 weeks while the unsuccessful group saw no significant rise in $TcPO_2$. These researchers suggested waiting 3 to 4 weeks for the definitive amputation when delay is possible [59]. Currently, timing of amputation after revascularization is determined anecdotally based on clinician experience rather than via sound research-based evidence. Clearly, further research with well-designed prospective methodology is necessary.

Digital Amputation (Fig. 62.11)

Indications for digital amputation in the diabetic foot most commonly include isolated gangrene of a toe, osteomyelitis, and severe soft tissue infection. Amputation of a single digit may be performed along any portion of the length of the digit including the distal or proximal interphalangeal joint or at the metatarsophalangeal joint. When possible, it is preferable to leave as much of the digit as possible. The remaining stump acts as to prevent the contiguous digits from falling into the space previously occupied by the amputated digit. Hammertoe contractures though must be taken into consideration as this may cause the remaining post-amputation portion of the toe to be plantar flexed with increased distal pressures and future ulceration.

Ray Amputation

Amputation of a toe (Fig. 62.12) and part or all of the associated metatarsal is another common procedure that is

Fig. 62.11 Digital amputation with disarticulation at the metatarsophalangeal joint on patient with second toe distal phalangeal osteomyelitis and necrotizing abscess formation. Partial closure immediately with delayed primary closure 3 days later

Fig. 62.12 Partial toe amputations. Left: 2 weeks postoperative with uneventful healing. Note buttressing effect the residual toe provides. Right: dislocation of first metatarsophalangeal joint with almost 90° hallux abduction due to prior lesser toe amputations and loss of lateral buttress

commonly performed on patients with osteomyelitis of a digit that extends into the metatarsophalangeal joint or abscess of the affected ray. Due to firm fascial septae that separate the individual rays, it is often possible to resect a ray in an isolated manner. This procedure is easily performed with a racket-type incision that extends proximally along the metatarsal to the necessary amputation level (Fig. 62.13).

Fig. 62.13 Recurrent neuropathic ulcer status post partial first ray amputation. Note the lesser hammertoe contractures and ulceration secondary to transfer pressure

Transmetatarsal Amputation

Amputation of all toes and a portion of their associated metatarsals, the transmetatarsal amputation, is a powerful and highly useful procedure in the diabetic foot. This procedure is indicated in forefoot gangrene, osteomyelitis, abscess, or forefoot tumor (Figs. 62.14 and 62.15). Due to increased plantar pressures and altered gait kinematics [60] percutaneous Achilles tendon lengthening is commonly performed with this procedure to prevent postoperative plantar stump ulceration. This procedure has a high success rate, allowing patients to ambulate with minimal shoe modifications.

Isolated and Panmetatarsal Head Resection

Although not considered true amputations, removal of an isolated metatarsal head or removal of all of the metatarsal heads (panmetatarsal head resection) may be important alternative tissue-sparing procedures useful in specific situations. These include neuropathic plantar ulcers and isolated or multiple metatarsal head osteomyelitis without extended bone or soft tissue involvement. A retrospective review of 34 panmetatarsal head resection procedures with average follow-up of 20.9 months revealed an overall success rate of 97% with 1 ulcer recurrence and no amputations [61].

Figure 62.16 demonstrates the utility of this procedure. Patient SR was a 48-year-old long-term diabetic male with a chronic right foot plantar neuropathic ulcer that did not respond to several offweighting modalities. The patient had previously undergone second and third metatarsal head resections with resultant rigid deformity. Due to peripheral arterial disease, the patient underwent a femoral to posterior tibial bypass and 1 month later panmetatarsal head resection. At 5-year follow-up, the patient remained ulcer free. Internally, offweighting the forefoot successfully resolved this patient's ulcer.

Tarsometatarsal (Lisfranc) Midtarsal (Chopart) Amputations (Figs. 62.17 and 62.18)

These more proximal foot amputations have historically been less utilized due to increased long-term complications, especially plantar reulceration [62]. Previously, this was due to a less biomechanically stable foot with focal plantar pressures and the absence of adequate prosthetic devices. When possible, a more distal amputation such as the transmetatarsal level is preferable. However, in cases of more significant tissue loss where limb

Fig. 62.14 Series of a patient who underwent transmetatarsal amputation after multiple prior digital and partial ray amputations with osteomyelitis of the second metatarsal head and a nonfunctional forefoot. Left: preoperative clinical appearance with visible second metatarsal head. Middle: preoperative dorsoplantar radiograph with second metatarsal head fracture and osteomyelitis. Right: postoperative dorsoplantar radiograph after successful transmetatarsal amputation

Fig. 62.15 Diabetic male with severe peripheral arterial disease and critical limb ischemia (top image). Patient underwent endovascular intervention and staged transmetatarsal amputation with Achilles tendon lengthening. Dorsal weightbearing view (bottom left) with plantar view (bottom right) demonstrating successful healing without recurrent ulceration

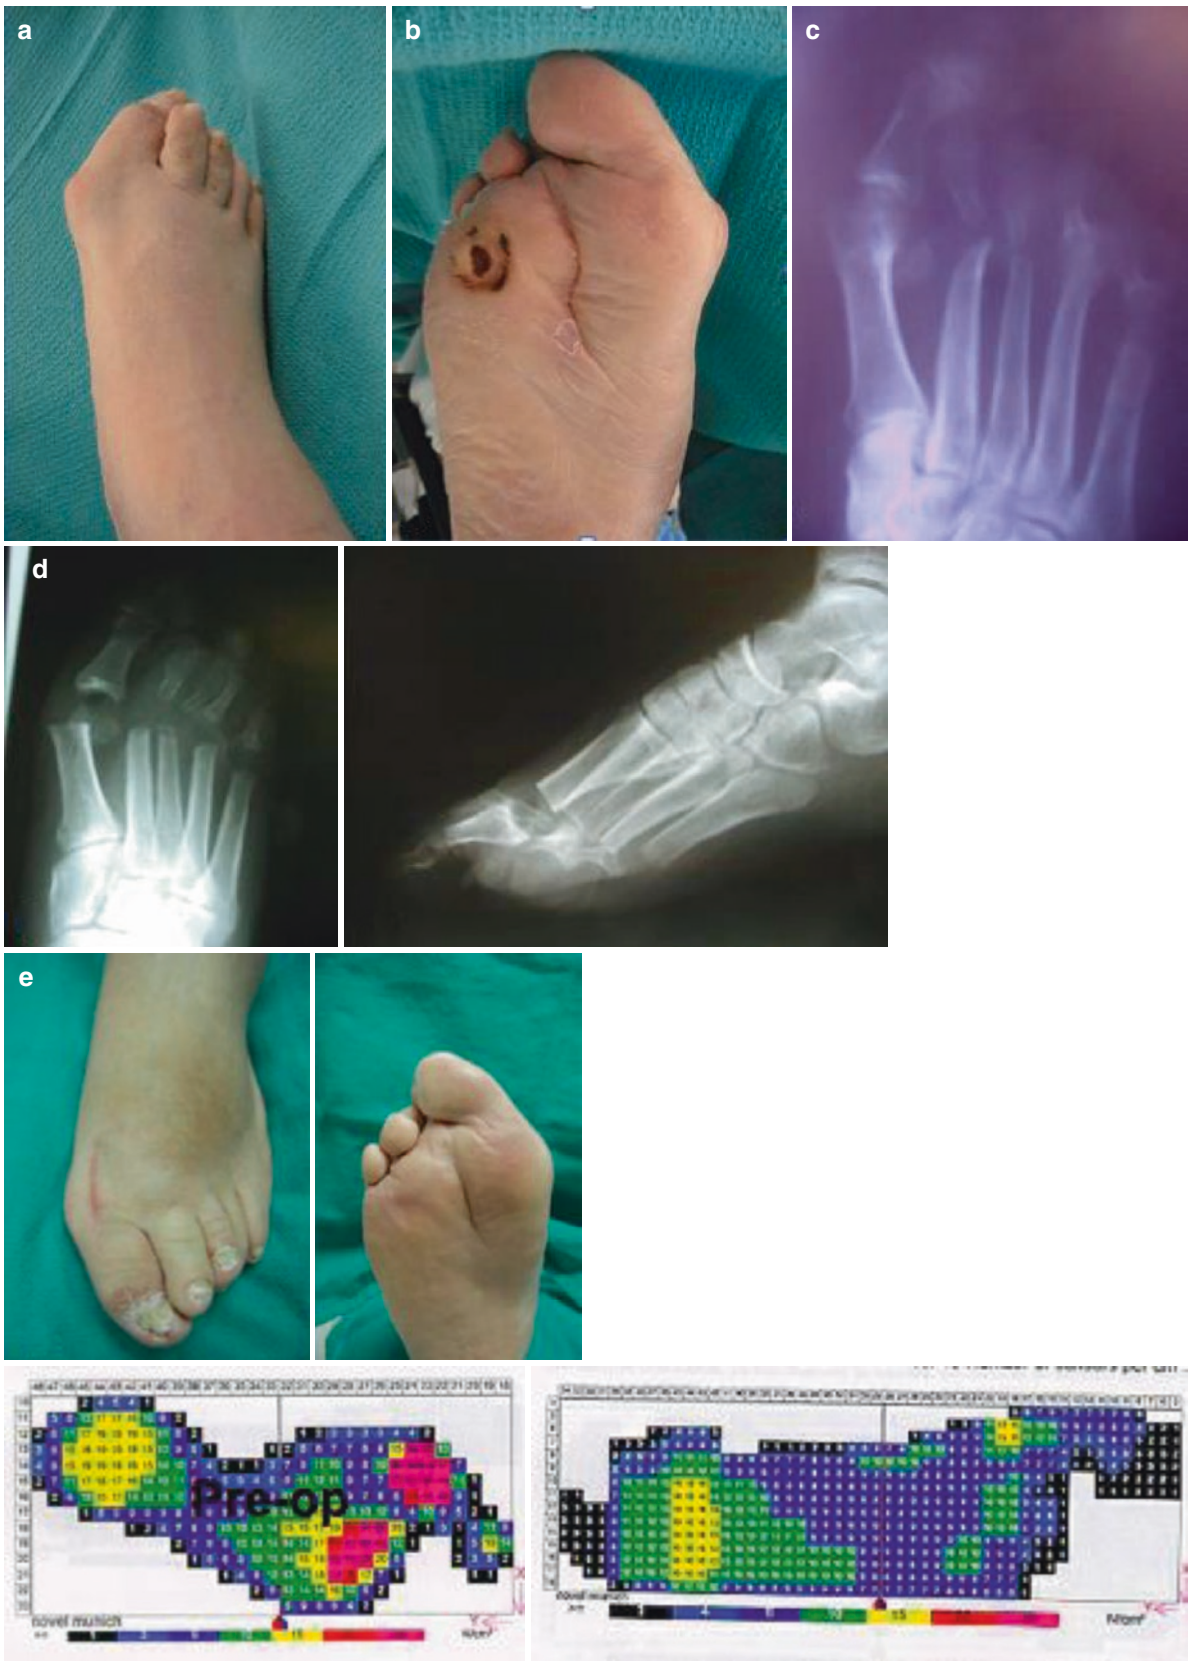

Fig. 62.16 Clinical and radiographic image series of patient SR who underwent panmetatarsal head resection after revascularization for non-healing plantar neuropathic ulceration. Images **A, B, C** = preoperative clinical and radiographic appearance. **D** = Postoperative radiographic appearance. **E** = 5-year follow-up clinical appearance. Note ulcer-free appearance. Bottom row shows E-med pressure sensing system with preoperative (left) and postoperative (right) pressures (red = highest pressures, black = lowest). Note the significant long-term pressure reductions

Fig. 62.17 Right foot Lisfranc amputation with removal of fifth metatarsal base and peroneus brevis attachment. Altered biomechanics led to varus foot position with lateral overload and recurrent plantar ulceration

salvage is attempted, these procedures have an important role. Preservation of the bases of the first and fifth metatarsals when possible retains their respective tendon insertions with improved outcomes. Accessary soft tissue balancing techniques improve the mechanical function of the residual foot. These include gastrocnemius recession, Achilles tendon lengthening, Achilles tenotomy or tenectomy, tibialis anterior transfer, peroneus brevis transfer, and posterior tibial tenotomy [62, 63].

The partial foot amputations outlined above have variable outcomes. The majority of clinical studies are retrospective in nature, and further well-designed prospective comparative studies are necessary. Given this limitation, there is a relative consensus that isolated partial or total digital amputations generally have positive results. However, amputation of the hallux or first ray is a unique situation that may have variably poor outcomes. In 1997, Murdoch et al. retrospectively reported on a 10-year cohort of diabetic patients who underwent either great toe or partial first ray amputations. Sixty percent of these patients eventually underwent a second amputation, 17% underwent a later below knee amputation, and 11% had a transmetatarsal amputation on the same extremity. The mean time to second amputation was 10 months from the index procedure [64]. Kadukammakal et al. retrospectively reviewed 48 patients who underwent 50 partial first-ray amputations between 2003 and 2009 and found 24 cases required further surgical intervention with 12 of those converted to a transmetatarsal amputation with a mean time of 9 months to definitive amputation [65]().

Similarly, Izumi et al. in 2006 retrospectively analyzed a population of 277 diabetic patients who underwent a first-time amputation. They looked at repeat amputation after first amputation at 1, 3, and 5 years [66]. They found the reampu-

Fig. 62.18 Chopart amputation for lesser tarsal osteomyelitis after failed Lisfranc amputation. Preoperative radiograph (left). Postoperative radiograph (right) and clinical appearance (bottom) after successful Chopart amputation and Achilles tendon lengthening

Table 62.3 Ipsilateral limb amputation rates by level of original amputation level [67]

Level of index amputation	1-year (%)	3-years (%)	5-years (%)
Toe	22.8	39.6	52.3
Ray	28.7	41.2	50
Transmetatarsal	18.8	33.3	42.9
Major limb	4.7	11.8	13.3

tation rates noted in Table 62.3. As indicated in the table these researchers found an increasing trend in future amputations over time. However, the rate of change decreased when comparing toe and ray amputations to the transmetatarsal level, indicating the inherent problematic long-term success of the more minor pedal amputations. This increased complication rate is due to the altered biomechanics of the residual foot in otherwise ambulatory patients. For example, after partial first ray amputation, it is highly predictable to see hammertoe contractures of the remaining toes and altered weightbearing plantar pressures. These deformities then predispose the neuropathic patient to further ulceration, infection, and subsequent amputation.

The transmetatarsal amputation has gained popularity as an increasingly successful forefoot amputation. The aforementioned studies demonstrate the decreased reamputation rates versus hallux and partial first ray amputation. This was shown early in a retrospective cohort study of 53 patients undergoing first-time amputation with a success rate of 37.1% in patients undergoing partial first ray amputations and 93.3% in patients undergoing transmetatarsal amputation [67]().

Conclusion

All interventions discussed herein rely fully on involvement of the patient and adherence to treatment regimens. Unfortunately, this may be difficult in practice. Nonadherence in patients with diabetic foot complications is high.

Depression has a significant effect on the diabetic patient and has been shown to decrease health-related quality of life, decrease self footcare, and increase number and severity of diabetes-related complications [68, 69]. Major depression has been linked with a two-fold increased risk of incident ulcers [70] and a five-fold increased risk of ulcer recurrence [71]. Depression also increases the amputation risk with a 33% increased risk of major amputation and 12% increased risk of any amputation (major or minor) [72].

Specialists caring for patients with diabetic foot complications must be cognizant of the home and social environment as well as any individual factors that may involuntarily increase nonadherence to medical therapy. Time should be taken to educate the patient about his or her situation and the steps necessary for care, and it must be determined if the patient is cognitively able to understand the various needs to effect positive outcomes.

The complications associated with the diabetic foot are highly significant and require greater focus to improve patient outcomes. Due to the complexity of the diabetic patient, no single medical provider can successfully perform all of the necessary interventions. Thus, a team approach is integral to appropriate care. The team approach, in which all providers involved with limb preservation participate in the joint care of patients, has become increasingly common with designated amputation prevention centers to focus on all aspects of the diabetic foot. Table 62.4 lists the possible members of the amputation prevention service [73], but it must be understood that at the center of this team is the patient.

Several recent studies have demonstrated both improved outcomes and decreased healthcare costs with this team approach. VanGils et al. reported on the outcomes of a collaborative approach between podiatry and vascular surgery services in a Veterans' Affairs population. During a 55-month follow-up, they found an 86.5% limb loss avoidance rate at 3 years which remained 83% at 5 years [74]. Similarly, a collaborative approach including vascular surgery, orthopedics, endocrinology, plastic surgery, and nursing in a Turkish limb preservation service found an overall amputation rate of 39.4% with 30% below knee amputations [75], an improvement in the rate of major amputations. Driver et al. reporting on the outcomes of a multispecialty limb preservation service, found an 82% decrease in any lower limb amputations over a 4-year period despite a rising number of diabetic patients [76].

Table 62.4 Potential members of an amputation prevention service

Certified diabetes educator
Endocrinologist
General surgeon
Infectious disease specialist
Internist
Nephrologist
Nurse
Nutritionist
Podiatrist/orthopedist
Pedorthotist/orthotist/prosthetist
Psychologist/psychiatrist
Vascular surgeon

In conclusion, diabetic foot complications were a previously poorly understood phenomenon that today has demonstrated significant improvements in outcomes. When understood properly and treated with a comprehensive interprofessional care model diabetic foot ulcers, Charcot neuroarthropathy, and infections such as osteomyelitis may be successfully treated with improved patient ambulatory activity and quality of life.

Multiple Choice Questions

1. Five year mortality rate for patients with neuropathic foot ulcers:
   (a) 30%
   (b) 35%
   (c) 40%
   (d) **45%**
   (e) 50%
2. Diabetic foot ulcers:
   (a) Are not preventable
   (b) Are mostly not preventable
   (c) **Are mostly preventable**
   (d) Are unavoidable
   (e) None of the above
3. Compared with some types of cancer, 5-year mortality rates from neuropathic ulcers and amputations:
   (a) **Are higher**
   (b) Are lower
   (c) Are equal
   (d) Have not been compared
   (e) Are not comparable
4. A crucial initial event on the development of diabetic foot ulcers:
   (a) Low grade microtrauma
   (b) **Loss of protective sensation**
   (c) Lower limb ischemia
   (d) Infection
   (e) Structural deformities
5. The stage at which the typical foot ulcer healing process stalls:
   (a) The hemostatic inflammatory phase
   (b) **The proliferative phase**
   (c) The remodeling phase
6. Compared to patients without diabetes, the risk of amputation in patients with diabetes and peripheral artery disease is:
   (a) Two times higher
   (b) Three times higher

(c) Four times higher
(d) **Five times higher**
(e) Six times higher

7. Historical components of the vascular risk spectrum include:
   (a) Macrovascular disease
   (b) Microvascular disease
   (c) Functional microvascular disease
   (d) A and B are correct
   (e) **A, B, and C are correct**
8. According to the UKPDS trial, each 1% increase in glycosylated hemoglobin increases the risk of peripheral artery disease:
   (a) 12%
   (b) **28%**
   (c) 34%
   (d) 43%
   (e) 51%
9. Independent risk factors for peripheral artery disease include all of the following, except:
   (a) Hyperglycemia
   (b) Smoking
   (c) Systolic blood pressure
   (d) **Diastolic blood pressure**
   (e) Dyslipidemia
10. Different studies have shown that a team approach reduces the risk of lower limb amputations approximately:
   (a) 30%
   (b) 40%
   (c) 50%
   (d) **80%**
   (e) Compared to traditional management, no reduction have been demonstrated.

Chapter Objectives

- The prevalence of diabetes mellitus type 2 and cancers of various sites is dramatically increasing nowadays. It was established that diabetes mellitus (mainly type 2 diabetes mellitus) predisposes do oncogenesis in various human organs.
- The main factors leading to neoplastic transformation in diabetics are hyperinsulinaemia, hyperglycaemia and chronic inflammation induced by excessive adipose tissue.
- Anti-diabetic medications interfere with the risk of neoplastic transformation—some of them elevate the risk, some reduce the risk and some express inconsistent activity.
- Certain anti-diabetic medications express potential usefulness in improving effectiveness of conventional chemotherapy.
- Diabetics with T2DM and coexisting neoplasm have worse disease-free and overall survival than patients with neoplasm but without T2DM.

Introduction

Diabetes mellitus (DM), one of the most common diseases all around the world, comprises a large group of metabolic disorders. DM is characterized by persistent hyperglycaemia caused by inaccurate function of insulin or its reduced excretion from pancreatic beta cells. Long-lasting hyperglycaemia results in damage and improper function of various organs. The morbidity of T2DM is rapidly increasing especially in middle-aged people (45–65 years). Interestingly, recent evidence implies that there is a significant correlation between DM and neoplastic transformation [1–9]. The association was observed both for type 1 diabetes mellitus (T1DM) and type 2 diabetes mellitus (T2DM) [10]; nevertheless the majority of studies concern T2DM [11, 12]. It has been shown that DM (especially T2DM) increases the risk of various cancers in men and women [10, 11]. Up to now, little is known about the links between T1DM and carcinogenesis. Nevertheless, it was observed that T1DM enhances the overall risk of pancreas, liver, oesophagus, colon and rectum, and stomach, thyroid, brain, lung, endometrium, ovary, cervix, squamous cell skin cancers and acute lymphatic leukaemia in women [10–13]. The strongest association between DM and carcinogenesis is observed for pancreatic and liver cancers in patients with T2DM [14]. Additionally, according to the current knowledge there is also a relationship between neoplastic transformation and anti-diabetic medications [6]. However, the exact mechanisms leading to this connection need further investigation [1, 15].

Historical Facts

The first description of diabetes (a state of polyuria) was found in the Ebers Papyrus in 1552 BC by Egyptian physician Hesy-Ra. This description was found in Thebes (Egypt) in 1862 AD by Egyptologist Georg Ebers. The term “diabetes” comes from Greek meaning “siphone” and was intro-

duced by Areteus from Cappadocia (81-138 AD) who described main symptoms of this disease [16, 17]. The main differences between the two most common types of DM (type 1 and type 2) were observed and described by Himsworth in 1936 [18].

Epidemiology

The number of persons with diabetes mellitus in 2021 estimated by the International Diabetes Federation (IDF) among adults (aged 20–79 years) reached 537 million of people [19]. Nevertheless, approximately 50% of DM cases remain undiagnosed. The IDF estimates that in 2040 the number of persons with diabetes will amount 785 million people [19].

The World Health Organization (WHO) has declared that cancer is the leading cause of death worldwide, accounting for nearly ten million deaths in 2020 [20]. The most common new causes of cancer in 2020 were breast (2.26 million cases), lung (2.21 million cases), colon and rectum (1.93 million cases), prostate (1.41 million cases), skin (non-melanoma) (1.20 million cases) and stomach (1.09 million cases) [20]. The most common causes of cancer death in 2020 were lung, colon and rectum, liver, stomach and breast, and according to the WHO, the annual incidence of new cancer cases will reach 22 million in the next two decades [20]. Normal cells transform into malignant cancer cells through a complex process, including initiation, promotion and progression involving more aggressive growth, angiogenesis and metastases [21].

Types of Diabetes Mellitus

Diabetes is a group of disease entities that can be classified as follows:

T1DM (previously known as "insulin-dependent diabetes mellitus") is caused by autoimmune or idiopathic process of self-aggression leading to rapid destruction of pancreatic β-cells. As a result, the level of insulin, the pancreatic hormone responsible for maintaining glycaemic control, is minimal or undetectable. T1DM usually appears as ketoacidosis with its main symptoms including polyuria, polydipsia, nausea, vomiting, stomachache, weakness, acetone breath and Kussmaul breathing. T1DM concerns 5–10% of all cases of diabetes. The autoimmune process is characterized by the presence of four types of antibodies: ICA (islet cell antibodies), IAA (insulin autoantibodies), anti-GAD (anti-glutamid acid decarboxylase), IA-2 and IA-2B (tyrosine phosphatase-related islet antibodies). These antibodies can be detected months of even years before first symptoms of the disease. Generally, T1DM is not an inherited disease; however, there is a proven genetic predisposition determined by HLA (human leukocyte antigens). The highest susceptibility to T1DM occurs in patients with haplotype HLA-DRB1*03 (DR3) or HLA-DRB1*04 (DR4) with DQB1*03:02 (DQ8) [22]. Conversely, the HLA-DQ6 haplotype is considered to protect against developing T1DM. T1DM may appear at any age but is usually diagnosed during childhood (before 30 years). The exception is LADA (Latent Autoimmune Diabetes of Adults) that occurs in adults. T1DM treatment is based on multiple doses of exogenous insulin preparations for the lifetime.

T2DM (previously known as "non-insulin-dependent diabetes mellitus") is the most common form of diabetes (up to 95% of all cases). T2DM is generally characterized by insulin resistance of insulin-dependent tissues (adipose tissue, liver and muscle cells) leading to improper, excessive secretion of insulin and hyperinsulinaemia [23]. Insulin insensitivity causes a decreased glucose uptake of target tissues and increased serum glucose level [18]. Other pathologies in T2DM comprise increased amount of circulating inflammatory cytokines, adipokines, lipotoxic free fatty acids or amyloid deposits in pancreatic islet cells [24]. Risk factors of T2DM include genetic, inherited predisposition, sedentary lifestyle, obesity, ageing, cigarettes smoking and/or excessive alcohol consumption. This type of diabetes commonly affects middle-aged or older people albeit during the last two decades an increasing trend has occurred in adolescents. The genetic susceptibility to T2DM is more significant than observed in T1DM. Confirmed positive family history is associated with a 2–4 times increased risk of T2DM [24]. Recently discovered genes connected with high risk of developing T2DM are insulin receptor, potassium channels, proteases or transcription factors genes [16, 24]. The onset and early stages of T2DM are usually asymptomatic and progressive, and the slow development of the disease leads to delayed diagnosis. Being asymptomatic years before diagnosis, patients with T2DM are more prone to develop macrovascular or microvascular complications [24]. Management in T2DM is based on lifestyle changes, medical nutrition therapy, physical activity, diabetes education and support, and anti-diabetics [25–27]. Reducing body weight and physical activity are the firsts steps of therapy and essential in every stage of the disease. Pharmacotherapy must be patient-adjusted and includes a variety of glucose-lowering drugs such as biguanides (metformin), sulfonylureas, meglitinides, α-glucosidase inhibitors, thiazolidinediones (TZD), dipeptidyl peptidase four inhibitors (DPP-4-i), glucagon-like peptide-1 agonists (GLP-1) and sodium-glucose co-transporter 2 inhibitors (SGLT2 inhibitors). If all mentioned methods are insufficient to achieve glycaemic control, insulin injections are required. Insulin may be used as monotherapy or in combination with other anti-diabetic drugs.

Additional etiological classes of diabetes include monogenic types, including MODY (maturity onset diabetes of the young), an inherited form caused by an autosomal dominant

gene. The pathophysiology of this type of diabetes is based on improper beta cells secretion of insulin with preserved insulin function [23]. Monogenic-type diabetes usually manifests in childhood (younger than 25) and is characterized by hyperglycaemia, insulin deficiency and mild clinical symptoms. Insulin resistance is not observed in MODY. Therapy in this type is of diabetes based on medical nutrition and oral anti-diabetics. Secondary causes of known aetiology include genetic defects of beta cells and insulin function, diabetes caused by drugs or other chemicals, infections, endocrinopathies, diseases of the exocrine pancreas or genetic syndromes.

Gestational diabetes (GDM) is a state of glucose intolerance that begins or is diagnosed during pregnancy. GDM is caused by insulin resistance during gestation and affects up to 7% of pregnant women. Insulin resistance in women with GDM is higher than in healthy ones, probably because of chronic insulin resistance observed in the first group [28]. During pregnancy, levels of hormones opposing insulin action (placental lactogen, oestrogen, progesterone and prolactin) are elevated, leading to excessive insulin secretion. Risk factors of GDM include obesity, GDM in previous pregnancies, positive family history of diabetes, current glucosuria and history of macrosomia in previous pregnancies. The management in GDM is based on medical nutrition, exercise and if this management is insufficient, insulin injections. Gestational diabetes is a risk factor for T2DM after childbirth T2DM [29]. Most of the studies about the association of diabetes are focused on Type 2 diabetes and cancer are focused on probably because of a higher prevalence of T2DM than T1DM.

Diabetes Mellitus and Oncogenesis—The Main Correlation

The association between DM and carcinogenesis was described for the first time in 1910 by Maynard and Pearson [30–31]. One hundred years afterwards, a consensus report presented by the American Diabetes Association (ADA) and the American Cancer Society (ACS) in 2010 described possible factors linking diabetes and cancer which could be divided into three main groups including modifiable risk factors, non-modifiable risk factors and biological links between DM and cancer [1, 32].

Links between DM and oncogenesis according to the ADA and the ACS:

- Modifiable risk factors:
  - overweight (BMI >25 and <30) and obesity (BMI >30)
  - physical activity (at least 5 days a week for 30 min a day reduces the probability of T2DM development)
  - smoking
  - alcohol abuse
- Non-modifiable risk factors:
  - sex (men are more prone than women)
  - age (adults aged between 55 and 60 years and older are more prone)
  - race (African Americans are more prone than Caucasians)
- Biological links:
  - hyperinsulinaemia (the effect of resistance to endogenous insulin or by exogenous insulin used as a medication).
  - hyperglycaemia
  - fat-induced chronic inflammation

Biological Linking Factors

(hyperinsulinaemia, hyperglycaemia, fat-induced chronic inflammation)

Role of Hyperinsulinaemia in Cancer Biology

Epidemiological studies have shown that high levels of insulin or C-peptide predict an increased risk for colorectal, breast, pancreas, bladder and endometrial cancer [21]. Insulin resistance and hyperinsulinaemia are important factors in the development of type 2 diabetes and additionally, insulin stimulates cell proliferation and promotes carcinogenesis in experimental animals [33]. Insulin resistance blocks signalling in the metabolic pathway involved in glucose metabolism, but does not inhibit activation of the cell signalling pathway involving cell differentiation [21]. The pro-neoplastic features of insulin are induced by activation of its receptors, Insulin Receptor [IR] and Insulin-like Growth Factor-1 is a polypeptide synthesized by almost all cells, although primarily by the liver [21]. Insulin resistance is able to activate the IGF-R receptor (IGF-R) because of approximately 60% structural homology of IGF-R and IR [33]. Similarly, IR may be stimulated by insulin and by both Insulin-like growth factors, IGF-1 and IGF-2 [34]. Ligand-induced IR autophosphorylation triggers intracellular mechanisms. The most important is activation of PI3K/Akt/mTOR (phosphoinositide 3-kinase/protein kinase B/mammalian target of rapamycin) signalling pathway. Stimulation of PI3K/Akt/mTOR signalling pathway plays a critical role in oncogenesis [35]. Interestingly, activation of IGF-R (by both insulin and IGF) results in more significant pro-neoplastic effects than activation of IR. IR and IGF-R are critical in tumourigenesis also because of the fact that their concentration in various cancer cells is higher than in normal cells; thus the effect of insulin and IGF on neoplastic cells is enhanced [36, 37].

Indirect Effects of Hyperinsulinaemia on Cancer Biology

- Up-regulation of bioavailable IGF-1 by hyperinsulinaemia-induced down-regulation of IGF-binding protein 1,2 and IGF-binding protein-3. IGF-binding proteins are crucial in IGF serum transfer and activity. IGF binding to specific proteins does not exert its biological effects (biological inactivity) [36, 38].
- Up-regulation of IGF-1 in growth hormone (GH)-dependent manner (*Explanation:* Insulin stimulates growth hormone receptors (GHR) located in the liver leading to elevated release of GH. Subsequently, GH promotes IGF-1 synthesis) [39].
- Up-regulation of leptin, a pro-neoplastic adipokine [40].
- Reduced synthesis of sex hormone binding protein (SHBG) in the liver (*Explanation:* SHBG plays an important role in transfer and activity of sex hormones (testosterone, oestrogen). Reduced amount of SHBG leads to high bioavailability of sex hormones that presumably results in development of hormone-related cancers (e.g. endometrial, breast cancer) [41].

The Role of Hyperglycaemia in Cancer Biology

It was established that cancer cells require high glucose levels to grow and survive. Cancer cells are more sensitive to high serum glucose levels than normal cells because of their elevated concentration of glucose receptors (GLUT-1, GLUT-3). These cells are characterized by rapid development and metabolism, and therefore they require high glucose resources [42]. The link between glucose and cancer dates back to the Warburg effect, described by Otto Warburg in 1924, which states that "the prime cause of cancer is the replacement of the respiration of oxygen (oxidation of glucose) in normal body cells by fermentation of sugar [43]. Hyperglycaemia enables neoplastic transformation via stimulation of cells' quick growth and development, suppression of apoptosis and metastasis promotion [44]. Increased blood glucose levels affect the normal cellular system at three steps contributing to dysregulated growth: (1) DNA (genetic), (2) RNA transcription, (3) Protein (translation) [45].

Mechanisms Leading to Proliferative Activity of Hyperglycaemia [21, 44, 45]

- Elevated expression of PPAR α and γ (*peroxisome proliferator-activated receptor) (Explanation:* PPAR α and γ interfere with lipid metabolic pathways and speed up neoplastic cells development).
- *Elevated expression of* glucose receptors (GLUT-1, GLUT-3) leading to increased cellular glucose intake.
- Elevated expression of EFG (epithelial growth factor) that activates neoplastic pathways via binding to its receptor EGFR (epithelial growth factor receptor).
- Increased amounts of ROS (reactive oxygen species) and SOD (superoxide dismutase) leading to free radicals and other reactive molecules which could produce oxidative damage to DNA, mutations in oncogenes and tumour suppressor genes (*Explanation:* Oxidative stress is a critical triggering factor of insulin resistance, a tumour-promoting factor. In addition, it induces glucose-mediated inflammation and increased synthesis of transcriptional factors including NF-κB, activating protein-1 and early growth response-1. These mechanisms lead to tumour growth and metastasis).

Mechanisms Leading to Anti-apoptotic Activity of Hyperglycaemia [44]

- Reduced amount of PDH (prolyl hydroxylase) resulting in increased levels of HIF-α (hypoxia-inducible factor α) (*Explanation*: The majority of energy in tumour cells is produced in a hypoxic environment, via aerobic glycolysis. HIF-α is a critical factor involved in cancer cell existence in hypoxic milieu; thus hyperglycaemia-induced high amount of HIF-α promotes tumour cells growth and survival).

Mechanisms Leading to Hyperglycaemia-Mediated Metastasis [44–47]

- Increased zinc intake resulting in cancer cells dislocation (*Explanation:* Increased zinc intake is caused by hyperglycaemia-induced high expression of zinc receptors. Zinc is an intracellular signalling molecule, able to convert extracellular impulses to intracellular processes and to mediate interaction between cells).
- Up-regulation of urokinase plasminogen activator (uPA), a critical mediator in cancer cells displacement.
- Stimulation of ETM (epithelial to mesenchymal transition) process, a mechanism that enables cancer cells to metastasise.

Moreover, hyperglycaemia induces epigenetic changes resulting in constant activation of oncogenic pathways, a

phenomenon called "hyperglycaemic memory". Activation of oncogenic pathways is regulated by overexpression of well-known neoplastic mediators, nuclear factor-κB (NF-κB) and neuregulin-1 (Nrg1) [44].

Role of Obesity and Fat-Induced Chronic Inflammation in Cancer Biology

Adipose tissue consists of adipocytes, endothelial, immune cells like and cytokines, associated with cancer risk and progression [21]. The vast majority of patients with T2DM are obese or overweight. Besides being a risk factor for T2DM and various cardiovascular disorders, obesity reveals pro-neoplastic activity [48–52]. Nowadays, the correlation between obesity and carcinogenesis has been widely discussed. It was reported that adiposity promotes the development of breast, endometrial, pancreatic, colorectal and oesophageal cancer [48–49]. Meta-analysis of case-control and prospective cohort studies has confirmed that T2DM is an independent risk factor for the development of non-Hodgkin lymphoma, and cancer of the bladder, breast, colon and rectum, endometrium, liver and pancreas [48], and some studies report that nearly 40% of all cancers can be attributed to overweight and obesity [49]. Obesity presumably exerts its pro-neoplastic activities in various ways. It interferes with sex hormones physiology, induces chronic inflammation and changes profile of adipose tissue polypeptide hormones (adipokines) [41, 49]. Adipose tissue is a crucial endocrine organ and in condition of abundance leads to dysregulation of endocrine mechanisms. Excessive adipose tissue expresses high amounts of aromatase, an enzyme critical in converting androgens to oestrogens, leading to high levels of oestrogens, which accompanied by low concentration of progesterone increases the risk of oestrogen-related breast and endometrial cancers [21, 41, 49]. Obesity-induced chronic inflammation is characterized by increased production of proinflammatory cytokines including interleukin-6, resistin and TNF-alpha (Tumour Necrosis Factor-alpha), which in turn lead to an increase in insulin levels, further increasing the inflammatory response [41]. Moreover, excessive adipose tissue secretes high amount of VEGF (Vascular Endothelial Growth Factor) and MMP (matrix metalloproteinases) leading to tumour growth and metastasis, respectively [41]. Adiponectin and leptin are two antagonist adipokines with significant impact on carcinogenesis [49, 50]. The level of adiponectin is decreased and the level of leptin is increased in patients with excessive adipose tissue. Adiponectin sensitizes cells to insulin, suppresses cells growth and metabolism, and exerts pro-apoptotic mechanisms, whereas leptin stimulates proliferation of cancer cells [49, 50]. In clinical studies, adiponectin inhibited tumour development in in vitro breast cancer cell lines and in animals afflicted by sarcomas [51, 52]. Conversely, leptin exacerbates insulin resistance and induces tumour-promoting processes, stimulates angiogenesis and tumour proliferation, and prevents apoptosis [49].

Diabetes and the Correlation with Oncogenesis in Particular Organs

Various studies emphasize that DM may induce neoplastic transformation [6]. Nevertheless, the exact influence of DM on carcinogenesis in particular organs has not been fully elucidated and the results of different studies remain conflicting. The positive correlation between DM and tumourigenesis was observed for organs of digestive system (pancreas, colon and liver), genitourinary system (bladder, kidney, endometrium), head and neck region and breast [53, 54]. On the other hand, a negative, inverse correlation was found only for prostate cancer which increases with increasing duration of diabetes [48]. The majority of the recent studies concern pancreatic and liver cancers; thus these two entities would be discussed more precisely than others. The current knowledge of the association between DM and cancers of particular organs is discussed below.

Pancreatic Cancer

The correlation between DM and increased risk of pancreatic cancer (PaC) was confirmed by various studies [55]. However, the association between diabetes and PaC remains unclear, because of a two-way relationship. PaC may lead to increased glucose and insulin levels followed by abnormal glucose metabolism, and abnormal glucose metabolism may cause neoplastic transformation in pancreatic cells. Huxley et al. reported a 50% increased risk of PaC in patients with T2DM history shorter than 5 years [56] and Elena et al. suggested that persons with diabetes have a 40% higher risk of PaC than people without diabetes [57]. In this study, the highest level of risk was observed in patients with DM lasting for 2–8 years; DM of 9 or more years was not associated with increased risk of PaC and may be possibly caused by hypoinsulinaemia that develops along with diabetes duration [57]. Conversely, an elevated risk of PaC in patients with long-lasting DM was reported in another study [58]. It has also been shown that patients with obesity and T2DM have a 54% higher risk of PaC [57]. On the other hand, Grote et al. observed a statistically significant increased risk of PaC in patients with HbA (1c) ≥6,5% compared with ≤5,4%, independently of obesity or insulin resistance [59]. It was found that patients with diabetes and T2DM have a higher propensity to suffer from PaC because of high serum concentration of insulin and its precursors. The authors did not find a significant association between T1DM and PaC [59, 214]. On the other hand, another study reported a two-times higher risk of PaC in patients with

T1DM or MODY than in people without diabetes [60]. There are also studies implying genetic predisposition to PaC in individuals with diabetes [61, 62]. Interestingly, Prizment et al. checked 10 different SNPs (Single Nucleotide Polymorphisms) related to DM and found a positive association between PaC incidence and DM only for one of the examined SNPs—GCKR rs780094 (glucokinase gene which rises plasma fasting glucose level) [61]. Additionally, it has been shown that GCKR rs780094 is associated with a higher risk of T2DM and PSA-detected prostate cancer [63]. Another research examining the genetic susceptibility to PaC in diabetics found a higher PaC risk in patients with glucose-rising allele of MADD rs11039149, FTO rs8050136 and MTNR1B rs1387153 variants. The inverse association was observed for BCL11A rs243021 [62].

Liver Cancer: it was established that T2DM as well as T2DM-related metabolic disorders stimulate tumourigenesis in hepatic cells. Hepatocellular carcinoma (HCC) is the most frequently observed primary malignant cancer in the liver and is also commonly present in diabetics [64]. In 1986 Lawson reported for the first time the positive association between higher prevalence of HCC in diabetics [65] and other authors confirmed this finding [66, 67]. Besides being observed in diabetics, HCC frequently occurs in patients with non-alcoholic fatty liver disease (NAFLD) and in those with obesity and insulin resistance [67]. NAFLD is a condition commonly seen in individuals with T2DM and is critically correlated with adiposity. NAFLD as well as T2DM and obesity stimulates tumourigenesis in liver cells via various mechanisms including modified adipokines profile (increased leptin level and decreased adiponectin level), oxidative stress (imbalance between antioxidant and prooxidant factors) and lipotoxicity (malfunction or death of non-adipose tissue cells caused by accumulation of excess lipids). Through the portal circulation, the liver is exposed to high amounts of circulating insulin. Constantly high insulin levels, via elevated production of IGF-1, lead to multiplication and apoptotic suppression in hepatic cells [68]. According to a meta-analysis of 25 cohort studies, the incidence of HCC is significantly increased in both men and women with DM [66], and other authors reached to consistent conclusions [64, 65, 68]. It is difficult to establish whether T2DM is an independent risk factor for HCC or whether T2DM leads to HCC via induction of other liver disorders including NAFLD, steatosis, alcohol abuse, cirrhosis and HCV/HBV infections [63, 69]. Beyond these contributing factors, the association between DM and HCC remains unclear [1].

Colon/Colorectal Cancer: a variety of studies established that T2DM predisposes to colon and colorectal cancers (CRC). A meta-analysis conducted by Larsson et al. revealed that DM is a significant risk factor for CRC [70]. The relative risk among diabetics was approximately 30% higher than in non-diabetics and was similar in both genders and the overall mortality of CRC is approximately 1.5 times higher in diabetics than in non-diabetics [70]. The positive association between T2DM and colon/colorectal cancer was also described in another study which found that the incidence of cancer was similar in colon and in rectum, with no statistically significant difference between genders [71]. Another meta-analysis revealed a 1.22-fold higher relative risk of CRC in people with diabetes [54]. Similar results were reported in other studies [53, 72].

Bladder Cancer: according to current knowledge there is also a positive association between T2DM and oncogenesis in bladder cells [73, 74]. The association was observed for both female and male diabetics. Woolcott et al. found an increased risk of bladder cancer in patients with diabetes with higher levels of risk in females [75]. Conversely, Zhu et al. reported a statistically significant increased risk for bladder cancer in men with T2DM [76].

Kidney Cancer: the clear association between renal cell cancer (RCC) and DM has not been fully elucidated. Various studies reported conflicting results. A prospective study of women with T2DM conducted by Hee-Kyung et al. revealed increased risk of renal cell cancer (RCC) in this group [77]. Similar associations were described in Japanese men and in Czech diabetics [78, 79]. No such correlation was found in another study [80]. Qayyum et al. suggested that DM is not an independent risk factor of RCC, but when combined with obesity or hypertension, it increased the risk of RCC [81]. Another study did not confirm that DM is a risk factor for RCC; however it revealed an increased risk of death from RCC in diabetics [82].

Endometrial Cancer: a significant role of DM in endometrial carcinogenesis was emphasized by a number of authors and it was also strongly implied that DM is an independent risk factor of endometrial carcinogenesis [83]. Lindemann et al. established a three times increased risk of endometrial cancer (EC) in diabetic women [84]. Interestingly, the risk of EC is more than six times higher in obese diabetics in comparison with non-obese non-diabetics [38]. An investigation on the influence of elevated serum glucose level on EC development revealed that both elevated serum glucose level caused by impaired glucose metabolism and DM increased the risk of EC [85]. It was suggested that DM might predispose to EC via hyperinsulinaemia-dependent reduced levels of adiponectin and through obesity-related decreased concentration of SHBG. The reduced levels of SHBG lead to elevated bioavailable oestrogen and testosterone amounts and eventually stimulate endometrial oncogenesis [49–86].

Breast Cancer: the significant correlation between DM and the high risk of oncogenesis in breast tissues has been widely discussed in the literature and is now well established [87, 88].

The revealed causes of breast carcinogenesis in DM include [87–89]:

- activation of IR or IGF-R through IGF
- overexpression of IR in breast tissue
- activation of insulin-dependent IP3-K/AKT/mTOR pathway
- hyperglycaemia
- insulin-induced increased level of bioavailable IGF-1
- insulin-induced increased concentration of leptin
- insulin-induced reduced level of adiponectin
- insulin-induced reduced level of SHBG resulting in increased amount of bioavailable oestradiol

The correlation between DM and breast cancer is mainly observed in postmenopausal women [87]. Nondiabetic postmenopausal obese women with hyperinsulinaemia are at higher risk of BC incidence in comparison to normoinsulinemic ones [90]. The presumed inequalities in the prevalence of BC in post- and premenopausal diabetic females may be induced by different oestrogen concentrations (modified indirectly by insulin) observed in these populations [32].

The correlation between T2DM and BC incidence was also studied in MKR (MKR is a mouse model of T2DM, which has a genetically modified IGF-1 receptor) [91]. The authors of this study documented a positive relationship between BC and high insulin concentrations in MKR female mice with hyperinsulinaemia. The hyperinsulinaemic milieu in MKR led to proliferation and oncogenesis in breast cells. Subsequently, specimens of tumour and breast tissues from examined mice were taken for further research. The obtained tissues presented elevated level of IR and increased IR/IGF-1R activation that resulted in insulin-dependent metabolic effects and proliferation of mammary glands [91]. Overexpression of IGF-1R in breast tissue in transgenic mice and its influence on BC incidence was also emphasized in another study [92].

Head and Neck Cancers: studies investigating the association between DM and head and neck cancers (HNCs) are sparse with conflicting results. Some authors reported positive association, some reported negative inverse association and some found no correlation. The majority of precise studies focus on particular organs of the head and neck area. In general, the incidence of HNC was weakly associated with T2DM or no significant relationship was revealed [93, 94]. On the other hand, there is also the presumption that head and neck squamous cell carcinoma (HNSCC) is slightly inversely associated with T2DM [95].

Laryngeal Cancer

Japanese men with diabetes present a significantly higher risk of laryngeal cancer independently of smoking status [96]. Other studies on Japanese population of diabetics found an increased risk of laryngeal cancer in both genders [78, 97]. Conversely, the risk of laryngeal cancer incidence was decreased in a large group of U.S. veterans with T2DM [98]. No significant association between these two diseases was observed in another study [99].

Pharyngeal Cancer

A significantly higher risk of oropharyngeal and nasopharyngeal cancers was reported in Taiwanese individuals with T2DM [3]. The risk of pharyngeal cancer is higher in those with long-lasting T2DM in comparison to those with a short history of T2DM [99].

Oral Cancer

The increased risk of oral cancer incidence in diabetics has also been described [3, 99].

Prostate Cancer: according to the current knowledge, prostate cancer (PC) is the only neoplasm that is inversely related to DM [100], and a number of research documented a significant protective influence of DM on PC incidence [100–102]. This association is presumably a result of hyperglycaemia-induced low concentrations of testosterone and hypoinsulinaemia in patients with T1DM or long-lasting T2DM. Physiologically, insulin inhibits the hepatic synthesis of IGF-1-binding protein leading to increased bioavailability of IGF-1, which subsequently may induce prostate cells' proliferation. Hypoinsulinaemia in T1DM or long-lasting T2D consequently results in low circulating IGF-1 and suppresses prostate cells' multiplication.

Opposite results implying that DM promotes the development of advanced PC were found in a Japanese population where it was shown that people with diabetes aged 40–64 years had a significantly increased relative risk of PC incidence [103]. Men older than 40–64 years had also elevated PC risk, but the risk was lower than in younger patients [104].

Anti-diabetic Medications and Their Influence on Neoplastic Transformation

It was widely discussed that via intervening in mechanisms of cell cycle and cellular survival, anti-diabetic medications have a potential impact on carcinogenesis [6]. Presumably, the main linking factor between oncogenesis and anti-diabetic medications is in their capacity to stimulate insulin secretion or from exogenous administration. T2DM can be controlled by either oral or injectable medications, whereas T1DM is based on

multiple insulin doses. A number of studies have examined the role of anti-diabetics to increase or decrease the risk of cancer development or mortality and the effects of cancer therapy on insulin resistance and hyperglycaemia [105].

- Anti-diabetic medications decreasing insulin levels include:
  - metformin
  - thiazolidinediones (TZD)
- Anti-diabetic medications increasing insulin levels:
  - sulfonylureas
  - exogenous insulin
- Anti-diabetic medications decreasing insulin resistance include:
  - metformin
  - TZD

Hyperglycaemia and hyperinsulinaemia are well-known carcinogenesis-promoting factors; normalizing serum glucose and insulin concentrations may presumably prevent neoplastic transformation. Conversely, other studies have shown that glucose-lowering therapies do not increase the risk of cancer in patients with T2DM [106, 107]. The majority of studies on the association between anti-diabetic medications and oncogenesis concern metformin; thus, this drug will be discussed in detail.

Metformin: Mechanism of Action and Its Influence on Carcinogenesis

Metformin is a member of the biguanide family with activity as insulin sensitizer. Current recommendations consider metformin as a first-line medication for T2DM therapy [26, 108–110]. It is established that metformin suppresses oncogenesis through systemic (indirect, interfering in serum levels of glucose and insulin) and cellular (direct, targeted at tumour cells) mechanisms [32, 36, 111–121]. By comparison to normal cells, cancer cells tend to synthesize more ATP through glycolysis than normal cells [114]. This metabolic shift is a hallmark of cancer and facilitates the uptake and incorporation of more nutrients into nucleotides, amino acids and lipids required for highly proliferating cells [114].

Indirect Impact of Metformin on Neoplastic Transformation [6, 105, 113–120]

- Reduction of the serum glucose concentration via:
  - inhibition of hepatic gluconeogenesis (in LKB1/AMPK-dependent and/or -independent way).
  - inhibition of hepatic glycogenolysis by promoting hepatic adenosine monophosphate kinase phosphorylation
  - prevention of glucagon-dependent release of glucose from liver cells by accumulating AMP
  - suppression of gastrointestinal absorption of glucose
- Reduction of the serum insulin concentration.
- Suppression of inflammatory response by inhibiting the activation of NF-κB (*Explanation*: NF-κB is a critical factor in inflammatory response. Chronic inflammation stimulates oncogenesis [122–124]).
- Inhibition of metastatic progression by interfering in cancer stem cells biology (*Explanation*: Cancer stem cells are capable of undergoing epithelial to mesenchymal transition (EMT), a crucial process in metastasis, and a marker of unfavourable prognosis and cancer aggressiveness. Metformin is able to inhibit metastasis by damaging cancer stem cells [125–127]).
- Stimulation of the immune system, leading to CD8 T-cells production, by modifying fatty acid metabolism [128].
- Suppression of UPR (unfolded protein response) leading to activation of apoptosis [36].
- High local concentration of metformin after oral intake reduces the risk of oncogenesis (observed for colon cancer) [129].

Direct Impact of metformin on Neoplastic Transformation

- Reduction of ATP synthesis leading to inhibition of the formation of factors crucial for cancer cell survival.
- (*Explanation:*
- *Metformin → modifications in respiratory complex I → energetic stress → reduced production of ATP → activation of AMPK → inhibition of mTOR pathway → antiproliferative and energy saving mechanisms, inhibition of growth factor formation (insulin, IGF-1, glucose, leptin), inhibition of proteins and fatty acids formation)*
- Inhibition of mTOR pathway in AMPK-independent manner by decreasing insulin and IGF-1 concentrations.
- Activation of LKB1-dependent signalling resulting in suppression of oncogenesis (LKB1, *liver kinase B1*, is a well-known neoplastic suppressor).
- Reduction of the reactive oxygen species (ROS) formation.
- Suppression of VEGF, a critical factor of tumour vascularity formation.

- Suppression of HIF-1, a critical factor of tumour cells perseverance in hypoxic milieu.
- Cell cycle arrest and apoptosis induction via activation of cell cycle inhibitory components (p53, p21, cyclin D1).
- Modification of multidrug resistance 1 gene (MDR1 gene) and microRNA encoding P-glycoprotein (*Explanation*: Tumour cells are characterized by high expression of P-lycoprotein. Because of the fact that P-glycoprotein has the ability to eliminate hydrophobic chemotherapeutics from cancer cell, high concentration of P-glycoprotein in tumour cells reduces the effectiveness of chemotherapy).

Effects of Metformin on Neoplasms of the Digestive System

1. *Pancreatic cancer:* it has been shown that patients taking metformin have significantly decreased risk of pancreatic cancer by comparison to non-users and in those on insulin administration [130, 131].
2. *Liver cancer:* the risk of liver cancer is also significantly reduced in diabetics on metformin therapy [132, 133].
3. *Colorectal cancer:* researches examining the effect of metformin on colorectal cancer presented conflicting results. Whereas some of them observed a protective activity of metformin on CRC, others reported opposite outcomes [133–135].

Effects of Metformin on Neoplasms of the Genitourinary System

1. *Prostate cancer:* It was established that anti-diabetic therapy based on metformin reduces the risk of prostate cancer (up to 44% reduction in Caucasians) [136]. Other studies consistently reported a decreased risk of prostate cancer in metformin users [137, 138]. Interestingly, metformin users had also significantly a lower risk of advanced prostate cancer. The anti-neoplastic effect of metformin increased with the duration on metformin therapy [139].
2. *Kidney cancer:* In vitro studies on human kidney cancer cell lines 786-O revealed that metformin-mediated increased expression of microRNA-26a, a regulatory RNA critical in cell diversification, led to suppression of 786-O cells proliferation and oncogenesis [140].
3. *Ovarian cancer:* Various authors described that metformin reduced the risk of ovarian cancer incidence in women with T2DM undergoing metformin therapy. Metformin also improved overall survival and extended disease-free period in females with ovarian cancer [141, 142]. An in vitro study conducted on epithelial ovarian cancer cell lines OVCAR-3 and OVCAR-4 documented metformin-mediated anti-oncogenic results. Moreover, chemotherapy for ovarian cancer revealed better anti-neoplastic effects of cisplatin when enriched with metformin usage [143].
4. *Breast cancer:* Besides being helpful in chemotherapy for ovarian cancer, metformin revealed its usefulness in chemotherapy for breast cancer. Metformin was able to damage BC stem cells refractory to chemotherapy based on doxorubicin. Such treatment schedule enabled destruction of BC stem cells (using metformin) and BC non-stem cells (using doxorubicin) [98]. Metformin also improved anti-neoplastic effects of chemotherapy for BC based on trastuzumab and on taxane [144, 145].

Effects of Metformin on Lung Cancer

It has been shown that the use of metformin may lead up to a 45% decrease in the incidence of lung cancer [146]. Metformin enhanced the effectiveness and final outcomes of chemotherapy for advanced non-small cell lung cancer (NSCLC) in individuals with T2DM [147].

Effects of Metformin on Head and Neck Cancers

According to sparse studies on the association between metformin and HNSCC in individuals with T2DM, metformin may presumably reduce the risk of HNSCC incidence. A statistically significant decrease was observed for nasopharyngeal and oropharyngeal cancers [148]. This anti-diabetic drug was also able to suppress the proliferation of HNSCC cells, and to decrease the probability of HNSCC recurrence and metastasis [149, 150]. It led to better overall condition in diabetics with HNSCC, especially in those with laryngeal cancer [151]. On the other hand, there is also a report of no substantial interference of metformin on the HNSCC risk in diabetics [95].

Sulfonylureas: Mechanism of Action and Influence on Carcinogenesis

The most important sulfonylureas used as anti-diabetic medications are Glyburide, Glimepiride and Glipizide. Their main mechanism of action is regulation of insulin secretion by closing the potassium channel located in pancreatic β

cells. Sulfonylureas-induced potassium channels closure results in elevated insulin efflux and increased postprandial and fasting insulin levels. Whereas potassium channels closure presumably induce anti-tumourigenic mechanisms, sulfonylureas-stimulated hyperinsulinaemia promotes tumourigenesis [152]. Nevertheless, the exact effect of sulfonylureas on oncogenesis and cancer biology has not been fully elucidated [153]. The results of various studies on this issue remain conflicting. In addition, particular sulfonylureas presumably have different influence on carcinogenesis. Significantly elevated risk of cancer incidence in individuals with T2DM undergoing sulfonylureas therapy was reported by a variety of authors [135, 154, 155]. Diabetics on sulfonylureas had an increased risk of liver and colon cancer and decreased risk of prostate cancer [155, 156]. According to clinical reports, gliclazide was able to reduce the risk of neoplasm development in diabetics, whereas glyburide reduced the risk in some studies, and increased in others [157–159]. Until today, the relationship between glimepiride, glipizide and oncogenesis has not been established [158].

Exogenous Insulin: Influence on Carcinogenesis

The group of exogenous insulins comprise human insulin and insulin analogues. The vast majority of studies investigating the association between exogenous insulin and oncogenesis imply tumour-promoting effects of exogenous insulin [154, 160]. Patients on long-acting insulin analogues (glargine and detemir) are more prone to undergo carcinogenesis in comparison to non-insulin users [113, 161]. Nevertheless, the risk is lesser than observed in human insulin users [162]. Diabetics on insulin revealed increased risk of liver, pancreatic, renal, stomach, liver and respiratory tumours, and reduced risk of prostate cancer [156, 163]. Studies focusing on glargine effect on cancer biology present conflicting results. Diabetics on glargine had increased risk of breast, prostate and pancreatic cancers incidence and reduced risk of colon and colorectal cancers [164–166]. Glargine investigations in vitro have shown suppressed apoptosis and tumour-promoting activity in human endometrioid endometrial carcinoma, breast adenocarcinoma and CRC cells [167–169]. No significant correlation between glargine and oncogenesis was observed in another study [170].

Thiazolidinediones: Mechanism of Action and Influence on Carcinogenesis

Thiazolidinediones are a group of PPARγ agonists currently used in T2DM treatment. The main components of this group are Pioglitazone, Rosiglitazone, Troglitazone, Netoglitazone, Ciglitazone and Efatutazone. TZD-induced stimulation of PPARγ sensitizes insulin-dependent tissues to insulin that leads to better glycaemic regulation. The speculation that TZD may presumably have an impact on cancer biology was made after finding that a variety of neoplasms are characterized by elevated expression of PPARγ. Nevertheless, the possible influence of TZDs on oncogenesis may be induced in PPARγ-dependent and PPARγ-independent manner. TZD-mediated activation of PPARγ in cancer cells interfered with cell cycle and led to cell cycle arrest and apoptosis [171].

PPARγ-independent anti-neoplastic activity of TZD [171, 172]:

- Suppression of antiapoptotic Bcl-2 (B-cell leukaemia/lymphoma)/Bcl-xL function resulting in apoptosis of cancer cells
- Inhibition of androgen activation by interfering in gene encoding androgen receptor
- Degradation of specificity protein 1 (Sp1) resulting in reduction of survivin (an apoptosis inhibitor), EGFR (epidermal growth factor), and intercellular and vascular cell adhesion molecules ICAM-1 and VCAM-1
- *(Explanation*: Specificity protein 1 is a critical protein in cell cycle. This protein is able to modify genes encoding cell cycle and vascular endothelial growth factor. Such ability enables Sp1 to interfere with development, metabolism and metastasis of cancer cells.)
- Down-regulation of various well-established cancer-promoting molecules including β-catenin, cyclin D1 and FLIP (FLICE-like inhibitory protein)

The majority of studies suggested that TZDs have anti-neoplastic activity and reduces the risk of various cancers incidence [155, 173, 174]. On the other hand, there are reports indicating that these drugs may also reveal tumour-promoting features. It was observed that TZDs as a group decreased the risk of breast, lung and colorectal cancers [175]. Pioglitazone and rosiglitazone were able to reduce the risk of liver cancer, pioglitazone but not rosiglitazone reduced the risk of breast cancer and rosiglitazone reduced the risk of colorectal cancer [174, 176]. Netoglitazone revealed anti-neoplastic activity against human pancreatic cancer cells, colorectal cancer cells, multiple myeloma and prostate cancer cells (mainly androgen-irrespective prostate cancer cells) [177–179]. Efatutazone suppressed colon cancer development in mice and suppressed in vitro anaplastic thyroid carcinoma cell lines [180]. Suppressed proliferation of ovarian, prostate and lung cancer cells was observed after Troglitazone administration [180]. Possibly, TZDs may also improve the efficacy of chemotherapy. Chemotherapy for breast and pancreatic cancer cells was improved after rosiglitazone administration. Rosiglitazone presumably reduced chemoresistance in neoplastic cells [181]. Additionally, TZDs enhanced the effectiveness of anti-neoplastic therapy for soft tissue sarcoma and thyroid cancer [182].

On the other hand, there are also studies implying that TZDs as a group may induce pro-neoplastic effects. Such significant correlation was found in diabetic women undergoing rosiglitazone treatment [183]. Several studies suggested that diabetics on Pioglitazone therapy had increased risk of bladder cancer, NHL and melanoma [22, 184–187].

Incretin-Based Medications: Mechanisms of Action and Influence on Carcinogenesis

Dipeptidyl peptidase-4 inhibitors (DDP-4-i) and Glucagon-like peptide 1 agonists (GLP-1 agonists) are anti-diabetic medications used in T2DM that interact with the incretin system.

Dipeptidyl Peptidase-4 Inhibitors (DDP-4-i) include Sitagliptin, Saxagliptin, Vildagliptin, Alogliptin and Linagliptin. Dipeptidyl peptidase-4 inhibitors' main function is based on inhibiting the enzyme Dipeptidyl peptidase-4 (DDP-4) that is critical in destruction of Glucagon-like peptide-1 (GLP-1). Consequently, suppression of DDP-4 leads to increased serum concentration of GLP-1. Unlike GLP-1 agonists, DDP-4-i do not delay the gastric emptying rate and do not promote the sensation of satiety. A variety of studies found that DDP-4-i users were at higher risk to suffer from pancreatic cancer. However, the risk was significantly lesser than observed in diabetics on sulfonylureas and comparable in individuals on TZDs [188–191]. No pro-neoplastic activity of DDP-4-i was found in mice and in human individuals with T2DM [106, 192]. On the other hand, laboratory studies on rats revealed diminished colon tumourigenesis and reduced reactive oxygen species in long-term administration of Sitagliptin [193]. In addition, sitagliptin enhanced engraftment of Umbilical Cord Blood transplantation in adults with haematological neoplasms [194].

Glucagon-like Peptide 1 Agonists (GLP-1 agonists) include Liraglutide, Exenatide and Semaglutide. GLP-1 agonists elevate glucose-mediated insulin synthesis and its efflux in pancreatic β *cells in a precise and controlled way. They reduce glycogenolysis and glucagon secretion. GLP-1 agonists slow down the* gastrointestinal motility leading to delayed absorption of carbohydrates and lesser increase in serum glucose level [27]. Additionally, they promote satiety via interfering in the central nervous system. Whereas several studies found decreased risk of oncogenesis in GLP-1 agonist users, other research reported opposite results. Exenatide was able to suppress the development of human prostate cancer cells and murine CT26 colon cancer cells [195–196]. Moreover, it presented anti-neoplastic activity against breast cancer cells [197]. Liraglutide-induced stimulation of GLP-1R (GLP-1 receptors) suppressed neoplastic transformation and metastasis in human pancreatic cancer cells in in vitro and in vivo investigation. The anti-neoplastic activity was a result of suppression of PI3K/Akt pathway [198]. On the other hand, GLP-1 agonists elicited tumourigenesis in rodent thyroid C-cells, but not in human thyroid C-cells nor in thyroid gland in diabetics [199–200]. The proliferation observed in rodent C-cells might be caused by GLP-1-receptors–mediated excretion of calcitonin [201]. Presumably, mainly various levels of GLP-1 receptors in humans and in rodents caused this difference. There are also reports implying elevated risk of pancreatic cancer incidence in GLP-1 agonist users [189, 191].

Alpha-Glucosidase Inhibitors (AGIs)

Mechanisms of Action and Influence on Carcinogenesis: the main components of this group are Acarbose, Voglibose and Miglitol. AGIs slow down digestion and absorption of polysaccharides in the gastrointestinal tract by inhibiting enzymes sucrose (invertase) and maltase in the proximal small intestine, leading to delayed increase in postprandial serum glucose level and better glycaemic control. AGIs elevated intestinal hormones activity and enhanced intestinal microbiota [202]. Reports of the influence of AGIs on oncogenesis are scarce. According to current knowledge AGIs may reduce the risk of colorectal, lung and gastric cancers [203, 204]. The risk of kidney cancer is presumably elevated in diabetics undergoing AGIs therapy [205]. Conversely, no significant influence of AGIs on both carcinogenesis and cancer-related mortality was revealed in another study [206].

Sodium-Glucose Co-transporter 2 Inhibitors (SGLT2 Inhibitors)

Mechanism of Action and Influence on Carcinogenesis: SGLT2 inhibitors are a new class of anti-diabetic medications used in T2DM treatment. The main components of this group are Empagliflozin, Canagliflozin, Dapagliflozin and Ertugliflozin. SGLT2 is a glucose transporter located in the proximal renal tubules; their main role is glucose reabsorption of approximately 90% of the renal glucose filtrate. Consequently, SGLT2 inhibitors are able to significantly lower serum glucose levels via enhancing glucose excretion by the kidneys. Additionally, SGLT2 inhibitors elevate insulin sensitivity, improve insulin secretion from pancreatic beta cells and decrease gluconeogenesis [207]. As SGLT2 inhibitors are quite novel drugs the precise association between them and oncogenesis has not been completely established. Correlation between these two entities has already been observed, but it is still based on sparse research. Studies assessing the correlation between Dapagliflozin and bladder cancer have shown that Dapagliflozin might elevate the risk of oncogenesis in bladder cells, albeit without statis-

tical significance. No increase in neoplastic transformation in bladder tissue was found in mice and rats receiving Dapagliflozin, and for in vitro human bladder transitional cell carcinoma (TCC) cell lines [208]. Moreover, Dapagliflozin presumably did not increased the risk of breast cancer [208]. Studies about Canagliflozin have not documented an increased risk of neoplastic transformation in bladder, breast and kidneys [208]. Another study on SGLT2-expressing neoplasms (pancreatic and prostate cancers) found that Dapagliflozin and Canagliflozin significantly reduced tumour growth and enhanced death of tumour cells [209]. This finding should draw attention to the potential anti-neoplastic role of SGLT2 inhibitors in SGLT2-expressing tumours. Tumour-suppressing activity of Canagliflozin was also observed for prostate and lung cancer cells. The anti-neoplastic role in this study was presumably induced by inhibiting mitochondrial complex-I supported respiration that resulted in limitation of cellular proliferation [210]. Nevertheless, observations about the potential anti-neoplastic activities of SGLT2 inhibitors require further investigation.

Summary

The prevalence of diabetes mellitus type 2 and cancers of various sites is dramatically increasing nowadays. Both entities are important causes of death all over the world. A number of studies proved that DM increases the risk of oncogenesis in various organs. The association was predominantly observed in T2DM possibly because of potential T2DM-induced tumour-promoting factors. The mechanisms linking DM and neoplastic transformation in various types of organs are probably different and have not been clearly explained yet. The vast majority of attention is put on three groups of linking factors, including modifiable, non-modifiable and biological**.** Modifiable risk factors include overweight and obesity, physical inactivity, smoking and alcohol abuse. Non-modifiable risk factors comprise age between 55 and 60 years or more, male gender and African American race. Biological risk factors include hyperinsulinaemia, insulin resistance, hyperglycaemia and chronic inflammation induced by excessive adipose tissue. According to current knowledge the most significant factor linking T2DM and oncogenesis is obesity. Moreover, several studies suggest that there is also correlation between DM duration and the risk of carcinogenesis albeit the results of these investigations are inconsistent. It was established that many tumours overexpress receptors for insulin leading to higher susceptibility to both metabolic and mitogenic activity of insulin in tumour cells. Furthermore, diabetics with T2DM and coexisting neoplasm have worse disease-free and overall survival than patients with neoplasm but without T2DM. In accordance with collected data, individuals with DM are more prone to suffer from cancers of digestive tract system (liver, pancreatic, colon/colorectal cancers) and genitourinary system (bladder and endometrial cancers). Breast cancer is also more commonly observed in diabetic women than in non-diabetic ones. Correlation between DM and renal cancer and HNC is not clear. Data investigating the association between DM and HNC are lacking. Current knowledge implies that DM increases the risk of both oral cavity and pharyngeal neoplasms. It was also established that DM predisposes to perineural invasion in patients with oral squamous cell cancer. In addition, the prognosis in patients with oral cavity cancer and DM is worse than in those without DM. The relationship between DM and laryngeal cancer is inconsistent; some authors suggest an increased risk, some authors report a lower risk and some have not found a relationship between these diseases. Conversely, several studies have reported a protective, anti-neoplastic effect of DM on the risk of prostate cancer, with a significantly inverse association between PC and DM. This protective association is presumably a result of hyperglycaemia-induced low concentration of testosterone and hypoinsulinaemia in patients with T1DM or long-lasting T2DM. Nevertheless, other reports indicate an increased risk of prostate carcinogenesis. The potentially protective effect of DM on prostate cancer requires further investigation.

Recent analyses have shown that anti-diabetic drugs may modify the risk of oncogenesis in persons with diabetes, albeit with inconsistent results. Some drugs presumably increase the risk, whereas others reduce the risk of tumourigenesis. The majority of studies on this matter concern metformin, a drug of first choice in T2DM. It was been shown that metformin reduces the risk of cancer and improves the overall survival in diabetics. Favourable outcomes with the use of metformin have been observed in a wide variety of cancers including breast, pancreas, liver, colon, prostate, lungs and ovaries. Several authors have also revealed an inhibitory effect of metformin on human renal cancer cell lines 786-O. According to studies examining the influence of metformin on HNC, metformin decreased the risk of HNC (the most significant reduction was found for oro- and nasopharyngeal cancers) and improved overall survival in patients with laryngeal squamous cell carcinoma. It has also been suggested that SGLT2 inhibitors express potential anti-neoplastic activity, albeit the evidence is still sparse. The influence of other anti-diabetic medications including sulfonylureas, exogenous insulin, TZDs, alpha-glucosidase inhibitors, incretin-based drugs (GLP-1 agonists and DDP-4-i) on cancer incidence and prognosis remains inconsistent.

Based on the above information, it can be assumed that diabetes mellitus and oncogenesis are presumably combined entities. It is increasingly recognized that diabetes increases the risk of developing cancer [211]. Diabetes and cancer

commonly coexist and outcomes in people with both conditions are poorer than in those who have cancer but no diabetes [211]. Greater attention should be devoted to screen patients with diabetes mellitus for the main causes of cancer, especially those with T2DM. These patients require precise, regular follow-up in order not to omit any neoplastic transformation [211]. Careful screening should also be performed in individuals on anti-diabetic drugs [212].

The correlation between DM/anti-diabetic medications and carcinogenesis requires further investigation to establish exact, general and cell-intrinsic mechanisms linking these entities. Attention should also be drawn to potential anti-neoplastic activities of particular anti-diabetic drugs. Therapeutic nihilism should be avoided and a personalized approach to managing hyperglycaemia in people with cancer is required [211].

Concluding Remarks

- Diabetics (mainly with T2DM) are more prone to suffer from cancers of digestive tract system (liver, pancreatic, colon/colorectal cancers) and genitourinary system (bladder and endometrial cancers). Breast cancer is also more commonly observed in diabetic women than in non-diabetic ones.
- Prostate cancer risk is presumably inversely associated with diabetes mellitus.
- Metformin may reduce the risk of cancer incidence and improve overall survival in diabetics. Favourable effect of metformin was observed in a wide variety of cancers including breast, pancreatic, liver, colon, prostate, lungs and ovaries. Its potential usefulness in chemotherapy is promising and still studied.
- SGLT2 inhibitors express potential anti-neoplastic activity. The influence of sulfonylureas, exogenous insulin, TZDs, alpha-glucosidase inhibitors, incretin-based drugs (GLP-1 agonists and DDP-4-i) on cancer incidence and prognosis remains inconsistent.

Multiple-Choice Questions

1. The linking factors between diabetes mellitus and oncogenesis are:
   (a) Hyperglycaemia
   (b) Hypoinsulinaemia
   (c) Hyperinsulinaemia
   (d) **a, c**. (The biological factors linking DM and oncogenesis include hyperinsulinaemia, insulin resistance, hyperglycaemia and chronic inflammation induced by excessive adipose tissue. According to current knowledge the most significant factor linking T2DM and oncogenesis is obesity.)
   (e) a, b, c
2. Fat-induced chronic inflammation leading to oncogenesis is characterized by:
   (a) Increased level of adiponectin and decreased level of leptin
   (b) Increased level of leptin and decreased level of adiponectin
   (c) Increased production of proinflammatory cytokines including IL-6, resistin and TNF-alpha
   (d) **b, c. (**Excessive adipose tissue interferes with sex hormones physiology (high amounts of aromatase converting oestrogens to androgens), induces chronic inflammation and changes profile of adipose tissue polypeptide hormones (adipokines). Obesity-induced chronic inflammation is characterized by increased production of proinflammatory cytokines including interleukin-6, resistin and TNF-alpha (Tumour Necrosis Factor-alpha). The level of adiponectin is reduced and the level of leptin is increased in patients with excessive adipose tissue. Adiponectin sensitizes cells to insulin, suppresses cells growth and metabolism, and exerts pro-apoptotic mechanisms, whereas leptin stimulates proliferation of cancer cells.**)**
   (e) All answers are false
3. Pro-neoplastic features of insulin are induced by activation of:
   (a) Insulin Receptor
   (b) Insulin-like Growth Factor Receptor
   (c) Growth Hormone Receptor
   (d) a, b, c
   (e) **a, b. (**The pro-neoplastic features of insulin are induced by activation of its receptors (Insulin Receptor and Insulin-like Growth Factor Receptor), as well as via Insulin-like Growth Factor. Ligand-induced IR autophosphorylation triggers intracellular mechanisms. The most important one is activation of PI3K/Akt/mTOR (phosphoinositide 3-kinase/protein kinase B/mammalian target of rapamycin) signalling pathway. Stimulation of PI3K/Akt/mTOR signalling pathway plays a critical role in oncogenesis. Activation of IGF-R results in more significant pro-neoplastic effects than activation of IR.)
4. Indirect effects of hyperinsulinaemia on cancer biology:
   (a) **Increased level of Growth Hormone (GH) leading to elevated concentration of Insulin Like Growth Factor-1 (IGF-1). (**Insulin stimulates growth hormone receptors (GHR) located in the liver leading to elevated release of GH. Subsequently,

GH promotes IGF-1 synthesis. IGF-1 is a mitogenic factor.)

(b) Increased concentration of pro-neoplastic adipose tissue hormone—adiponectin
(c) Increased concentration of anti-neoplastic adipose tissue hormone—leptin
(d) a, b, c
(e) All answers are false

5. Tumour-promoting mechanism of hyperglycaemia:
   (a) Reduced expression of glucose transporters (GLUT-1 and GLUT-3)
   (b) Reduced level of hypoxia-inducible factor α (HIF-α), a critical anti-neoplastic factor
   (c) **Increased expression of PPAR α and γ (peroxisome proliferator-activated receptor)** (PPAR α and γ interfere with lipid metabolic pathways and speed up neoplastic cells development)
   (d) a, b, c
   (e) b, c
6. Which statements are correct:
   (a) Diabetes mellitus type 2 elevates the risk of endometrial cancer
   (b) Diabetes mellitus type 2 elevates the risk of prostate cancer via reducing testosterone levels
   (c) The risk of hepatocellular carcinoma is increased in patients with type 2 diabetes mellitus
   (d) a, b, c
   (e) **a, c.** (It is suggested that DM might predispose to EC via hyperinsulinaemia-dependent reduced level of adiponectin and via obesity-related decreased concentration of SHBG. Reduced level of SHBG leads to elevated bioavailable oestrogen and testosterone amounts and eventually stimulates endometrial oncogenesis

      Liver is exposed to circulation of high amounts of insulin because of its portal vessels. Constantly high insulin levels, via elevated production of IGF-1, lead to multiplication and apoptosis suppression in hepatic cells.

      According to current knowledge prostate cancer (PC) is the only neoplasm that is conversely related to DM. This association is presumably a result of hyperglycaemia-induced low concentration of testosterone and hypoinsulinaemia detected in T1DM or long-lasting T2DM.)
7. Anti-neoplastic features of metformin comprise:
   (a) Reduction of the serum insulin concentration
   (b) Reduction of the serum glucose concentration via inhibition of gluconeogenesis and glycogenolysis in the liver
   (c) Stimulation of mTOR pathway, a critical anti-neoplastic pathway
   (d) a, b, c
   (e) **a, b (answer c is false because metformin** inhibits mTOR pathway in AMPK-independent manner by decreasing insulin and IGF-1 concentrations. mTOR pathway plays a critical role in oncogenesis).
8. Choose the correct statement:
   (a) Metformin reduces the risk of liver cancer
   (b) Metformin reduces the risk of pancreatic cancer
   (c) Metformin reduces the risk of ovarian cancer
   (d) **All answers are correct**
   (e) All answers are false
9. Anti-diabetic medications that influence the risk of neoplastic transformation are:
   (a) Metformin
   (b) Thiazolidinediones
   (c) Sulfonylureas
   (d) Dipeptidyl peptidase-4 inhibitors
   (e) **a, b, c, d.** (A majority of studies present that metformin reduces the risk of neoplastic transformation. The influence of sulfonylureas, thiazolidinediones and dipeptidyl peptidase-4 inhibitors on cancer incidence and prognosis remains inconsistent.)
10. Diabetes mellitus type 2 promotes oncogenesis via:
    (a) Activation of insulin-dependent IP3-K/AKT/mTOR pathway
    (b) Insulin-induced increased level of bioavailable IGF-1
    (c) Insulin-induced increased concentration of leptin
    (d) Insulin-induced reduced level of SHBG resulting in increased amount of bioavailable oestradiol
    (e) **a, b, c, d**

Glossary

Hyperinsulinaemia Increased serum insulin level.
Hyperglycaemia Increased serum glucose level.
Pro-neoplastic Promoting neoplastic transformation.
PI3K/Akt/mTOR signalling pathway (phosphoinositide 3-kinase/protein kinase B/mammalian target of rapamycin signalling pathway)— Critical pathway in oncogenesis.
IGF-binding proteins Proteins crucial in IGF serum transfer and bioavailability.
Urokinase plasminogen activator (uPA) A critical mediator in cancer cell displacement.
ETM (Epithelial to Mesenchymal Transition process) A mechanism that enables cancer cells to metastasise.
Adipokines Adipose tissue polypeptide hormones, e.g. leptin, adiponectin.
SNPs (Single Nucleotide Polymorphisms) A sequence in a single nucleotide that is observed at a specific position in the genome.

NAFLD (non-alcoholic fatty liver disease) A condition of fat deposits accumulation not induced by alcohol abuse. NAFLD is associated with metabolic syndrome and insulin resistance.

Lipotoxicity Malfunction or death of non-adipose tissue cells caused by accumulation of excessive lipids.

Oxidative stress Imbalance between antioxidant and pro-oxidant factors.

Oncogenesis, tumourigenesis, carcinogenesis A group of mechanisms leading to transformation of normal cells to cancer cells.

Milieu A setting in which something happens (environment, surrounding).

Gluconeogenesis A process of glucose biosynthesis.

Glycogenolysis A process of biochemical degradation of glycogen to glucose.

NF-κB A factor controlling transcription of DNA and cells survival.

OVCAR Epithelial ovarian cancer cell lines.

Stem cell Undifferentiated cells which have the ability to differentiate into specialized cells, and to divide to synthesize more stem cells.

Part X

Diabetes in Special Populations

Diabetes in Children and Adolescents

64

América Liliana Miranda Lora,
Montserrat Espinosa Espíndola, Martha Beauregard Paz,
Jorge Mario Molina Díaz, and Miguel Klünder Klünder

Objectives

- To identify the types of diabetes mellitus that can affect children and adolescents.
- To provide information about diagnostic tests for identifying the etiology of diabetes mellitus in children and adolescents.
- To describe the epidemiology, risk factors, clinical presentation, treatment, and follow-up for comorbidities in pediatric patients with type 1 and 2 diabetes.

Introduction

Diabetes mellitus is one of the most common chronic diseases in pediatric patients. The prevalence of diabetes in adolescents from 12 to 19 years of age in the United States during 2005–2014 was 0.8%, of which 28.5% was undiagnosed, and the prevalence of prediabetes was 17.7% [1].

Several decades ago, type 1 diabetes was considered to occur only in children; and T2D, only in adults. However, the proportion of adult patients with type 1 diabetes and the incidence of T2D in children and young adults have been increasing. Given the current obesity epidemic, distinguishing between type 1 and 2 diabetes in children can be difficult. Currently, excessive weight is common in children with type 1 diabetes, whereas autoantibodies and ketosis may be present in patients with T2D. However, the identification of the type of diabetes is important for the choice of treatment, educational approach, nutritional program, and prevention of complications.

The care and management of children and adolescents with diabetes have unique aspects such as the following: (1) changes in insulin sensitivity related to growth and sexual development; (2) dependency care; and (3) neurological susceptibility to changes in glucose levels. A multidisciplinary team of specialists in pediatric diabetes should provide care to these patients. Family and individual management education are important for achieving a balance between adult supervision and independent self-care [2].

Definition and Diagnostic Tests for Diabetes in Children

The term *diabetes mellitus in children* describes a group of disorders of abnormal carbohydrate metabolism that result in hyperglycemia in patients ≥10 and <18 years of age [3]. The diagnostic criteria for diabetes mellitus and increased risk of diabetes (prediabetes) of the Expert Committee of the American Diabetes Association are essentially the same in children and adults [4].

Diagnostic Tests for Diabetes

- Measurement of fasting plasma glucose levels ≥126 mg/dL with no caloric intake for at least 8 h.[1]
- Measurement of 2-h plasma glucose levels ≥200 mg/dL during an oral glucose tolerance test using a glucose load containing 1.75 g of anhydrous glucose per kilogram of body weight dissolved in water, with a maximum of 75 g of anhydrous glucose (footnote 1).

[1]In the absence of unequivocal hyperglycemia, results should be confirmed by repeat testing.

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_64

- Measurement of HbA1c levels ≥6.5% using a method certified and standardized to the Diabetes Control and Complications Trial assay.* Marked discordance between the measured HbA1c and plasma glucose levels should raise the possibility of assay interference. In conditions such as hemoglobinopathies, pregnancy, glucose-6-phosphate dehydrogenase deficiency, HIV, hemodialysis, recent blood loss, or transfusion or erythropoietin therapy, HbA1c should not be used to diagnose diabetes. However, the studies that formed the basis for this recommendation included only adults, and whether the same HbA1c cutoff point should be used to diagnose diabetes in children and adolescents remains unclear. The American Diabetes Association has suggested that this criterion underestimates the prevalence of prediabetes and diabetes in obese children and adolescents [4–6].
- Measurement of random plasma glucose levels ≥200 mg/dL in a patient with classic symptoms of hyperglycemia or hyperglycemia crisis.

Diagnostic Tests for Increased Risk of Diabetes (Prediabetes)

- Impaired fasting glucose test: fasting plasma glucose levels of 100–125 mg/dL
- Impaired glucose tolerance test: 2-h plasma glucose levels of 140–199 mg/dL during an oral glucose tolerance test
- HbA1c analysis: 5.7–6.4% [4]

Etiological Classification

Distinguishing among the types of diabetes in all groups at onset has difficulties, and the true diagnosis becomes more obvious over time. The diabetes mellitus classification of the American Diabetes Association, which depends on causation, distinguishes the following types [4]:

- **Type 1 diabetes mellitus.** This is characterized by an absolute insulin deficiency, usually as a result of the autoimmune destruction of pancreatic beta cells (type 1A) or secondary to defects in insulin secretion from inherited defects in pancreatic beta cell glucose sensing (type 1B).
- **T2D mellitus.** This is characterized by insulin resistance resulting from defects in the action of insulin on its target tissues and is associated with varying and usually progressive failure of beta cell secretion.
- **Genetic defects of beta cell function (monogenic diabetes).** This type of diabetes is characterized by impaired insulin secretion by pancreatic beta cells caused by a single gene mutation. This genetically heterogeneous group includes the following: neonatal diabetes, mitochondrial diabetes, and maturity-onset diabetes of the young (MODY). These forms of diabetes represent <5% of patients with diabetes and are generally characterized by onset before the age of 25 years. The diagnosis of monogenic diabetes should be considered in children with the following conditions [7–10]:
  - Diabetes in the first 6 months of life
  - A family history of diabetes in first-degree relatives who lack the characteristics of type 1 diabetes (no islet autoantibodies, low or no insulin requirements >5 years after diagnosis [stimulated C-peptide level >200 pmol/L]) [9]
  - Strong family history of diabetes but without typical features of T2D (nonobese and low-risk ethnic group)
  - Mild fasting hyperglycemia (100–150 mg/dL), especially if young and nonobese
  - Children with diabetes not characteristic of type 1 or 2 diabetes that occurs in successive generations (suggestive of an autosomal dominant pattern of inheritance)
  - A prolonged honeymoon period of >1 year or an unusually low requirement of insulin (<0.5 U/kg/day) after 1 year of diabetes

    Neonatal diabetes. This rare disorder has an incidence of 1:300,000–1:400,000 live births [11]. It presents in the first 6 months of life and can be either transient or permanent. All children diagnosed with diabetes in the first 6 months of life should undergo immediate genetic testing for neonatal diabetes [4]. In patients diagnosed between 6 and 12 months of age, testing for neonatal diabetes mellitus should be limited to those without islet antibodies, as most patients in this age group have type 1 diabetes [9]. Almost 50% of cases are permanent, and the most common cause is an autosomal dominant defect in *KNJ11* or *ABCC8*, which encode the Kir6.2 and SUR1 subunits of the ATP-sensitive potassium channel, respectively. However, other genetic defects include the following [4, 12]:

    KCNJ11. Autosomal dominant inheritance. It causes a permanent or transient form. Clinical features include intrauterine growth restriction, possible developmental delay, and seizures and response to sulfonylureas.

    INS. Autosomal dominant inheritance. This is a permanent form of neonatal diabetes associated with intrauterine growth restriction and controlled with insulin.

ABCC8. Autosomal dominant inheritance. It causes a permanent or transient form. Patients usually have intrauterine growth restriction, rare developmental delay, and response to sulfonylureas.

6q24 (*PLAG1, HYMA1*). The inheritance is autosomal dominant. Mechanisms include uniparental disomy of chromosome 6, paternal duplication, or maternal methylation defect. It is a transient form. The clinical features are intrauterine growth restriction, macroglossia, and umbilical hernia. It may be treatable with medications other than insulin therapy.

GATA6. Autosomal dominant inheritance. It is a permanent form with pancreatic hypoplasia, cardiac malformations, pancreatic exocrine insufficiency, and insulin requirement.

EIF2AK3. Autosomal recessive inheritance. It is a permanent form of neonatal diabetes. It is known as Wolcott-Rallison syndrome, which includes epiphyseal dysplasia, pancreatic exocrine insufficiency, and insulin requirement.

EIF2B1. Autosomal recessive inheritance. It causes a permanent form and can be associated with fluctuating liver function.

FOXP3. X-linked inheritance. It is a permanent form. The clinical features include immunodysregulation, polyendocrinopathy, enteropathy X-linked syndrome (autoimmune diabetes, autoimmune thyroid disease, and exfoliative dermatitis), and requires insulin for treatment.

Patients with the permanent forms could be treated with sulfonylureas rather than insulin. Sulfonylureas trigger beta cell membrane depolarization, electrical activity, calcium influx, and insulin release. Patients with neonatal diabetes require 0.5 mg/kg/day on average, although some patients may need higher doses of up to 2.3 mg/kg/day [4, 13].

Mitochondrial diabetes. Some mitochondrial DNA mutations are strongly associated with diabetes, with the most common mutation being the A3243G mutation in the mitochondrial DNA-encoded tRNA gene. A gradual development of pancreatic beta cell dysfunction upon aging, rather than insulin resistance, is the main mechanism of glucose intolerance development. This mutation affects insulin secretion and may involve an attenuation of cytosolic ADP/ATP levels, which leads to a resetting of the glucose sensor in the pancreatic beta cells. Unlike MODY-2, mitochondrial diabetes shows a pronounced age-dependent deterioration of pancreatic function. In clinical practice, mitochondrial diabetes is suspected when a strong familial clustering of diabetes is present. Mitochondrial diabetes can be discriminated from MODY based on the presence of maternal transmission in conjunction with a bilateral hearing impairment in most carriers, although the final proof is provided by genetic analysis [14].

MODY. This is the most common form of monogenic diabetes and is caused by the autosomal dominant transmission of a genetic defect in insulin secretion. It is characterized by impaired insulin secretion with minimal or no defects in insulin action. The clinical characteristics of patients are heterogeneous, and MODY is often misdiagnosed as type 1 or 2 diabetes mellitus. MODY has many subtypes (Table 64.1). MODY-2 is the most common type occurring during childhood, and MODY-3 is the most common type after puberty [15, 16].

MODY should be considered in the following situations [7, 8]:

- Individuals with mild stable fasting hyperglycemia.
- Multiple family members with diabetes without type 1 characteristics (no islet autoantibodies and low or no insulin requirements 5 years after diagnosis) or T2D (marked obesity and acanthosis nigricans).

In the above-mentioned situations, children and those diagnosed in early adulthood with diabetes not characteristic of type 1 or 2 that occurs in successive generations should have genetic testing for MODY [4]. These individuals should be referred for further evaluation and genetic testing confirmation. Some forms of MODY, such as *HNF1A* and *HNF4A*, are sensitive to sulfonylureas. Mild fasting hyperglycemia due to CGK is not progressive during childhood, does not develop complications, and does not respond to low-dose insulin or oral agents, so these patients should not receive treatment [4, 7].

Genetic defects in insulin action. There are rare genetic abnormalities in the insulin receptor or signal transduction. One of them is Donohue syndrome (leprechaunism), a genetic autosomal recessive disorder that results from the presence of homozygous or compound heterozygous mutations in the insulin receptor gene (*INSR*; 19p13.3-p13.2). The incidence of this pathology is 1 in 1,000,000 births. The characteristics of this syndrome include severe intrauterine and postnatal growth retardation, multiple endocrine dysfunction, hypertrichosis, virilization, emaciation, acanthosis nigricans, lipoatrophy, genitomegaly, postprandial hyperglycemia, fasting hypoglycemia, insulin resistance, hyperinsulinemia, and eventual ketoacidosis. Infants with Donohue syndrome also have distinc-

Table 64.1 Classification of MODY (adapted from references [4, 7, 15])

MODY type	Gene and locus	Age at diagnosis	Primary defect	Associated features	Severity of diabetes
1	*HNF-4a* 20q	Post-puberty	Gene transcription defects in beta cells	Macrosomia and/or neonatal hypoglycemia. It is characterized by a progressive insulin secretory defect with presentation in adolescence or early adulthood. It is sensitive to sulfonylureas	Severe
2	*GCK* 7p	Childhood	Impairment of beta cell sensitivity to glucose and defect in hepatic glycogenesis	Reduced birth weight. This is the most common cause in the absence of symptoms or marked hyperglycemia. This is a stable form with nonprogressive elevated fasting blood glucose levels. Typically, it does not require treatment; microvascular complications are rare	Mild
3	*HNF-1a* 12q	Post-puberty	Similar to MODY-1	Renal glycosuria. This form occurs with a progressive insulin secretory defect with presentation in adolescence or early adulthood; decreased renal threshold for glucosuria; and marked increase in postprandial glucose levels. It is sensitive to sulfonylureas	Severe
4	*PDF1 (IPF-1)* 13q	Early adulthood	Defects in transcription factors during embryogenesis lead to abnormal beta cell development and function	–	Mild
5	*HNF-1b* 17cen-q21.3	Post-puberty	Similar to MODY-1 and MODY-3	Glomerulocystic kidney disease, female genital malformations, hyperuricemia, gout, abnormal liver function tests, and atrophy of the pancreas	Mild
6	*NeuroD1/ BETA2* 2	Early adulthood	Abnormal development and function of beta cells	–	Unknown
7	*KLFA11* 2p25	Early adulthood	Reduced glucose sensitivity of beta cells	Phenotype similar to T2D	Unknown
8	*CEL* 9q24	<20 years	Impaired endocrine and exocrine pancreatic function	Exocrine pancreatic dysfunction	Unknown
9	*PAX4* 7q32	<20 years	Impaired transcription of apoptosis- and proliferation-related genes in pancreatic beta cells	–	Diabetic ketoacidosis is possible
10	*INS* 11p15.5	<20 years	Loss of beta cell mass through apoptosis	–	Unknown
11	*BLK* 8p23	<20 years	Decreased insulin synthesis and secretion in response to glucose	Higher incidence in obese individuals	Unknown

tive characteristics, with elfin facies, low birth weight, skin abnormalities, and large, low-set ears. The diagnosis is based on a combination of typical dysmorphic characteristics and clinical evaluation supported by glycemic and insulin results and genetic analysis. The treatment of these patients is supportive and requires a multidisciplinary team. For instance, blood glucose levels may be maintained with frequent or continuous feeds and complex carbohydrates. Currently, treatment with recombinant insulin-like growth factor 1 has demonstrated effectiveness. The prognosis for this disorder is complicated and fatal; most fetuses with the disorder are either aborted or die within the first year of life [17].

- **Endocrinopathies.** Several hormones such as cortisol, growth hormone, epinephrine, and glucagon antagonize the action of insulin. Over-secretion of these hormones can result in glucose intolerance or diabetes mellitus [18].
- **Drug- or chemical-induced diabetes.** Drugs may induce hyperglycemia through different mechanisms, including alterations in insulin secretion and sensitivity, direct cytotoxic effects on pancreatic cells, and increases in glucose production. The drugs included in this list are antihypertensive drugs, lipid-modifying agents, protease inhibitors, nucleoside reverse transcriptase inhibitors, phenytoin, valproic acid, second-generation antipsychotics, antidepressant agents, glucocorticoids, chemotherapeutic agents, some oral contraceptives, growth hormone, and somatostatin analogs [19].
- **Cystic fibrosis-related diabetes.** Diabetes is the most common comorbidity in patients with cystic fibrosis, occurring in approximately 20% of adolescents and 40–50% of adults with cystic fibrosis. Insulin insufficiency is the primary defect, although genetically determined beta cell function and insulin resistance associated with infection and inflammation may also contribute.

Annual screening for cystic fibrosis-related diabetes with an oral glucose tolerance test beginning at age 10 years is recommended. HbA1c test is not recommended. Screening for cystic fibrosis-related diabetes should be performed using the 2-h (1.75 g/kg maximum 75 g) oral glucose tolerance test [20].

- Patients with cystic fibrosis should be treated with insulin. For patients with impaired glucose tolerance, prandial insulin therapy should be considered to maintain weight. Oral diabetes agents are not as effective as insulin in improving nutritional and metabolic outcomes in cystic fibrosis-related diabetes and are not recommended [20].
- Annual monitoring for complications of diabetes beginning 5 years after the diagnosis of cystic fibrosis-related diabetes is recommended [4].
- **Post-transplantation diabetes mellitus.** In this type of diabetes, individuals develop new-onset diabetes after transplantation. Patients should be screened after organ transplantation for hyperglycemia once they are stabilized with an immunosuppressive regimen and in the absence of an acute infection. Oral glucose tolerance test is the preferred diagnostic test [4].

The main types of diabetes mellitus are types 1 and 2, which will be discussed in detail below.

Type 1 Diabetes Mellitus

Epidemiology

Type 1 diabetes is one of the most common chronic diseases of childhood and affects males and females equally, with a slight male predominance in younger children. Type 1 diabetes has increased in recent years in both sexes, all age and race/ethnic subgroups, except for those with the lowest prevalence (age 0–4 years and American Indians) [21]. Globally, type 1 diabetes represents approximately 2% of the estimated total cases of diabetes, ranging from <1 to >15% [22]. The incidence and prevalence of type 1 diabetes mellitus vary according to the following factors:

- Age. The highest incidence occurs between 10 and 14 years of age [23].
- Season. Type 1 diabetes appears mostly in autumn and winter [23].
- Geographic location. The lowest incidence was reported in Pakistan and Venezuela (0.1 per 100,000 per year); and the highest incidence, in Finland and Sardinia [24].
- Racial and ethnic groups. In the United States, the highest prevalence was in white youths, and the lowest prevalence was in American Indian youths [21].

The incidence of type 1 diabetes mellitus has been increasing at an annual rate of approximately 2.8% [24]. The increasing incidence of type 1 diabetes in children across the world over a short period cannot be explained by genetic factors; environmental risk factors have been suggested to contribute to the increasing trend in its incidence. Several risk factors have been associated with type 1 diabetes mellitus (e.g., infections, dietary factors, air pollution, and vaccines); however, most have been inconclusive [25].

Pathogenesis of Type 1 Diabetes Mellitus

Type 1 diabetes is an autoimmune disease. The pathogenesis of type 1 diabetes begins with the appearance of beta cell autoimmunity, which is primarily directed against insulin, glutamic acid decarboxylase (GAD), or both. Subsequently, other autoantibodies against islet antigen-2, tyrosine phosphatase-like insulinoma antigen 2, or the ZnT8 transporter may also appear. Dysglycemia and the symptoms of diabetes appear later [10, 26].

The rate of beta cell destruction is quite variable, but it is usually faster in infants and children than in adults. Pediatric patients may present with ketoacidosis as the first manifestation of the disease; other patients have modest hyperglycemia, which may increase with infection or other stressors. By contrast, adults may retain sufficient beta cell function to prevent ketoacidosis and eventually become insulin dependent [4].

Progression to diabetes occurred in 14–44% of children with persistent single insulin autoantibodies or GAD autoantibodies within 10 years. The incidence of progression in children with multiple islet autoantibodies was 50–70% within 10 years and 84% within 15 years. The progression to type 1 diabetes was faster in children younger than 3 years, children with the human leukocyte antigen genotype DR3/DR4-DQ8, and girls [27, 28]. Although accepted screening programs for type 1 diabetes are lacking, screening for type 1 diabetes risk with islet autoantibodies is recommended as an option for first-degree family members of a proband with type 1 diabetes. Individuals who test positive will be counseled about the risk of developing diabetes [4, 29].

Type 1 diabetes includes the following stages [4, 29]:

- Stage 1. A presymptomatic stage with autoimmunity (multiple autoantibodies) with normoglycemia
- Stage 2. A presymptomatic stage with autoimmunity but with dysglycemia (impaired fasting glucose or glucose tolerance), or HbA1c levels of 5.7–6.4% or ≥10% increase in HbA1c level
- Stage 3. A symptomatic stage and new-onset hyperglycemia according to the standard diabetes criteria
- Stage 4. Long-standing type 1 diabetes

Genetic Risk Factors of Type 1 Diabetes Mellitus

The primary risk factor of beta cell autoimmunity is genetic and mainly occurs in individuals with HLA-DR3-DQ2 and/or HLA-DR4-DQ8 haplotypes. The region encoding HLA contributes approximately 50% of the genetic risk. Although non-HLA genetic factors have a slight individual effect, 58 genomic regions show substantial genome-wide evidence of a type 1 diabetes association. Some candidate genes with likely functional effects are *IL27*, *BAD*, *CD69*, *PRKCQ*, *CLEC16A*, *ERBB3*, and *CTSH* [26].

Environmental Risk Factors of Type 1 Diabetes Mellitus

The increase in the incidence of type 1 diabetes mellitus can be explained by changes in environment or lifestyle. A trigger from the environment in an autoimmunity-genetically susceptible individual is generally needed. These factors may be present in both the prenatal and postnatal life stages. Candidate triggers with the strongest evidence include maternal or postnatal enteroviral infection, older maternal age, infant weight gain, serious life events, overweight or increased height velocity, puberty, insulin resistance, and psychological stress. Other suggested triggers include the following: congenital rubella; cesarean section; higher birthweight; low maternal intake of vegetables; frequent respiratory or enteric infections; abnormal microbiome; early exposure to cereals, root vegetables, eggs, or cow milk; persistent or recurrent enteroviral infections; high glycemic load, fructose intake, dietary nitrates, or nitrosamines; and steroid treatment [30].

By contrast, evidence shows that higher omega-3 fatty acids are a postnatal protective factor, and higher maternal vitamin D intake or concentrations in late pregnancy, probiotics in the first month of life, and the introduction of solid food while breastfeeding after age 4 months have also been suggested to be protective factors [30].

Clinical Presentation

Children with type 1 diabetes typically present with symptoms of polyuria, polydipsia, and diabetic ketoacidosis. However, children often do not present with the classical signs and symptoms of diabetes. Physicians should be aware of other presentations such as the following: bedwetting in children who had no previous night bedwetting episodes, unintended weight loss, irritability and other mood changes, fatigue, weakness, blurred vision, candida diaper dermatitis, and vaginal yeast infection.

The prevalence of diabetic ketoacidosis in youths with type 1 diabetes is nearly 30%, and a higher prevalence has been associated with younger age at diagnosis, minority race/ethnicity, and low income [31]. The frequency of diabetic ketoacidosis at diagnosis ranges from 12.8 to 80% among countries. This variation may be explained, at least in part, by different levels of disease awareness and health-care provision [32].

Situations that cause diagnostic difficulties that may delay diagnosis include the following [33]:

- The hyperventilation of ketoacidosis may be misdiagnosed as pneumonia or asthma (cough and breathlessness distinguish these conditions from diabetic ketoacidosis).
- Abdominal pain associated with ketoacidosis may simulate an acute abdomen and lead to referral to a surgeon.
- Polyuria and enuresis may be misdiagnosed as a urinary tract infection.
- Polydipsia may be thought to be a psychogenic disorder.
- Vomiting may be misdiagnosed as gastroenteritis or sepsis (Codner limited care).

Management of Type 1 Diabetes Mellitus

Diabetes Self-Management Education and Support

All people with diabetes should participate in diabetes self-management education and receive support to obtain the knowledge and skills for diabetes self-care. The four critical time points to promote education skills are at diagnosis, annually, or when treatment targets are not met, in cases of medical, physical, or psychosocial complicating factors, and in transitions in life and care [34]. The treatment of patients with diabetes can only be effective if the family implements it. Health-care providers must be capable of evaluating individual and family psychosocial factors to overcome barriers to treatment plans. In addition, other people who participate in the patient's care must be involved. As a large portion of a child's day is spent in school, communication and cooperation with school personnel is essential for optimal diabetes management [2]. Optimal management of diabetes at school is a prerequisite for optimal school performance and the prevention of diabetes-related complications. Schools should facilitate prescribed medical interventions, including support of insulin administration, and manage appropriately the effects of low and high blood glucose levels according to parent and health-care team instructions [35].

Diabetes Education

Pediatric patients and caregivers should receive culturally sensitive and developmentally appropriate individualized diabe-

tes education [2]. Education is key to the successful management of diabetes and maximizes the effectiveness of diabetes treatment. Structured educational programs should be aimed at the patient's achievement of diabetes care goals, improved psychosocial adaptation, and enhanced self-efficacy, in addition to implementing measures of glycemic control.

Educational interventions shown to be effective include the following [36]:

- Clear theoretical psycho-educational principles
- Integration into routine clinical care
- Ongoing provision of individualized self-management and psychosocial support
- Involvement of the continuing responsibility of parents and other caregivers
- Making use of cognitive behavioral techniques most often related to problem-solving, goal setting, communication skills, motivational interviewing, family conflict resolution, coping skills, and stress management
- Utilizing new technologies in diabetes care as one of the vehicles for educational motivation

Glycemic Control

Sufficient glycemic control must be achieved to prevent diabetes-related complications; however, strict glucose levels carry the risk of hypoglycemia. Although young children were previously thought to be at risk of cognitive impairment after episodes of hypoglycemia, current data have not confirmed this notion. Hence, current standards recommend lowering glucose levels to the safest possible level to prevent chronic complications. The blood glucose and HbA1c goals for type 1 diabetes across all pediatric age groups are as follows [2, 8, 37]:

- Blood glucose goal range before meals: 90–130 mg/dL
- Bedtime/overnight: 90–150 mg/dL
- HbA1c level: <7%, with an emphasis on target personalization

Goals should be individualized, and lower goals may be reasonable if they can be achieved without excessive hypoglycemia. Blood glucose goals should be modified in children with frequent hypoglycemia or hypoglycemia unawareness. A higher HbA1c level <7.5% may be more suitable for youth who cannot identify symptoms of hypoglycemia, with hypoglycemia unawareness, without access to analog insulins, or who cannot monitor blood glucose regularly. Even less stringent HbA1c targets (e.g., <8%) may be recommended for children with a history of severe hypoglycemia, severe morbidities, or short life expectancy. On the contrary, a lower goal (HbA1c level of 6.5%) may be appropriate if achievable without excessive hypoglycemia, impairment of quality of life, and undue burden of care. A lower goal may also be appropriate during the honeymoon phase of type 1 diabetes [2, 8, 38].

Assessment of glycemic status (HbA1c or other glycemic measurement) should be performed at least two times a year in patients who meet treatment goals and at least quarterly in patients whose therapy recently changed or who do not meet glycemic goals [37].

Continuous glucose monitoring devices are rapidly improving diabetes management and could estimate the time in range as a useful metric of glycemic control. These devices report the number of days they are worn, the percentage of time they are active, and the mean glucose levels. The glycemic variability target recommended is ≤36%, with a target range of 70–180 mg/dL at >70%, <70 mg/dL at <4%, <54 mg/dL at <1%, >180 mg/dL at <25%, and >250 mg/dL at <5% [37, 39].

Blood Glucose Monitoring

Glucose monitoring enables patients, parents, and clinicians to evaluate the efficacy of current therapy, make treatment adjustments, and ensure that glucose levels are within the safe goal ranges [40, 41]. Glucose monitoring allows decisions about the insulin dose in patients with intensive management. Sleep is a time of particular risk for severe and asymptomatic hypoglycemia; hence, overnight routine testing is recommended [42].

Increased daily frequency of self-monitoring of blood glucose levels is associated with lower HbA1c levels (−0.2% per additional test per day) and fewer acute complications. When children are old enough, they should be encouraged to auto-self-monitor their glucose levels. All children and adolescents with type 1 diabetes should self-monitor glucose levels up to 6–10 times/day with a glucometer or by continuous glucose monitoring, including prior to meals and snacks, at bedtime, and as needed (during exercise, when driving, and when symptoms of hypoglycemia occur) [2].

Capillary blood and continuous glucose monitoring enable patients to detect the impacts of diet, exercise, illness, stress, and medications on glucose levels. Both types of devices allow patients to recognize hypoglycemia and hyperglycemia. Continuous glucose monitoring has become a standard of care in patients with type 1 diabetes. The advantages of using this technology are the high number of glucose readings per day (up to 288), the alert provided when the blood glucose threshold has been crossed, and the impact on glucose levels (lower HbA1c level, less hypoglycemia, and more time and time in range). However, this benefit is mediated by adherence to sensor therapy, with at least 60% use being associated with these findings [33, 43, 44]. Intermittently scanned continuous glucose monitoring devices may also be available at lower costs than traditional meter-based testing, do not require calibration, and are safe for the pediatric population [44, 45].

Insulin Therapy

Patients with type 1 diabetes mellitus lack sufficient insulin to maintain normoglycemia. Intensive insulin regimens delivered by combinations of multiple daily injections or pump therapy with differential substitution of basal and prandial insulin to obtain optimal metabolic control has become the gold standard for all age groups in pediatric diabetology [46]. The insulin requirement is 0.25–0.5 units/kg/day for children 9 months–2 years of age, 0.5–0.6 units/kg/day for children between 1 and 6 years of age, 0.75 units/kg/day for children ≥7 years until the onset of puberty, and 0.75–1.5 units/kg/day for children starting puberty. For patients with diabetic ketoacidosis, the starting dose may be 1 unit/kg/day. Insulin dose adjustments are based on blood glucose [41]. Daily insulin dosage varies greatly between individuals and changes over time. It therefore requires regular review and reassessment [46]. The pharmacokinetic parameters of insulin commonly used in pediatric patients are shown in Table 64.2.

Intensive management with multiple-dose insulin and/or continuous subcutaneous insulin infusion in children and adolescents with type 1 diabetes mellitus showed marked declines in HbA1c level and chronic complications [47].

The primary goal of treatment is to mimic natural insulin secretion. To achieve this, patients require administration of the following [41, 42]:

1. Basal insulin to maintain near-normal blood glucose levels to prevent starvation between meals and suppress hepatic glucose production. Patients can use continuous subcutaneous insulin infusion or intermediate- or long-acting insulin to mimic basal insulin secretion.
2. Short-acting insulin to cover the carbohydrates consumed during meals and normalize blood glucose levels by intermittent injections based on glycemic corrections and carbohydrate foods throughout the day. As a normal daily diet includes three meals per day, short-acting insulin should be administered at least three times daily. Patients using this regimen need to establish the following parameters:
   - The units of rapid-acting insulin to be injected per gram of carbohydrates (insulin-to-carbohydrate ratio)
   - The amount of glucose that decreases with 1 unit of rapid-acting insulin (sensitivity factor)

Table 64.2 Pharmacokinetic parameters of insulin commonly used in pediatric patients (adapted from Beck and Cogen [41])

	Action profile		
Insulin	Onset	Peak	Duration
Rapid-acting			
Lispro	15–30 min	30–90 min	3–6 h
Aspart	10–20 min	40–50 min	3–5 h
Glulisine	20–30 min	30–90 min	3–4 h
Short-acting			
Regular	30 min–1 h	2–5 h	5–8 h
Intermediate-acting			
NPH	2–4 h	4–12 h	12–18 h
Long-acting			
Glargine	1–1.5 h	No peak	20–24 h
Detemir	1–2 h	No peak	14–24 h

Although no insulin injection regimen satisfactorily mimics normal physiology, premixed insulins are not recommended for pediatric use. When the option is to use regular and NPH insulins, the recommendation should be to provide them as separate insulins, not premixed. Delivering prandial insulin before each meal is superior to postprandial injection and should be preferred if possible [46].

Insulin pumps have become increasingly available to patients with diabetes, and experts highlight their use as the chosen treatment option for many people across all age groups with type 1 diabetes. In adolescents, continuous use of subcutaneous insulin infusion was associated with lower rates of retinopathy (OR, 0.66; 95% CI, 0.045–0.95) and peripheral nerve abnormality (OR, 0.63; 95% CI, 0.42–0.95), suggesting an apparent benefit of continuous subcutaneous insulin infusion over multiple daily injections independent of glycemic control [48]. Insulin pump therapy can assist with reducing episodes of hypoglycemia and is appropriate for youth with diabetes regardless of age. Automated insulin delivery (closed loop) systems improve time in range, including minimizing hypoglycemia and hyperglycemia. Low-glucose suspend systems reduce the severity and duration of hypoglycemia while not leading to deterioration of glycemic control, as measured by HbA1c level. Predictive low-glucose suspend systems can prevent episodes of hypoglycemia and have been shown to be useful for reducing hypoglycemic exposure [44].

Nutritional Management

Nutritional management is one of the fundamental elements of care and education in type 1 diabetes and should be provided at diagnosis and reviewed at least annually by a specialist pediatric diabetes dietitian to increase dietary knowledge and adherence [49]. This management should focus on interventions to ensure normal growth and development, promote lifelong healthy eating habits, optimize glycemic control, prevent associated complications, and avoid overweight and underweight [39, 50]. To establish a nutritional program, health-care providers should consider an individual's energy needs and insulin regimen. In addition, nutritional management and education should be individualized, considering family habits, food preferences, religious or cultural needs, schedules, physical activity, and the patient's and family's abilities in numeracy, literacy, and self-management. The best approach to healthful eating is within the context of the family, focusing on healthy eating for all members [39, 50].

Healthy eating principles targeting an increased consumption of vegetables, fruits, legumes, whole grains, and dairy products are important, with an emphasis on foods with higher fiber contents and lower glycemic loads [50]. Decreased saturated fat intake underlies education; thus, the aim of improving diabetes outcomes and reducing cardiovascular risk is achieved [49, 51]. Recent studies have shown that meals with protein, fat, and more complex carbohydrates delay glucose level increases [52, 53]. Therefore, patients should be taught about all components of food intake and their respective contributions to the daily intake of calories [39, 50].

Matching insulin to the carbohydrate intake in patients receiving intensive insulin therapy requires comprehensive education in carbohydrate counting or experience-based estimation. Regular dietetic assessments by a specialist pediatric diabetes dietitian are necessary to adapt nutritional advice to growth, diabetes management, and lifestyle changes and to permit the identification and treatment of disordered eating patterns [49].

Patients with type 1 diabetes require specialized dietetic support, especially when eating disorders and celiac disease occur, which are more common in type 1 diabetes mellitus [49, 51].

Key dietary behaviors have been associated with improved glycemic outcomes such as the following [49]:

- adherence to an individualized meal plan, particularly carbohydrate intake recommendations;
- avoidance of frequent snacking episodes or large snacks without adequate insulin coverage;
- intake of regular meals and avoidance of skipping meals; and
- avoidance of overtreatment of hypoglycemia and insulin boluses before meals.

At diagnosis, appetite and energy intake are often high to compensate for catabolic weight loss; however, energy intake should be reduced when appropriate weight is restored to prevent overweight or obesity. Energy intake should be sufficient to achieve optimal growth and maintain an ideal body weight [49, 51].

In general, the nutritional recommendations for child and adolescent diabetics are the same as those for children and adolescents without diabetes. No single ideal dietary distribution of calories among carbohydrates, fats, and proteins has been established for people with diabetes, including children; therefore, macronutrient distribution should be individualized while keeping total calorie and metabolic goals in mind [50].

A guide to the distribution of macronutrients that reflects guidelines for healthy eating among children without diabetes could be used when individualizing the dietary management, distributed as follows [49, 51]:

- Carbohydrate, 45–65%
  - Moderate sucrose intake (up to 10% of the total energy intake)
- Fat, 30–35%
  - <10% saturated fat + trans-fatty acids; ≤7% when hyperlipidemia management is required
  - <10% polyunsaturated fat
  - >10% monounsaturated fat (up to 20% of total energy)
- Protein 15–20% (up to 25% in overweight or obese adolescents)

Carbohydrate intake should not be restricted, as it is essential for growth, and as internationally agreed, an excessive restriction of carbohydrates may result in deleterious effects on growth, a higher cardiovascular risk metabolic profile, and increased risk of disordered eating behaviors, as it also may increase the risk of hypoglycemia or potentially impair the effect of glucagon in hypoglycemia treatment. The mean requirement for carbohydrate if a child is consuming 45% energy from carbohydrates is up to 170 g at the age of 10 years and approximately 213 g in adolescents aged 14 years. However, high-quality carbohydrates are important. With a lower carbohydrate intake, children tend to consume more saturated fat. Carbohydrate intake should come predominantly from whole-grain breads and cereals, legumes, fruits, vegetables, and low-fat dairy foods (except for children aged <2 years), preferring those over other sources, especially those containing added sugars [50, 54].

Children and adolescents with type 1 diabetes require education regarding the amount, type, and distribution of carbohydrates over the day. Day-to-day consistency in carbohydrate intake using serving sizes or 15-g carbohydrate exchanges is encouraged for those receiving fixed mealtime insulin doses. A more flexible carbohydrate intake can be achieved using the insulin-to-carbohydrate ratio for children receiving intensive insulin therapy [49, 51].

Carbohydrate counting is a key nutritional intervention for patients with an intensive insulin regimen focused on carbohydrate as the primary nutrient affecting postprandial glycemic response. It aims to improve glycemic control, allows flexibility of food choices, and enables adjustment of the prandial insulin dose according to carbohydrate consumption. The commonly used methods of quantifying carbohydrate include the following: (1) gram increments of carbohydrate, (2) 10- to 12-g carbohydrate portions, and (3) 15-g carbohydrate exchanges. Research has not yet demonstrated a superior method of teaching carbohydrate counting [49].

Nutrition education begins with carbohydrate counting, where consistency rather than accuracy results in optimal glycemic outcomes. Over- or under-calculation by up to 10 g and 15% of the carbohydrate amount is unlikely to yield substantial hypoglycemia and hyperglycemia, respectively [50].

These programs should also consider the glycemic index of foods, which is a ranking of foods based on their acute glycemic impacts. The use of the glycemic index has been shown to provide additional benefit to glycemic control over that observed when only the amount of carbohydrates is considered. Low-glycemic-index foods decrease postprandial glucose excursion compared with carbohydrates with higher glycemic index values [50, 54].

As mentioned earlier, fat and protein are becoming increasingly recognized to also contribute to postprandial hyperglycemia. Both have been found to further delay the increase in postprandial glucose level. Consideration of the impact of fat and protein on glucose levels involves the application of advanced nutritional concepts that are best taught after basic carbohydrate counting skills have been established [54].

The primary goal regarding dietary fat intake in clinical practice is usually to decrease the intakes of saturated fat and trans-fatty acids. Saturated fat is the principal dietary determinant of plasma low-density lipoprotein (LDL) cholesterol. These types of fats are found in full-fat dairy products, fatty meats, and high-fat snacks, which should be avoided. Trans-fatty acids are formed when vegetable oils are processed and solidified. They are found in margarines, deep-frying fat, cooking fat, and manufactured products. Conversely, monounsaturated fatty acids and polyunsaturated fatty acids, which are found in vegetable oils, nuts, nut butters, and oily fish, can be used as substitutes to improve the lipid profile [54].

Recommendations for decreasing protein intake during childhood range from approximately 2 g/kg/day in early infancy to 1 g/kg/day for 10-year-olds and to 0.8–0.9 g/kg/day in later adolescence. Protein intake promotes growth only when sufficient total energy is available. High-protein diets (>25% total energy) are not generally advised for children with type 1 diabetes, as they may impact growth and vitamin and mineral intakes, except for obese adolescents. Inclusion of sources of vegetable proteins, such as legumes, in diets should be encouraged, as well as that of sources of animal protein, such as fish, lean cuts of meat, and low-fat dairy products [51, 55].

Children with type 1 diabetes have the same vitamin and mineral requirements as healthy children [51], so their intake should be as recommended in nutritional guidelines for the general pediatric population [56]. No clear evidence of the benefit from vitamin or mineral supplementation has been found in children diagnosed with type 1 diabetes who do not have underlying deficiencies [51].

High dietary sodium intake in children with type 1 diabetes is common and relates to vascular dysfunction. Sodium intake should be limited to at least that recommended for the general population. The guidelines for sodium intake in children 1–3 years are as follows: 1000 mg/day (2.5 g salt/day); 4–8 years, 1200 mg/day (3 g salt/day); and 9 years and older, 1500 mg/day (3.8 g salt/day) [54].

Antioxidants are strongly recommended for cardiovascular protection in young people with type 1 diabetes. Many fresh fruits and vegetables are naturally rich in antioxidants (tocopherols, carotenoids, vitamin C, and flavonoids), so their intake should be encouraged [51].

Estimates of dietary fiber intakes in children in many countries are lower than those recommended (3.3 g of fiber per megajoule or 14 g/1000 kcal in children aged >1 year). Intake of a variety of fiber-containing foods such as legumes, vegetables, fruits, and whole-grain cereals should be encouraged, as it promotes healthy bowel function, helps reduce lipid levels, and may be useful for enhancing protection against cardiovascular disease. Fiber-containing foods may also help improve satiety and replace more energy-dense foods. Processed foods tend to be lower in fiber; hence, unprocessed fresh foods should be encouraged. Fiber in the diet should be increased slowly to prevent abdominal discomfort, and any increase in fiber intake should be accompanied by an increase in fluid intake [49].

The dietary recommendations for specific insulin regimes include the following [54]:

Twice daily insulin regimens: Day-to-day consistency in carbohydrate intake to balance the insulin action profile and prevent hypoglycemia during periods of peak insulin action. The carbohydrate content consumed in the meals eaten at the time of insulin doses can be flexible if the patient or the family is taught to adjust the short/rapid-acting insulin to the carbohydrate eaten. Most of the time, this type of regimen requires carbohydrate intake before bed to help prevent nocturnal hypoglycemia.

- Intensive insulin regimens: individualized insulin-to-carbohydrate ratios should be used, as they enable the pre-prandial insulin dose to be matched to the carbohydrate intake. Snacks without meal boluses should be avoided, as it results in deterioration in glycemic control.

Exercise Management in Type 1 Diabetes

Regular exercise is important because it promotes and improves health and well-being, physical fitness, strength building, weight management, social interaction, self-esteem building, and creation of healthful habits for adulthood, and can help patients achieve their target lipid profile, body composition, fitness, and glycemic goals. However, barriers to exercise include fear of hypoglycemia and hyperglycemia, loss of glycemic control, and inadequate knowledge around exercise management [57].

Children and adolescents with diabetes have the same physical activity requirements as their peers without diabetes. The physical activity targets for toddlers (1–2 years)

and preschoolers (3–4 years) are a minimum of 180 min of physical activity of any intensity throughout the day with an emphasis on movement-developing skills and varied activities throughout the day. Preschool physical activity should progress toward at least 60 min of energetic play near the age of 5 years. The recommendations for children (5–11 years) and youths (12–17 years) are a minimum of 60 min of moderate- to vigorous-intensity physical activity daily to achieve health benefits (at least 420 min/week of exercise); vigorous-intensity aerobic activities at least 3 days/week, with ≤2 consecutive days between aerobic activities; and muscle- and bone-strengthening activities (resistance training) at least 3 days/week in the absence of contraindications [58–60].

Overall, youths with type 1 diabetes are recommended to participate in ≥60 min of daily physical activity, including resistance and flexibility training. Although comorbid conditions or diabetes complications are uncommon in the pediatric population, patients should be medically evaluated for these conditions, which may restrict participation in an exercise program [50].

Sedentary time should also be minimized to achieve health benefits. Recreational screen time (television, computer, and video games) is not recommended for infants and toddlers, should be limited to <1 h/day for preschoolers, and should not exceed 2 h/day for older children. Patients should also minimize the time spent indoors, prolonged sitting, and sedentary transport [61].

To avoid hypoglycemia, patients should take the following precautions [57]:

- Decrease the prandial insulin level for the meal/snack before exercise and/or increasing food intake. Patients on insulin pumps can lower basal rates by approximately 10 to ≥50% or suspend the increase in basal rates for 1–2 h during exercise.
- Decreasing basal rates or long-acting insulin doses by approximately 20% after exercise may reduce delayed exercise-induced hypoglycemia.
- If patients are unable to lower their insulin levels through exercise, they should consider increasing their carbohydrate intake at a rate of approximately 0.5 g/kg/h of activity.
- If patients are able to lower their insulin levels, they should consider the timing of exercise relative to their last meal.
  - If activity occurs ≤3 h after a meal, they should consider bolus insulin reduction. In case of <60 min duration, the reduction will depend on the exercise intensity as follows: light, 25%; moderate, 50%; or heavy, 75%. In case of ≥60 min duration, they should consider a 50% reduction in light-intensity exercise and 75% reduction in moderate/heavy-intensity exercise.
  - If activity occurs >3 h after a meal, patients must consider basal insulin reduction. Patients with multiple-dose insulin should consider a 20% reduction in basal insulin on days with prolonged activity. Patients with continuous subcutaneous insulin infusion may reduce their basal insulin levels by 50–90% in the 60–90 min before the start of exercise until the exercise ends or even consider pump suspension at the start of exercise.
- Aerobic exercise may require an initial carbohydrate intake (15–20 g). The response to a downward trend in glucose during exercise should be the ingestion of 8–20 g of rapidly acting carbohydrate.
- Consider an overnight basal rate reduction of 10–40% on evenings after prolonged aerobic exercise or resistance training.

Blood glucose targets prior to exercise should be 90–250 mg/dL (5.0–13.9 mmol/L). Additional carbohydrate intake during and/or after exercise should be considered, depending on the duration and intensity of physical activity, to prevent hypoglycemia. Prior to exercise (1–3 h), a low-fat, 1- to 1.5-g/kg carbohydrate containing meal should be consumed to maximize glycogen stores and the availability of carbohydrate for exercise without prior insulin adjustment. If the patient has a blood glucose level of <5 mmol/L, engages in low- to moderate-intensity aerobic activities, and is fasting, 10–15 g of carbohydrate may prevent hypoglycemia. After exercise, carbohydrate intake must be sufficient to ensure replacement of both muscle and hepatic glycogen stores and prevent post-exercise hypoglycemia. Consuming as high as 1.5 g/kg of carbohydrate mixed with protein and low-fat snack after training ensures muscle recovery, requiring carefully adjusted insulin doses. Exercise lasting ≥60 min may require additional carbohydrate to maintain performance [50, 54].

Effect of Treatment on the Honeymoon Period of Type 1 Diabetes

A beneficial effect of intensive early insulin therapy on the protection of pancreatic beta cell function in newly diagnosed type 1 diabetes mellitus has been demonstrated [62, 63]. This protective effect results in better glycemic control and fewer complications [62, 64]. Early small doses of insulin have been observed to be effective to prevent beta cell failure in slowly progressive type 1 diabetes and have been recommended for patients with positive antibodies [65, 66]. During the honeymoon phase, the insulin requirement decreases, and basal insulin doses of 0.2–0.6 units/g/day during this phase may preserve beta cell function [41].

Immunomodulatory agents have been used to preserve beta cell function, with promising results reported for anti-CD3, Diapep277, oral insulin, and GAD65 treatments. The possibility of beta cell function (high residual C-peptide secretion) preservation in individuals within the first months of diagnosis has been shown in clinical trials with these immunomodulators [63, 64, 66, 67].

Glucagon

Intensive insulin treatment in type 1 diabetes reduces the incidence of complications but has an increased risk of hypoglycemia and weight gain. The main goal of type 1 diabetes treatment has been the simulation of physiological insulin secretion in healthy people. However, type 1 diabetes is a dual-hormone disease, for which the combination of insulin and glucagon might be more appropriate. Glucagon substitution in response to hypoglycemia as an alternative to carbohydrate consumption could potentially reduce the risk of weight gain. Closed-loop dual-hormone treatment could potentially benefit the treatment of type 1 diabetes. Until now, the use of glucagon has been limited by the need for reconstitution immediately before use. However, it can be expected that stable compounds available for dual-hormone treatment in the future will improve metabolic control for patients with type 1 diabetes [68, 69].

Islet Transplantations and Stem Cell Therapy

The only possible cure for patients with type 1 diabetes is the possibility of replacement pancreatic beta cells. Hence, transplantation strategies have gained much interest. Research into the replacement of beta cells has had significant advances in islet isolation, engraftment, and immunosuppressive strategies. However, the main remaining limitations are the insufficient supply of human tissue and the need for lifelong immunosuppression therapy [70, 71]. In an effort to find sources of insulin-producing beta cells, alternatives such as nonhuman donor cells (mainly porcine beta cells) or the possibility of deriving pluripotent stem cells from somatic cells have been encouraged. Cell reprogramming and differentiation to obtain patient-specific beta cells have allowed the possibility of cell therapy without immunosuppression [71].

Addition of Metformin for Children with Type 1 Diabetes Mellitus

Frequently, the metabolic control of patients with type 1 diabetes mellitus worsens during adolescence secondary to increases in weight and insulin resistance as a result of puberty hormones. Therefore, the use of metformin to improve insulin sensitivity in this group of patients has been considered. In a recent meta-analysis (6 clinical trials, $n = 325$), the addition of metformin in the treatment of pediatric patients with type 1 diabetes resulted in a modest decrease in total insulin daily dose (mean difference, −0.15 unit/kg/day; 95% CI, −0.24 to 0.06) and body mass index (mean difference, −1.46; 95% CI, −2.54 to 0.38). In addition, metformin was not superior to placebo in other metabolic control variables such as HbA1c level, lipid profile, and ketoacidosis events. The authors noted that the current evidence does not support the use of metformin in type 1 diabetes mellitus in pediatric patients to improve HbA1c. Future studies are needed to evaluate the long-term durability of the reductions in total insulin daily dose and body mass index achieved by adding metformin to insulin [72].

Management of Hypoglycemia in Children and Adolescents with Diabetes

Hypoglycemia is the most common acute complication of type 1 diabetes and is the major barrier to achieving optimal glycemic control [40, 73].

Hypoglycemia is defined as a decrease in the blood glucose level that exposes the patient to potential harm. Blood glucose levels <65 mg/dL have been often accepted as the cutoff level for defining hypoglycemia. However, a threshold of 70 mg/dL is used to start treatment because of the possibility of further decreases [40, 74].

Hypoglycemia is also classified as symptomatic or asymptomatic. The signs and symptoms in children are as follows [40, 75]:

- **Autonomic:** shakiness, sweatiness, trembling, palpitations, and pallor
- **Neuroglycopenic:** poor concentration, blurred or double vision, disturbed color vision, difficulty hearing, slurred speech, poor judgment and confusion, problems with short-term memory, dizziness and unsteady gait, loss of consciousness, seizure, and death
- **Behavioral:** irritability, erratic behavior, agitation, nightmares, and inconsolable crying
- **Nonspecific symptoms:** hunger, headache, nausea, and tiredness

Symptoms of hypoglycemia may occur at higher glucose levels in children compared with adults, and the thresholds may be altered by chronic hypoglycemia. Children have a higher risk of severe hypoglycemia than adults. In this age group, severe hypoglycemia is most often defined as an event associated with seizure or loss of consciousness [40].

Milder hypoglycemia should be treated with 10–15 g of oral glucose (approximately 0.3 g/kg) to increase blood glucose to approximately 54–70 mg/dL. This can be achieved by glucose tablets or sweetened fluids such as juice. After initial treatment, blood glucose should be retested in 10–15 min. In case of an inadequate response, treatment should be repeated, and the blood glucose level must be retested in another 10–15 min to confirm that a glucose level of 100 mg/dL has been reached. In some circumstances, this should be followed by additional complex carbohydrates (fruit, bread, cereal, or milk) to prevent the recurrence of hypoglycemia [40].

However, if the child is semiconscious/unconscious, sugar or any other powdery substance or thin liquids such as a glucose solution or honey should not be given forcibly to the child. The child should be put in a lateral position to prevent aspiration, and a thick paste of glucose (glucose powder with a few drops of water or table sugar crushed into powdered sugar with the consistency of thick cake icing) should be smeared inside the cheek; the efficacy of this practice is anecdotal [33].

Severe hypoglycemia requires urgent treatment. In a hospital setting, patients should be treated with intravenous glucose. The recommended dose is 10–30%, for a total of 200–500 mg/kg of glucose (10% glucose, 2–3 mL/kg). Rapid administration or excessive concentration (i.e., glucose 50%) may result in an excessive rate of osmotic change and risk of cerebral edema [40].

In settings outside the hospital, intramuscular or subcutaneous glucagon should be given (<12 years: 0.5 mg, >12 years: 1.0 mg or 10–30 μg/kg body weight). Caregivers should always have glucagon available and receive training in using it [40, 75].

Hypoglycemia should be prevented because it is associated with psychosocial dysfunction and, in rare cases, leads to permanent long-term sequelae and may be potentially life-threatening. Diabetes education is critical for preventing hypoglycemia. Patients, parents, and caregivers should be alert to situations in which increased glucose monitoring is required and when treatment regimens need to be changed. They should be alert to recognize the early signs of hypoglycemia, have a glucometer available for confirmation, and provide some source of glucose. Sleep is a time of particular risk for severe hypoglycemia, and asymptomatic hypoglycemia is common; for this reason, glucose levels are recommended to be monitored overnight, particularly in the presence of an additional risk factor that may predispose to nocturnal hypoglycemia. Currently available technologies such as continuous glucose monitoring and automated insulin suspensions have reduced the duration of hypoglycemia [75].

Children and adolescents with type 1 diabetes should wear some form of identification to alert others of their diabetes. If unexplained hypoglycemia occurs frequently, evaluation for unrecognized celiac and Addison's disease should be considered [40].

Sickness

Children and adolescents whose diabetes is under good metabolic control should not experience more illness or infections than children without diabetes. However, when any illness occurs, someone with diabetes potentially experiences hyperglycemia, hyperglycemia with ketosis, hyperglycemia with ketoacidosis, or hypoglycemia, and requires education and treatment to prevent exacerbation or even possible death [76, 77].

Many illnesses are associated with higher levels of stress hormones, which promote gluconeogenesis and insulin resistance. Severe illness increases ketone body production because of the inadequate provision of insulin under such circumstances and thus can contribute to acidosis, nausea, and vomiting, worsening dehydration and ultimately compromising the acid-base balance, resulting in metabolic decompensation, ketoacidosis, coma, and death. Illnesses associated with vomiting and diarrhea, such as gastroenteritis, often lower blood glucose levels rather than cause hyperglycemia while simultaneously producing a type of starvation ketosis, which exacerbates the situation [76].

Education about the effects of sick days is a critical component of diabetes management at home. The general sick-day diabetes management principles include the following [76, 77]:

- More frequent blood glucose and ketone (urine or blood) monitoring, at least every 3–4 h and sometimes every 1–2 h, including throughout the night.
- During sick days, do not stop insulin, even in the fasting state.
- During sick days, the insulin dose may need to be temporarily increased or decreased.
- When vomiting occurs, it should always be considered a sign of insulin deficiency until proven otherwise.
- Monitor and maintain salt and water balance.
- Treat the underlying precipitating illness.
- Sick-day guidelines, including insulin adjustment, should be taught soon after diagnosis and reviewed at least annually with patients and family members with a goal of minimizing and/or avoiding diabetic ketoacidosis and similarly minimizing and/or avoiding illness-associated hypoglycemia.

In case of loss of appetite, replacing meals with easily digestible food and sugar-containing fluids provides energy (carbohydrates) and may help prevent further ketosis. Necessary sick-day management supplies at home include glucose tablets, sweets, or candies, as well as dried fruit to prevent hypoglycemia; clean cool water to provide hydration and prepare salty soups; sugar- and electrolyte-containing fluids such as sports drinks or electrolyte mixtures to provide hydration,

glucose, and salts; and easy-to-digest carbohydrates such as crackers or rice [76, 77].

Additional doses of short/rapid-acting insulin are required, with careful monitoring to reduce blood glucose levels, prevent ketoacidosis, and avoid hospital admission. The dose and frequency of injection will depend on the level and duration of hyperglycemia and the severity of ketosis (Table 64.3). Such supplemental doses are usually given subcutaneously but may also be given intramuscularly with health-care professional advice.

In the case of a patient who is a pump user, the previously mentioned key points of sick-day management are the same as those for a patient on insulin injections; however, specific management is recommended as follows [77]:

Hyperglycemia with negative ketones

- Give a correction bolus using a pump, and perform a blood glucose test hourly.
- Drink low-carbohydrate fluids or salty liquids.
- If the blood glucose level is decreased after 1 h, recheck again in 1–2 h to decide whether another bolus is needed.
- If the blood glucose level has not decreased, then give a bolus by syringe or pen.

Hyperglycemia with blood ketone levels >0.6 mmol/L or positive urine ketones

- Give a sick-day bolus by injection with pen or syringe using the guidelines in Table 64.3.
- Change the catheter, and check to be sure the pump is working.
- Reestablish insulin infusion with a new insulin infusion set and a cannula, with a temporary basal rate increase of 120–150%.
- Monitor blood glucose levels hourly, and recheck ketone levels at least every 4 h.
- Drink extra high-carbohydrate fluids if ketone levels are elevated and the blood glucose level is low or low-carbohydrate fluids if the blood glucose is elevated with or without elevated ketone levels.
- If the blood glucose level remains high; ketones persist; nausea, vomiting, or abdominal pain develops; or confusion or problems of staying awake and alert develop, proceed to the hospital for assessment.

If hypoglycemia (<65–70 mg/dL) and nausea or food refusal persists, a "mini glucagon treatment" (if available) may reverse the hypoglycemia and enable oral fluid intake. The recommended doses are as follows [77]:

Table 64.3 Fast-acting insulin dose calculation on sick days (adapted from Brink et al. [77])

Ketones		Blood glucose				
Blood (mmol/L)	Urine ketones	<100 mg/dL	100–180 mg/dL	180–250 mg/dL	250–400 mg/dL	400 mg/dL
<0.6	Negative or trace	Do not give extra insulin	No need to worry	Increase the insulin dose in the next meal if the blood glucose level is still elevated	Give extra 5% of the total daily dose or 0.05 U/kg	Give extra 10% of the total daily dose or 0.1 U/kg. Repeat if needed
0.6–0.9	Trace or small	Extra carbohydrates and fluids are needed	Extra carbohydrates and fluids are needed	Give extra 5% of the total daily dose or 0.05 U/kg	Give extra 5–10% of the total daily dose or 0.05–0.1 U/kg	Give extra 10% of the total daily dose or 0.1 U/kg. Repeat if needed
1.0–1.4	Small or moderate	Extra carbohydrates and fluids are needed	Extra carbohydrates and fluids are needed. Give an ordinary bolus dose	Extra carbohydrates and fluids are needed. Give 5–10% of the total daily dose or 0.05–0.1 U/kg	Give extra 5–10% of the total daily dose or 0.05–0.1 U/kg	Give extra 10% of the total daily dose or 0.1 U/kg. Repeat if needed
1.5–2.9	Moderate or high	Extra carbohydrates and fluids are needed	Extra carbohydrates and fluids are needed. Give 5% of the total daily dose or 0.05 U/kg. Repeat when the blood glucose level has increased	Extra carbohydrates and fluids are needed. Give 10% of the total daily dose or 0.1 U/kg	Give extra 10–20% of the total daily dose or 0.1 U/kg. Repeat the dose after 2 h if the ketone levels do not decrease	Consider evaluation at the emergency department
>3.0	High	Extra carbohydrates and fluids are needed. May need IV glucose if the child cannot eat or drink	Extra carbohydrates and fluids are needed. Give 5% of the total daily dose or 0.05 U/kg. Repeat when the blood glucose level has increased	Extra carbohydrates and fluids are needed. Give 10% of the total daily dose or 0.1 U/kg	Give extra 10–20% of the total daily dose or 0.1 U/kg. Repeat the dose after 2 h if the ketone levels do not decrease	Consider evaluation at the emergency department

- <2 years old = 0.02 mg = 2 units on insulin syringe
- 2–15 years old = 0.01 mg per year of age = 1 unit on insulin syringe per year of age
- >15 years old = 0.15 mg = 15 units on insulin syringe

Diabetes may also be an important risk factor for increased severity of illness and mortality in COVID-19 infections. An association between COVID-19 and new-onset type 1 diabetes and severe metabolic complications of preexisting diabetes, including DKA and hyperosmolarity, for which exceptionally high doses of insulin have been needed, has been reported. In the context of the COVID-19 pandemic, telephone consultations for sick-day management and routine diabetes care should be encouraged. This may help in the identification of children at risk of DKA, prevention of DKA, and avoiding urgent hospital visits. Families should be educated to not omit insulin, maintain hydration, treat the underlying symptoms of an intercurrent illness, and follow the general advice regarding healthy eating and continuing physical activity at home [78].

Surgery

When children with diabetes require surgery or other procedures requiring sedation or anesthesia, optimal management should maintain adequate hydration and near-normal glycemia while minimizing the risk of hypoglycemia [76]. The safe management of patients with type 1 diabetes in the perioperative period requires a consideration of each child's specific treatment, glycemic control, intended surgery, and anticipated postoperative course [79].

The presurgical assessment should be performed several days before surgery to allow an assessment of glycemic control, electrolyte status, and ketone levels. If glycemic control is known to be poor and surgery is not urgent, the procedure should be delayed until glycemic control has improved. If surgery cannot be delayed, admission to the hospital before surgery should be considered for stabilization of glycemic control [79].

Intravenous access, infusion of glucose, and frequent blood glucose monitoring are essential whenever general anesthesia is given. Glucose 5% is usually sufficient, but glucose 10% may be necessary when the risk of hypoglycemia is high. To minimize the risk of hypoglycemia, children should receive a glucose infusion when fasting for >2 h before general anesthesia [76, 79, 80].

The glucose target during surgical procedures is 90–180 mg/dL [79]. The appropriate glycemic targets during the perioperative period remain controversial and are less clear than that for surgery or postoperative control. However, studies in adults have not demonstrated any adverse effects of maintaining perioperative glycemic levels between 90 and 200 mg/dL [76, 80].

The stress from surgery leads to a complex neuroendocrine stress response characterized by hyperglycemia and a catabolic state [80]. In addition, hyperglycemia has been associated with an increased risk of postoperative infection, so it must be avoided. To achieve optimal glycemic control, the insulin dosage may need to be increased on the day of a major surgery and for approximately 2 days after surgery. This is best achieved by continuous IV insulin infusion even after the resumption of oral feeding [76, 80].

Before emergency surgery, the blood glucose, blood ß-hydroxybutyrate (if available), or urinary ketone concentration, serum electrolyte levels, and blood gases should always be checked if ketone or blood glucose levels are high. If ketoacidosis is present, the established treatment protocol for diabetic ketoacidosis should be followed and surgery should be delayed, if possible, until circulating volume and electrolyte deficits are corrected. If no ketoacidosis is observed, IV fluids and insulin management are started for elective surgery [79, 80].

Pediatric patients with type 1 diabetes need insulin, even while fasting, to avoid ketoacidosis and require careful blood glucose monitoring (hourly) before the procedure to detect hypoglycemia and hyperglycemia. At least 2 h before surgery, an IV insulin infusion (dilute 50 units regular [soluble] insulin in 50 mL of normal saline; 1 unit = 1 mL) and administration of glucose 5% (10% if increased risk of hypoglycemia is a concern) are started. If the blood glucose level is high (>250 mg/dL), 0.45 or 0.9% NaCl without glucose is used and the insulin supply is increased, but 5% dextrose should be added if the blood glucose level decreases to <250 mg/dL. Infusion is started at the following blood glucose levels: 0.025 mL/kg/h for <100–140 mg/dL, 0.05 mL/kg/h for 141–215 mg/dL, 0.075 mL/kg/h for 220–270 mg/dL, and 0.1 U/kg/h for >270 mg/dL [76, 79].

Blood glucose level should be monitored every 30–60 min during the operation and until the child recovers from anesthesia. The dextrose infusion and insulin must be adjusted to maintain the blood glucose levels within 90–180 mg/dL. Insulin infusion is continued if the blood glucose level is <90 mg/dL, as this will cause rebound hyperglycemia; instead, the rate of infusion is reduced. The IV insulin infusion may be stopped temporarily if the blood glucose level is <55 mg/dL, but only for 10–15 min [33, 76, 80].

Patients may initially receive an intravenous (IV) infusion without dextrose for minor surgeries or procedures lasting for <2 h if treated with basal/bolus insulin regimen or continuous subcutaneous insulin infusion. They should initially receive an IV infusion with dextrose for major surgeries or procedures (lasting for at least 2 h) or if treated with NPH insulin [80].

Once the child is able to resume oral nutrition, the child's usual diabetes treatment regimen should be continued. Short- or rapid-acting insulin (based on the child's usual insulin:

carbohydrate ratio and correction factor) should be administered, if needed, to reduce hyperglycemia or to match the food intake [79, 80].

Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar State

Diabetic ketoacidosis results from a deficiency of circulating insulin and increased levels of counter-regulatory hormones. Several risk factors lead to diabetic ketoacidosis in newly diagnosed cases, such as younger patients (<2 years), delayed diagnosis, lower socioeconomic status, and countries with low prevalence rates of type 1 diabetes. In the case of patients with a known diagnosis, the risk factors include insulin omission, poor metabolic control, previous episodes of diabetic ketoacidosis, gastroenteritis with persistent vomiting, inability to maintain hydration, psychiatric and eating disorders, challenging social and family circumstances, peripubertal and adolescent girls, limited access to medical services, and failures of insulin pump therapy [81].

The combination of absolute or relative insulin deficiency and high counter-regulatory hormone concentrations results in an accelerated catabolic state with increased glucose production, resulting in hyperglycemia and hyperosmolality; it also increases lipolysis and ketogenesis and causes ketonemia and metabolic acidosis. If this cycle is not interrupted by exogenous insulin and fluid and electrolyte therapies, fatal dehydration and metabolic acidosis will ensue [81].

The clinical signs of diabetic ketoacidosis include the following: dehydration, tachycardia, tachypnea, deep respiration (Kussmaul respiration), ketone smell on the breath (odor of nail polish remover or rotten fruit), nausea, vomiting, abdominal pain (which may mimic an acute abdominal condition), confusion, drowsiness, progressive reduction in the level of consciousness, and eventually, loss of consciousness [81].

The biochemical criteria for the diagnosis of diabetic ketoacidosis are as follows [81]:

- Hyperglycemia (blood glucose level >200 mg/dL)
- Venous pH < 7.3 or bicarbonate level <15 mmol/L
- Ketonemia and ketonuria

The criteria for hyperglycemic hyperosmolar state (HHS) include the following [81]:

- Plasma glucose concentration >600 mg/dL
- Venous pH > 7.25; arterial pH > 7.30
- Serum bicarbonate level >15 mmol/L
- Low ketonuria and absent-to-mild ketonemia
- Effective serum osmolality >320 mOsm/kg
- Altered consciousness (e.g., obtundation and combativeness) or seizures

Emergency assessment should follow the general guidelines for Pediatric Advanced Life Support and include the following: immediate measurement of blood glucose level, blood or urine ketone levels, serum electrolyte levels, blood gases, and full blood count, and assessment of the severity of dehydration and level of consciousness [81].

The goals of therapy are to correct dehydration, correct acidosis, and reverse ketosis; slowly correct hyperosmolality and restore blood glucose to near-normal; monitor for complications of diabetic ketoacidosis and its treatment; and identify and treat any precipitating event. Management should be conducted in centers that are experienced in the treatment of diabetic ketoacidosis in children and adolescents and where vital signs, neurological status, and laboratory results can be monitored frequently [81].

Fluid replacement should begin before starting insulin therapy. Expand the volume, as required, to restore peripheral circulation. For patients who are severely volume depleted but not in shock, volume expansion should begin with 0.9% saline with 10- to 20-mL/kg doses over 1–2 h and may need to be repeated until tissue perfusion is adequate. In patients with diabetic ketoacidosis in shock, circulatory volume with isotonic saline in 20-mL/kg boluses should be infused as quickly as possible [82].

The subsequent rate of fluid administration, including the provision of maintenance fluid requirements, to replace the estimated fluid deficit evenly over 48 h should be calculated. Subsequent fluid management should include an isotonic solution for at least 4–6 h. Deficit replacement after 4–6 h should be with a solution with a tonicity of ≥0.45% saline with added potassium [82].

Insulin therapy should begin with 0.05–0.1 U/kg/h at least 1 h after starting fluid replacement therapy. In HHS, insulin administration should begin at a dose of 0.025–0.05 U/kg/h once plasma glucose is no longer declining at a rate of at least 3 mmol/L (50 mg/dL) per hour with fluid alone [81, 82].

During volume expansion and after commencing insulin therapy, the plasma glucose concentration typically decreases. To prevent a rapid decrease and hypoglycemia, 5% glucose should be added to the IV fluid when the plasma glucose level decreases to approximately 250–300 mg/dL or sooner if the rate of decrease is precipitous. Dextrose at 10% or even 12.5% may be needed to prevent hypoglycemia while continuing the insulin infusion to correct metabolic acidosis [81].

If the patient is hyperkalemic, potassium replacement therapy is deferred until the urine output is documented. Otherwise, 40-mmol potassium/L is started in the infusion or 20-mmol potassium/L in a patient receiving fluid at a rate of >10 mL/kg/h [81].

Bicarbonate administration is not recommended, except for the treatment of life-threatening hyperkalemia. The warn-

ing signs and symptoms of cerebral edema, including headache and slowing of heart rate, a change in neurological status (restlessness, irritability, increased drowsiness, or incontinence), specific neurological signs, increasing blood pressure, and decreased oxygen saturation, should be monitored. In patients with multiple risk factors of cerebral edema, mannitol or hypertonic saline should be available at bedside, and the dose to be given should be calculated beforehand. If the patient's neurological status deteriorates acutely, hyperosmolar therapy should be given immediately [81].

Management of an episode of DKA is not complete until an attempt has been made to identify and treat the cause so that it could be prevented. Recurrent DKA without a preceding febrile or vomiting illness is almost always the result of psychosocial problems and failure to take insulin [81].

In cases with uncomplicated mild to moderate ketoacidosis, subcutaneous rapid-acting insulin analogs are effective and can be used if IV insulin is not feasible. Subcutaneous regular insulin is also an alternative if rapid-acting insulin analogs and IV regular insulin infusion are not available. The suggested starting dose is 0.15 U/kg every 2–4 h. Subcutaneous insulin therapy may not be appropriate in youths with severe dehydration or young children (aged <2 years) [78].

Autoimmune Conditions

Patients with type 1 diabetes have an increased frequency of other autoimmune diseases. Autoimmune thyroid disease is the most common (17–30%). At the time of diagnosis, approximately 25% of patients have thyroid autoantibodies, and their presence is predictive of thyroid dysfunction (most commonly hypothyroidism). Thyroid dysfunction can alter glycemic control and linear growth rate. Therefore, thyroid function tests should be performed soon after a period of metabolic stability. Testing for anti-thyroid peroxidase and anti-thyroglobulin antibodies and measurement of thyroid-stimulating hormone concentrations soon after diagnosis are recommended. If the values are normal, rechecking should be performed every 1–2 years or sooner if the patient presents symptoms of thyroid dysfunction, goiter, abnormal growth rate, or unexplained glycemic variation [2, 83]. Hyperthyroidism is less common than hypothyroidism in association with type 1 diabetes but is still more common than in the general population. Hyperthyroidism may be due to Graves' disease or the hyperthyroid phase of Hashimoto's thyroiditis [83].

Celiac disease occurs in 1.6–16.4% of patients with type 1 diabetes. Screening by measuring serum levels of IgA and anti-tissue transglutaminase antibodies is recommended and should be performed at the time of diabetes diagnosis and at 2 and 5 years thereafter, as it is frequently asymptomatic [83]. In cases of IgA deficiency, IgG tissue transglutaminase antibodies or IgG deamidated gliadin peptide antibodies should be measured. Repeat screening within 2 years of diabetes diagnosis and then again after 5 years is recommended. More frequent screening is recommended for patients with first-degree relatives with celiac disease, growth failure, weight loss, failure to gain weight, gastrointestinal symptoms (diarrhea, flatulence, abdominal pain, or signs of malabsorption), unexplained hypoglycemia, or uncontrolled glycemia. The diagnosis could be confirmed with a small bowel biopsy, and patients should be placed on a gluten-free diet to reduce symptoms and frequency rates of hypoglycemia [2].

Addison's disease is suspected on the basis of the clinical picture of frequent hypoglycemia, unexplained decrease in insulin requirements, increased skin pigmentation, lassitude, weight loss, hyponatremia, and hyperkalemia. The diagnosis is confirmed by the demonstration of low morning cortisol levels in the presence of elevated basal ACTH levels, with an inadequate response to an ACTH stimulation test and positive anti-adrenal (21-hydroxylase) antibodies. Treatment with a glucocorticoid is urgent and lifelong. In some cases, the therapy must be supplemented with a mineralocorticoid such as fludrocortisone [83].

Another rare disorder is autoimmune gastritis, which includes chronic inflammation with destruction of parietal cells of the corpus and fundus of the stomach as a consequence of parietal cell antibodies as the principal immunological marker. Chronic damage to the proton pump may result in hypochlorhydria/achlorhydria, hypergastrinemia, and iron deficiency anemia due to decreased gastric secretion and decreased iron absorption. Parietal cell antibodies may also inhibit intrinsic factor secretion, which leads to vitamin B12 deficiency and pernicious anemia. The prevalence rates of parietal cell antibodies in children with type 1 diabetes range from 5.3 to 7.5%. Physicians should be aware of the possibility of parietal cell antibodies in cases of unclear anemia (microcytic and macrocytic) or gastrointestinal symptoms [83].

Psychosocial Issues

Type 1 diabetes places a substantial behavioral and psychological burden on young people and their families. Approximately one-third of adolescents with type 1 diabetes need mental health support, and their parents are also at increased risk of psychological distress [84]. Youth with diabetes should be assessed for psychosocial and diabetes-related distress, generally starting at 7–8 years. The offering to Adolescents should be offered the opportunity to interact with their care providers strting at the age of 12, or

when developmentally appropriate [2]. Diabetes management in pediatric patients confers challenges that require family teamwork to maintain adherence and glycemic control. During follow-up, health-care providers should be alert to psychosocial issues and stresses that could affect adherence to treatment. Diabetes can impact mental health problems such as distress, fear of hypoglycemia and hyperglycemia, anxiety, disordered eating behaviors, or depression [2, 34]. In case of hospitalization, children with type 1 diabetes have higher odds (3.5) of being discharged from the hospital with a comorbid mood or anxiety disorder than other children [85]. These psychosocial factors are related to nonadherence, poor glycemic control and quality of life, and diabetes complications. Thus, screening for psychosocial distress and mental health problems is important, and referrals to trained mental health professionals as integral members of the pediatric diabetes multidisciplinary team should be provided to ensure optimal clinical care and long-term outcomes for these children [2, 34].

Young people with diabetes, especially those with a background of early diabetes onset, severe hypoglycemia, or chronic hyperglycemia, are at increased risk of mild decrements in general cognitive ability, information processing skills, executive functions, and academic achievement. Therefore, assessment of developmental progress in all domains of functioning (physical, intellectual, academic, emotional, and social development) should be conducted on a routine basis. Children with learning difficulties should be referred for a psycho-educational or neuropsychological evaluation to determine if learning disabilities are present [86].

Routine assessment should be performed with developmental adjustment to and understanding of diabetes management, including diabetes-related knowledge, insulin adjustment skills, goal setting, problem-solving abilities, regimen adherence, and self-management autonomy and competence. This is especially important during late childhood and prior to adolescence, when in many families, the child may take on diabetes management responsibilities without adequate maturity for effective self-management. The interdisciplinary team should provide interventions to emphasize appropriate family involvement and support in diabetes management, effective problem-solving and self-management skills, and realistic expectations about glycemic control [86].

Vaccination

Patients with diabetes mellitus are more susceptible to infections, for which immune system deficiency could be a reason. Routine vaccinations are recommended for children with diabetes, as for the general population, according to age [87]. However, the antibody responses to pertussis, diphtheria, tetanus, mumps, and hepatitis B vaccines are similar between patients with and without diabetes, although the response to measles and rubella vaccinations could be lower [88].

Pregnancy Prevention

Pre-pregnancy counseling is an important tool in chronic endocrine conditions to reduce the risk to mother and fetus. Starting at puberty, preconception counseling should be incorporated for all girls [2]. The management of pregnancies complicated by diabetes mellitus requires coordination among the team of obstetricians, endocrinologists, dietitians, and psychologists. The prevention of unintended pregnancies among teens with diabetes mellitus is critically important because these patients are as likely as healthy teens, in whom 83% pregnancies are unintended, to be sexually involved. Implants and intrauterine devices represent the most effective, safest, and most successful contraceptive options for adolescents [89].

Management of Cardiovascular Risk Factors

Pediatric patients with type 1 diabetes are at higher risk of early adult-onset cardiovascular disease. Adolescents with type 1 diabetes exhibit early changes in blood pressure, peripheral vascular function, and left ventricular myocardial deformation indexes, and detection could benefit from early therapeutic interventions [90].

Hypertension

Blood pressure should be measured at each consultation using an appropriate-size cuff, with the patient seated and relaxed. The result should be compared with normal levels for age, sex, and height. Children with high normal blood pressures (≥90th percentile, or in adolescents aged ≥13 years, systolic blood pressure 120–129 mmHg with diastolic blood pressure <80 mmHg) or hypertension (≥95th percentile or in adolescents ≥13 years systolic blood pressure >130 mmHg with diastolic blood pressure ≥80 mmHg) should have blood pressure confirmed on three separate days. Initial treatment includes dietary modification, increased exercise, and weight control. If high normal blood pressure persists for 3–6 months or in cases of hypertension, pharmacological treatment with angiotensin-converting enzyme inhibitors (ACE inhibitors) or angiotensin receptor blockers should be considered if ACE inhibitor is not tolerated. The goal of treatment is to maintain blood pressures consistently at <90th percentile or <120/80 mmHg in children ≥13 years of age [2, 33].

Dyslipidemia

The atherosclerotic process begins in childhood, and youths with type 1 diabetes may have subclinical cardiovascular disease abnormalities within the first decade of diagnosis. Screening for dyslipidemia should be performed soon after diagnosis and when initial glycemic control has been achieved in all children with type 1 diabetes from age 11 years. If normal results are obtained, this should be repeated every 5 years. If there is a family history of hypercholesterolemia or early cardiovascular disease, or if the family history is unknown, screening should commence as early as the age of 2 years. If LDL cholesterol is <100 mg/dL, a lipid profile testing is suggested every 3 years [2, 91].

The first step of therapy is optimizing glucose control and medical nutrition therapy. For patients aged >10 years, the addition of statin is suggested if despite medical nutrition therapy and lifestyle changes, the patient continues to have LDL cholesterol levels >160 mg/dL or LDL cholesterol levels >130 mg/dL and one or more cardiovascular disease risk factors. (The American Heart Association categorizes children with type 1 diabetes in the highest tier for cardiovascular risk.) The goal of therapy is to achieve a LDL cholesterol value of <100 mg/dL [2].

Nephropathy

Diabetic nephropathy (e.g., albuminuria) most commonly occurs after the onset of puberty and after 5–10 years of diabetes duration. Good glycemic and blood pressure control, mainly as the diabetes duration increases, is important to reduce the risk of nephropathy. Routine screening is important to ensure timely detection and treatment. Annual screening for albuminuria with a random (morning sample to avoid the effects of exercise) spot urine sample for albumin-to-creatinine ratio should be considered at puberty or at >10 years, once the child has had diabetes for 5 years [2]. Estimation of the glomerular filtration rate using equations for serum creatinine level, height, age, and sex at baseline is also recommended and should be repeated on the basis of clinical status. Treatment with an ACE inhibitor or an angiotensin receptor blocker titrated to normalization of albumin excretion should be considered when an elevated urinary albumin-to-creatinine ratio (>30 mg/g) is documented with at least two of three urine samples over a 6-month interval after efforts to improve glycemic control and normalize blood pressure [2].

Retinopathy

Diabetic retinopathy most commonly occurs after the onset of puberty and after 5–10 years of diabetes duration; however, it has been reported in pre-pubertal children and after a diabetes duration of only 1–2 years [2]. Early subclinical retinopathy may exist and can be detected through corneal confocal microscopy by the identification of corneal cellular pathology (lower epithelial and endothelial densities and higher keratocyte density) and small nerve fiber pathology in young patients with type 1 diabetes [92].

An initial dilated and comprehensive eye examination must be performed once youths with type 1 diabetes are aged ≥11 years or after puberty has started, whichever is earlier, in patients with a diabetes duration of 3–5 years. After the initial examination, patients must undergo repeat dilated and comprehensive eye examinations every 2 years or less frequently (every 4 years) on the advice of an eye care professional based on risk factor assessment, including a history of glycemic control with HbA1c levels <8%. Eye examinations could be more frequent if high-risk factors of vision loss are present [2, 33, 91].

Neuropathy

Diabetic neuropathy rarely occurs in pre-pubertal children or after 1–2 years of diabetes. Screening for peripheral neuropathy should start from the age of 11 years with 2–5 years of diabetes duration and annually thereafter [91]. A foot inspection at each medical visit is important to educate youths regarding the importance of foot care [33] (Codner limited care). A comprehensive foot examination should include an assessment of symptoms of neuropathic pain, inspection, palpation of pulses, assessment of reflexes, and determination of proprioception, vibration, and monofilament sensation [2].

Smoking

Smoking is a well-recognized cardiovascular disease risk. In youths with diabetes, additional cardiovascular disease risk factors must be avoided. Smoking increases microvascular and macrovascular complications. For these reasons, smoking avoidance (including cigarettes, other tobacco products, e-cigarettes, and secondhand smoke) is important to prevent microvascular and macrovascular complications and should be part of routine diabetes care [2, 34].

Quality of Life

Although the health-related quality of life of children/adolescents with type 1 diabetes may not be adversely affected compared with that of siblings without diabetes [93], burdens are imposed on children and their parents by a diagnosis of type 1 diabetes mellitus, which affects their health-related quality of life [94]. In general, type 1 diabetes is associated with lower health-related quality of life, higher unemployment rates, and additional sick leaves in adults [95]. Health-related quality of life is a critical diabetes outcome, but discrepancies exist between youth and parent-proxy reports in the Pediatric Quality of Life Inventory. Parents often underestimate their child's health-related quality of life, except in the youngest

children. Although examining both reports is optimal, the youth report should be prioritized, particularly for young children and adolescents [96]. Although no correlation may exist between metabolic control and health-related quality of life in children, lower numbers of hypoglycemic and hyperglycemic episodes were associated with an increase in psychosocial and physical health scores [94].

Type 2 Diabetes

Over the last three decades, the incidence and prevalence of T2D have markedly increased in the pediatric population. Before the 1990s, T2D was rare in children and adolescents in the United States. However, by 1994, T2D had represented up to 16% of new cases of diabetes in children in urban areas; after 1999, the range of new cases of T2D was 8–45%, mainly among minority populations [97]. In the United States, the estimated T2D prevalence per 1000 youths aged 10–19 years increased significantly from 0.34 in 2001 to 0.46 in 2009 to 0.67 in 2017, an absolute increase of 0.32 per 1000 youths and a 95.3% relative increase over 16 years. The greatest absolute increases were observed among non-Hispanic Black and Hispanic youths. The projections of the Centers for Disease Control and Prevention assume a 2.3% annual increase in the prevalence of T2D in people aged <20 years, which will quadruple in 40 years [4].

The diagnosis of childhood T2D is based on the presence of diabetes mellitus in a child who typically shows the following characteristics:

- Overweight or obese (body mass index ≥85th to 94th percentile and >95th percentile for age and sex, respectively)
- A strong family history of T2D
- Residual insulin secretory capacity at diagnosis (reflected by normal or elevated insulin and C-peptide concentrations)
- Insidious onset of disease
- Demonstrated insulin resistance, including polycystic ovarian syndrome or acanthosis nigricans
- Lacking evidence of diabetic autoimmunity
- Higher likelihood of having hypertension and dyslipidemia

Although diabetic ketoacidosis is more frequent in type 1 diabetes, patients with T2D may occasionally have this presentation [31].

Testing to detect prediabetes or T2D should be considered in the following cases [2, 4]:

- Children and adolescents aged 10 years or at onset of puberty (if it occurs at a younger age)
- Children and adolescents who are overweight or obese (body mass index ≥85th percentile for age and sex, weight for height >85th percentile, or weight >120% of the ideal for height)
- Children and adolescents with one or more of the following additional risk factors for diabetes:
  - Family history of T2D in first- or second-degree relatives
  - Native American, African–American, Latino, Asian American, or Pacific Islander
  - Signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, polycystic ovary syndrome, or small-for-gestational-age birth weight)
  - Maternal history of diabetes or gestational diabetes mellitus during gestation

If the test results are normal, repeat testing at a minimum of 3-year intervals or more frequently if BMI is increasing. Fasting plasma glucose level, 2-h plasma glucose level during oral glucose tolerance test, and HbA1c level can be used to test for prediabetes or diabetes in children and adolescents. Pediatric patients with overweight or obesity in whom T2D is considered should have a panel of pancreatic autoantibodies to exclude the possibility of type 1 diabetes [2, 98].

Pathophysiology of T2D Mellitus

Insulin resistance in muscle, fat, and liver, with progressive beta cell failure, and ongoing loss of insulin secretion in response to glucose characterize T2D mellitus. The following risk factors associated with this disorder can affect individuals beginning in childhood:

- **Obesity and insulin resistance**. Insulin resistance produces hyperinsulinism, and unsuccessful compensation from increased insulin secretion results in glucose intolerance and T2DM [99].
- **Intrauterine environment.** Poor intrauterine growth is associated with the subsequent development of metabolic syndrome and T2D. The effects of poor nutrition in early life produce changes in glucose-insulin metabolism, such as reduced capacity for insulin secretion and insulin resistance [100].
- **Exposition to gestational diabetes.** Maternal gestational diabetes is independently associated with a subsequent risk of T2D in offspring in the first 30 years of life; the risk is approximately threefold higher than among offspring of mothers without diabetes [101].
- **Ethnicity.** Ethnic differences in diabetes prevalence persist, even after adjustment for lifestyle and other risk fac-

tors. Diabetes mellitus is more likely (relative to Caucasians) among Asians, Native Americans, and Hispanics [102].

- **Sex and puberty.** Puberty represents a state of insulin resistance. This developmental stage is accompanied by a 30% decrease in insulin sensitivity and a compensatory increase in insulin secretion. The mean age at diagnosis of T2D in children is between 12 and 16 years, corresponding to the peak of adolescent growth. Girls are 1.5- to 3-fold more likely than boys to develop T2D as children or adolescents [103].
- **Family history.** Between 74 and 100% of children with T2D have a first- or second-degree relative with T2D. The lifetime risk is 40% if one parent is affected and 70% if both parents are affected [104].
- **Genetics.** The identification of the genetic factors involved in pediatric T2D has been a great challenge. In adults, several association studies have been conducted in which numerous SNPs have been shown to contribute to the risk of the disease; however, these SNPs currently account for only approximately 20% of heritability. By contrast, only few studies have involved pediatric patients, in whom the early onset of the disease may be due in part to greater genetic susceptibility, which makes them less tolerant of environmental aggressors. In this sense, a strong familial history of the disease suggests the involvement of genetic factors. We reported that the heritability of pediatric-onset T2D in Mexican youths was as high as 0.50 [105]. Likewise, the most important diabetes susceptibility variants reported to date are SNPs in the *TCF7L2* gene, which have strong associations with T2D in multiple ethnic populations [106]. Dabalea et al. identified *TCF7L2* variants associated with an increased risk of T2D among African–American youths [107]. In addition, we recently reported an association between SNPs in *SLC16A11* (rs13342232) and pediatric-onset T2D in the Mexican population. Our research group reported that SNPs previously associated with obesity, such as *ADORA/rs903361*, *CADM2/rs13078807*, *GNPDA2/rs10938397*, *VEGFA/rs6905288*, and *FTO/rs9939609*, were associated with an increased risk of pediatric-onset T2D in the Mexican population [108].

- The combination of multiple SNPs improves the prediction of the risk of T2D in youths with a modest significance. On the contrary, clinical factors such as body mass index and family history of T2D continue to have the highest predictive value in some populations [109].

Treatment

The treatment goals for T2D are the same as those for type 1 diabetes. In addition to blood glucose control, treatment must include attention to metabolic disorders such as obesity, hypertension, and dyslipidemia [2]. Lifestyle changes should be initiated at the time of diagnosis of T2D [110]. Education should focus on behavioral changes (diet and activity) and education on the administration of oral hypoglycemic agents and insulin as needed. The education and treatment team for a patient with T2D should ideally include a nutritionist, psychologist and/or social worker, and an exercise physiologist [3, 110].

The entire family will need education to understand the principles of the treatment of T2D and the critical importance of lifestyle changes for the entire family to successfully manage a youth with T2D [110].

Nutritional and Exercise Management

The aims of nutritional management must be focused on a multidisciplinary, family-centered, culturally appropriate approach that promotes the achievement of normal glycemia and HbA1c levels, preventing further weight gain in patients with a body mass index in the 85th–95th percentile or achieving weight loss for those with a body mass index >95th percentile while maintaining a normal linear growth. Physicians and dietitians should focus on nutritional counseling for children with T2D at the time of diagnosis and as a part of ongoing management [49, 51].

The entire family should be included in the education because caregivers influence the child's food intake and physical activity. The dietary recommendations should target dietary modifications and should be culturally appropriate, sensitive to family resources, and provided to all caregivers [49, 51, 110].

Healthy eating patterns should be encouraged, with an emphasis on consuming nutrient-dense, high-quality foods and reducing calorie-dense, nutrient-poor foods [111]. The dietary modifications should include the following:

- Eliminating sugar-containing soft drinks and juices and substitution of water, diet soft drinks, and other calorie-free beverages, which can result in substantial weight loss [110, 112]. FDA-approved non-nutritive sweeteners can be used, as they may help consumers limit their carbohydrate and energy intake as a tactic to manage blood glucose and/or weight [113].
- Increasing fruit and vegetable intake, which is known to confer several health benefits [110, 114].
- Reducing the use of processed, prepackaged, and convenience foods and the intake of foods made from refined, simple sugars, such as processed candy and high-fructose corn syrup [110].
- Control portions. Food and snacks should be served in a plate or bowl and not eaten directly from a box or can [110].

- Reducing the number of meals eaten away from home [110].
- Changing staple foods from enriched white rice and white flour to brown rice and whole-grain items with lower glycemic index values to promote gradual and sustainable energy elevations with meals [110].
- Changing family diet behaviors: limiting the availability of high-fat, high-caloric-density foods and drinks in the home; teaching families to interpret nutrition fact labels; emphasizing healthy parenting practices related to diet and activity; encouraging positive reinforcement of all goals achieved and avoiding blame for failure; and promoting that meals should be eaten on schedule, in one place, preferably as a family unit, and with no other activities (e.g., television, computer, or studying) [110].

In addition to following the above-mentioned recommendations, an individualized meal plan incorporating low-fat energy choices and carbohydrate management and the substitution of high- for low-glycemic-index foods may help control appetite, weight loss, blood glucose targets, and lipid levels [51].

Increasing daily physical activity to 60 min of moderate-to-vigorous exercise is an important component of treatment and a key strategy to increase energy expenditure; exercise can be completed in multiple shorter sessions. Promoting physical activity as a family event, including daily efforts to be more physically active, such as using stairs instead of elevators, walking or bicycling to school and shopping, and doing house and yard work, can help promote adherence to the plan. Limiting sedentary behaviors such as television viewing and computer use to <1 h a day has been shown to be an effective way of increasing daily physical activity and help maintain or achieve a healthy weight in children [51, 110].

Youth with overweight/obesity and T2D and their families should be provided with developmentally and culturally appropriate comprehensive lifestyle programs that are integrated with diabetes management to achieve a 7–10% decrease in excess weight [98].

Smoking and Tobacco Use

Cigarette smoking is damaging to all youths, but patients with diabetes are especially vulnerable to the negative health costs of smoking as a result of their compromised health status and disease and treatment-related complications [110, 114].

Additional research is needed to develop and study the efficacy of interventions specifically targeting smoking among youths with T2D within health-care settings. Patients should be asked at each visit if they smoke and counseled against beginning smoking. Youths who do smoke should be counseled on the importance of smoking cessation and provided resources for support [110].

Glycemic Monitoring

Limited evidence shows that self-monitored blood glucose has an impact on glycemic control in individuals with T2D. Blood glucose self-monitoring should be performed regularly, and the frequency should be individualized and include a combination of fasting and postprandial glucose measurements with a regularity based on the degree of glycemic control and available resources. Once glycemic goals have been achieved, limited at-home testing is needed; at most, several fasting and postprandial values per week are satisfactory. If values consistently exceed the target range, more frequent testing should be recommended because a change in therapy might be needed. During acute illness or when symptoms of hyperglycemia or hypoglycemia occur, patients should undergo more frequent testing and be in contact with their diabetes care team for advice [110].

Glycemic Targets

Glycemic status should be assessed every 3 months. A reasonable HbA1c target for most children and adolescents with T2D is <7% (53 mmol/mL). More stringent targets (e.g., <6.5% [48 mmol/mol]) may be appropriate for selected individual patients if they can be achieved without significant hypoglycemia or other adverse effects of treatment. Appropriate patients might include those with a short diabetes duration and less severe β-cell dysfunction and those treated with lifestyle or metformin alone and achieve significant weight improvement [2]. Self-monitoring of blood glucose needs to be individualized depending on the intervention for T2D [98, 115].

Pharmacological Treatment

The treatment of diabetes in children and adolescents cannot simply be derived from the pharmacological management that is routinely provided to adults with diabetes. The epidemiology, pathophysiology, developmental considerations, and response to therapy in pediatric-onset diabetes are different from those of adult diabetes [2]. A more aggressive phenotype of T2D exists in the pediatric population, which predisposes patients to an earlier dependence on insulin treatment and a presentation of chronic complications in an earlier term [98].

The aims of therapy for pediatric-onset T2D are to improve glycemia, prevent acute and chronic complications, prevent metabolic decompensation, improve insulin sensitivity and endogenous insulin secretion, and if possible, restore glucagon and incretin physiology [98].

Great uncertainty remains about the use of many novel drug treatments in the pediatric population, in whom the absence of information about safety limits their use [116]. The glycemic goals can usually be accomplished with metformin and basal insulin, alone, or in combination. The initial treatment is determined by symptoms, severity of hyperglycemia, and presence or absence of ketosis/ketoacidosis [76, 110].

Metformin

Metformin is a biguanide that increases insulin-mediated glucose uptake in the peripheral tissues and decreases hepatic glucose production, thereby promoting a decrease in plasma glucose levels [117, 118]. Currently, metformin is the only oral hypoglycemic agent approved for use in children with T2D [119].

Metformin monotherapy treatment should begin at 500 mg daily. The dose should be titrated by 500 mg once per week over 3–4 weeks to the maximal dose of 1000 mg twice daily. Blood glucose self-monitoring should be performed regularly and should be individualized on the basis of the degree of glycemic control and available resources [98, 110].

Metformin is associated with several gastrointestinal side effects, mainly nausea, abdominal pain, and headache; therefore, some patients may require slower dose escalation or may not be able to tolerate the maximum dose. Extended-release metformin preparations may have less frequent gastrointestinal side effects and are now currently available in tablet and suspension forms. Contraindications for metformin include renal and hepatic insufficiency, cirrhosis, hepatitis, and cardiopulmonary insufficiency, as metformin can lead to lactic acidosis in this setting. In addition, the absorption of vitamin B12 and folic acid can be impaired in patients taking metformin, and vitamin B12 deficiency may frequently occur in patients with anemia and peripheral neuropathy. Therefore, children and adolescents taking metformin should be advised to take multivitamins daily [115, 120].

For children on oral treatment, discontinuation of metformin 24 h before a major surgery (lasting at least 2 h) and on the day of surgery for a minor surgery is recommended. Hourly blood glucose monitoring is also recommended. If the blood glucose level is >180 mg/dL, IV insulin should be administered (as for elective surgery) to normalize levels; or subcutaneous insulin, if the patient is to undergo a minor procedure [76, 80].

In patients with ketosis, ketonuria, or ketoacidosis, treatment with subcutaneous or intravenous insulin should be initiated to rapidly correct the metabolic abnormality. Once a day of intermediate-acting or basal insulin (0.25–0.5 units/kg starting dose) is generally effective in attaining metabolic control. Metformin can be started along with insulin; once acidosis is resolved, the transition to metformin monotherapy can usually be achieved safely over 2–6 weeks [98].

If the patient fails to achieve a target HbA1c of <6.5% within 3–4 months on metformin monotherapy, the addition of basal insulin should be considered. If the target is not achieved on a combination of metformin and basal insulin (up to 1.2 units/kg), prandial insulin should be initiated and titrated to reach a target HbA1c level of <6.5% [110].

Glucagon-like peptide-1 analogs

Glucagon-like peptide-1 (GLP-1) is a hormone produced by the gut enteroendocrine cells, specifically the L cells of the small intestine, and is secreted after the ingestion of nutrients. Therefore, it controls meal-related glycemic excursions through augmentation of insulin levels and inhibition of glucagon secretion. GLP-1 also improves insulin biosynthesis and secretion and decreases β-cell apoptosis. In addition, it inhibits gastric emptying and food intake, actions maximizing nutrient absorption while limiting weight gain [120].

Liraglutide, a GLP-1 analog, has been recently approved by the Food and Drug Administration (FDA) and European Medicines Agency (EMA) for children and adolescents aged ≥10 years who have T2D according to the ELLIPSE Study data [121]. Liraglutide is efficacious for improving glycemic control and is started at a dose of 0.6 mg subcutaneously once daily, with incremental doses every 1–2 weeks or longer until fasting glucose targets are achieved to a maximum of 1.8 mg daily [115, 121]. Adverse effects with the use of liraglutide include nausea, vomiting, diarrhea, addominal pain and headache. In addition, a higher frequency of mild hypoglycemic episodes was also found [121].

If glycemic targets are no longer met with metformin (with or without basal insulin), liraglutide therapy should be considered in children 10 years of age or older if they have no past medical history or family history of medullary thyroid carcinoma or multiple endocrine neoplasia type 2 [39].

Insulin

When the individualized glycemic target can no longer be met with metformin alone or if metformin intolerance or renal or hepatic insufficiency develops, insulin therapy should be initiated alone or in combination with metformin unless metformin is contraindicated. The long-acting insulin analogs (glargine, detemir, or degludec) may be preferred [122].

Patients with ketosis, ketoacidosis, or a glucose concentration ≥200 mg/dL or HbA1c level ≥8.5% require a period of insulin therapy until glycemia has been restored to near-normal [2]. These patients require basal insulin (0.25–0.5 units/kg/day), and the dose can be adjusted according to the blood glucose values. Long-acting once daily insulin preparations could be administrated at bedtime [110]. Multiple daily injections with prandial short-acting insulin should be recommended in youths receiving high doses of basal insulin (up to 1.5 units/kg/day) [115, 122, 123].

Ongoing trials are evaluating the effects of sodium-glucose co-transporter 2 (SGLT2) inhibitors, dipeptidyl peptidase-4 (DPP-4) inhibitors, and sulfonylureas in children and adolescents with T2D. The results from these trials would soon expand the availability of pharmacological options to youths with T2DM [115, 122, 124].

Bariatric Surgery

Bariatric surgery, also called metabolic surgery, including Roux-in Y gastric bypass, vertical sleeve gastrectomy, laparoscopic adjustable gastric banding, laparoscopic gastric plication, and biliopancreatic, has been shown to significantly reduce weight, BMI, and cardiovascular comorbidities [2]. In addition, bariatric surgery has been shown to improve glucose metabolism in adolescents and adults with morbid obesity, which seems to be independent of weight loss, suggesting a direct hormonal effect [125].

The selection criteria for adolescent bariatric surgery include BMI ≥35 kg/m^2 and severe comorbidities such as T2D mellitus [98, 125, 126]. Recent results have demonstrated the remission of T2D and other comorbidities in nearly all youths after undergoing bariatric surgery [126–128], with attainment of HbA1c targets exceeding that observed with medical therapy [129]. A study conducted in México in adolescents with morbid obesity and T2D with gastric sleeve presented complete remission [130].

All bariatric procedures have an effect on glucose metabolism. The mechanisms responsible for improved glycemic control after bariatric surgery are thought to be associated with decreased nutritional intake, weight loss, and/or hormonal changes. The metabolic abnormalities associated with T2D mellitus can be reversed by bariatric surgery in most patients [125]. Roux-in-Y gastric bypass, the traditional surgical procedure for weight loss, can cause significant morbidity and mortality; however, newer techniques, which appear to be safer, include gastric banding and sleeve gastrectomy [110, 128].

Comorbidities

In children and adolescents with T2D and insulin resistance, the presence of multiple cardiovascular risk factors is likely to be associated with earlier severe complications [51]; thus, regular follow-up is essential to monitor weight and glycemic control and to prevent and address the development of diabetes-related complications such as hypertension and dyslipidemia [49, 51]. Hyperglycemia, dyslipidemia, and hypertension are contributors to the acceleration of atherosclerosis in T2D, along with oxidative stress, glycation of vascular proteins, and abnormalities in platelet function and coagulation. Endothelial dysfunction is an early sign of increased risk of cardiovascular disease, is predictive of cardiovascular events, and occurs in obese children relative to their level of obesity and degree of insulin resistance [110].

Blood pressure measurements, lipid panel, liver enzymes, albumin excretion, and dilated eye examinations should be performed at diagnosis because comorbidities may already be present at the time of diagnosis in youths with T2D. Then, the screening guidelines and treatment recommendations are similar to those for patients with type 1 diabetes. In addition, patients with T2D may need attention to other disorders, including polycystic ovary disease, obesity, sleep apnea, hepatitis steatosis, orthopedic disorders, and psychosocial concerns [2, 98].

Obesity

Weight loss and exercise both improve insulin resistance and glycemia, so the assessment of body mass index and pattern of weight gain should be considered a routine part of monitoring in youths with T2D, as obesity has deleterious associations with morbidity independent of insulin resistance and diabetes [110].

Hypertension

Hypertension is associated with endothelial dysfunction, arterial stiffness, and increased risk of both cardiovascular and kidney disease [131]. According to the TODAY study [132], hypertension was present in 13.6% of 699 US youths at a median diabetes duration of 7 months. Higher rates have been reported in Australia, with 36% of youths with T2D having hypertension within 1.3 years of diagnosis [133].

Several recommendations should be followed, such as measuring blood pressure with an appropriate-sized cuff at every clinic visit and normalizing the results for sex, height, and age. The initial treatment for blood pressure that is consistently ≥95th percentile at three visits should consist of efforts at weight loss, dietary salt restriction, and increased physical activity [110]. If blood pressure is still ≥95th percentile after 6 months, initiation of angiotensin-converting enzyme inhibitor therapy should be considered to achieve blood pressure values <90th percentile [134]. If the angiotensin-converting enzyme inhibitor is not tolerated due to adverse effects, an angiotensin receptor blocker is often used as a second-line therapy [98, 110].

Nephropathy

Early diabetic kidney disease (microalbuminuria and renal hyperfiltration) is common in adolescents with T2D and carries a higher risk of progression than the adult-onset type. Diabetic kidney disease is characterized by a long period with no signs of disease. One challenge in preventing the disease is the difficulty of identifying it at an early stage [135].

Albuminuria should be evaluated at diagnosis and annually thereafter. The definition of microalbuminuria used by the American Diabetes Association is either an albumin-to-creatinine ratio (ACR) of 30–299 mg/g in a spot urine or timed overnight sample or 24-h sample collections, with an albumin excretion rate of 20–199 μg/min. An elevated value may be secondary to exercise, smoking, menstruation, or

orthostasis [110]. Abnormal screening tests should be repeated, as albuminuria may be transient. Therefore, the diagnosis of persistent abnormal microalbumin excretion requires the documentation of two of three consecutive abnormal values obtained on different days [91, 98, 110].

Non-diabetes-related causes of renal disease should be excluded, and consultation must be sought, especially if macroalbuminuria (ACR > 300 mg/g) is present [110]. Angiotensin-converting enzyme inhibitors are the agents of choice because of their beneficial effects for preventing diabetic nephropathy, even with normal blood pressures [103]. Albumin excretion should be monitored at 3- to 6-month intervals, and therapy doses should be titrated to achieve normal albumin-to-creatinine ratios as much as possible [110]. Non-diabetes-related causes of renal disease especially in the presence of ACR >300 mg/g can be referred to nephrologists [98].

Dyslipidemia

Hypertriglyceridemia and decreased HDL cholesterol levels are hallmarks of dyslipidemia, which is characteristic of insulin resistance and T2D in children and adolescents. Testing for dyslipidemia should be performed soon after diagnosis when blood glucose control has been achieved and annually thereafter. The target levels are as follows [110]:

- LDL cholesterol <100 mg/dL (2.6 mmol/L)
- HDL cholesterol >35 mg/dL (0.91 mmol/L)
- Triglycerides <150 mg/dL (1.7 mmol/L)

In the case of persistent dyslipidemia despite dietary and exercise counseling, pharmacotherapy may be initiated. Statin therapy has been shown to be as safe and effective in children as in adults and should be the first pharmacological intervention, beginning with the lowest available dose. Treatment with a fibric acid medication should also be considered when fasting triglycerides are >400–600 mg/dL [98, 110].

Polycystic Ovarian Syndrome

Polycystic ovarian syndrome (PCOS) is increasingly recognized in adolescents as part of insulin resistance syndrome. Adolescents with PCOS had an approximately 40% reduction in insulin-stimulated glucose disposal compared with body composition-matched non-hyperandrogenic control subjects [98, 136].

Reducing insulin resistance with weight loss, exercise, and metformin therapy improves ovarian function and increases fertility. Menstrual history taking should be performed for all girls with T2D at diagnosis and at each visit. An evaluation for PCOS should be considered if primary or secondary amenorrhea, hirsutism, and/or significant acne are found. PCOS is diagnosed on the basis of the presence of oligomenorrhea or amenorrhea with biochemical or clinical evidence of hyperandrogenism, with or without evidence of polycystic ovaries. Girls receiving diabetes treatment should also be counseled that fertility may improve as a result and that proper birth control should be used to prevent any unwanted pregnancy [98, 110].

Non-alcoholic Fatty Liver Disease

Hepatic steatosis is present in 25–50% of adolescents with T2D, and more advanced forms of non-alcoholic fatty liver disease (NAFLD), such as non-alcoholic steatohepatitis (NASH), have become increasingly common and are associated with progression to cirrhosis, portal hypertension, and liver failure. NAFLD is now the most frequent cause of chronic liver disorders among obese youths [110].

Interpretation of ALT levels should be based upon the sex-specific upper limits of normal in children (22 U/L for girls and 26 U/L for boys) and not on individual laboratory upper limits of normal. NAFLD/NASH or other causes of chronic hepatitis should be considered for persistently (>3 months) elevated ALT levels >3 times the upper limit of normal. The patients should be referred to the gastroenterology department if liver enzymes remain elevated >3 times [98].

Weight loss improves NAFLD, and metformin has been shown to improve liver enzymes and liver steatosis in insulin-resistant adolescents [137]. T2D therapies that improve insulin resistance appear to improve NAFLD and are therefore the standard approach to youths with both NAFLD and T2D. However, owing to the potential for progression to NASH, fibrosis, and cirrhosis, ongoing monitoring of liver enzymes is recommended in youths with T2D. Referral for biopsy is recommended if enzymes remain markedly elevated despite weight loss and/or diabetes therapies [110].

Obstructive Sleep Apnea

Obstructive sleep apnea is common in obese youths, but its prevalence in pediatric T2D has not yet been well documented. However, the prevalence is likely high, as the prevalence in adults is between 70 and 90% [138, 139]. Obstructive sleep apnea not only causes poor sleep quality and daytime sleepiness but also has clinical consequences, including hypertension, left ventricular hypertrophy, and increased risk of renal and cardiovascular disease [98, 110].

Youths with T2D can be screened for obstructive sleep apnea by questioning them about snoring, sleep quality, apnea, morning headaches, daytime sleepiness, and enuresis. If symptoms are suggestive, a diagnosis is made through a formal sleep study and referral to a sleep specialist [110].

Depression

Youths with T2D are at increased risk of major clinical depression, which is associated with poor adherence to diabetic treatment recommendations. Signs include depressed mood, markedly diminished interest or pleasure, increased or decreased appetite, insomnia or hypersomnia, psychomotor agitation or retardation, fatigue or loss of energy, feelings of worthlessness, and recurrent thoughts of death [98, 110].

Youths with T2D, particularly those with frequent emergency department visits or poor glycemic control, should be assessed for depression at diagnosis and periodically thereafter [110]. Patients identified as depressed should be referred to appropriate mental health-care providers experienced in addressing depression in youths [140].

Additional Health Problems Related to Obesity and T2D

All patients with T2D may have additional health problems related to the disease, such as orthopedic problems resulting in diminishing physical activity, pancreatitis, cholecystitis, pseudotumor cerebri, and deep tissue ulcers. These additional health problems should be screened at diagnosis and rescreened periodically [110].

Transition from Pediatric to Adult Care

The care and close supervision of diabetes management are increasingly shifted from parents and other adults to the youth with type 1 or 2 diabetes over the course of childhood and adolescence [141]. The shift from pediatric to adult health care is inevitable, and the transition is always difficult regardless of age. However, in some places, more than half of patients continued to receive pediatric care even after the age of 30 years [142].

The transition often occurs abruptly as older teens enter the next developmental stage, referred to as emerging adulthood, and a lack of consistent care may follow the transition in 30–40% of patients [76, 141]. The transition is a period associated with deterioration in glycemic control; increased occurrence of acute complications, psychosocial, emotional, and behavioral challenges; and the emergence of chronic complications [76, 141].

During this period, youths with T2D often struggle with becoming fully responsible for their diabetes care; therefore, discussion about the transition during the several visits before it occurs may help prepare the patient [76, 141]. Health-care providers and families should begin to prepare youths with diabetes in early- to mid-adolescence and at least 1 year before the transition to adult health care, and both pediatricians and adult health-care providers should assist in providing support for the teen and emerging adult [141].

Concluding Remarks

- The pathophysiology and diagnostic criteria for diabetes mellitus are the same in children and adults.
- However, issues specific to early childhood diabetes include changes in insulin sensitivity due to growth and development, dependence on care, and neurological susceptibility to changes in glucose.
- The younger age of presentation of diabetes in pediatric patients causes a longer disease exposure, with the development of chronic complications at an early age; therefore, close surveillance is required.
- Children are not small adults; thus, treatment should be adapted to age-related physiological changes.
- The only pharmacological treatments approved for children and adolescents are insulin for type 1 diabetes mellitus, metformin, liraglutide, and insulin for T2D mellitus and sulfonylureas for some types of neonatal diabetes. Pediatric patients with T2D could also be candidates for bariatric surgery.

Multiple-Choice Questions

1. What is the most common type of diabetes mellitus in children and adolescents?
   (a) **Type 1 diabetes mellitus**
   (b) Type 2 diabetes mellitus
   (c) Monogenic diabetes
   (d) MODY
   (e) Neonatal diabetes

   Although type 2 diabetes is occurring more frequently in pediatric patients and other forms such as neonatal diabetes are unique to this age range, type 1 diabetes is the predominant form in this age group.
2. Which of the following clinical features raises the suspicion of monogenic diabetes?
   (a) Diabetic ketoacidosis in a school-age child
   (b) A random plasma glucose level ≥200 mg/dL in a child with obesity, acanthosis nigricans, and a family history of type 2 diabetes
   (c) **Diabetes in the first 6 months of life, a strong family history of type 2 diabetes in a nonobese patient or low-risk ethnic group, and fasting glycemia of 100–150 mg/dL**
   (d) Neonatal hyperglycemia in infants with elfin facies, low birth weight, and skin abnormalities
   (e) Diabetes mellitus associated with autoantibodies

   Monogenic diabetes is characterized by impaired insulin secretion by pancreatic beta cells caused by a single gene mutation. These forms of diabetes represent less than 5% of patients with diabetes and are charac-

terized by onset generally before age 25 years, without clinical features of insulin resistance in type 2 diabetes and with negative associated autoantibodies.

3. What are the blood glucose and HbA1c goals for type 1 diabetes mellitus across all pediatric age groups?
   (a) Blood glucose level of 100–150 mg/dL before a meal and 100–125 mg/dL at bedtime/overnight, and HbA1c level of <8.5% in infants, <8.0% in school-children, and <7.5% in adolescents
   (b) **Blood glucose of 90–130 mg/dL before a meal and 90–150 mg/dL at bedtime/overnight, and HbA1c level of <7.5% across all pediatric age groups**
   (c) Blood glucose level of <100 mg/dL before a meal, <140 mg/dL after a meal, and 100–125 mg/dL at bedtime/overnight, and HbA1c level of <6.5% across all pediatric age groups
   (d) The lowest HbA1c level is possible regardless of the degree of hypoglycemia
   (e) Blood glucose level of <200 mg/dL after a meal and HbA1c level of <8.5% across all pediatric age groups

   Glycemic control needs to be of a sufficient degree to prevent diabetes-related complications; however, strict glucose levels carry the risk of hypoglycemia. Although young children were previously thought to be at risk of cognitive impairment after episodes of hypoglycemia, current data have not confirmed this notion. Hence, current standards recommend lowering glucose to the safest possible level to prevent chronic complications.
4. In an oral glucose tolerance test, what is the glucose load used to diagnose diabetes mellitus in children and adolescents?
   (a) 1.75 g of anhydrous glucose per kg body weight, with a maximum of 50 g
   (b) 1.50 g of anhydrous glucose per kg body weight, with a maximum of 75 g
   (c) 1.50 g of anhydrous glucose per kg body weight, with a maximum of 50 g
   (d) 1.75 g of anhydrous glucose per kg body weight, with a maximum of 65 g
   (e) **1.75 g of anhydrous glucose per kg body weight, with a maximum of 75 g**

   The loading of anhydrous glucose in the oral glucose tolerance test must be calculated per body weight, with a maximum adult load of 75 g. In the absence of unequivocal hyperglycemia, results should be confirmed by repeat testing.
5. Which of the following is the best treatment option for mild hypoglycemia in pediatric patients with type 1 diabetes?
   (a) Intravenous 10% glucose, 2–3 mL/kg
   (b) 10–15 g of oral glucose using complex carbohydrates
   (c) **10–15 g of oral glucose using simple carbohydrates**
   (d) Glucagon 10–30 μg/kg of body weight
   (e) Switching off the insulin pump

   Milder hypoglycemia should be treated with 10–15 g of oral glucose in the form of simple carbohydrates such as glucose tablets or sweetened fluids such as juice. Subsequently, blood glucose levels should be retested in 10–15 min. In case of an inadequate response, treatment should be repeated and blood glucose levels should be retested in another 10–15 min to confirm that a glucose level of 100 mg/dL has been reached. In some circumstances, this should be followed by administration of additional complex carbohydrates to prevent the recurrence of hypoglycemia. Intravenous glucose and glucagon are used in more severe hypoglycemia.
6. Which treatment has been observed to be effective at preventing beta cell failure in the honeymoon phase?
   (a) **Insulin**
   (b) Glucagon
   (c) Metformin
   (d) Sulfonylureas
   (e) None of the above

   Early small doses of insulin have been observed to be effective at preventing beta cell failure in slowly progressive type 1 diabetes, and they have been recommended for patients with positive antibodies. During the honeymoon phase, the insulin requirement decreases, and basal insulin of 0.2–0.6 units/g/day during this phase may preserve beta cell function.
7. If diabetes occurs at puberty and the patient has obesity, insulin resistance data, and a genetic background for T2DM, what type of diabetes are we required to rule out?
   (a) Neonatal diabetes
   (b) Type 1 diabetes mellitus
   (c) Monogenic diabetes
   (d) MODY
   (e) **Type 2 diabetes mellitus**

   The clinical data that usually support the presence of T2DM are overweight or obesity, first- or second-degree relatives with diabetes, presence of acanthosis nigricans, hypertension, dyslipidemia, non-alcoholic fatty liver, exposure to gestational diabetes, low height or macrosomia at birth, obstructive sleep apnea syndrome, and polycystic ovary syndrome. C-peptide levels ≥0.5 ng/dL may be an indirect marker that endogenous insulin secretion still exists and therefore lead to T2DM. However, this may be decreased at the beginning of diagnosis and late illness.
8. Which of the following is true regarding insulin therapy in patients with type 1 diabetes mellitus?
   (a) The insulin requirements are the same across all age groups (0.5 units/kg/day).

(b) Treatment regimens with two doses of insulin, multiple doses of insulin, or continuous infusion are equally effective.
(c) To avoid hypoglycemia, the short-acting dose of insulin should consider the amount of food to be consumed without taking into account glucose levels.
(d) The insulin pump is indicated only in patients for whom control with multiple injections is not achieved.
(e) **The insulin scheme should mimic natural production, with basal insulin to maintain glucose levels between meals and rapid insulin to cover carbohydrates and normalize glucose.**

Insulin requirements range from 0.25 to 1.5 units/kg/day according to age and pubertal development. Intensive management with the use of multiple-dose insulin and/or continuous subcutaneous insulin infusion in children and adolescents with type 1 diabetes mellitus showed a marked decline in HbA1c level and chronic complications. The primary goal of treatment is to mimic natural insulin secretion, with basal insulin to maintain near-normal blood glucose levels between meals and short-acting insulin to cover the carbohydrates consumed during meals and normalize blood glucose levels. Insulin pumps have become increasingly available to patients with diabetes, and experts highlight their use as the chosen treatment option for many people across all age groups living with type 1 diabetes.

9. How should the total energy intake be distributed in the management of type 1 diabetes mellitus?
(a) Restricted energy intake with carbohydrate 50%, fat 30%, and protein 20%
(b) Normal energy intake with a low-carbohydrate intake of 20% to prevent hyperglycemia
(c) Normal energy intake with low fat to prevent ketosis
(d) **Normal energy intake with carbohydrate 45–65%, fat 30–35%, and protein 15–25%**
(e) Restricted energy intake with carbohydrate 60%, fat 25%, and protein 15%

Energy intake should be sufficient to achieve optimal growth and maintain an ideal body weight. The total daily energy intake should be distributed as follows: carbohydrate 45–65%, fat 30–35%, and protein 15–25%. Carbohydrates should not be restricted, as they are essential for growth.

10. Which pharmacological treatment(s) is/are approved to treat type 2 diabetes in children and adolescents?
(a) **Liraglutide, metformin, and insulin**
(b) Thiazolidinedione and metformin
(c) Same as in adults
(d) Insulin only
(e) SGLT2 inhibitor and metformin

Metformin is the only oral hypoglycemic agent approved for daily use in children with type 2 diabetes. Treatment with metformin monotherapy should begin at 500 mg daily. The dose should be titrated by 500 mg once per week over 3–4 weeks to the maximal dose of 1000 mg twice daily. If the patient fails to achieve a target HbA1c level of <6.5% within 3–4 months on metformin monotherapy, the addition of basal insulin should be considered. Liraglutide is a GLP-1 analog approved by the FDA and EMA in 2019 for children and adolescents aged ≥10 years with T2DM.

11. Which of the following is true about follow-up for pediatric patients with type 2 diabetes?

(a) Nutritional management must be focused on achieving normal glycemia regardless of the body mass index.
(b) Moderate-to-vigorous exercise for 15–30 min twice per week is recommended.
(c) **The examination of comorbidities should be performed at diagnosis.**
(d) Patients with type 2 diabetes do not need to self-monitor their blood glucose levels.
(e) The target levels for dyslipidemia are LDL-C <200 mg/dL, HDL-C >35 mg/dL, and triglycerides <150 mg/dL.

Nutritional management must be focused on achieving normal glycemia and HbA1c levels, preventing further weight gain, or achieving weight loss while maintaining normal linear growth. Patients should increase their daily physical activity to 60 min of moderate-to-vigorous exercise. Blood pressure measurements, lipid panel, albumin excretion, and dilated eye examinations should be performed at diagnosis because comorbidities may already be present at that time. Blood glucose self-monitoring should be performed regularly. The target levels for dyslipidemia are LDL-C <100 mg/dL, HDL-C >35 mg/dL, and triglycerides <150 mg/dL.

Pregnancy: Pregestational and Gestational Management

65

María Isabel García Argueta, Maricela González Espejel, and Joel Rodriguez-Saldana

Introduction

Gestational diabetes (GD) is defined as an alteration in carbohydrate metabolism diagnosed for the first time in the second or third trimester of gestation, it being clear that the diagnosis of same during the first trimester indicates preexisting type 1 or 2 diabetes. The growing index of obesity is a global problem, where the main factors that unleash it are bad eating habits and sedentary lifestyle. Obesity in pregnancy is a risk factor for developing diabetes, which goes hand in hand with an increased maternal and fetal risk and hypertensive disorders. Women of a reproductive age are not the exception in regard to obesity; the U.S. National Health and Nutrition Survey (1999–2008) reveals that more than one third of the women of reproductive age are obese, and 7.6% of these women are extremely obese, with body mass indices (BMIs) equal or greater than 40; the percentage of pregnant women with obesity is estimated between 18 and 38% [1, 2]. In regard to Mexico, we have one of the highest prevalence of overweight, obesity, and diabetes in the world. Studies based on the Encuesta Nacional de Salud y Nutrición (ENSANUT, National Health and Nutrition Survey, in English) 2012 show that in the last decades, an increase has been observed in body mass and waist perimeter in the population, with a higher prevalence among young Mexican women of reproductive age, compared with other populations [3], and these changes evidently have attention-getting metabolic repercussions, above all because the female reproductive population is implicated. In consequence, pregnancy-associated diabetes is more and more frequent, and it is estimated that it significantly complicates around 1–16% of all births worldwide, depending on the population studied. The prevalence of GD has a variation directly proportional to the prevalence of type 1 diabetes (T1D) and type 2 diabetes (T2D), depending on the population under study. Other estimates indicate that 6–7% of pregnancies are complicated by this disease and that approximately 90% of the cases are represented by women with T1D and T2D. It has also been established that the highest prevalence is found among Hispanics, Afro-Americans and natives of America, Asia, and the Pacific islands [4]. Suffering GD significantly increases the risk of adverse results of the pregnancy compared with normal pregnancy: congenital malformations in 5% against 2% in the general population, perinatal mortality in 2.7% against 0.72%, premature birth in 25% against 6%, and fetal macrosomia in 54% against 10% [5]. This pregnancy complication is a growing problem for public health, with genetic, environmental, and social determinants; but obesity has a major importance as a risk factor. There exists the hypothesis that fetal overnutrition during maternal exposure GD is associated with increased overall abdominal adiposity, and a more central fat distribution pattern in 6- to 13-year-old children from a multi-ethnic population [6]. Therefore, the combination of diabetes and pregnancy is not a desirable situation due to the possible complications it incurs, so that it is necessary to detect and treat it in a timely fashion. Recent evidence suggests that there is an intrauterine programming related to hyperglycemia during pregnancy, which could explain the increased risk of metabolic alterations, obesity, and diabetes among the offspring of mothers who had a pregnancy associated with diabetes [7]. Epertise by health personnel who care pregnant women is essential primordial, and is fundamental for reducing maternal and fetal morbimortality in the pregnant diabetic. It is of vital importance to identify, from the first level of care, patients with risk factors and to implement strategies that include pre-conception and dietary counseling, promoting lifestyle changes that combat a sedentary lifestyle, and timely medical intervention with the various alternatives available [8]. Luckily the current panorama for the gestating individual has improved dramatically, since in the past a pregnant woman with diabetes was inconceivable. The dis-

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_65

covery of insulin in 1921 by the investigators Banting, MacLeod and Bets from the University of Toronto radically changed the prognosis for those ill with diabetes, as well as for gestating diabetes. Likewise, the use of glyburide and metformin during pregnancy, accepted in recent years, is one more tool in the treatment of pregestational and gestational diabetes. However, the pregnant woman with diabetes is exposed to high obstetric risk and elevated perinatal morbimortality, so it has not ceased to be a health problem.

Classification and Diagnosis

For many years, GD has been defined as an alteration in glucose metabolism, first recognized during pregnancy. In the 2016 publication of the American Diabetes Association (ADA), diabetes is classified in four general categories [9, 10]. This new classification, in contrast to the old classification by White, has greater clinical usefulness, since it is concrete, easy to remember, and applicable to diabetes during pregnancy.

1. Type 1 diabetes (T1D) which is secondary to the destruction of the beta cells of the pancreas, and in general leads to absolute insulin deficiency.
2. Type 2 diabetes (T2D) due to a progressive loss of insulin secretion.
3. GD, which is diabetes diagnosed in the second or third trimester of pregnancy and which is clearly not a previously manifested diabetes.
4. Specific diabetes, which is due to other causes, such as monogenic diabetes syndrome (such as the neonatal appearance and that in Young adults—MODY), diseases of the exocrine pancreas (like cystic fibrosis), and diabetes induced by chemical products (use of glucocorticoids after transplant or drugs for treating HIV/AIDS).

In this category, it is given as fact that both T1D and T2D may be pre-existing or pre-established in pregnancy, and that in both types there may or may not be vascular complications such as chronic hypertension, retinopathy, or nephropathy.

GD carries risks for the mother and neonate, and these risks increase with the levels of maternal glycemia after the period of pre-conception and throughout the pregnancy. GD is diagnosed based on the general criteria of the World Health Organization (WHO) of plasma glucose, or better the fasting plasma glucose and plasma glucose 2 h postprandial, or with the glucose tolerance test after ingesting 75 g of glucose orally or with the criteria of glycosylated hemoglobin (Table 65.1).

Fasting is understood as null consumption of foods for a period of 8 h; the glucose intolerance test is performed with 75 g of anhydrous glucose dissolved in water. In regard to the determination of A1c, it is worth noting that it requires standardized methods and certification for this determination.

Table 65.1 WHO criteria for diagnosing diabetes

Criteria	
Fasting plasma glucose	Equal or greater than 126 mg/dL (7.0 mmol/L)
Plasma glucose 2 h postprandial	Equal or greater than 200 mg/dL (11.1 mmol/L)
Glycosylated hemoglobin (A1c)	Equal or greater than 6.5% (48 mmol/L)
Random plasma glucose	Equal or greater than 200 mg/dL (11.1 mmol/L)

The ADA recommends a selective screening in the first prenatal visit, where the patient risk of developing GD is stratified. The risk criteria are the following: over 25 years of age, weight above normal, first-degree family history of diabetes, background of glucose tolerance disorders, background of adverse obstetric events such as stillbirths, premature or macrosomic birth, and belonging to racial-ethnic groups at high risk for diabetes (Hispano-Americans). Patients with high risk should submit to an oral glucose tolerance test. In case of not agreeing with the diagnosis at that time, the test should be repeated between 24 and 28 weeks of gestation.

The Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study in 2008 showed evidence that the increase in just one standard deviation in fasting glucose and 2-h postprandial levels is associated with a higher risk of birth weight above the 90 percentile, cesarean birth, neonatal hypoglycemia, blood levels of C-peptide above the 90 percentile (related to fetal hyperinsulinemia and neonatal hypoglycemia), birth before 37 weeks, shoulder dystocia or damage to the newborn, requiring intensive neonatal care, hyperbilirubinemia, and preeclampsia [11]. Consequently, after the International Association of Diabetes in Pregnancy Study Groups (IADPSG 2010) and the American Diabetes Association (ADA), proposed reducing the parameters in plasma glucose levels for the diagnosis of diabetes and a universal screening where in the first prenatal evaluation baseline glucose, glycosylated hemoglobin or casual glycemia should be determined for early detection of diabetes not recognized previously, and to start treatment and follow-up as done with previously recognized diabetes (Tables 65.2 and 65.3). It should be mentioned that ADA and the American College of Obstetricians and Gynecologists (ACOG) support the two-step strategy proposed by the National Institutes of Health (NIH) in 2013, which consists of performing a first glucose tolerance test with 50 g and in positive cases a second test with 100 g of oral glucose.

Despite differences regarding glucose levels, these diagnostic approaches have been accepted to establish the diagnosis of gestational diabetes. The results of meta-analysis comparing diagnostic criteria show similar associations in both systems, but it is evident that with the IADPSG

Table 65.2 IADPSG 2010 criteria for GD diagnosis during a glucose tolerance test with 75 g of glucose anhydrate dissolved in water

Baseline or fasting glucose	≥92 mg/dL (5.1 mmol/L)
First hour glucose	≥180 mg/dL (10.0 mmol/L)
Glucose at 2 h	≥153 mg/dL (8.5 mmol/L)

One or more of these values should be equal or greater to establish the diagnosis of diabetes

Table 65.3 Two-step strategy for the diagnosis of GD

Step 1. Perform the glucose tolerance test between weeks 24 and 28 of gestation with 50 g, without considering fasting, with determination of glucose at 1 h, in women not previously diagnosed with diabetes
1 h ≥140 mg/dL[a] (7.8 mmol/L), proceed to glucose tolerance curve with 100 g of glucose
Step 2. Glucose tolerance curve considering fasting, with 100 g of glucose and determinations of the first, second, and third hour
Fasting 95–105 mg/dL (5.3–5.8 mmol/L)
1 h 180–190 mg/dL (10.0–10.6 mmol/L)
2 h 155–165 mg/dL (8.6–9.2 mmol/L)
3 h 140–145 mg/dL (7.8–8.0 mmol/L)
The diagnosis is established when at least two of the four values are equal or greater

[a]The ACOG recommends levels below 135 mg/dL (7.5 mmol/L) in populations ethnically at high risk for GD; some experts recommend values of at least 130 mg/dL (7.2 mmol/L)

criteria, more patients are diagnosed with GD, which may lead to over-diagnosis and overtreatment. Putting the differences to one side, we do not adhere to the recommendations of ADA and IADPSG 2010, where it is established that every patient receiving prenatal care should be screened from the first prenatal visit for diabetes, preferably during the first trimester of gestation, since patients at low risk of developing GD represent barely a low percentage of the population and repeating the plasma glucose test between weeks 24 and 28 if the diagnosis is not established previously [12–14]. It is obvious that its practice will have a benefit in results that favor the pregnant woman.

Recommendations for the Diagnosis of Diabetes in the Pregnant Woman (American Diabetes Association, 2016)

1. Perform on every pregnant woman in her first visit for prenatal control a determination of fasting glucose using the standard diagnostic criteria, above all in pregnancies with risk factors in which there is not a previous diagnosis of T2D.
2. Test for a diagnosis of diabetes between weeks 24 and 28 of gestation in pregnant women not known to have previous diabetes.
3. Screening with a glucose tolerance test between weeks 6 and 12 post-partum for all women who had GD, with the object of detecting persistence of hyperglycemia and establishment of T2D.
4. Women with background of GD should have a permanent follow-up for developing diabetes or pre-diabetes at least every 3 years, since it is estimated that a considerable percentage (15–50%) of women that suffer GD develop T2D in a period of no more than 10 years.
5. All women with established history of GD or a pre-diabetic condition should receive interventions to change lifestyle or to use of metformin to prevent or delaying the development of diabetes.

Changes in Carbohydrate Metabolism in the Pregnant Woman

The metabolic changes natural in pregnancy have the object of creating an environment that allows embryogenesis, the growth of the fetus, its maturity and survival. In a normal pregnancy, directly or indirectly, the growth of the fetal placental unit increases levels of cortisol, growth hormone, human placental lactogens, estrogens, progesterone, and prolactin. In the first week of gestation, the increase in the production of estrogens and progesterone produces hyperplasia of the β cells of the pancreas, followed by an increase in the production of insulin and increased tissue sensitivity to same. This anabolism is translated into an increase in the response to insulin, which leads to fasting hypoglycemia, increased plasma lipids, hypoaminoacidemia, and a marked sensitivity to starvation. During the second half of pregnancy (particularly weeks 24–28), carbohydrate metabolism is affected by the increased production of human placental chorion gonadotropin, tumor necrosis factor α, prolactin, cortisol, and glucagon. These changes contribute to improved glucose tolerance, greater insulin resistance, reduced reserves of hepatic glycogen, and increased hepatic glycogenesis. As the gestation progresses, this response comes to be inadequate and insulin resistance is presented, which promotes a lipolysis and fasting ketonemia, as well as postprandial hyperglycemia, in which there is a greater supply of nutrients for the fetus. Placental transport of glucose is carried out through facilitated diffusion, so that maternal serum levels determine fetal levels; in a pregnancy with diabetes there is elevated fetal insulin, promoting the growth of same with increased fatty tissue and increased reserves of hepatic glycogen, which is associated with macrosomia, lipogenesis, organomegaly, polyhydramnios, etc. [15, 16]. Recently, there has been talk of leptin, which is a hormone produced mainly by fatty tissue cells, and its circulating levels are proportionate to adipose tissue mass; in the second and third

trimesters of pregnancy its levels increase substantially; its role is related to mitogenic and angiogenic processes, in the regulation of immune response and in the transportation of nutrients, all important processes during placentation and embryonic development [17].

Treatment

The handling of diabetes should comprise a preventive focus in all senses; that is why it is determinant that all women of reproductive age have access to health services, information regarding reproductive health, a family planning method, methods to prevent sexually transmitted diseases, and that they are informed of the risk a pregnancy implies in association with overweight and obesity, nutritional advice during pregnancy, and the promotion of breastfeeding since abandoning this practice increases the risk of maternal overweight and obesity. Weight gain during pregnancy should be inversely proportional to the body mass index (BMI) previous to the pregnancy, so the intervention of nutritionists and dieticians is recommended in nutritional advice to achieve objectives regarding expected weight gain during pregnancy (Table 65.4).

In patients with pregestational diabetes, it is of vital importance that the pregnancy occurs in a euglycemic environment to avoid fetal complications that accompany periconception hyperglycemia, congenital malformations, and miscarriages being frequent. In the patient that debuts with diabetes in pregnancy, education regarding self-monitoring of glucose and the presence of ketonuria is primordial, as well as educating families in the identification of hypoglycemia data. Opportune treatment of GD will significantly reduce perinatal complications such as fetal death, congenital malformations, fetal macrosomia, shoulder dystocia, bone fractures secondary to obstetric trauma, nerve lesions, and newborns with delayed intrauterine growth; it will even be a factor that will influence the future reduction in risk of juvenile obesity in the children of mothers with diabetes. The main objective in treatment is the strict control of blood glucose levels; Table 65.5 lists the main care to which every patient with pre-existing diabetes should have access. It is worth mentioning that if the healthcare model is applied by levels, the first contact doctors are in charge of detecting those patients of reproductive age with risk factors, especially patients with pre-existing diabetes (T1D or T2D) susceptible to getting pregnant, so the pregnancy is in conditions of metabolic control, and they are referred timely to second or third level care for its management.

Table 65.4 Expected weight gain during pregnancy in relation to BMI

Total gain at the end of pregnancy	BMI
12–18 kg (28–40 lb)	<18.5
11.5–16 kg (25–35 lb)	18.5–25
6.8–11 kg (15–25 lb)	25–30
5–9 kg (11–20 lb)	>30

In countries like Mexico, it has been established that women represent an intermediate-risk group from an ethnic point of view, for developing diabetes, and therapeutic goals have been established for the treatment of GD, recommended in national Clinical Practice Guides—Guías de Práctica Clínica 2009 (GPC 2009), where the objective is to achieve blood glucose levels described in Table 65.6. The implementation of the GPC in recent years in Mexico has the goal of unifying medical criteria in the diagnosis and treatment of various pathologies.

ADA, in its publication in 2016 [18], proposes the following general recommendations for the management of patients with diabetes:

1. Offer pre-conception advice that covers the importance of glycemia control as normally and safely as possible; ideally A1c should be <6.5% with the object of reducing the risk of congenital anomalies. For the area of pregnancy in the peri-conception period and an adequate prenatal control, the gynecologist and obstetrician should recommend to the woman with pregestational type 1 and type 2 diabetes, fasting glucose levels ≤90 mg/dL (5.0 mmol/L), in the first postprandial hour ≤130–140 mg/dL (7.2–7.8 mmol/L), and at 2 h postprandial ≤120 mg/dL (6.7 mmol/L).
2. Family planning is an obligatory subject, prescribing a safe, efficient anti-conceptive method until the woman is prepared and ready to be pregnant.

Table 65.5 Pregestational and antenatal care in women with pre-existing diabetes

Pregestational
Prophylactic folic acid 3–5 mg a day
Optimization of glucose levels
Retina examination
Urine examination in search of albuminuria
Blood pressure control in the case of hypertension
Advice regarding the increase in the incidence of fetal morphological malformations and increase in the risk of severe hypoglycemia events during the first trimester of gestation
Antenatal
Adequate glucose control during pregnancy
Advice for optimum weight gain during the pregnancy, based on the mother's body mass index
Ultrasound examination in search of fetal malformations between weeks 12 and 14 and around 20 weeks
Evaluation of fetal growth (cephalic and abdominal circumference) every 4 weeks after 20 weeks and every 2 weeks after 28 weeks. Determinations of amniotic fluid
Advice on the incidence of fetal movement (perceived by the mother)
Determination of the time and birth type based on gestational age, glucose control, and estimated fetal weight

Table 65.6 Therapeutic goals in the management of GD in Mexico

Fasting glucose	60–90 mg/dL (3.3–5 mmol/L)
1 h postprandial	≤140 mg/dL (7.7 mmol/L)
2 h postprandial	≤120 mg/dL (6.6 mmol/L)
If fetal growth is equal to or greater than the 90 percentile, glycemia goals will be more strict:	
Fasting	≤80 mg/dL (4.4 mmol/L)
2 h postprandial	≤110 mg/dL (6.1 mmol/L)

Table 65.7 Dietary portions in relation to the body mass index (BMI)

Caloric portion	BMI
36–40 kcal/kg of current weight	<19.8
30 kcal/kg of current weight	19.8–26
24 kcal/kg of current weight	26–29
And should be personalized	>29

Of the total kilocalories, 40 m to 45% should correspond to carbohydrates, 20–25% proteins, and 40% or less fats, of which less than 10% should be saturated fats

3. Women with pre-existing type 1 or type 2 diabetes who plan to get pregnant or are pregnant should be advised of the risk of developing and/or the progression of diabetic retinopathy. Vision examinations before the pregnancy or in the first trimester of gestation, then every trimester, every year after the birth, and as suggested by the specialist according to the degree of retinopathy.
4. Change in lifestyle is an essential component in the management of GD and can be the first pattern for treatment.
5. Medications should be added if necessary with the goal of reaching glycemic objectives. The pharmaceuticals broadly accepted in GD are insulin and metformin; glyburide can be used, but it has a higher rate of neonatal hypoglycemia and macrosomia compared with insulin or metformin. Other agents have not been adequately studied. The majority of the oral agents cross the placenta, and all lack long-term safety data.
6. The change in lifestyle means reducing to a minimum the sedentary lifestyle and promoting adequate diet. It is of vital importance to have nutritional counseling for the patient with pre-existing diabetes or diabetes which is manifested during pregnancy, since in the majority of cases it can be sufficient to reach adequate control of glucose levels. Nutritional counseling is not exclusive to a nutritionist, since from the first office visit the doctor or prenatal nurse can orient the pregnant patient, whether or not she has diabetes. And when conditions allow it, every pregnant patient with diabetes or risk factors should be referred to a nutritionist. The recommended dietary portions are the following (Table 65.7).

Insulin

Insulin does not cross the placental barrier and has been, for many decades, the basis of treatment for glycemic control in pregnant women, and it has the consensus of various international organizations such as the American College of Obstetricians and Gynecologists (ACGO), the American Diabetes Association (ADA), and the Food and Drug Administration (FDA). It is the pharmacological intervention of first choice in GD, accepted by various organizations and countries. The insulins approved for use during pregnancy are immediate and rapid (INPH and IR), along with short-action analogues such as lispro and aspart. Not approved for use during pregnancy are long-term insulin analogues such as glargine and determir. Insulin schema may be somewhat complex to indicate to the patient, and the success of their administration depends on various factors, among them the ability of the patient and skill given before application. The total dose may vary from patient to patient, which is calculated by kilo of weight per day; if the patient is thin 0.1–0.3 IU per kilo of weight per day is considered, and if obese 0.4–0.7 IU per kilo of weight per day. At the start of pharmacotherapy, it is important to start with lower dosage, in order to avoid unexpected hypoglycemia. One common strategy for dosing consists in dividing the total dose into two applications in which 2/3 will be applied in the morning before breakfast and 1/3 before dinner. IR is added when the therapeutic goal of postprandial glycemia is not reached, in which case the morning 2/3 dose would be INPH and 1/3 rapid action, and at dinner it would be ½ INPH and ½ rapid action. This schema can be adjusted with dosage up to 1.5 IU/Kg of weight/day, according to the evolution of the patient and the time of gestation, since in the second and third trimester a greater need for insulin is expected due to the resistance found in this stage of pregnancy [19].

The Use of Oral Hypoglycemic Drugs in Pregnancy

In the United States, oral hypoglycemic drugs have not been specifically approved by the FDA for treatment in GD. However, in the last decade there has been growing scientific evidence in favor of oral hypoglycemic drugs, which, compared with insulin, have the advantage of not requiring multiple injections and therefore fewer events of hypoglycemia, as well as a lower cost. Their use during pregnancy is increasing, above all in women with GD and pre-existing T2D, and especially in women with excess weight. Glyburide and metformin are within group B of the FDA as medications for use during pregnancy. This means that reproduction studies in animals have not demonstrated risks to the fetus. There are no studies in pregnancies, but their use has been

approved in pregnancy. Before prescribing any oral hypoglycemic drugs, one should remember that they cross the fetal placental barrier and, although no adverse effects to the fetus have been reported, long-term studies are scarce. Therefore, we will concentrate on the details of only two oral antidiabetics: glyburide and metformin.

Glyburide

Glyburide is a potent anti-diabetic agent belonging to the second generation of sulfonylureas and also known as glybenclamide. Its hypoglycemic drugs action is due to stimulation of beta cells in the pancreatic islets that cause an increase in the secretion of insulin. Also considered a secretagogue, it is absorbed orally and does not depend on food; it is metabolized in the liver and reaches maximum concentrations in approximately 3 h, with a half-life of 8 h. Sulfonylureas join the receptors in the ATP-dependent potassium channels, reducing the passage of potassium and producing depolarization of the membrane. This depolarization stimulates the entry of calcium through the calcium channels, increasing intracellular calcium concentrations, which in turn induces the secretion and/or exocytosis of insulin. For this drug to be effective, it requires a minimum number of viable beta cells. Prolonged administration of glyburide also causes extra-pancreatic effects that contribute to its hypoglycemic drugs activity, such as reduction of hepatic glucose production and improved insulin sensitivity in peripheral tissues, the latter due to an increase in the number of insulin receptors and more efficient union of insulin with its receptor. Glyburide reduces the circulating levels of glucose by 20% and is most efficient in patients with normal weight or slight overweight. It was the first oral hypoglycemic drugs tested and used prospectively to manage GD, and its effectiveness is similar to insulin. In comparison with insulin, it is less likely to experience maternal hypoglycemia, and only 1–15% experience symptomatic hypoglycemia. The most common side effects are at the gastrointestinal level, and include slight nausea, epigastric burning, or the sensation of fullness; dermatological ones such as a slight itch or rash and increasement in hepatic function tests that are rarely associated with icterus. The current recommended dosage is 2.5–5 mg a day or twice a day, with a maximum dose of 20 mg. Its use is not recommended if the patient is lactating, although this is not an indication for suspending lactation since lactation at the maternal breast has many benefits for both fetus and mother [20].

Metformin

This is a biguanide that has the effect of reducing insulin sensitivity. Like glyburide, metformin and other biguanides require residual function of the pancreatic β cells in order to be effective. It reduces fasting and postprandial glucose. It acts through three mechanisms: (1) it reduces hepatic production of glucose by inhibiting gluconeogenesis and glycogenolysis, (2) in muscle it increases insulin sensitivity and improves the capture of peripheral glucose, as well as its use, and (3) it delays intestinal absorption of glucose. It does not stimulate insulin secretion, so it does not provoke hypoglycemia. It is used alone or in combination with glybenclamide or with insulin. The dose is 1000–2000 mg a day, divided into two doses with food or after it. The commonly reported side effects are nausea, vomiting, and increase in intestinal movement. Its widespread use in women with pregestational diabetes, with polycystic ovary syndrome and low fertility, marked the pattern for its use in pregnant patient with diabetes. When metformin use continued into the end of the third trimester, no side effects were observed to mother or fetus associated with its consumption. Recent studies have evaluated glycemic control in women with GD treated with metformin vs. insulin and have demonstrated that metformin is an effective agent for adequate glycemic control; it was also observed that women treated with metformin have less weight gain during pregnancy [21]. Meta-analysis studies have established that metformin has efficacy and safety similar to insulin in terms of neonatal hypoglycemia; the frequency of products with higher weight for gestational age, newborn entry into phototherapy, respiratory stress syndrome, and perinatal death. Metformin is safe in regard to incidence of peaks in hypoglycemia. However, it is necessary to state that there is a need for additional studies, with greater sample sizes that evaluate the long-term effect on children born to women with GD treated with metformin [22, 23]. Metformin is excreted in human mother's milk. No adverse effects have been observed in newborns or breastfed babies. However, as there is only limited data available, breastfeeding is not recommended during treatment with metformin. Each individual case should be decided as to interruption of breastfeeding, taking into account that the benefits of maternal breastfeeding are greater compared with the potential risk of adverse effects in the breastfed.

Management of Pregnancy

To date there is no consensus regarding how to solve pregnancy of the patient with diabetes, and most is based on recommendations and points of good practice. Every patient with GD should be referred for its control and treatment from the moment this diagnosis is known, to a second or third level hospital that has a multidisciplinary team that includes the services of obstetrics, perinatology, endocrinology, nutrition and diet, social work, psychology, etc. Structural ultrasound should be performed between weeks 18 and 22, to discard

fetal malformations, and series of ultrasounds every 4 weeks with measurement of fetal abdominal perimeter at the start of the third trimester to identify fetuses with greater risk of macrosomia. At week 32 of gestation cardiotocographic tests should start without stress once a week and increase to twice a week from week 36. There should be evaluations by ultrasound of amniotic fluid levels, estimated weight, and fetal abdominal perimeter. There is no evidence-based medication regarding the decision to induce labor or keep waiting, but this is a decision that worries the obstetrician since in these patients there is a higher rate of intrauterine fetal death and higher risk of shoulder dystocia associated with fetal macrosomia. In addition, the fetus may have greater weight for gestational age, situation that can cause confusion at the time of deciding the time for interruption and conditions a premature birth that has hyaline membrane and respiratory stress. These patients have four times more mortality compared with nondiabetic pregnancy. Scheduling the birth by cesarean to avoid obstetric trauma is normally offered to patients with GD in order to prevent cases of obstetric trauma in newborns with macrosomia. Induced labor at term may have a success rate of 80%, but with a significantly higher rate of cesareans compared with uncomplicated pregnancies. Studies recommend the induction of labor at 39 weeks of gestation for women with glucose levels controlled with insulin or oral hypoglycemic drugs [24, 25]. During labor in patients with pre-existing or gestational diabetes, glucose levels should be monitored and maintained at a range between 70 and 110 mg/dL (3.6–6.1 mm/L), ranges that are recommended by ACOG and the American College of Endocrinology (ACE) [26], since high levels of glucose during labor have been associated with a greater risk of neonatal hypoglycemia. Achieving this goal requires glucose intravenous solutions and continuous insulin infusions or else rapid action insulin previous to capillary glucose medication. The demands for glucose as a source of energy increase during labor, contrary to the many institutions that restrict caloric consumption due to the risk of maternal aspiration. Women with T1D require glucose supplements to maintain adequate blood values in order to reduce cetoacidosis. Women with T2D and GD may have sufficient reserves of glycogen to maintain glucose levels around 70 mg/dL, during the latent phase of labor, without the need for glucose supplementation. However, glucose requirements increase during the prolonged induction of labor, active labor, and during the expulsion phase. Neonate should be monitored regarding hypoglycemia, hypocalcemia, and hyperbilirubinemia. In the post-labor phase, women should be able to restart normal diet. After birth, the hyperglycemic effects of placental hormones quickly disappear and plasma glucose levels return to normal, but it is recommended to test glucose concentrations for the first 24–72 h with capillary glucose to exclude persistent hyperglycemia in the post-birth period. Women with a background of GD should have follow-up for the next 6–12 weeks' post-birth with a glucose tolerance test to discard diabetes or carbohydrate intolerance, since it is estimated that 70% of these women have a risk of developing T2D up to 10 years later [27]. Maternal breastfeeding alone the first 6 months and complementary until 2 years offers benefits that prolong the effects of intrauterine hyperglycemic environment in newborns and infants of mothers with obesity or diabetes; likewise, it has benefits in maternal glucose metabolism that prevents or delays the establishment of metabolic syndrome or T2D [28, 29].

Conclusions

Women in whom GD is diagnosed should be treated with nutrition therapy and, when necessary, medication for both fetal and maternal benefit. Insulin and oral antidiabetics have equivalent in efficacy, and either can be an appropriate first-line therapy in GD. During the first trimester of gestation all pregnant women should be screened for GD, whether by the patients medical history, clinical risk factors, or laboratory screening test results to determine blood glucose levels. Women with GD should be counseled regarding the option of scheduled cesarean delivery when the estimated fetal weight is 4500 g or more. Women with GD with good glycemic control and no other complications can be managed expectantly. In most cases, women with good glycemic control who are receiving medical therapy do not require delivery before 39 weeks of gestation. Postpartum screening at 6–12 weeks is recommended for all women who had GD to identify women with T2D, impaired fasting glucose, or glucose tolerance test repeat testing at least every 3 years.

Multiple-Choice Questions

1. Gestational diabetes is defined as:
   (a) The lipid metabolism disorder during all of pregnancy.
   (b) **Carbohydrate metabolism alteration first diagnosed in the second or third trimester of gestation.**
   (c) Amino acid metabolism alteration after the second half of pregnancy.
   (d) Carbohydrate metabolism alteration first diagnosed in the first or second trimester of gestation.
   (e) Carbohydrate metabolism alteration first diagnosed in the third trimester of gestation.
2. The growing index of obesity is a global problem; bad dietary habits and sedentary lifestyle are the main factors unleashing the development of GD.
   (a) False.
   (b) **True.**
   (c) Only obesity is a factor.

(d) Only bad dietary habits.
(e) Only a sedentary lifestyle.

3. What percentage of pregnancies are complicated by diabetes?
   (a) **6–7%**
   (b) 50%
   (c) 1%
   (d) 90%
   (e) 20%
4. In GD, it is known that there is a risk factor related to ethnicity. Which populations are most susceptible to suffering GD?
   (a) **Hispanics, Afro-Americans, Native Americans, Asians and Pacific Islanders.**
   (b) Nordics and Africans.
   (c) Asians, French and Russians.
   (d) Muslims.
5. The following is true in regard to the classification of diabetes, as published by ADA 2016.
   (a) Type 1 diabetes (T1D) is secondary to the destruction of the beta cells of the pancreas and leads to absolute insulin deficiency.
   (b) Type 2 diabetes (T2D) is due to a progressive loss of insulin secretion.
   (c) GD is diabetes diagnosed in the second or third trimester of pregnancy which is not a clearly manifested diabetes.
   (d) Specific diabetes is due to other causes, such as monogenic diabetes syndrome (such as neonatal appearance diabetes and in youths—MODY), diseases of exocrine pancreas (such as cystic fibrosis), and diabetes induced by chemical products (use of glucocorticoids after transplant or drugs for HIV/AIDS).
   (e) **All of the above.**
6. Are risk factors for developing GD?
   (a) Age under 25 years, weight below normal, family history of breast cancer.
   (b) Age over 35 years, history of stillbirth and sterility.
   (c) **Age over 25 years, weight above normal, first-degree family history of diabetes, background of glucose intolerance, history of adverse obstetric events such as stillbirth, prematurity or macrosomies and belonging to ethno-racial groups at high risk for diabetes (Hispano-Americans).**
   (d) Background of previous pregnancies with fetal microsomia.
   (e) Background of previous births with intrauterine death.
7. What percentage of women that suffer GD develop type 2 diabetes in a lapse of no more than 10 years?
   (a) **15–50%**
   (b) 1%
   (c) 0%
   (d) 100%
   (e) 3%
8. Diagnosis criteria for GD during a glucose tolerance test with 75 g of glucose dissolved in water of the IADPSG 2010:
   (a) Fasting glucose equal or greater than 200 mg/dL (5.1 mmol/L), glucose at the first hour equal or greater than 180 mg/dL (10.0 mmol/L), glucose at 2 h equal or greater than 153 mg/dL (8.5 mmol/L), one or more of these values to establish diagnosis.
   (b) **Fasting glucose equal or greater than 92 mg/dL (5.1 mmol/L), glucose at 1 h equal or greater than 180 mg/dL (10.0 mmol/L), glucose at 2 h equal or greater than 153 mg/dL (8.5 mmol/L), one or more of these values to establish the diagnosis.**
   (c) Fasting glucose equal or greater than 300 mg/dL (5.1 mmol/L), glucose at 1 h equal or greater than 180 mg/dL (10.0 mmol/L), glucose at 2 h equal or greater than 153 mg/dL (8.5 mmol/L), one or more of these values to establish diagnosis.
   (d) Fasting glucose equal or greater than 400 mg/dL (5.1 mmol/L), glucose at 1 h equal or greater than 180 mg/dL (10.0 mmol/L), glucose at 2 h equal or greater than 153 mg/dL (8.5 mmol/L), one or more of these values to establish diagnosis.
   (e) Fasting glucose equal or greater than 500 mg/dL (5.1 mmol/L), glucose at 1 h equal or greater than 180 mg/dL (10.0 mmol/L), glucose at 2 h equal or greater than 153 mg/dL (8.5 mmol/L), one or more of these values to establish diagnosis.
9. The insulin dose for GD is:
   (a) **The total dose may vary from patient to patient, which is calculated for kilo of weight per day; if the patient is thin use 0.1–0.3 IU per kilo of weight per day and if obese, 0.4–0.7 IU per kilo of weight per day.**
   (b) The total dose may vary from patient to patient, which is calculated for kilo of weight per day; if the patient is thin use 1–2 IU per kilo of weight per day and if obese, 0.4–0.7 IU per kilo of weight per day.
   (c) The total dose may vary from patient to patient, which is calculated for kilo of weight per day; if the patient is thin use 0.1–0.3 IU per kilo of weight per day and if obese, 1–2 IU per kilo of weight per day.
   (d) The total dose may vary from patient to patient, which is calculated for kilo of weight per day; if the patient is thin use 3 IU per kilo of weight per day and if obese, 4 IU per kilo of weight per day.
   (e) The total dose may vary from patient to patient, which is calculated for kilo of weight per day; if the patient is thin use 5 IU per kilo of weight per day and if obese, 3 IU per kilo of weight per day.

10. Of oral hypoglycemic drugs, the following is false:
    (a) In the last decade, there is growing scientific evidence in favor of oral hypoglycemic drugs to manage GD, which in comparison with insulin have the advantage of not requiring multiple injections; there are fewer events of hypoglycemia and the cost is lower.
    (b) Glyburide is a potent anti-diabetic agent belonging to a second generation of sulfonylureas and also known as glybenclamide. It is a biguanide that reduces insulin sensitivity.
    (c) Like glyburide, metformin and other biguanides require residual function of the beta cells of the pancreas to be effective in managing GD and T2D.
    (d) The current recommended dose of glyburide is 2.5–5 mg a day or twice a day, with a maximum dose of 20 mg. The recommended dose of metformin is 1000–2000 mg a day, divided into two doses with food or after same.
    (e) **No oral hypoglycemic drugs should be used in treating GD.**

Glossary

ACOG The American College of Obstetricians and Gynecologists.

ADA The American Diabetes Association.

BMI is the result of dividing the weight of a person in kilograms by the square of his height in meters.

Congenital malformations are anatomic alterations that occur in the intrauterine stage and may be alterations in organs, extremities, or systems, due to environmental, genetic factors, deficiencies in nutrient capture, or consumption of noxious substances.

ENSANUT 2012 National health and nutrition survey 2012 (Mexico).

FDA The Food and Drug Administration.

Fetal macrosomia Traditionally, fetal macrosomia has been defined as arbitrary weight at birth, such as 4000, 4100, 4500, or 4536 g. It is currently defined as a fetus that is large for gestational age (>90 percentile).

GD Gestational diabetes, which is defined as alteration in carbohydrate metabolism diagnosed for the first time in the second or third trimester of gestation.

HAPO Study Hyperglycemia and Adverse Pregnancy Outcomes study.

IADPSG The International Association of Diabetes in Pregnancy Study Groups.

Insulin From the Latin "isla." It is a polypeptide hormone formed by 51 amino acids, produced and secreted by the beta cells of the Isles of Langerhans of the pancreas. Discovered by Frederick Grant Banting, Charles Best, James Collip, and J.J.R. Macleod of the University of Toronto, Canada, in 1921.

NIH National Institutes of Health.

Obesity Obesity and overweight are defined as abnormal or excessive accumulation of fat that may prejudice health. A simple way to measure obesity is the body mass index (BMI), which is the weight of a person divided by height in meters squared. A person with BMI equal or above 30 is considered obese and with a BMI equal or greater than 25 is considered overweight.

Oral hypoglycemic drugs Anti-diabetes drugs which are classified as sulfonylureas, biguanides, alpha-glucosidase inhibitors, meglytinids (Repaglinide, Nateglinide), and thiazolidinediones.

Perinatal mortality is the fetus and newborn risk of dying as a consequence of the reproductive process.

Premature birth According to WHO, birth that occurs after week 20 and before 37 complete weeks.

T1D Type 1 diabetes, which is secondary to the destruction of the beta cells of the pancreas, and in general leads to absolute insulin deficiency.

T2D Type 2 diabetes, which is due to a progressive loss of insulin secretion.

WHO World Health Organization.

Women of reproductive age Women between 15 and 44 years.

The Elderly with Diabetes

66

Willy Marcos Valencia

Diabetes in Older Adults

Diabetes is chronic and progressive, with increasing prevalence in older age groups [1]. Moreover, with longer disease duration, there is greater risk to develop its complications. In parallel, aging itself increases the risk for age-related or age-dependent chronic diseases, such as cardiovascular [2], cancer [3], depression [4], dementia [5], and frailty (increased vulnerability and poor health outcomes) [6]. Ultimately, the scenario of diabetes in the older adult is more complex and complicated than in younger age groups, with heterogeneous presentations at the real clinic setting, even for subjects of the same age and similar comorbidities [7].

There will be two billion people older than 60 by the year 2050, from which 434 million will be older than 80, and about 1 out of 4 will have diabetes [8]. Therefore, we need to increase our understanding and dissemination toward better, safer, effective, and efficient approaches to this group.

To accomplish this goal, it is necessary to enhance the understanding of diabetes and aging in the older population. Figure 66.1 offers a magnified visual perspective, aiming to summarize the multiple factors that ought to be considered when evaluating an older patient with diabetes.

Geriatric Considerations in the Management of Diabetes in the Older Adult

The guidelines from the American Diabetes Association (ADA, Chap. 11) [14] provide multiple recommendations and considerations to expand the approach to diabetes especially for this age group. Notably, this approach was built upon a consensus by experts from both the ADA and the American Geriatrics Society (AGS) [15]. What might be the most valuable contribution is the framework to stratify patients according to their health status and disease burden (summarized in the form of a table), which was then adopted by the ADA guidelines.

The framework (presented as a table) provides clinicians with a practical framework how to stratify their patients, and from there, individualize targets and therapies. This approach offers a tool to disseminate the need for individualization of targets and therapies based on factors that go beyond the presence of macrovascular complications.

Nevertheless, while there can be other suggested approaches, including those for specific settings such as long-term care [16], we recommend clinicians to take advantage from this framework, especially intended to those teams without formal training in geriatrics.

The approach stratifies patients in three settings. A reasonable approach to present this information would be as follows:

The healthy older adult: As long as there are no major multiple and/or life-threatening diseases, and in the absence of functional or cognitive deficit, these older adults could potentially benefit from approaches similar to those of younger age. We recommend considering factors such as life expectancy, in addition to patient-centered discussions for preferences and feasibility of implementing escalating strategies to achieve the desired targets. As with everything in geriatrics, the principle of "start low, and go slow" will also apply in this setting. On the other hand, having such patient with uncontrolled diabetes and not providing further interventions would be consistent with clinical inertia, which can also be observed in this population.

The older adult with severely complex health scenario: This is the third situation, in which older patients are enduring multiple severe chronic diseases, with impairment in physical function (activities of daily living) and memory disorders. Many are already in long-term care, or palliative care, or are eligible for those services.

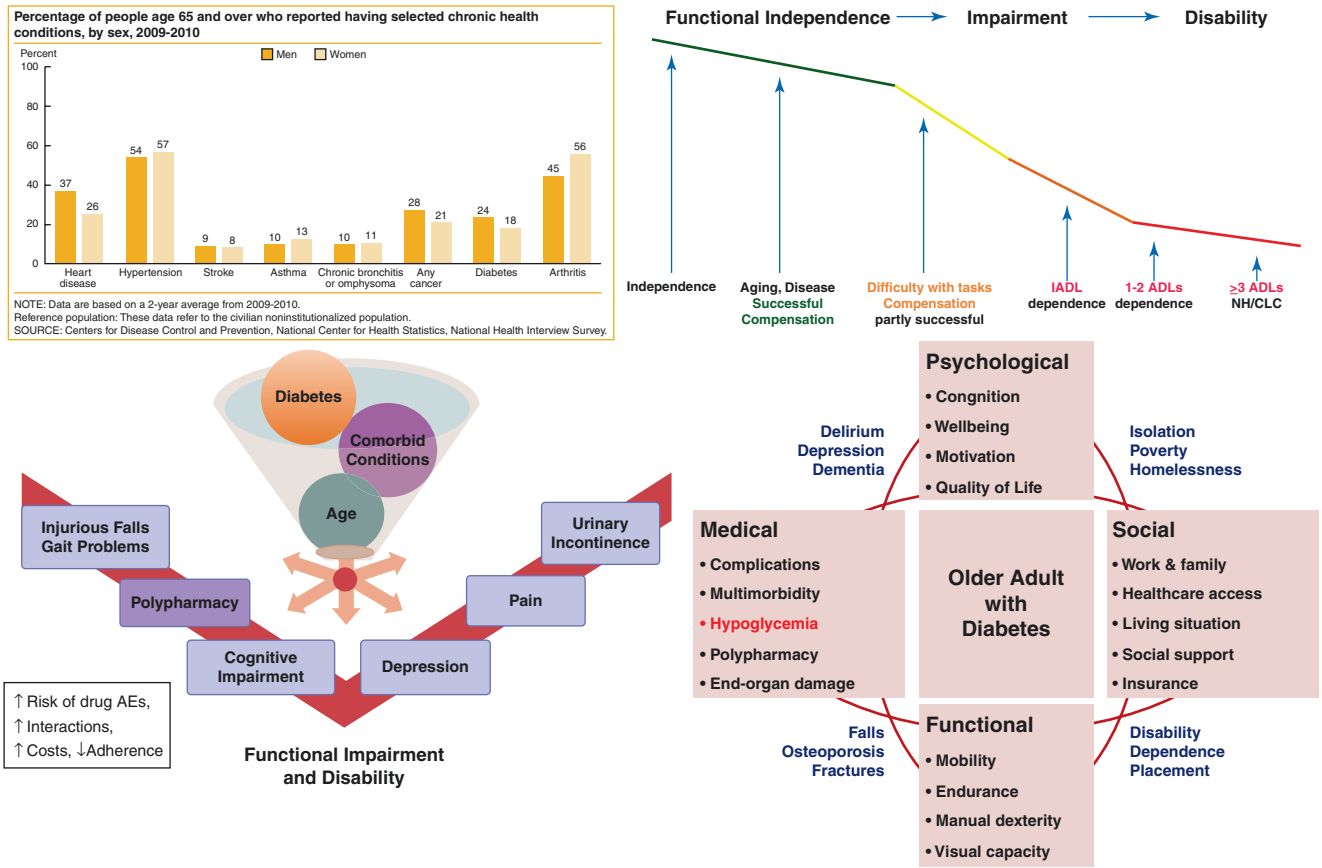

Fig. 66.1 A geriatrics approach to understanding diabetes in the older adult. On the left upper corner, the prevalence of chronic diseases increases in the older population [9]. Beyond the traditional diabetes-related complications, older adults with diabetes will also have a variety of multiple other chronic diseases, increasing their pharmacologic needs and regimens, the risk for drug-to-drug and drug-to-disease interactions. Thus, their diabetes care will start at a higher level of burden, complexity, and impact to their lives. On the right upper corner, a simplified yet powerful depiction on how function changes, and declines, throughout the lifespan of a person (slide courtesy of Hermes Florez, based on literature from Verbrugge et al. [10]). Younger patients will usually be considered as independent and able to compensate for the disease burden (granted there will be a spectrum of reactions). In this setting, providers would usually give for granted the young patients' ability to take care of themselves. On the other hand, with accumulating/worsening chronic diseases, all human beings go through an aging process that culminates with certain death. Excluding those who may suffer an acute fatal event (e.g., sudden cardiac death or accidents), the rest will go through a progressive course of functional decline (some earlier, other later). Clinicians must recognize that these processes are very heterogeneous, and for those unable to compensate, there will be a loss of the ability to carry the instrumental activities of daily living (or IADLs), which include managing medications. On the left lower corner, the additive effects of diabetes, aging, and multimorbidity can be associated with a variety of geriatric syndromes, further increasing the risk for progressive functional decline and disability (slide courtesy of Hermes Florez, based on literature from Laiteerapong et al. [11]). Hence, considering the physical/mental decline, in the setting of multiple diseases and complex regimens, the negative consequences also include greater risks for adverse complications (e.g., hypoglycemia), poor quality of life, and increased social and economic burden [12]. Finally, on the right lower corner, a previously presented visual summary of our geriatrics approach to the older adult with diabetes [7]. The four geriatric domains are intertwined, especially in the setting of this chronic disease, causing complications of its own (within the medical domain), and also interacting with the functional, mental/psychological, and social domains. The arrows go in both directions. From one side, diabetes fosters new medical issues (e.g., diabetes leading to depression leading to poor motivation and poor quality of life), and on the other direction, situations that hinder diabetes management (e.g., poor family support leading to social isolation leading to poor diabetes control). In summary, the clinical scenario of an older adult with diabetes, and multimorbidity, impaired physical and cognitive function (both a consequence from diabetes itself, or associated with age-related diseases), will have implications and consequences for diabetes self-management and self-efficacy, quality of life, and increasing vulnerability [13]. Hence, the need to implement strategies that can counter the challenges, while adjusting therapeutic targets and interventions. To do so, provider caring for older adults with diabetes will benefit from gaining insights to the "geriatrics field"

Then, the scenario in between, defined for older patients with chronic diseases but still independent, without severe physical or cognitive dysfunction, and preserved activities of daily living, but might have issues with instrumental activities of daily living (which include management of medications).

One of the most striking points from this framework is that geriatric syndromes (falls and urinary incontinence) are determinant factors and need to be incorporated in the assessment and plan. Note that clinicians need not become Geriatricians, but rather incorporate some geriatric approaches to the care of older patients with diabetes.

Geriatric Syndromes and Assessments for Older Patients with Diabetes

In order to effectively apply the framework from ADA/AGS as discussed in the prior section, we need to expand the description of geriatric syndromes and the comprehensive geriatrics assessment. Noteworthy, addressing, assessing, and incorporating these factors into the care of an older patient with diabetes will be feasible to conduct, even at a busy clinic setting.

As previously established, older age and the aging process lead to greater risk for developing chronic medical diseases, functional and cognitive decline, and then, the geriatric syndromes. These geriatric syndromes, while being syndromes, can have multifactorial etiologies, but usually share common risk factors and pathophysiologic mechanisms. Screening and detection is a key factor for management, even if the final diagnosis is not ultimately defined [17].

Considering the setting of diabetes, we can map them all to the heightened burden produced by long-standing disease, especially if complications presented. The geriatric syndromes include polypharmacy, urinary incontinence, impaired mobility, falls, frailty, persistent pain, cognitive impairment, and depression, and they add further complexity to older patient with diabetes [17–19]. Progression in these syndromes lead to poor quality of life and loss of independence, a situation where patients will require assistance to care for themselves, and even transition to institutionalization of different types (assisted living facilities, community living centers, or nursing homes).

The connection between diabetes and geriatric syndromes has been described. For example, a French study of 987 older patients (age ≥ 70) with diabetes found that both macrovascular [20] and microvascular [21] complications were associated with cognitive function, nutritional risk, and evidence for self-care deficit. The authors highlighted the multiple and potential bidirectional pathways between cardiovascular disease and geriatric syndromes.

Table 66.1 presents a distribution of geriatric syndromes within each of the four geriatric domains. This operationalization is solely for practical purposes, since in reality, there will be significant overlap (one syndrome connected to more than one domain), related to pathophysiology and outcomes.

Table 66.1 Geriatric syndromes within the four geriatric domains

Medical	Functional	Psychological	Social
Polypharmacy	Impaired mobility	Dementia	Social isolation
Multimorbidity	Falls	Depression	Homelessness
Malnutrition	Urinary incontinence	Poor quality of life	Food insecurity
	Frailty		
	Self-care deficit		

Medical Domain

Polypharmacy: There are several ways to define polypharmacy (based on the total number of medications, the number of medications for one condition and the use of medications that are not justified by benefits over risks) [22]. However, it is easy to understand how an older person with diabetes and diabetes-associated complications will likely meet the first two definitions, just by following the standard-of-care treatment [23]. The issue is that as these medications accumulate, polypharmacy leads to increased costs and non-adherence [24], and non-adherence leads to uncontrolled glycemic control. Moreover, increased economic costs lead to mental preoccupation/anxiety as well as socioeconomic burden.

Each visit is an opportunity to review the medication profile, and ensure (1) patient knowledge and justification for each medication, (2) advise against non-required over the counter, and (3) promptly adjust therapeutic interventions, striving to reduce medications when there is no certainty that the benefits outweigh the risks. Moreover, the patient can be further engaged in self-management as improvements in lifestyle could be clinically significant enough and warrant fewer medications, ultimately improving diabetes and patient-centered goals.

Unfortunately, polypharmacy will be quite prevalent in the older population with diabetes, and will often be related to other geriatric syndromes such as falls [25, 26], which will be further reviewed in a subsequent section. Additionally, a vast majority of older patients with diabetes will have an indication for an antihypertensive medication, with indications ranging from primary/secondary prevention of diabetic nephropathy in normotensive patients, all the way to established hypertension, heart disease, and others. The key factor will be to ensure the patients do not have orthostatic hypotension, and to adjust pharmacologic therapies accordingly. Most notably, these changes can greatly benefit the patient. Decreasing psychotropic agents and polypharmacy reduces the risk for falls [27, 28].

Multimorbidity: The accumulation of multiple chronic diseases is a common scenario in the older patient [29], but not always associated with non-disease-based physical limitations [30]. Hence, their presentation and impact is highly variable, leading to different health status, between individuals, and over time. Most notably, different older persons with similar conditions may present with different clinical status.

Researchers have modeled the disease clusters from 750 aging patients, and found that older patients with established cardiovascular disease and highest burden of comorbidities (≥6 per their study) will benefit less from intensive regimens [31]. From our standpoint, we agree with this concept, consistent with the different strata presented in the ADA/AGS framework, but emphasize that the "paper can be deceiving." Before meeting a new patient, most clinicians review the clinical information available in medical records, and we have found a very heterogeneous presentation of health status, beyond the records, based on physical and cognitive function. Notwithstanding, chronic medical conditions might impact daily functioning and health-related quality of life (HRQOL). Older adults with longer disease duration, or uncontrolled disease, with complications, will be at greater risk for impaired daily functioning and poor HRQOL.

Nutritional Status: While this is not a geriatric syndrome per se, we need to unveil, even if only briefly, the associated syndromes of frailty with sarcopenic obesity. Diabetes is associated with obesity as we age [32]. Many older patients with diabetes, as they age, and as they develop functional impairment due to the diabetes and its complications and other age-related problems, then remain with increased weight, but endure changes in body composition, with loss of lean mass. Obesity itself affects all four geriatric domains, and if left untreated, leads to a vicious cycle of progressive deterioration of physical activity, function, worsening of diseases, further weight gain, and further worsening of this "setting" [33]. Consequently, the success on diabetes management will be challenged by the persistence of such negative scenarios in the geriatric population.

Malnutrition

On the other hand, despite the obesity epidemic and the clear relationship between obesity, insulin resistance, and diabetes, the proportion of malnutrition risk is similar in subjects with diabetes than in others in the community [34] and in hospital [35]. In other words, older patients with obesity may suffer from macro- and micronutrient deficiency. Moreover, in connection to the aging process and concomitant chronic diseases, the risks for malnutrition are greater in this age group. It has even been shown that diabetes in stroke patients is a risk factor for malnutrition, probably due to dietary restriction and higher rate of dysphagia [36]. Thus, oral health and swallowing capacities must be checked. Particularly, oral candidiasis must be searched and treated and patient referred to dentist surgeon. Nutritional interventions and lifestyle changes need to be adapted to individualized nutritional risks.

Functional Domain

Diabetes is associated with early declines in physical function [37]. Hence, older patients with long-standing disease have been exposed to diabetes-related decline, apart from the "expected" age-related decline.

Moreover, dexterity and physical capacity are needed to perform diabetes self-management (for instance, visual loss can impair the ability to read glucose results and inject insulin units). Tools such as the insulin delivery systems, with training for those with visual impairment, can be implemented to allow the person to maintain independence in the management of diabetes.

Within this domain, we assess the geriatric syndromes of falls, impaired mobility, functional decline, vision loss, and hearing loss, which are among the most common geriatric syndromes. More recently, the frailty syndrome continues gaining increasing attention, and the future might have evidence to support that frailty ought to be included in the framework as well as falls and urinary incontinence.

Impaired Mobility

The most common risk factors are older age, low physical activity, strength or balance impairment, and chronic diseases such as obesity, diabetes, and osteoarthritis [38]. Hence, unsurprisingly, mobility impairment is common in older adults. Unfortunately, with diabetes and other diseases sharing mutual risk factors, and in itself, counters the potential for disease prevention. Clinicians need to assess and understand the impact from impaired mobility, dexterity, and function to define the most appropriate plan of care.

Self-Care Deficit and Functional Decline

The assessment of Instrumental Activities of Daily Living (IADLs) [39] explores capacities to live in an autonomous way at home. These activities include shopping, cooking, household cleaning/laundry, telephone use, managing medications, finances, and driving/using public transportation. The inability to carry at least two or more IADLs would place a patient in the second category from the ADA guidelines. Nevertheless, limitations on these IADLs can be supplemented through informal (family/friends) or formal support (e.g., home health nurse to assist with medication management). The assessment of Activities of Daily Living (ADLs) [40] explores the actions to take care of basic needs without help. These include dressing, toileting, bathing, eating, and getting around the home. Limitations in two or more ADLs are consistent with the highest complexity in the ADA

model, and glycemic targets are further increased. These limitations are also consistent with nursing home level of care. However, again, these limitations can be supplemented by formal or informal support, with the main objective to keep the patient at home. Often, structural modifications are helpful.

The dependency in IADLs is mainly associated with cognitive troubles. Particular attention should be given to the capacities to self-manage medications. Care plan can be adjusted based on the outcomes from this assessment. Sensory loss, particularly but not only visual loss, can impact diabetes self-management and self-efficacy. When detected, referral to specialist and subsequent intervention may facilitate the management of diabetes in the older person.

Falls

Due to the strong connection between diabetes and falls, we decided to expand this section. Falls are generally driven by a combination of intrinsic (the person's characteristics) and extrinsic (exogenous, the environment) factors. Falls risk is already increased by age (without diabetes), due to age-related decline in gait, balance, proprioception, and sarcopenia [41, 42]. In addition, there are multiple mechanisms by which diabetes and its complications increase the risk for falls. Diabetes can contribute in several ways to the intrinsic factors, impairing gait (diabetic peripheral polyneuropathy, diabetic peripheral vascular disease and amputations, neuropathic pain), vision (diabetic retinopathy), judgment (dementia in diabetes), balance (autonomic dysfunction), and the combination of impaired judgment and balance (pharmacotherapy and hypoglycemia) [43–47]. Ultimately, the combination of older age and diabetes increases falls risk by 17-fold [42, 48], while the involved diabetes-related factors will have an additive effect and worsen this risk [49].

Falls are terribly under-detected, and it is imperative to understand its definition. A true fall is defined as a person coming to rest inadvertently on a level below their prior location [50]. Falling from a standing position to the ground is not the only scenario. An older patient might try to go from supine to sitting and from sitting to standing, and they might go back to supine or sitting, respectively, and these will qualify as falls too. Even without considering those scenarios (which are severely under-detected) "traditional" falls are more prevalent in older people, and this is the age group at the greatest risk for serious injury or even death [51], constituting a public health problem that is largely preventable [52]. Unfortunately, less than half of providers know that their patients are falling [53]. Furthermore, the quality of bone in diabetes is affected, making them more vulnerable for fragility fractures [54]. Patients receiving insulin therapy are at greater risk for falls (requiring hospitalization) compared to those without diabetes [55]. Additionally, a fall can be the presentation of hypoglycemia, requiring the clinician to purposely inquire about the occurrence of previous falls. It cannot be overstated how important this matter is, especially since it may lead to a life-changing injury [56]. Those at high risk for hypoglycemia should be screened for falls as a routine CGA to be added to the CDE. Then, a comprehensive fall risk assessment may follow if falls occur more than once per year, or if there are issues with gait and balance [57].

Urinary Incontinence

Urinary incontinence is frequent in older people with diabetes. It can worsen quality of life, depression, disability, morbidity, and mortality [58, 59]. Similar to other geriatric syndromes, it is rarely due to a single disease. Older patients with diabetes are exposed to diabetes-related factors, such as uncontrolled diabetes with hyperglycemia, leading to glycosuria, polyuria, and from there, urinary incontinence, which can then become a hazard if the patient has other detrimental ongoing issues, such as impaired mobility, or falls risk. In addition, the pharmacology of Sodium Glucose Co-Transporter 2 inhibitors would increase the risk for urinary incontinence, and also increase the risk for urinary infections, which are also associated with urinary incontinence.

A study of community-dwelling older adults with diabetes identified geriatric factors (e.g., inability to ambulate or transfer independently) as important predictors for urinary incontinence in the setting of diabetes and frailty [60].

The intervention is to inquire about symptoms, incorporate those into the clinical decision making, and refer the patient to the corresponding specialists. Nevertheless, we recommend ensuring that reversible factors are considered, such as glycemic control.

Psychological Domain

Depression, delirium, and dementia are the classic most common geriatric syndromes. Notably, personality disorders and addictions are increasing in prevalence in this age group. In addition, we incorporate the sphere of poor quality of life within this domain.

Dementia

Both obesity and diabetes are recognized as risk factors for cognitive decline [61]. While there is no clear pathophysio-

logic pathway (most likely, it is multifactorial), the epidemiological links between diabetes and dementia are quite strong. The current understanding of cognitive decline and dementia put them closer with diabetes and cardiometabolic dysfunction. Alzheimer's disease is the sixth leading cause of death in the United States and is the fifth leading cause among people aged 65 years and over [62]. Compared to those without diabetes, older adults with diabetes are 50–100% more likely to develop dementia, and the risk is greater with longer diabetes duration, poorer glycemic control, and coexistent chronic vascular complications [63]. Furthermore, as another example of the interconnection between geriatric domains, patients with dementia are at greater risk for falls [64].

Thus, the evaluation of cognitive function in older adults with diabetes is warranted, especially for the oldest and those with longer duration of disease [65]. We would suggest additional interest for those patients who volunteer symptoms of memory dysfunction, or who volunteer having issues managing their pharmacologic interventions for diabetes. Quite often, clinicians are used to developing very accurate and complex insulin regimens, but must realize that as plan of care that is not feasible to be effectively implement, will not be efficacious, and only look good on paper. Hence, understanding the cognitive function of the older patient with diabetes will facilitate strategizing targets and interventions. Notably, an earlier detection and diagnosis of dementia will provide additional benefits and opportunities, such as to address proper resources and support, and increase the understanding by providers and family to start dealing with the dementia disease.

Depression

The incidence of depression in diabetes is double than in the general population [66], and it becomes a greater problem in the older population. This is not only due to diabetes-related issues, such as the impact from diabetic complications [67], but also because of age-related issues, such as advancing age, personal loss of function, loss of friends and family support. Furthermore, depression as a separate disease in and of itself will often require pharmacologic therapy, which will further increase the complexity of the case, and negatively impacts diabetes outcomes, such as glycemic control [68], self-care [69], and greater risk for diabetes complications, creating a vicious cycle. Moreover, a study evaluating a survival analysis between younger and older adults with diabetes (and controlling for covariables) found that depression increased mortality risk in the group aged 65 and older (78% greater than in those without depression), while there was no major difference in the younger group [70].

Poor Quality of Life

Older adults have an increased prevalence of multimorbidity and lower QOL [71]. They also present greater coexistence of diabetes and depression [72], which as discussed, negatively impacts HRQOL, diabetes itself, and its outcomes [73].

The Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial compared intensive versus standard glycemic control. They used SF-36 to evaluate HRQOL and found intensive glycemic control did not lead to QOL benefits (no change) [74].

Social Domain

Elder abuse, social isolation, poverty, lack of family or social support are common scenarios affecting the older person. The social network of people decreases, as family and friends may age and die, or become ill and dependent themselves, so that they are no longer part of the support system. In the general population with diabetes, the economic costs from diabetes are composed of direct (management-related costs) and indirect (work absenteeism, reduced productivity at work and at home, reduced labor force participation from chronic disability, and premature mortality) [75]. In the geriatric older person with diabetes, it is possible that the latter may be less frequent (since many have already retired). However, the costs of management may actually be higher than in younger patients, if we consider the natural history of the disease, which may require a greater number of medications to achieve control, as well as the development of complications and the increase in life expectancy [76–78]. The economic situation can be a major constraint for those who are depending on insurance status and family support, an important resource that could be lacking more in this age group.

Food Insecurity

While it appears that this scenario is gaining more prevalence, it is possible that what has increased is the detection and awareness for this social issue. Food insecurity increases the older patients' vulnerability and risk to develop hypoglycemia. A study reported that patients with limited income have 40% greater risk of having food insecurity and inadequate glucose control [79]. Another study evaluated food insecurity in patients with homelessness, and of those who screened positive and had diabetes, 43.5% reported hypoglycemia symptoms [80].

Table 66.2 Addressing geriatric syndromes in the assessment of older patients with diabetes

Domain	Syndrome	Assessment and intervention
Medical	Polypharmacy	Medication reconciliation at each visit. For each prescription, ask yourself the question: does the patient benefit from this medication (dose, frequency) at this moment?
	Multimorbidity	Older patients are at greater risk for new diseases or complications. A patient could have been in the healthy category by the last visit, but now present after a stroke. Then, his targets and approaches need to be adjusted accordingly
	Malnutrition	Involve the nutritionist team
Functional	Impaired mobility	Consider if the patient has the functional ability to carry the proposed plan of care
	Falls	Ask if the patient has fallen in the past year
		Observe gait and balance while the patient walks into the office
		If these issues are present, the patient has falls risk, refer to the local geriatrician, or falls clinic
		In addition, adjust the glycemic regimen. Avoid hypoglycemia. Avoid regimens with increased risk for hypoglycemia
	Urinary incontinence	Ask if the patient has any issues with urinary incontinence
		Offer referrals to the geriatrician, urologist, gynecologist
		Avoid hyperglycemia
		Consider caution with medications that increase glycosuria
	Frailty	If the patient reports involuntary weight loss, fatigue, weakness, muscle loss, decrease the intensity of the glycemic regimen, avoid hypoglycemia, and refer the patient to a geriatrician
	Self-care deficit	If the patient has ≥2 limitations for IADLs, suggested HbA1c target is between 7.5 and 8%
		If the patient has ≥2 limitations for ADLs, suggested HbA1c target is between 8 and 8.5%
		Ensure the primary care or geriatrician is involved, to facilitate support at home or living situation
		Adjust pharmacologic regimens accordingly. Especially, if the patient has issues with medication management, consider regimens compatible with home health nurse services
	Dementia	Counsel the patient on the potential role for diabetes, but once the dementia disease is established, the priorities shift toward patient safety, avoidance of hypoglycemia
		Refer the patient to the neurologist or geriatrician for further assessment
	Depression	Refer the patient to the geriatric psychiatrist team, aiming to improve depression, as its relationship with glycemic control is bidirectional
	Food insecurity	Adjust glycemic targets, avoiding agents with the highest risk for hypoglycemia. Counsel on strategies to decrease antihyperglycemic medications if eating less and/or losing weight. Refer the patient to the primary care team and social worker team, to address potential community resources

Special Consideration for Diabetes Management in Older Adults

This book offers separate chapters addressing lifestyle, nutrition and exercise, obesity, and pharmacologic interventions. We would emphasize the consideration for modest intentional weight loss as a desirable outcome, as long as it is compatible with the broad comprehensive plan of care for the management of an older patient with diabetes [33]. Exercise interventions in this age group are effective and feasible to implement, providing multiple health benefits beyond diabetes control [81].

Most notably, there are no large randomized clinical trials aiming to prove or disprove the expert-based recommendations (as summarized in this chapter) for the individualized care (targets and strategies) for older adults with diabetes, at different levels of disease burden and health status [82].

Prevention of hypoglycemia is a major priority that should be addressed as soon as detected, through an adjustment of the therapy required to accomplish the established target. Nevertheless, treatment intensification should not be neglected, as macrovascular and microvascular complications should still be prevented in this age group.

Regarding geriatric syndromes, we do not suggest that all practices taking care of diabetes perform a complete geriatrics assessment. First of all, we recommend awareness to this geriatric issues, and then provide a few practical suggestions to address these issues (Table 66.2).

Hypoglycemia in Older Adults: Primary and Secondary Prevention

Hypoglycemia is associated with cognitive impairment, both acute (erratic and irrational behavior, confusion, impaired vision and balance, which can result in falls or accidents) and chronic (leading to dementia) [83]. A prospective cohort study that followed 16,667 patients with diabetes without dementia at study entry found that severe hypoglycemia was associated with greater risk of dementia [84]. However, in

frail, elderly patients with diabetes, avoidance of hypoglycemia, hypotension, and drug interactions due to polypharmacy is of even greater concern [85].

Hypoglycemia events require a clear understanding of their etiology to avoid a recurrence. Details on the history may reveal that the patient accidentally injected the correct dose twice because of forgetting an earlier dose, or that the patient was interrupted during a meal that remained unfinished. In both scenarios, the regimen may remain effective and safe if the events are isolated and conditions do not change. However, recurrent events can be a sign of cognitive decline or early self-care deficits. Regardless of this, glycemic targets need to be adjusted, and further coordination of services (formal or informal) will be required in order to deliver the injectable therapeutic plan and to avoid hypoglycemia.

Secondary Prevention

While one isolated event of hypoglycemia due to a very specific and likely isolated scenario (e.g., patient describes that skipped a meal due to an urgent phone call, which ultimately led to a hypoglycemic event), it is feasible to continue the same regimen, and emphasize education to prevent any future events.

However, if there is evidence for recurrent events, the team needs to address:

- Patient-related factors.
- Modifications to the pharmacologic regimen.
- Reassess glycemic targets.

Primary Prevention

We recommend especial care for those patients at the highest risk (older, on insulin or sulfonylurea, low HbA1c). Considering the potential devastating consequence from even one adverse event (e.g., hypoglycemia leading to a fall, hip fracture, institutionalization, death), we recommend providers to consider strategies to identify patients in whom hypoglycemia has not been present, but who remain at high risk. Our Miami VA team collaborates with the leaders in diabetes care for the Veterans Administration in the USA, fostering the use of electronic tools to detect patients at high risk and avoid overtreatment [86]. While this specific approach might only apply to our healthcare system, the concept could be translated to other healthcare systems.

Pharmacotherapy

Finally, Table 66.3 presents a summary of considerations regarding specific pharmacologic agents and strategies for the management of diabetes in the older patient.

Table 66.3 Special considerations for pharmacologic therapy of diabetes in older adults [7, 14–16, 87]

Order of priority	Pharmacologic agents	Advantages	Disadvantages
Standard first line	Metformin	– No hypoglycemia	– GI side effects are easily countered by always taking with meals
		– Safe and effective	– Risk of vitamin B12 deficiency: monitor and supplement
		– Lowers CV and cancer risk	– The risk for lactic acidosis is actually very low
1	Dipeptidyl-4 inhibitors (Sitagliptin, Vildagliptin, Saxagliptin, Linagliptin, Alogliptin)	– Low hypoglycemia risk	– CV and heart failure risk (saxagliptin)
		– Weight neutral	– Increased upper respiratory infections
		– Safe and effective (especially when aiming for less than strong reductions in HbA1c)	– Expensive
			– Limited long-term data in older adults
1	Sulfonylureas (Glimeperide, Glipizide)	– Effective	– Moderate risk hypoglycemia (glyburide is contraindicated)
		– Long-term experience in this age group	– Weight gain
		– Lower CV risk	– Patients losing weight or doing exercise require close monitoring (increased risk for hypoglycemia)

Table 66.3 (continued)

Order of priority	Pharmacologic agents	Advantages	Disadvantages
1	Sodium Glucose co-transporter 2 inhibitors (Canagliflozin, Empagliflozin, Dapagliflozin, Ertugliflozin)	– Low hypoglycemia risk	– High cost
		– Lower weight	– GU infections and urinary incontinence, especial care is required in this age group
		– Lower systolic blood pressure	– Risk for volume depletion, orthostatic hypotension, possibly falls
		– Improve CV risk/mortality (empagliflozin, canagliflozin), renal (empagliflozin)	– Limited long-term data in older adults
1	Glucagon-like peptide 1 receptor agonists (Exenatide, Liraglutide, Albiglutide, Dulaglutide, Lixisenatide, Semaglutide)	– Low hypoglycemia risk	– High cost
		– Lower weight	– GI side effects
		– Reduce CV risk (liraglutide)	– Risk for acute pancreatitis (exenatide and liraglutide)
		– Convenient formulation (daily or weekly)	– Risk for acute kidney injury (exenatide)
2	Long-acting insulin (Glargine, Detemir, Degludec)	– Effective	– Hypoglycemia risk
		– Long-term experience in this age group	– Weight gain
2	GLP-1RA and insulin fixed combinations (insulin glargine + lixisenatide, insulin degludec + liraglutide)	– Effective	– Moderate hypoglycemia risk
		– Convenient formulation (daily or qod)	– High cost
			– Not applicable to all subjects (e.g., not for those who require high dosages)
3	Alpha-glucosidase inhibitors (Acarbose, Miglitol)	– Mild to moderate hypoglycemia risk	– Frequent dosing schedule
		– Effective (especially when aiming for less than strong reductions in HbA1c)	– GI side effects might not be countered easily
			– Contraindication with chronic renal failure (miglitol)
3	Thiazolidinediones (Pioglitazone)	– Low hypoglycemia risk	– Suspected CV risk, heart failure exacerbation
		– Convenient formulation (daily)	– Suspected risk for bladder cancer
4	Intermediate-acting insulin (NPH)	– Long-term experience in this age group	– High risk for hypoglycemia
			– Weight gain
			– Schedule requires at least two injections per day to cover basal needs
4	Pre-mixed insulin	– Long-term experience in this age group	– High risk for hypoglycemia
	70/30 (NPH + regular, NPH + aspart)		– Risk for BID regimens would leave lunch time uncovered
	75/25 (lispro protamine + lispro)		

Multiple-Choice Questions

1. Geriatric syndromes in diabetes management:
   (a) Are of exclusive competency of geriatricians
   (b) **Are determinant and essential in the assessment and plan**
   (c) Are only secondary to glycemic control
   (d) Are uncommon and irrelevant for the clinical outcomes
2. Geriatric syndromes include all of the following except:
   (a) Polypharmacy
   (b) **Type 2 diabetes**
   (c) Persistent pain
   (d) Urinary incontinence
   (e) Falls
3. Macrovascular and microvascular diabetes complications are associated with:
   (a) Cognitive function
   (b) Nutritional risk
   (c) Self-care deficit
   (d) **All of the above**
   (e) None of the above
4. Polypharmacy:
   (a) Is an expected consequence of aging
   (b) **Represents a geriatric syndrome by itself**
   (c) Supports the use of multiple anti-diabetic medications in this age group

(d) Is essential to address patients' needs
(e) Increases costs and non-adherence

5. Each medical visit is an opportunity to address the following aspect of drug treatment:
   (a) Patients' compliance with medical orders
   (b) **Striving to reduce medications when there is no certainty that benefits outweigh the risks**
   (c) The opportunity to add new medications
   (d) The adequate use of **over the** counter medications
   (e) Encourage the use of high-cost medications that these patients can afford
6. Patients who will benefit less from intensive regimens:
   (a) Are extremely rare
   (b) Are less years of education
   (c) Are the ones with less comorbidities
   (d) **Are the ones with six or more comorbidities**
   (e) Are the ones with cardiovascular disease
7. Diabetes in older patients is a risk factor of:
   (a) **Malnutrition**
   (b) Falls
   (c) Dehydration
   (d) Peripheral artery disease
   (e) All of the above
8. The functional domain in the elderly includes all of the following except:
   (a) **Intelligence**
   (b) Eating
   (c) Vision loss
   (d) Hearing loss
   (e) Cooking
9. The following factors account for the increased risk of falls in elderly with diabetes:
   (a) Impaired gait
   (b) Loss of vision
   (c) Cognitive impairment
   (d) Polypharmacy
   (e) **All of the above**
10. Intensive glycemic control in the elderly clearly and remarkably improves quality of life in the elderly with diabetes:
   (a) True
   (b) **False**

Part XI

Novel Therapeutic Approaches: Evidence-Based and Others

The Artificial Pancreas

67

Barry H. Ginsberg, Richard Mauseth,
and Joel Rodriguez-Saldana

Abbreviations

AP	Artificial pancreas
CGMS	Continuous glucose monitoring system
FDA	US Food and Drug Administration
HbA1c	Hemoglobin A11c
iOS	Apple operating system
MPC	Model predictive control. A controller algorithm
PID	Proportional integral derivative. A controller algorithm

Objectives

- Describe the need for an artificial pancreas.
- Describe the history of artificial pancreas.
- Describe the components of an artificial pancreas.
- Describe the algorithms used in an artificial pancreas.
- Describe the clinical testing of an artificial pancreas.
- Describe the current and future devices.

Introduction

The artificial pancreas is an imprecise term that can mean a bioengineered product, such as an islet cell transplant, gene therapy to replace the pancreas, or the combination of a continuous glucose sensor, an insulin pump (with or without a glucagon pump), and a computer with an algorithm to control the delivery of insulin. In this chapter, we will consider only the last. This is an exciting topic with products being developed by an unusual consortium of academics, the JDRF, the NIH, the FDA, the Helmsley Foundation, and medical device companies. The first artificial pancreas was approved by the FDA in October of 2016 and was first marketed in June 2017 [1].

History

The first attempt at an artificial pancreas was a hybrid external device that measured venous glucose and delivered IV insulin. It was created by Kadish and colleagues in 1964 [2] and was followed over the next 10 years by a series of 5 hybrid devices, one of which, the Biostator, was commercially available [3, 4]. The Biostator worked with a complex, expensive dual lumen catheter, measuring venous glucose and delivering IV insulin. It drew some blood into its tubing, mixed with reagents and measured the glucose. It used the glucose value with an algorithm to deliver insulin and control the blood glucose. It did this very well. The Biostator was a tremendous research tool and had some medical therapy applications, but was too big, too complicated, too invasive, too expensive, and used too much blood to be used long term by individual patients (Fig. 67.1).

The pathway of development soon split, with some working on an implantable device, whereas others worked on a totally external device (Fig. 67.2). Implantable devices got an early start with the development of implantable insulin pumps by Infusaid, Siemens, and Minimed (1980–1981). In 1986 a fully automated artificial pancreas with an IV glucose monitor was tested by Minimed. Because of multiple problems including frequent catheter blockage, sensor fouling, and the invasiveness of the system, further work on the project was suspended.

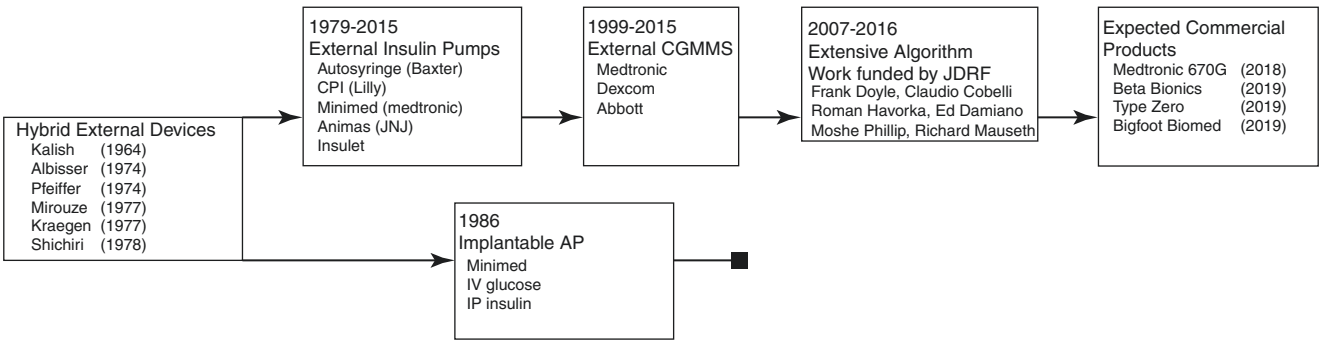

Fig. 67.2 Timeline of development of the Artificial Pancreas

Work on an external artificial pancreas progressed slowly, as the individual components, the insulin pump, and the subcutaneous continuous glucose monitor progressed. A major stimulus to the development was the decision by the Juvenile Diabetes Research Foundation in 2007 to extensively fund research on artificial pancreas algorithms. The project led by Aaron Kowalski set up 8 major artificial pancreas centers and funded research on three different types of algorithms: Proportional Integral Derivative (PID), Model Predictive Controller (MPC), and Fuzzy Logic systems. With their funding for the basic science and clinical studies and their coordination with the major stakeholders, the field progressed rapidly and the first artificial pancreas was approved in September 2016. Special thanks for helping this development should also go to the NIH which had multiple special award cycles for the artificial pancreas and to the FDA which set up a special committee to coordinate regulation of the artificial pancreas.

The Medtronic 670G, first marketed in June, 2017, is the first artificial pancreas, but many new systems are on their way with additions of a modular approach (Type Zero), addition of glucagon (Beta Bionics), and a leasing approach (Bigfoot). Second generation systems using better insulins, smaller devices, and extending the wear time are also in development.

Technology

Components of an Artificial Pancreas

Insulin Pump

An artificial pancreas consists of at least three components, an insulin pump, a continuous glucose monitoring system, and a computer, running an AP algorithm (Fig. 67.3). To understand the artificial pancreas, you need to fully under-

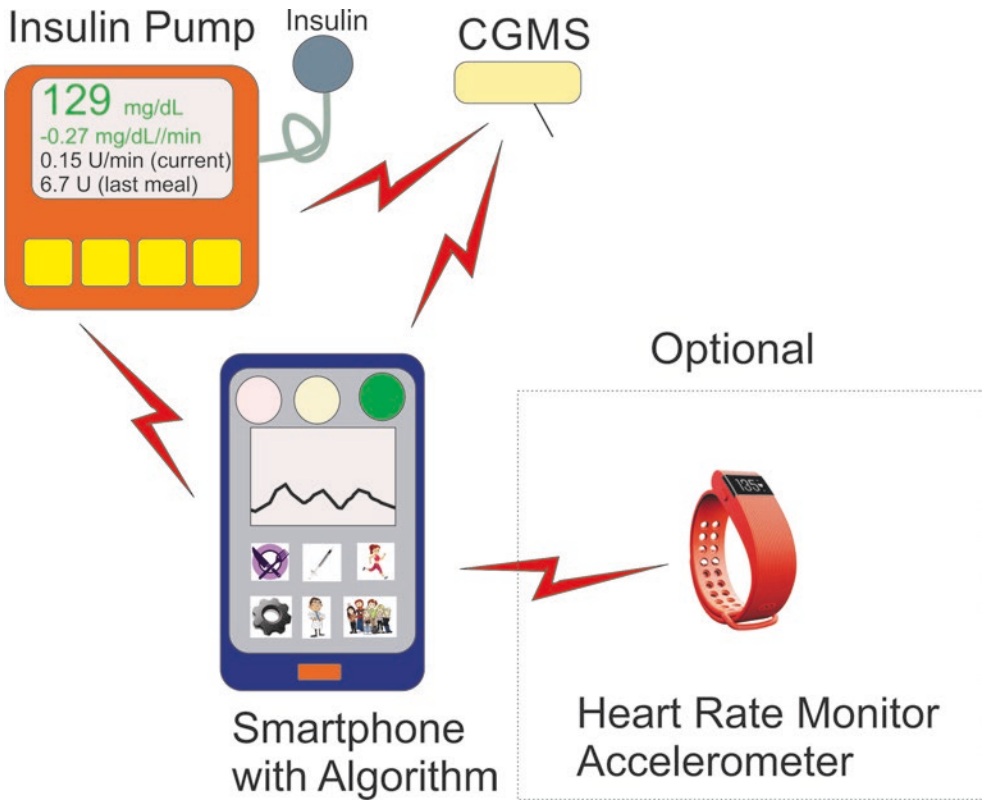

Fig. 67.3 Components of an Artificial Pancreas System

stand an insulin pump, continuous glucose monitoring (CGMS), and intensive insulin therapy. You should review those chapters before proceeding here.

Modern insulin pumps are fully digital. The digital motors are capable of infusion rates as low as 0.05 U/min and as high as 10 U/min with about 5% inaccuracy. They need to communicate with the controller and for an artificial pancreas they also need to communicate with the Computer/Smartphone and generally do so with Bluetooth 4.0 or later. In practice, they also often communicate with the CGMS system. The pumps can work without the artificial pancreas algorithm and should the AP fail, the patient can use the pump as an open loop system.

Continuous Glucose Monitoring

Continuous glucose monitoring (CGM) has been available in some form for almost 20 years but have only become very accurate in 2015. These systems monitor glucose frequently (every 1 to 5 min) rather than continuously and they do not measure blood glucose but rather the glucose in the interstitial space which lags blood glucose by 5–15 min. The best current systems work well in an artificial pancreas. They report glucose every 5 min, have median errors of about 10 percent, and can connect to a controller with Bluetooth 4 or later. Appropriate systems are available as a needle catheter lasting 1–2 weeks and an implantable system that lasts 6–12 months.

Most interesting is the development of a CGMS system built around the needle of an insulin pump catheter, expected to be released sometime in 2017.

Computer

Early experimental systems used laptop computers. As computers got smaller, some systems used netbook computers. Most algorithms for an artificial pancreas do not require extensive computing power and can easily be run by the best of current smartphones. There are experimental systems that run on the Apple iOS and others that run on the Google Android operating system. Additional advantages of running on a smartphone include availability of broadband internet connections and the ability to transmit directly over cellular networks (like texting). There are now smartphones with dual SIMs, so that the personal telephone system and the operating system of the AP are separate. The Medtronic 670G has a computer built into the insulin pump.

Algorithms

For an artificial pancreas, there are 3 common types of algorithms [5]. They differ in their basic approach to calculating the amount of insulin needed at any point.

PID

The first controllers for modern artificial pancreas systems are the PID or proportional, integral, derivative controllers.

These controllers, well established in industrial processes, assess the error in the system, *i.e.,* the difference between the current glucose and the desired glucose using three terms, as seen in Fig. 67.4.

The first term is *Proportional*, a function of the difference between the current glucose (in red) and the desired glucose (in green), shown in the figure as a black two headed arrow. The greater the discrepancy from the desired glucose, the more insulin the controller will suggest.

The second term is *Integral*, a function of the length of time the glucose has been different than the desired glucose. This term is a function of the area under (or above the curve if hypoglycemic) the curve, *i.e.,* the integral of the difference over the past time (shown in yellow). The higher this term, the more insulin the controller will suggest.

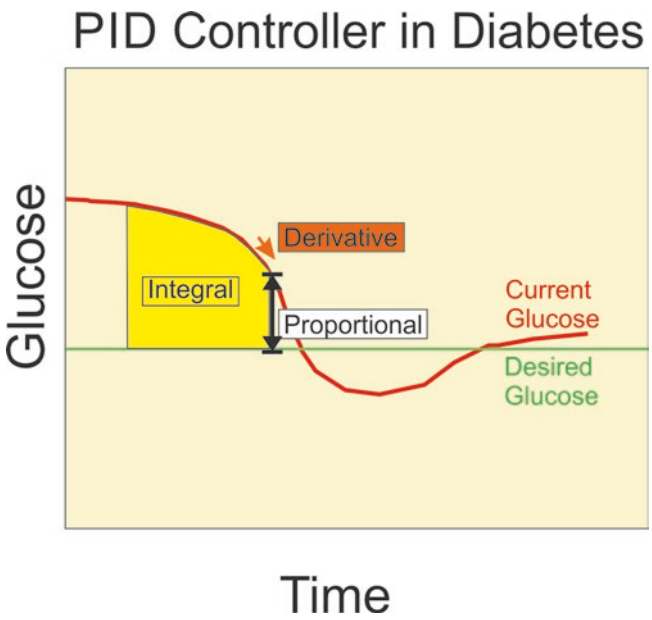

Fig. 67.4 PID control of glucose

The last term is *Derivative*, a function of the slope of the glucose curve (shown in orange). The more rapidly the current glucose is approaching the desired glucose, the less insulin the controller will suggest (if approaching from above).

Thus, the PID controller evaluates the current glucose (proportional), the past glucose (integral), and the future glucose (derivative).

PID controllers are very stable and have been incorporated into the first implanted artificial pancreas and the currently only FDA approved artificial pancreas, the Medtronic 670G.

Model Predictive Controller

Model Predictive Controllers are also very stable "industrial" controllers. Figure 67.5 shows a block diagram of a simple MPC, adapted from Lunze et al. [6]. In this controller, the glucose is separately evaluated to optimize the model parameter and to compare to the current glucose target. These feed the controller, which is based upon the model of diabetes with various food, glucose, and insulin compartments (glucagon too in some) and parameters for the movement among them. The MPC controller generates an insulin infusion rate, which is tested for safety then applied to the patient, altering the glucose value and the process repeats. Variations on this basic approach use glucagon, are modular, or learn from previous days.

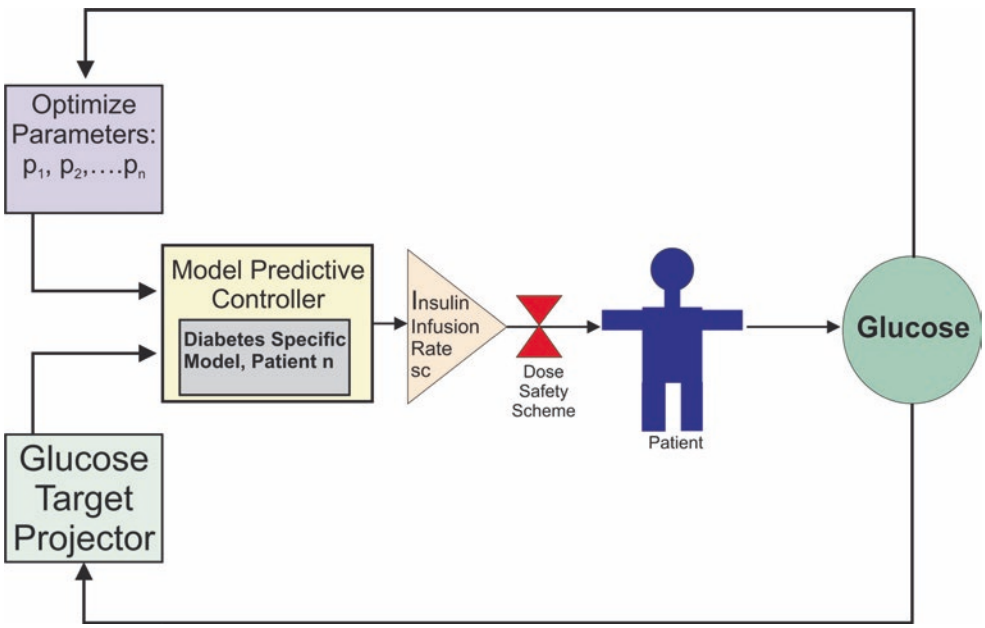

Fig. 67.5 Block diagram of a simple MPC

Fuzzy Logic

Fuzzy logic controllers use analog processes and fuzzy logic principles to mimic the approach a skilled diabetes caregiver would use to manage glucose levels. The MD Logic Artificial Pancreas was the first approved algorithm for an artificial pancreas, being cleared by the European Union in 2015, but there was no hardware approved with it, so there was no product. Another major fuzzy logic system is currently under development by Dose Safety.

Clinical Testing

Evaluating an Artificial Pancreas

Clinical Trial Structure

Clinical trials of the artificial pancreas go through 2 stages after individual components are validated. The first part is feasibility, usually done in 3 parts. The first trials are always done in a clinical research facility with medical personnel always readily available. The second set of trials are often done at a hotel or a diabetes summer camp with medical personnel nearby. The subjects can participate in activities of daily living although a nurse will generally accompany them the first time. The last part is usually a short home trial of 2–4 weeks. The subjects are often remotely monitored and medical personnel are available by phone at all times. Most of these trials will have 15–30 subjects. The second part is the pivotal trial, usually done at home. Twenty-five to 100 subjects are followed at home for 3–6 months.

Safety

Mild hypoglycemia is common in type 1 diabetes with about 20,000 to 40,000 episodes occurring daily in the USA [7]. Serious hypoglycemia occurs about once every two years. Thus, the most important safety feature of an artificial pancreas is no increase in hypoglycemia (a reduction in hypoglycemia would be considered an effectiveness outcome). Similarly, ketoacidosis occurs in about 2–4% of patients with type 1 diabetes each year and we would expect this and episodes of hyperglycemia to be no higher with an artificial pancreas [8, 9].

Effectiveness

Tests of effectiveness are tricky. The gold standard for effectiveness is hemoglobin A1c (HbA1c). This marker, however, is improved by hypoglycemia. Thus, a new therapy could eliminate hypoglycemia and result in an increased HbA1c. Thus, the time in the normal range as determined by CGMS is also important. Most clinical trials have reported normal values as Time in Range (TIR) of 70–140 mg/dL or 70–180, low values as time <70, and high values at time >180 as well as the number and severity of hypoglycemia and the number of hyperglycemic events.

Clinical Trials of Artificial Pancreas Devices

The clinical trials of the devices being currently tested are remarkably similar. All eliminate most of the hypoglycemic episodes in the tested patients. Hemoglobin A1c has generally fallen slightly but glucose time in range 70–180 mg/dL has increased, generally to the 70–80% range. This achievement is dramatic, since the trials are generally done in patients who are already in very good glucose control.

Available Devices

As of August 1, 2017, only a single device has been cleared by the FDA and marketed to patients with Type 1 diabetes, the Medtronic 670G. The AP uses a Medtronic insulin pump and CGMS and a PID algorithm that is built into the pump.

The major clinical trial had 124 participants who used the device for 3 months. The trial demonstrated a difference in the average glucose values and a decrease in HbA1c from 7.4 to 6.9. There was a dramatic decrease in hypoglycemia and time in hypoglycemia and an increase in time in range 70–140 and a corresponding decrease in time > 140. Overall it was an impressive demonstration of the power of the artificial pancreas, even compared to patients already using an insulin pump and a CGMS.

Future Devices

Other groups are close to reaching the market. Type Zero diabetes has taken a modular approach. They have built each part of the controller into a separate module. Thus, they test each module for safety and effectiveness and add new modules to the system as they are approved. The system is designed to be run on an Android phone but is otherwise hardware independent. Much like devices that work with your computer, every device that works with the Type Zero device will have a "driver" to allow the device to communicate with the algorithm. Some devices may also need a module to ensure proper use of the device.

Beta Bionics, a company commercializing the algorithms of Boston University, is developing a system using two pumps, delivering insulin and glucagon. Because there is currently no stable liquid glucagon formulation, their first device will be an insulin-only device.

The third company is Bigfoot Biomedical. They are using a proprietary algorithm developed by the company. Their commercial model, unique in many ways, is to lease the device and all disposables for a single monthly fee. This simplifies the usage of the device and the reimbursement.

Cyber-Security

A few years ago, it became clear the insulin pumps could be "hacked" and forced to deliver a lethal dose of insulin. The risk is much higher with an artificial pancreas. The Diabetes Technology Society set standards for diabetes medical devices to prevent such attacks. Using the Common Criteria, they suggested at least a level 4 security was needed. This level of security needs to be designed with the device and built into it. It cannot be added on later. Thus far, none of the companies creating an artificial pancreas had used these standards.

Concluding Remarks

- The artificial pancreas is now available after 20 years of promises.
- Current devices are hybrid devices. The patient still needs to enter information about diet and exercise.
- More systems are on their way with better algorithms and a larger choice of devices.

Questions

1. What are the components of an Artificial Pancreas?
2. What types of algorithms are available? How do they work?
3. Describe currently available devices.
4. How are AP systems clinically tested?
5. What are the advantages of an AP?

Unproven Therapies for Diabetes

68

Jothydev Kesavadev, Anjana Basanth, and Sanjay Kalra

Introduction

Prevalence and History of Diabetes

There has been a pronounced upsurge in worldwide diabetes prevalence during the past few decades, more notably in developing countries, owing to the rapid globalisation and changing lifestyles. Diabetes-associated complications such as coronary artery and peripheral vascular disease, stroke, diabetic neuropathy, amputations, renal failure, and blindness also add to this burden. According to the recent IDF estimates, one in 10 are living with diabetes. Diabetes-related deaths (6.7 million) were also higher than the total number of deaths caused by HIV (0.068.0 million), tuberculosis (1.5 million), and malaria (0.0627 million) combined. Nearly 537 million people worldwide are estimated to have diabetes, and IDF has raised the concern that by 2030 almost 643 million people and by 2045 almost 783 million adults will have diabetes [1, 2].

The history of diabetes dates back to 3500 years ago, where the first-ever mentioning of clinical features similar to diabetes mellitus is found to have been made in the greatest Egyptian medical document 'Ebers Papyrus' in 1500 BC (Ebbell 1937). Descriptions of this devastating disease have also been found in ancient Indian and Chinese medical literature, as well as in the work of ancient Greek and Arab physicians [3]. Indian physicians named the condition 'madhumeha' or 'honey urine' observing that the urine from diabetes affected individuals attracted ants and flies [4]. Apollonius of Memphis is believed to have coined the term 'diabetes' in 230 BC, meaning 'to pass through' and it was Aretaeus of Cappadocia (second century AD) who provided the first accurate description of diabetes [5]. Later on the Indian physician Sushruta and the surgeon Charaka (400–500 AD) differentiated between the two types of diabetes primarily based on their occurrence in lean or overweight individuals [5, 6].

Remarkable advancements in understanding and management of diabetes took place in the nineteenth century, mostly attributable to the significant progress achieved in various scientific disciplines. Until the discovery of insulin in the 1920s by Banting and colleagues, diabetes treatments mostly adapted highly crude methods for which the success rates were extremely poor [5] and physicians of those times used to make interesting recommendations such as 'oil of roses, dates, raw quinces and gruel, jelly of viper's flesh, broken red coral, sweet almonds and fresh flowers of blind nettles' which represented a variety of beliefs and practices of the times [7]. There are also mentions of opium being prescribed liberally [7, 8] (probably for easing the symptoms of complications like gangrene). Of note, in 1897, the average life expectancy for a 10-year-old child diagnosed with diabetes was 1.3 years, compared with 4.1 years for a 30-year-old person [9].

The first-ever scientific remedy, discovered in 1922, and awarded the Nobel Prize in 1923, insulin turned out to be a major advancement in treating diabetes and enabled patients to live near-normal life [3, 10]. The first-ever oral scientific remedy Sulphonylurea was added to the treatment armamentarium, only in the 1950s. Consequently, other oral scientific remedies with diverse mechanisms of action such as metformin, glucosidase inhibitors, and insulin sensitizers were discovered, enabling better management of the disease. Currently, our treatment armamentarium consists of a vast array of technologies and therapeutic options to make individualised treatment more of a reality. Depending on the type of diabetes and its aetiology, patients may be treated with oral drugs or injectables or sometimes a combination of both. For absolutely insulin-deficient type 1 diabetes mellitus (T1DM) patients, insulin pump therapy or multiple daily insulin injections are the only scientifically recognised modalities of therapy; in the absence of them, subjects are likely to die. With such advances in modern medicine, a dra-

matic improvement in life expectancy has been noted after 1940. As per WHO, the average lifespan of a child born in 2015 is predicted to be 71.4 years whereas earlier estimates of global life expectancy were 30.9 years in 1900, 46.7 in 1940, 61.13 in 1980 [11, 12].

Complementary and Alternative Medicine

Definition and Epidemiology

According to National Center for Complementary and Integrative Health (NCCIH), a subsidiary of the National Institutes of Health (NIH), USA, Complementary and Alternative Medicine (CAM) are those healthcare approaches that have developed outside the realm of conventional medicine. Types of complementary and alternative health approaches fall into one of the 2 subgroups, viz. natural products or mind and body practices. Natural products (available widely and often sold as dietary supplements) consist of herbs (or botanicals), vitamins and minerals, and probiotics. Mind and body practices include a variety of procedures or techniques administered or taught by a trained practitioner or teacher (e.g. yoga, chiropractic and osteopathic manipulation, meditation, massage therapy, acupuncture, relaxation techniques, tai chi, etc.). However, some approaches may not neatly fit into either of these groups—e.g. the practices of traditional healers, Ayurvedic medicine, traditional Chinese medicine, homoeopathy, and naturopathy [13].

Of the various demographic descriptors and characteristics of users documented for an inclination towards CAM, more consistent ones include being female, more highly educated, wealthier, employed, and having private health insurance [14–17]. Research has also demonstrated that individuals who possess positive health behaviours and exhibit fewer health risk factors are more frequent CAM users [18].

According to the statistics from 2012 National Health Interview Survey (NHIS), 33.2% of US adults and 11.6% of US children aged 4 to 17 used complementary health approaches. The most commonly used approach was natural products (dietary supplements other than vitamins and minerals). The mind and body approaches most commonly used by adults included yoga, chiropractic or osteopathic manipulation, meditation, and massage therapy. The popularity of such practices might definitely increase in coming years as evident from the data on the percentage of adults who practice yoga. The percentage of followers of this system of practice was found to be increased substantially, from 5.1% in 2002 to 6.1% in 2007 and 9.5% in 2012. As per the survey, nearly 59 million Americans spend money out-of-pocket on complementary health approaches, and their annual spending totalled around 30 billion dollars [19, 20].

Possible Reasons Towards CAM Popularity

A vast majority of patients opt for CAM therapies as a complement to conventional care rather than as an alternative choice [21]. In a US-based study, total visits to complementary medical practitioners (629 million) exceeded total visits to US primary care physicians (386 million) [22]. Traditional CAM practices are extremely popular in South-Asian countries, where modern conventional medicines are often inaccessible and unaffordable to the majority of individuals. Therefore despite the perception about the efficacy of modern medicines, traditional medicine continues to relish acceptance among these populations [23].

Several factors have been noted as reasons for the extensive use of these rather scientifically unproven methods of CAM therapies (Table 68.1). Dissatisfaction arising from conventional therapies, at times, clubbed with higher treatment expenses, concern over side effects of drugs, an urge to have a grip on the course of the disease, and a notion of CAM therapies being compatible with patient's values and beliefs [17, 24–27] are some of them. Patients' expectations of their efficacy [27, 28], advanced stage of the disease [29, 30], experiences with conventional healthcare professionals and complementary medicine practitioners, and 'healthcare pluralism' are also identified as the reasons for this widespread acceptability of CAM therapies. The later term describes the fact that when people become ill they can opt for seeking assistance and treatment advice from diverse sources ranging from friends/family, conventional/CAM practitioners etc. which essentially will have an impact on their treatment choices [31, 32]. Analysis of the 2002 National Health Interview Survey pointed out that around six million American adults had opted CAM therapies predominantly because they found conventional medical treatments unaffordable. Among 63% of the individuals who faced such cost constraints, herbal remedies were found to be the most popular approach [33].

Table 68.1 Reasons for CAM popularity

- Belief that CAM practices are devoid of any side effects and are totally safe
- Non-invasive nature
- Easy accessibility
- Advanced stage of the disease and unpleasant experiences with conventional healthcare professionals
- As recommended by someone close (family members, friends, etc.)
- Pleasant therapeutic experience
- Modern conventional medicines being inaccessible and unaffordable
- Dissatisfaction arising from conventional therapies
- Poor doctor–patient relationship
- Insufficient time with doctor
- Concern over side effects of drugs
- An urge to have a grip on the course of disease
- Notion of CAM therapies being compatible with patient's values and beliefs

CAM Therapies for Diabetes Management

Many Anti-diabetic Medications Have a Natural Origin

Many of the standard conventional drugs have a history of natural origin. However, administering them in their natural form may not be of much benefit. Phytochemicals or compounds present in the natural sources often serve as 'lead' molecules for the synthesis of bioactive compounds and also newer analogues could be derived from some of them. This search for novel bioactive from nature plants, animals, or microflora still continues to widen our treatment armamentarium. Estimates suggest that around one-half of all licensed drugs that were registered worldwide in the 25 year period prior to 2007 were either natural products or their synthetic derivatives [34, 35].

Over 400 traditional plant treatments for diabetes have been reported and only a few of them have undergone valid scientific scrutiny to prove their safety and efficacy [36]. Metformin, a popular anti-diabetic drug and widely accepted first-line agent, was derived from a traditional anti-diabetic plant *Galega officinalis* (Goat's Rue or French Lilac) [37] whose active ingredient was found to be glargine or isoamylene guanidine. While guanidine and certain derivatives were found to have toxic effects, the biguanides (two linked guanidine rings) turned out beneficial and were available for therapeutic use since the 1950s [38]. Further research confirmed antihyperglycaemic efficacy of metformin without causing overt hypoglycaemia or weight gain. Metformin in addition to its antihyperglycaemic properties also stands out for its effects beyond glycaemic control such as improvements in endothelial dysfunction, haemostasis and oxidative stress, insulin resistance, lipid profiles, and fat redistribution [39, 40]. The United Kingdom Prospective Diabetes Study demonstrated that early use of metformin reduced cardiovascular mortality and increased survival in overweight and obese T2DM patients beyond that expected for the prevailing level of glycaemic control [41]. This proven efficacy, safety, beneficial cardiovascular and metabolic effects, and its capacity to be associated with other anti-diabetic agents make metformin the first line of choice for T2DM patients [42] and is included in the World Health Organization (WHO) list of essential medicines [43]. Phlorizin, isolated from the bark of apple trees, was found to cause glycosuria [44] but later led to the discovery of better analogues with SGLT2 inhibiting activity such as dapagliflozin, empagliflozin, and canagliflozin [45, 46].

The discovery of insulin by Frederick Banting and Charles Best in 1921 was indeed a major breakthrough in the treatment of diabetes and it all began with a murky concoction of canine pancreas extract [34, 47]. Likewise, Exenatide and highly accepted insulin with anti-diabetic activities have their origin from animals. Exenatide, a glucagon-like peptide-1 (GLP-1) agonist, is a synthetic version of exendin-4, a hormone found in the venom of Gila monster *Heloderma suspectum* which was isolated by Dr. John Eng in 1992 [48, 49]. This drug has been approved for use in T2DM management [50].

Apart from anti-diabetic compounds of plant and animal origin, some have been derived from microbes. Examples include Acarbose (from Actinoplanes sp.), Miglitol (from Bacillus and Streptomyces sp.), Voglibose (from Streptomyces hydroscopicus subsp. Limoneus) [46], etc. The alpha-glucosidase inhibitor Acarbose used in T2DM is a pseudo-oligosaccharide isolated from the culture broths of various actinomycetes [51]. It is probably the most widely used digestive enzyme inhibitor for the treatment of T2DM, acting on α-glucosidase, α-amylase, sucrase, and maltase, but without insulinotropic properties [52]. With regulated research and controlled clinical trials, there is a higher probability that many more natural agents could be incorporated into the modern stream of medicine.

Prevalence and Patterns of CAM Use Among Diabetes Patients

According to Villa-Caballero and colleagues, the presence of diabetes is a predictor of CAM use and ethnicity determines the types of CAM followed. Of the different CAM modalities, biologically based practices (e.g. dietary supplements, herbal products, and botanical products) are the most commonly used and studied for treating diabetes [53, 54] which is probably due to their wider and cheaper availability, and also being inherent in the cultures and ancestral beliefs of the individuals. Egede et al. using the data from the 1996 Medical Expenditure Panel Survey compared the prevalence and pattern of use of complementary and alternative medicine (CAM) in individuals with and without diabetes and identified factors associated with CAM use. Analysis revealed that diabetes affected individuals were 1.6 times more likely to use CAM than those without diabetes and the most commonly used CAM therapies among diabetes patients were found to be, in the order of importance, nutritional advice and lifestyle diets, spiritual healing, herbal remedies, massage therapy, and meditation training [55]. Another study from Israel reported that almost every fourth patient with diabetes uses CAM [56]. India, a country with a rich history of traditions, rituals, and healing practices, has a very high CAM use of 67% among its diabetic population, of which majority (97%) used Naturopathy, which often included herbalism [57]. An ethnographic study conducted in Kerala revealed that the patient's perceptions of disease as well as its management are influenced by their cultural background

and environmental resources. Many of them frequently used Ayurvedic and traditional herbal medicines as supplements to conventional therapy [58].

The National Center for Complementary and Alternative Medicine (NCCAM now re-named as NCCIH) conducted an analysis of the data from National Center for Health Statistics, Centers for Disease Control and Prevention (CDC), and demonstrated that, among adults with T2DM, 30.9% used complementary medicine for any reason, but only 3.4% used complementary medicine to treat or manage their T2DM versus 7.1% of those with T1DM. Almost 77% of the T2DM patients, who used complementary medicine to treat/manage their disease, used it in conjunction with their conventional prescription medicine. Furthermore, individuals with more severe diabetes were predicted to be more likely to use complementary medicine. The most prevalent types of complementary medicine therapies followed included diet-based interventions and non-vitamin/non-mineral dietary supplements [30]. In a study that determined the nature and prevalence of dietary supplement use among chronically ill children, 60% of the patients with T1DM reported using supplements to manage their disease and 31% admitted non-prescribed use [59].

Concerns with CAM Therapies

The widespread use of CAM practices poses several risk factors (see Table 68.2) such as the patients getting overloaded with consecutive unsuccessful therapeutic measures owing to false diagnosis, running into life-threatening situations, adverse effects, and hidden costs of treatment. Opting for these unconventional practices might delay the initiation of effective modern conventional treatments and thereby increase the chances of treatment failures and unbearable treatment expenses [60–64]. Drug–herb interactions, compromised quality of the products due to adulteration or presence of inappropriate amounts of active ingredients, lack of proper regulations on various CAM practices and CAM practitioners, underdeveloped research, poor quality of clinical trials, false claims and fake publicity, absence of proper communication with health practitioners, etc., are all known to be the contributing risk factors towards the failure of CAM therapies [65–68].

Table 68.2 General concerns associated with CAM therapies

- Adverse drug interactions
- Patient's belief of receiving optimum therapy and finally running into life-threatening conditions and increased treatment costs
- CAM products not meeting quality standards due to reasons such as:
  - Products being adulterated with modern medicines to achieve/enhance the efficacy
  - Inadvertent incorporation of unintended constituents due to errors with herb selection, good manufacturing procedures, etc.
    - Intra- and inter-product variations
    - Mislabelling of the contents
- Poor quality of the clinical trials making it difficult to arrive at a definite conclusion regarding efficacy and safety of CAM practices
- Patient's prejudice that CAM therapies are natural and safe, which increases their tendency towards self-treatment practices and use of over-the-counter products
- Lack of proper communication between the patients and health practitioners regarding CAM use
- Polypharmacy with CAM and conventional treatments resulting in decreased medication adherence and more negative quality of life
- Lack of stringent regulations to guard against quackery in CAM practices

Compromised Quality of CAM Products

Lack of proper adherence to manufacturing, marketing, and storage protocols might lead to deterioration in product quality, viz. contamination with undesirable substances; intra-product and inter-product variations; mislabelling of the contents, misidentification, etc., which leaves us highly unsure regarding their safety and efficacy [61, 69–71]. Considering the example of herbs, they do not have a consistent, standardised composition and different plant parts have a different profile of constituents. Furthermore, several factors such as climate, growing conditions, time of harvesting, and post-harvesting factors such as storage conditions and processing are all known to influence the content and concentration of constituents. Although standardisation of many of these products has been implemented, it may not be always feasible since active constituents of many botanicals are still unknown [31]. In a meta-analysis conducted, high variability in ginsenosides levels in ginseng across different source parameters, viz. ginseng-type, assay technique, and ginsenoside type, was shown to result in high variability in their efficacy. This is a warning signal that the reported safety and efficacy data of a particular product may highly differ when compared to other over-the-counter batches, preparations, varieties, and species of the herb [72].

Many US-manufactured and Indian-manufactured Ayurvedic medicines that were sold over the Internet were adulterated with unacceptable levels of lead, mercury, or arsenic [73], and serious consequences were also reported with the use of 'herbal' products that contained 'hidden' active drug compounds or heavy metal contaminants [74–78]. The Centers for Disease Control and Prevention (CDC), USA, had reported lead intoxication from Ayurvedic medications among pregnant women [79]. Since 2007, the FDA has imposed an import alert on certain Ayurvedic products to prevent such products from entering the United States [80]. Accidental or intentional contamination of CAM products with conventional drugs (e.g. corticosteroids) or poisonous substances (e.g. heavy metals, pesticide residues) and microorganisms is also reported [81, 82]. Chinese 'herbal' creams were found to contain corticosteroids [83], and some Indian

Ayurvedic remedies contained heavy metals [74]. Likewise, deterioration in the quality of 'homoeopathic' remedies [84, 85] as well as that of therapeutic essential oils [86], is also a major concern. Another classic example is 'Chinese herb nephropathy' where weight reduction pills supposed to contain the herb *Sephania tetrandra* were inadvertently contaminated with nephrotoxic herb *Aristolochia fangchi,* causing nephropathy and/or cancer in women attending a slimming clinic in Belgium [87–89].

Complications from Drug Interactions

When CAM products such as herbal medicines or dietary supplements are used concomitantly with conventional drugs, a very common practice, there may be a potential for drug–product interactions. Product–product interactions may also occur when many of these products are used concurrently [90]. These interactions often alter the pharmacokinetics or pharmacodynamics of conventional drugs, thereby altering their absorption, distribution, metabolism, and/or excretion [66, 67]. Herbs possessing hypoglycaemic activity like ginseng, garlic, and bitter melon are all reported to have additive effects in patients taking oral hypoglycaemics or insulin [72, 91–93]. In contrast, dietary gums (e.g. gum guar) usually prescribed to overcome postprandial hyperglycaemia were found to reduce the absorption of hypoglycaemic agents like metformin and glibenclamide by prolonging gastric retention [92, 94, 95]. Since diabetes patients are often burdened with many other comorbidities, the majority of them would require lifelong polypharmacotherapy (multiple medications) and hence stand at increased risk of such harmful drug interactions [96].

Underdeveloped Research and Poor Quality of Clinical Trials

Unlike conventional medicine, CAM in general lacks an established research infrastructure and therefore many of the already available scientific evidence are methodologically weak or outright flawed [97–101]. Measures such as the implementation of CONSORT guidelines [102, 103] for reporting and the establishment of a 'field' for CAM in the Cochrane database [104] have allowed us to make a more reliable assessment of the safety and efficacy of these systems of medicinal practices [101].

False Claims and Fake Publicity

Alternative medicine is widely promoted among the public and some of them even claim these therapies to be highly effective with no side effects [105]. The inherent notion among the public that these therapies are 'natural' and hence 'completely safe' enables easier exploitation by advertisers and commerce. The absence of stringent regulations in many countries can allow exaggerated claims to be made and this is more pronounced in areas of commerce that are difficult to control, for example products sold over the internet [106]. It is often seen that the lay literature and even certain 'professional' texts based on some CAM practices make unsubstantiated medical claims as well as encourage self-treatment for even some serious conditions [31, 107].

In India, 'The Drugs and Magic Remedies (Objectionable Advertisements) Act', 1954, controls the advertising of drugs and restricts advertisements of such 'wonder-drugs or remedies' [108].

Lack of Proper Regulations and Policies

Among WHO's 194 countries 97 countries have a national policy on TM/CAM and only 124 countries regulate herbal medicines [109]. The WHO has published a series of technical guidelines and reviewed regulations on herbal medicines in the document 'Regulatory Situation of Herbal Medicines: a Worldwide Review' [110]. In the United States, national non-governmental organisations, such as the Accreditation Commission for Acupuncture and Oriental Medicine, the American Board of Medical Acupuncture, the Council of Chiropractic Education, etc., accredit education in some of them, while most other nations are devoid of these [68]. In the United States prior to 1994, CAM supplements were classified as either foods or drugs depending on the intended use and later Dietary Supplement Health and Education Act (DSHEA 1994) framed a better definition for 'dietary supplement'. It effectively took out any product containing a vitamin, mineral, herb, or amino acid marketed as a supplement to the normal diet from obtaining USFDA approval. This legislation allows such products to forego the stringent approval processes and does not require any proof of their safety and efficacy before being marketed. However, this has led to the situation where many of them are available over the counter even in grocery stores [61, 111].

Similar is the situation of CAM practitioners in many countries where they are not regulated in any manner. There are no systems in place to evaluate the training or expertise of these practitioners [68, 112–114]. In rural areas where timely access to treatment is challenging, this poses a major problem. Many of the times, local practitioners become the primary point of approach and thus the lack of authentic therapists can aggravate the situation [68, 114]. Therefore, imposing restrictions on CAM practitioners without any acceptable educational qualifications and adopting standards of practice should be given due priority to minimise such practice risks [115].

Absence of Proper Communication with Health Practitioners

When the extent of patients' utilisation of complementary medicine, and their knowledge and attitude regarding the same, was studied by Giveon et al., more than half of the respondents believed that natural drugs are safe with no side effects. Users may not relate their symptoms to CAM and not disclose its use to their physician, leading to complications such as delayed diagnosis and treatment, delaying or replacing a more effective form of treatment or even compromise the efficacy of certain conventional drugs. The situation becomes even worse when CAM users are advised by the healers to discontinue the use of prescription drugs, particularly in those with chronic disease conditions [116]. CAM practitioners usually do not encourage inquiries regarding the constituents of their preparations, and most patients are least interested to know about the same as they consider such preparations to be 'natural', otherwise 'safe'. Healthcare professionals are mostly unaware of CAM use by their patients and are not consulted prior to their use [117]. Unfortunately, there are also instances where even when the physicians are aware of their patients using such unproven remedies, they may not be trained to recognise potentially serious side effects [33]. Therefore, it becomes practically impossible to apprehend whether CAM therapy played any significant contributory role towards the efficacy or failure of conventional treatment [118].

In its Position Statement on 'Unproven Therapies', ADA raises the concern that most patients do not disclose the use of alternative medicine and hence conventional practitioners need to specifically ask their patients about the same. ADA continuously evaluates the usefulness of different CAM therapies, their potential risks to the patients and so on to characterise the effectiveness of such treatment modalities. They, however, do not recommend the use of any such unless their safety and efficacy has been established by current standards [119]. In the United Kingdom, the House of Lords' Select Committee on Science and Technology's report on CAM recommended statutory regulation of CAM practitioners and recommended regulatory bodies of healthcare professionals to develop guidelines on CAM competence and training. By this regulation, conventional healthcare professionals are expected to have a basic knowledge of such therapies, and conventional health providers may have interactions with state registered CAM practitioners [120].

Concerns with Other CAM Therapies

Homoeopathy, for example, even though accepted widely, the methodological quality of the trials based on this system of therapy is found to be very poor. Arguments are still on in the view whether homoeopathy is superior to the placebo as a treatment concept [121–123]. Adverse effects can occur if the remedies are not highly diluted since most but not all homoeopathic remedies are devoid of active molecules. Many of the homoeopathic prescriptions include remedies containing arsenic or other highly poisonous substances and in case such a remedy is used in its undiluted form by any chance, it could result in life-threatening consequences [124]. Therapies involving mechanical techniques might cause detrimental effects. Chiropractors, for example, apply a controlled force to a spinal joint and can cause vertebral arterial dissection after upper spinal manipulation [125]. Acupuncture (stimulates specific points on the body by inserting thin needles through the skin) can cause complications like pneumothorax [126, 127], cardiac tamponade [128–130], and central nervous system injuries [131]. Serious infectious complications (like hepatitis, HIV, sub-acute bacterial endocarditis, etc.) can also arise when the practitioners are not concordant with aseptic techniques [132, 133].

Impact of CAM on Diabetes Treatment Outcomes

In a survey conducted among participants of SEARCH for Diabetes in Youth, patients who followed a 'CAM diet' reported a better quality of life (QOL), whereas supplement use and stress reduction activities resulted in decreased QOL. Moreover, children who did not follow any CAM practices experienced lesser treatment barriers [134]. In another study among patients with T2DM and/or cardiovascular disease, higher CAM use was highly correlated with a decreased quality of life in. This was attributed to the negative effects of using multiple therapies where some of them could, in fact, interfere with conventional care [135]. CAM use was also found to decrease the adherence towards prescribed medications in different patient populations [136] including those with diabetes. Patients with T2DM who used CAM were almost 6.16 times less adherent to their prescribed diabetes medication than the non-CAM using counterpart [137, 138]. One of the major reasons postulated towards this diminished adherence is that CAM users are both logistically and psychologically burdened and may need to sacrifice part or all of their prescribed diabetes medication so as to continue using CAM. Another reason pointed out was that the patients believed in CAM healers more than the conventional practitioners [136].

In spite of branding 'natural' and a long history of use, most of these traditional medicines are not necessarily safe. As noted earlier, use of CAMs may delay the use of effective modern conventional treatments and cause adverse effects. Health risks can arise from issues such as drug–herb interactions, adulteration of the products, or the presence of inappropriate amounts of active ingredients in the products [65–67]. Diabetic patients frequently undergo treatment for associated diseases such as hypertension, neuropathy, car-

diovascular disease, and so on. While evaluating the effect of CAMs, it is important to understand drugs and drug interactions in depth, and the failure to record the present history of CAM use may lead to problems with other medicines that the patient uses [65, 139]. Instances such as renal failure with use of the dietary supplement chromium picolinate, hepatotoxicity with ingestion of sheep bile, and poor outcomes in a group of patients after abrupt stopping of insulin injections to initiate various CAM therapies have been documented [140]. Another very common drawback noted with CAM products used in diabetes is that when combined with insulin or secretagogues, the patient may experience additive hypoglycaemia due to drug interactions [53]. Herbal medications that claimed to treat diabetes were found to illegitimately incorporate modern medicines with chlorpropamide [141], glibenclamide [142] etc. with a view to enhancing their efficacy and finally resulting in undesirable outcomes. Lead poisoning from herbal remedies is another grave concern [143, 144]. Furthermore, CAM practitioners, as well as manufacturers of such ethnic herbal remedies, even provide patients with fatal advice such as urging them to stop all medicines of diabetes and injections while following CAM therapies which makes the situation even worse [142, 145]. Nutritional advice and lifestyle modifications form essential components of diabetes management, and such recommendations are also often prescribed by many of the CAM providers. The risk lies with the fact that such advice often differs from those endorsed by conventional diabetes care providers and even does not adhere to the guidelines of ADA for diabetes management. Whether these additional nutritional advice and lifestyle diets complement and reinforce ADA guidelines or conflict with the conventional system is another matter of debate [55]. American Diabetes Association's Standards of Medical Care do not support the use of vitamin, mineral, or herbal supplements for diabetes management, due to the lack of sufficient evidence [146].

Fatty liver, non-alcoholic steatohepatitis (NASH), and subsequent cirrhosis are becoming very common in diabetes and associated disorders. Despite the lack of studies or evidence, more and more people are accepting natural remedies with the belief that they are effective with no side effects. But here, the dictum, 'medications with efficacy will also have side effects' stands true. However, those who are advising as well as using it are totally unaware of adverse events. Several observational studies have reiterated the potential hepatotoxic effects of herbal preparations, including asymptomatic minor transaminase elevations, acute and chronic hepatitis, granulomatous hepatitis, asymptomatic to severe cholestasis, sinusoidal obstruction syndrome, acute liver failure requiring transplantation as well as progression to cirrhosis and portal hypertension [194].

Several systematic reviews have been published that weighed the impact and efficacy of various CAM therapies on preventing and treating diabetes. Recently, the effect of Ayurveda on treating diabetes mellitus was studied by Sridharan et al., and the effect of Chinese herbal medicines on impaired glucose tolerance or impaired fasting blood glucose was assessed by Grant et al. Both these reviews pointed out the benefits of following these traditional systems of medicine in treating diabetes or pre-diabetic conditions. The authors, however, stop short of recommending such practices citing the biased nature of certain studies and lack of sufficient evidence [99, 147]. An overview of beneficial and adverse effects identified with some of the widely used herbs, herbal products, and supplements for diabetes management is provided in Table 68.3.

Table 68.3 Commonly used herbs and supplements for diabetes management [53, 64, 69, 95, 148–151, 194, 195]

Name of herb, herbal product, or supplement	Beneficial effects/ hypothesised mechanism of action	Side effects/drug interactions and contradictions
Cinnamomum zeylanicum	Increases insulin sensitivity by increasing PPAR (alpha and gamma) expression, increases cellular glucose entry by enhanced insulin receptor phosphorylation and translocation of GLUT4 glucose transporter to the plasma membrane, promotes glycogen synthesis	Skin irritations if used topically, interacts with secretagogues and causes hypoglycaemia, coumarins possess anticoagulant, carcinogenic, and hepatotoxic properties
Gymnema sylvestre	Insulin secretagogue, increases glucose uptake promoting enzymes, stimulates and increases beta cell number	May cause hypoglycaemia when combined with secretagogues
Bitter melon (*Momordica charantia*)	Hypoglycaemic action, insulin mimetic, enhances glucose uptake by tissues, inhibition of glucose producing enzymes, enhances glucose oxidation (G6PDH pathway)	Gastrointestinal discomfort, hypoglycaemic coma, favism, haemolytic anaemia in persons with G-6PDH deficiency, abortifacient activity of α and β momorcharin, hypoglycaemia when used with sulfonylureas
Fenugreek (*Trigonella foenum-graecum*)	Insulin secretagogue, hypoglycaemic activity, lipid-lowering effects, increases HDL cholesterol, slows carbohydrate absorption and delays gastric emptying, inhibits glucose transport, increases insulin receptors, improves utilisation of peripheral glucose	Diarrhoea, gas, uterine contractions, allergic reactions, drug interaction with hypoglycaemic agents, anticoagulant drugs, MAO inhibitors, contraindicated in pregnancy

(continued)

Table 68.3 (continued)

Name of herb, herbal product, or supplement	Beneficial effects/ hypothesised mechanism of action	Side effects/drug interactions and contradictions
Guar gum	Alters gastrointestinal transit and delays glucose absorption, lipid-lowering effects by decreasing its absorption and increasing bile excretion	Gastrointestinal upset, may delay the absorption of drugs, possibility of hypoglycaemia when combined with secretagogues, additive lipid lowering when used along with antihyperlipidemic agents
Noni *(Morinda citrifolia)*	Reduces fasting glucose, HbA1c, serum triglycerides, and LDL cholesterol and improves insulin sensitivity (data limited to in vivo and in vitro studies)	Severe acute liver failure; acute hepatitis with portal inflammation and periportal necrosis
Gurmar *(Gymnema sylvestre)*	Gymnemic acid type A, phytochemical compound present in shoot tips and seeds, is one of the most potent hypoglycaemic components. Some of the alkaloids and saponins in the plant also act as appetite suppressants	Hepatotoxicity, may cause acute hepatitis
Chromium	Lipid-lowering effects, insulin sensitising effect by decreasing tyrosine phosphatase activity or direct effect on insulin receptor by increasing tyrosine kinase activity at the insulin receptor, may promote glucose transport	Renal toxicity and dermatological reactions, potential hypoglycaemia with secretagogues, steroids may decrease chromium levels, vitamin C may increase chromium absorption
Alpha-lipoic acid	Improves insulin resistance and increases glucose effectiveness	Can affect thyroid function in patients with thyroid disease, might produce allergic skin reactions, abdominal pain, nausea, vomiting, diarrhoea, and vertigo
Omega-3 fatty acid/fish oil	Lowers triglycerides, anti-inflammatory, anti-platelet, hypotensive, slight increase in blood glucose	High intake might cause bleeding, fish meat to be eaten with caution due to contamination with high levels of methyl mercury; may increase LDL, drug interactions with anticoagulant and anti-hypertension drugs

Evidence regarding the use of other systems of CAM for diabetes is also in its infancy and in fact, the available little evidence cautions the patients and the practitioners regarding their safe and effective use. Studies which assess acupuncture are methodologically problematic mainly due to reasons such as the procedure has no adequate control condition, treatments in daily practice are mostly individualised, short duration of the studies, etc. [152–154]. None of the trials conducted in diabetes patients could provide convincing evidence on acupuncture for treating conditions like insulin resistance [154], diabetic gastroparesis [155], and diabetic peripheral neuropathy [156]. Practitioners and patients who support acupuncture for diabetic neuropathy may also bear in mind the increased risk of acupuncture needle site infection with high blood glucose levels [157]. Opting for acupuncture after discontinuing conventional therapy recently led to the death of a 30-year-old T1DM individual in India [158]. 'Sweet therapy' is another peculiar diabetes treatment practised in Kerala, which claims to stimulate the sleeping pancreas to secrete insulin by intake of glucose-rich foods such as sweet desserts. However, the long-term serious implications of such modalities on the health of the patients are not documented.

Trials that investigated the effects of tai chi [159–163] and qi gong [152, 164] on diabetes also could not reach any definitive conclusions. Such mind–body therapies which involve movements can at best be considered as alternative modes of exercise [165, 166]. The perceived advantage of these therapies is that they can be performed at almost any level of exercise tolerance when compared to traditional exercise, and thus might be helpful for increasing movement and activity especially for some persons with diabetes such as older and obese individuals [152]. They might also be helpful in imparting behavioural and psychological changes and thereby help patients to cope with the disease and increase their quality of life [167]. However, neither yoga [168, 169] nor tai chi [170–172] has been shown to have any significant impact on improving the glycaemic status. In diabetes patients who follow practices such as massage, Therapeutic Touch, Healing Touch, and Reiki, appropriate blood glucose monitoring and titration of anti-diabetes medications should be recommended when blood glucose levels become lower as pain and discomfort decrease. During energy therapy, catecholamines like epinephrine and norepinephrine get released which can increase lipolysis and thermogenesis, leading to increased energy expenditure and weight changes [157].

Recommendations for a Prospective CAM Use

Proper Patient–Physician Fit and Judicious Choice of Therapies

The current hypothesis is that treatment settings influence a patient's mindset and even influence the effects of inter-

ventions. This speaks volumes regarding the importance of maintaining a positive relationship between the patient and the caregiver in achieving commendable treatment efficacy [121]. Unfortunately, most of the times patients following conventional medicine were dissatisfied with the manner of communication by the practitioners, were worried about the side effects of pharmacotherapy, and also felt the lack of a holistic treatment approach. On the other hand, CAM seemed to reinforce a patient's own self-healing capacity. Alternative therapists tend to spend more time with their patients which help to develop a good patient–physician fit, and many of the patients appreciated this approach [173].

CAM use often remains underreported and thus a lack of proper communication between patients and healthcare providers can often end up in treatment failures or adverse events. Care providers should put in their efforts to understand the motivations behind a patient's CAM use and be prepared to counsel such patients, when needed, about the options available and should be able to assess, as well as present information to the patients regarding the expected risks, side effects, benefits, and choices regarding self-management and its cost to the patient, helping them to make an informed choice [53, 136, 174]. In patients who persist on following CAM, it is advisable to identify the effects of each of the components of these medications so that patients can be counselled regarding any contraindications to any of the constituents. Patients should be adequately monitored and warned of the potential side effects, and healthcare practitioners should be aware of the potential interactions between the active components of the alternative medications and other prescribed medications [175]. For individuals exploring supplements, FDA's documents such as 'Tips for the savvy supplement user', 'Tips for Older Dietary Supplement Users', and 'Questions and Answers on Dietary Supplements' might turn helpful (accessible at http://www.fda.gov). A database of natural medicine available at 'www.prescribersletter.therapeuticresearch.com' provides necessary information regarding the usage of herbs and supplements and their safety issues [176]. The American Diabetes Association in two of its articles 'A Step-by-Step Approach to Complementary Therapies' and 'Guidelines for Using Vitamin, Mineral, and Herbal Supplements' has offhandedly acknowledged the popularity of CAM for diabetes and provides a set of approaches that could be undertaken in order to safely integrate complementary therapies into an individual's healthcare plan [177, 178]. In its position statement, ADA proposes to evaluate each questionable diagnostic or therapeutic modalities and recommends proving new and innovative, but unproven, diagnostic and therapeutic measures for patients based on certain preset criteria and also encourages healthcare providers to ask patients about their alternative therapy practices [179].

Proper Regulations and Well-Conducted Research

Although anti-diabetic drugs used in modern medicine have a natural origin [34], administering them in their natural form may not be of much benefit. Randomised clinical trials of herbal medicine interventions too often underreport the crucial characteristics of the intervention, thereby deviating from the standards set by Consolidated Standards of Reporting Trials (CONSORT) [180, 181]. However, with regulated research, there is a higher probability that many more natural agents could be used in modern medicine. Experts recommend that CAM and dietary supplements should be subject to scrutiny similar to conventional medicines by organisations such as the NIH and FDA. Any measure to bypass these may render the healthcare system inefficient, incapable, and dangerous [182, 183]. Adequate or accepted research methodology for evaluating these healthcare practices needs to be developed. Consideration should also be given to increase the overall quality of research, avoid publication bias, protect intellectual property, and also to certify authentic CAM products and practices from illegitimate ones [184].

Integrating CAM into Conventional Care

Although CAM practices lack sufficient evidence, the popularity of such practices is ever increasing and its integration into mainstream health care is much looked at. In certain regions, CAM practices are included under health insurance coverage and certain 'integrated' delivery systems have also been established [15, 185]. While considering the integration of medical systems, apart from emphasising patients' expectations and needs, it should be prioritised that accepted standards of medical and scientific principles of practice remain unaltered [186]. With such integration, patients are believed to get benefited at multiple levels such as better decision-making, enhanced physical and emotional well-being, and gaining knowledge on health-promoting practices (Furnham 1996). Healthcare providers can also get benefitted in terms of greater satisfaction through learning new treatment strategies and developing skills to implement them [187]. Thus a more integrated system is expected to facilitate discussion and collaboration between the two systems of medicine to improve healthcare delivery [188]. A snapshot of the recommendations suggested towards a prospective CAM use is provided in Table 68.4.

Table 68.4 Recommendations for a prospective CAM use

Developing a proper patient–physician fit that can encourage patients to openly communicate regarding CAM use – Healthcare providers should try to understand patient's motivations behind CAM use so as to choose an optimal treatment plan – Healthcare providers can take efforts to assess, as well as present necessary information to the patients regarding different aspects of CAM use and thus help them make a more informed choice
Validating the safety and efficacy of CAM therapies through well-planned clinical trials that meet quality research standards
Impose proper regulations and scrutiny on CAM practices, products, and practitioners to ensure their safety, quality, and efficacy
Integration of CAM and conventional medical systems by giving emphasis to patient's expectations and needs, without altering the accepted standards of medical and scientific principles

CAM Therapy and COVID-19

The Coronavirus disease 2019 (COVID-19) caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has met international health systems with a low level of preparedness and emergency response [189]. A wide range of CAM therapies are being practised worldwide including acupuncture, acupressure, cupping, massage, gestalt therapy, reflexology, muscle therapy, etc. for the prevention and cure of COVID-19 [190]. With a rich history of traditional medicines, countries like China and India explored the effectiveness of their traditional medicines to prevent and cure COVID-19.

In India, the ministry of AYUSH (Ayurveda, Yoga and Naturopathy, Unani, Siddha, and Homoeopathy) to encourage research in various traditional drugs on COVID-19 established guidelines focusing on multi-pronged approach of Ayurvedic medications, which are already in use for a long time for ailments like fever, cough, and respiratory distress [191].

Evidence from several studies has shown that some plant preparations and spices such as pepper, ginger, cumin, and coriander seeds have anti-viral, anti-bacterial, and anti-microbial properties [192, 193]. Given that some of these preparations lack data related to efficacy, adverse events, manufacturing method, and quality control. However, many preparations are also being propagated without having any scientific evidence.

Currently, there is only limited research from human clinical trials in regard to the effectiveness of CAM in prevention, treatment, or symptom relief in COVID-19.

Conclusion

Even with the advancements achieved in modern conventional medicine, a lot many patients still continue to follow traditional CAM practices due to a variety of reasons such as their perceived safety and efficacy, easy availability or matching with their cultural beliefs and practices, and so on. However, the risk–benefit ratio of these CAM practices on the disease outcomes especially the chronic one like diabetes still remains unproven. Conventional healthcare providers in most cases are not aware of their patients following such modes of therapies and also are not in a position to comment on regarding the same. They should put in efforts to maintain a good rapport with the patients so as to enable open communication regarding CAM use so as to help them make a judicious choice of such therapies. Imposing stringent rules and regulations as well as conducting clinical trials that meet quality research standards can no doubt reveal the true potential of at least some of these age-old practices. With that achieved, the successful integration of reliable and safe CAM practices into mainstream health care can be thought of in order to improve the overall treatment experience and outcomes.

Multiple-Choice Questions

1. Complementary and alternative medicines:
   (a) Are essential additional elements of diabetes management
   (b) **Are healthcare approaches developed outside the realm of conventional medicine**
   (c) Are exclusively medicines
   (d) Include surgical interventions
   (e) Are evidence-based
2. Complementary health approaches:
   (a) Are rarely used
   (b) Are largely used by people with low economic resources
   (c) **Are used by 33.2% of adults in the United States**
   (d) Are used mostly by men
   (e) Represent a minimal amount of healthcare costs
3. Reasons for the popularity of complementary alternative medications include all of the following, except:
   (a) Easy accessibility
   (b) Dissatisfaction with conventional medical care
   (c) Belief of safety
   (d) **High costs**
   (e) Poor doctor–patient relationship
4. Many currently approved anti-diabetic medications have a natural origin:
   (a) **True**
   (b) False
5. Examples of anti-diabetic drugs with natural origin:
   (a) Insulin
   (b) Sulfonylureas
   (c) **Metformin**
   (d) **SGLT2 inhibitors**
   (e) **GLP-1 agonists**

6. The percentage of patients with type 2 diabetes using complementary medicine in addition to conventional prescriptions:
   (a) 15%
   (b) 27%
   (c) 48%
   (d) 60%
   (e) **77%**
7. The use of complementary alternative medications has several risks, including:
   (a) Adverse effects
   (b) Hidden costs
   (c) Overload with unsuccessful therapies
   (d) Lack of proper regulations
   (e) **All of the above**
8. The hypothesised mechanism of action of chromium:
   (a) Insulin secretagogue
   (b) **Insulin sensitizing agent**
   (c) Insulin mimetic
   (d) Inhibits glucose transport
   (e) Alters gastrointestinal transit
9. The hypothesised mechanism of action of guar gum:
   (a) Insulin secretagogue
   (b) Insulin sensitizing agent
   (c) Insulin mimetic
   (d) Inhibits glucose transport
   (e) **Alters gastrointestinal transit**
10. Recommendations for the prospective use of complementary alternative medications involve:
    (a) Recognition as essential elements of management
    (b) Learning about their effectiveness
    (c) **Judicious choice of therapies**
    (d) Combination with standard therapies
    (e) Discourage their use by patients

Insulin Delivery: An Evolution in the Technology

69

Jothydev Kesavadev, Gopika Krishnan, and Nelena Benny

Introduction

All patients with type 1 diabetes (T1DM) require insulin due to absolute deficiency, and most type 2 diabetes (T2DM) patients require insulin at one time or the other due to progressive β-cell failure, to sustain life [1, 2]. In people with diabetes, the most efficient therapeutic option available to reduce hyperglycemia continues to be insulin even though they experience numerous challenges with the use of insulin including interference with daily living, financial constraints, the complexity of regimens, injection discomfort, and public embarrassment for injecting insulin [3, 4]. Therefore, to avoid the complications related to diabetes such barriers have to be handled with advanced and proven technologies for insulin delivery [5].

Beginning with the syringe for injecting insulin, progressing to insulin pumps, insulin pens, and sensor-augmented pumps, the growth of diabetes technologies accelerated with the introduction of hybrid closed-loop systems, integration with consumer electronics, and cloud-based data systems [6, 7]. These devices have favorably improved patients' perceptions about insulin therapy along with improving their quality of life [8]. However, the right choice and application of diabetes technologies are essential for positive outcomes.

The first manufactured insulin pump was introduced as early as in the 1970s, whereas the first manufactured insulin pen was introduced only in 1985 [9].

Insulin Delivery Devices

Insulin Vial and Syringe

In 1924, 2 years after the discovery of insulin, Becton, Dickinson and Company (BD) made a syringe specifically designed for insulin injection [10] (Fig. 69.1). Initially, syringes were made of metals and/or glass, which were reusable and after each use, required boiling for sterilization. In 1925, Novo Nordisk launched the first insulin syringe, the "Novo Syringe" (Fig. 69.2). To reduce the extent of needle-associated infections, disposable syringes were developed. In 1954, BD mass-produced the first glass disposable syringes called the BD Hypak. In 1955, an all-plastic Monoject syringe (Roehr Products Inc) was introduced onto the market. In the 1960s, BD introduced the 1-mL LuerLok insulin syringe available with either a detachable needle or a permanently attached needle. Disposable plastic syringes from numerous vendors were available on the market by the mid-1960s [11]. These syringes reduced pain and the rate of needle-associated infections [12]. In spite of all these advances, many patients did not feel to inject insulin 3–4 times a day due to needle phobia.

By 1970, BD manufactured the first one-piece insulin syringe with an integral needle [13]. Following, U-100 plastic insulin syringes with units marking down the side of the syringe came into use [11]. In 1988, the BD Safety-Lok insulin syringe with advanced safety features was introduced. In 2012, BD introduced the BD Veo insulin syringe with an Ultra-Fine 6-mm needle, offering less pain and reduced plunger force to ease the flow of large insulin doses [14]. Due to the reduced risk of intramuscular injections, this syringe has been widely preferred [15]. The FDA approved a U-500 specific insulin syringe designed by BD to address the dosing errors while administering doses from a U-500 vial with a U-100 insulin syringe in 2016 [16]. Instead of the long, large bore-sized and reusable needles used in earlier years, nowadays, small bore-sized and short-length needles (8 mm, 6 mm, and 5 mm) are used for insulin injection.

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_69

Fig. 69.1 First insulin syringe

Fig. 69.2 Novo syringe

For more than 50 years, vials and syringes have remained as the only option for insulin delivery although "conventional" syringe technology has become less popular in the current era.

Insulin Pen

Due to inconvenience and inaccuracy in preparing the insulin dose, insulin shots using vial and syringe have a lot of challenges [9]. These issues contributed to the development of insulin pens. The introduction of insulin pens was a phenomenal achievement in insulin delivery. In 1985, the first insulin pen, the NovoPen, was launched by Novo Nordisk followed by NovoPen 2 in 1988. NovoPen 2 has a distinct dial-up setting to measure the required dose [17]. In common, pens provide more simple, accurate, and convenient insulin delivery over syringes (Table 69.1). An insulin pen has mainly three components: an insulin cartridge, a disposable short needle, and an incremental "one-click per unit" dosing. These devices can be either reusable or disposable. Reusable insulin pens have a replaceable cartridge whereas disposable pens have a prefilled cartridge and are discarded after use.

Table 69.1 Advantages and disadvantages of insulin delivery methods

Methods	Advantages	Disadvantages
Vial and syringe	• Less expensive compared to insulin pen and pump	• Increased pain at the site of injection versus pen • Inconvenience in carrying • Decreased accuracy when compared to pens • Less patient-friendly
Insulin pen	• Efficient and convenient delivery of insulin • Accurate dosing and flexible because of disposable and reusable options • Ease of injection and time saving • Easy to carry • Better treatment compliance and long-term cost-effectiveness	• More expensive than syringes • Does not allow the mixing of different insulin types • Low dosing
Insulin pumps	• Continuous delivery of insulin • Better glycemic control • Increased patient compliance and acceptance • Decreased hypoglycemia	• More expensive • Increased risk of DKA if pump fails • Injection site infection • Technical and safety issues with the cannula and infusion set (detach, crimp, or leakage) • Can cause skin irritability or hypersensitivity in patients
Intraperitoneal	• Direct insulin delivery to the portal vein • More physiological	• Invasive • More cost • Increased risk of infection and portal vein thrombosis
Inhaled insulin	• Noninvasive • Increased patient compliance • Rapid onset of action (10–15 min) • Better PPBG control	• Reduced bioavailability • Inhalational devices issues • Decreased lung function • Transient cough
Oral insulin	• Increased portal insulin concentration • Noninvasive • Patient-friendly	• Reduced bioavailability
Buccal insulin	• Relatively large surface for absorption • Presystemic metabolism in the GI and liver avoided • The level of vascularization is very high in some areas	• Great variations of permeability among the different areas of the oral mucosa • Reduced bioavailability
Nasal insulin	• No interference with pulmonary functions	• Reduced bioavailability (15–25%) • Local irritation • Nasal irritation
Transdermal insulin	• Needle-free	• Skin irritation, blister, pain and redness • Safety not established

PPBG Postprandial blood glucose

Novo presented the world's first disposable, prefilled insulin pen known as "Novolet" in 1989 [18]. Insulin adsorbs onto the plastic surface of these prefilled pens over time and a precise concentration can be accomplished by legitimate blending. Therefore, the dose accuracy and blood glucose (BG) stability between cartridge changes are increased by pens [19].

The newer insulin pens are more accurate and furnish with safety features such as audible clicks with each dose to improve accuracy and reduce the chances of human errors [9, 20]. Another achievement in the pen device (HumaPen® Memoir™) is integrated with recording the time and date of the last 16 injections [21].

Compared with syringes, pens offer more flexibility, accuracy, discreetness, and long-term cost-effectiveness, providing improved treatment continuity and adherence. Therefore, the use of insulin pens exhibits better glycemic control and has wider acceptance [22, 23]. Despite insulin pens being convenient, less painful, and patient-friendly, they are related with higher cost in comparison with vial and syringe [24, 25].

Technologic refinements over the fundamental features of the earlier versions have produced more advanced insulin pens. Finer and safer needles which are shorter and thinner (31–32 G × 4–5 mm) that offer reduced pain perception and require less thumb force and time to inject insulin have also been developed resulting in improved patient satisfaction [26, 27].

First Generation Insulin Pens

From the 1990s, first-generation insulin pens are available on the market. The prominent insulin pens in this category are multiple generations of durable pens of the NovoPen family, AllStar (Sanofi), and prefilled pens, such as FlexPen, FlexTouch (Novo Nordisk), Humalog Pen, Kwikpen (Eli Lilly), and SoloSTAR (Sanofi) (Fig. 69.3). NovoPen 3, a durable pen allowing a maximum dosage of 70 U, was launched in 1992 (Fig. 69.4). The essential feature of this device was less wastage of insulin while resetting the dose at the dial and push-up buttons. This pen was more economical and was further refined for patient subsegments, such as NovoPen 1.5 and NovoPen Junior. In 1996, NovoPen 1.5 was launched, a shorter version of NovoPen 3, which can hold smaller insulin cartridges. NovoPen3 Demi, the first Novo family member to allow half-unit dose increments, was advertised in 1999. In 2001, FlexPen, a prefilled insulin pen, was introduced. In 2003, NovoPen Junior, with vibrant colors, specifically designed for children with diabetes, was initiated [28]. The NovoPen 4 (dose increments of 1.0 U, maximum dose of 60 U) was launched in 2005. In 2007 and 2008, refilled insulin pens, Kwikpen (Eli Lilly) and SoloSTAR (Sanofi), were launched respectively [29].

Fig. 69.3 First generation insulin pens

Fig. 69.4 NovoPen®

In 2011, Novo Nordisk introduced FlexTouch, a re-engineered version of the original FlexPen. It is the single prefilled insulin pen with an easy touch button, which improves the ease of use and device handling for the patients [30]. In 2012, Sanofi India launched its first indigenously developed reusable insulin pen, AllStar, specifically designed for diabetes patients in India. The key features of this pen are the slim and discreet design, clear dose magnification window, dose arrow on both sides, bayonet cartridge lock, short dial-out distance, penalty-free reverse dialing, audible click sound with every unit dialed and dispensed, and non-rotating dial button during dispensing [31]. In 2017, Junior KwikPen, a prefilled half-unit

insulin pen, was considered to be lighter and smaller than other half-unit insulin pens and was approved on the market.

In 2021, Toustar Reusable Insulin Pen Sanofi was intended to be used in conjunction with the insulin glargine 300 U/mL in a dedicated cartridge (Toujeo® 1.5 mL cartridges) to deliver insulin through subcutaneous injection using commercially available needles. The key features are user can reverse dial without losing insulin and simple "push-to-reset" plunger (no screwing required) [32].

Insulin pen needles of 4 mm, 5 mm, 6 mm, 8 mm, and 12.7 mm lengths are used. The Nano 4-mm pen needle (BD), the shortest pen needle, is more comfortable and easiest to use. These needles require low thumb force and allow higher flow rate and insulin absorption [33].

Next-Generation Insulin Pens

Since 2007, second-generation pen devices or "smart pens" with a memory function were available on the market. These devices have a multidose memory feature that allows storing the date, time, and amount of the previous doses [34, 35]. These devices are unified with USB or Bluetooth features for efficient monitoring and data management. In 2007, Eli Lilly launched HumaPen MEMOIR, the world's first digital insulin pen with memory, and HumaPen LUXURA HD, a reusable pen for people who require insulin dosing in half-unit increments from 0.5 to 30 units. In 2010, Novo Nordisk launched NovoPen Echo, the first insulin pen with memory and half-unit dosing features [36]. In 2012, NovoPen 5, a successor to NovoPen 4 was launched with a simple memory function for use with the 3-mL Penfill cartridge [37].

The newer smart pens are designed to guide the individual with diabetes about the insulin dosage (by means of inbuilt calculators), memory functions to remember the amount and time of insulin dosage, and automatic transmission of insulin dose to the mobile logbook through Bluetooth technologies [12].

Connected Pens

Connected pens are next-generation insulin pens with characteristics that go beyond the memory function. In 2017, Pen System was launched by Companion Medical which consists of a Bluetooth-enabled wireless insulin pen with a smartphone interface and bolus advisor [38]. These pens will automatically record the dose of insulin injected, and the data can be shared with collaborating CGM devices and Glooko's Diasend digital diabetes management platforms and are expected to be synced with Roche's mySugr app [39]. Novo

Fig. 69.5 NovoPen 6 and NovoPen Echo Connected pens

Nordisk's NovoPen 6 and NovoPen Echo Plus also fall into this category of pens (Fig. 69.5). These pens will automatically record the dose of insulin injected and the data will be shared with Dexcom G6 CGM, FreeStyle Libre system (Abbott), and Glooko's Diasend digital diabetes management platforms. Connected pens are furnished with NFC (near-field communication) technology that permits scanning of these devices to transfer the data off to another device [40]. Another advanced innovation in pen technology was Bluetooth/internet-connected insulin pen cap that aids the generation of smart dosing systems through a mobile app for the convenience of T1DM patients who do not use an insulin pump [41].

Even though insulin pens offer the convenience of use, less pain, and better treatment adherence and health outcomes, they have limitations such as difficulty in applying a mixture of insulins, higher cost, and lack of universal insurance coverage [42]. Regardless of the ease of use, pens are mechanically more complex than insulin syringes [43].

InPen Smart Insulin Pen

In 2020, Medtronic launched connected smart insulin pen, the InPen, acquired from Companion Medical. The InPen is the only FDA cleared, smart insulin pen system that combines the freedom of a reusable Bluetooth pen with the intelligence of an intuitive mobile app that helps users administer the right insulin dose, at the right time (Fig. 69.6). The InPen sends dose information to a mobile app and the app uses the glucose levels and a carbohydrate estimate to recommend the dose. It even considers the amount of insulin that is still working in the body, to help avoid low glucose.

Fig. 69.6 InPen with Guardian connect and connected app

Injection Aids: I-Port Advance Injection Port

To reduce the frequency of multiple injections and needle phobia in patients with diabetes, injection aids are also used in practice. In 2016, an injection port was designed known as i-port Advance launched by Medtronic. It is a small and discrete patch, which can be attached to the skin and the device remains adhered to the skin for up to 72 h and allows multiple injections. It is the first device to combine an injection port and an inserter in one complete set which helps to eliminate the need for multiple injections without puncturing the skin for each dose. This device is useful for insulin requiring patients having needle phobia and helps them to accomplish glycemic control effectively [44, 45]. Although there was an initial excitement, this device remains unpopular probably because insulin shots with newer needles are virtually painless.

Insulin Pumps

Insulin pumps are small, computerized devices that imitate the way the human pancreas works by delivering small doses of short acting insulin continuously (basal rate). The device is also used to deliver variable amounts of insulin when a meal is eaten (bolus). Pumps are modernized gadgets for the delivery of insulin and can be used for dispensing insulin in any patient who exhibits the desire to initiate pump therapy and fulfills the criteria for a pump candidate [1].

Continuous Subcutaneous Insulin Infusion (CSII)

In normal physiology, a continuous small amount of insulin secretion from the beta cells of the pancreas reduces hepatic glucose output, and when food is ingested a larger amount of insulin is secreted to maintain euglycemia [46]. The CSII therapy was used by DCCT trial in nearly 40% of the participants in the intensive arm [47]. The current generation of insulin pumps are more patient-friendly due to its smaller size and smart features such as built-in-dose calculators and alarms [46]. The main components of an insulin pump are an insulin reservoir, infusion set, and tubing. The insulin reservoir is connected to the infusion set and a catheter helps to continuously deliver insulin to meet the daily requirement. The pump has user-specific inbuilt programs to dispense insulin at basal rates (slow, continuous) and in incremental (bolus) doses before meals [48]. This characteristic helps in the removal of the inherent variations associated with the injection depth and multiple injection sites that are typical of conventional subcutaneous injections. The infusion site needs to be changed only once every 2–3 days. Therefore, insulin pumps terminating the need for multiple injections on a daily basis can lead to less insulin variation [49, 50].

In 1963, the first portable insulin pump was invented by Dr.Arnold Kadish but it was limited by its size and technical issues [51](Fig. 69.7). In 1979, the first commercial insulin pump was introduced in the USA [20]. In 1976, Dean Kamen introduced the first wearable insulin pump, known as the "blue brick" and later the "autosyringe," and led to the introduction of insulin pump therapy in the same year [52]. The first SOOIL insulin pump was clinically evaluated at Seoul National University Hospital in 1979 [53]. In 1983, MiniMed introduced their first insulin pump, MiniMed 502. In 1986, MiniMed introduced the implantable insulin pump to deliver insulin intraperitoneally. Insulin delivered through this device was absorbed quickly and directly to the portal system [54]. In 2000, new versions of the pump with improved memory and battery life were launched on the market. Later in 2007, implantable insulin pump devices were discontinued by Medtronic.

In the 1990s, new-generation external pumps were released which are comparatively small, compact, handy, and effective. These "smart pumps" have characteristics as built-in bolus calculators, personal computer interfaces, and alarms [55]. The insulin pump models which are approved on the global market are Medtronic MiniMed,

Fig. 69.7 Dr. Arnold Kadish with the first insulin pump

OmniPod (Insulet), T:Slim (Tandem), DANA R (SOOIL), Cellnovo, Accu-Chek Solo Micropump (Roche), and Ypsomed [56].

Medtronic introduced the first-ever "intelligent" insulin pump in 2003. The system comprises a MiniMed Paradigm 512 insulin pump and a Paradigm Link blood glucose monitor. Nowadays, BG readings from the glucometer are wirelessly and automatically transmitted to the insulin pump, and the required insulin doses are recommended by a Bolus Wizard calculator [57].

Insulin pumps are commonly used for insulin replacement in T1DM patients, but it has now been widely used by T2DM patients as well [58]. In patients with hyperglycemia, diabetes management with CSII provides better glycemic and metabolic control (reduces HbA1c, glycemic variation, and hypoglycemia) [59, 60]. The use of insulin pumps contributes to the patients' quality of life. However, the major limitations associated with the infusion sets are that they can exhibit handling issues and can detach, leak, or cause skin irritability, thus undermining the convenient use of insulin pumps [61]. Patient education before starting CSII therapy is of utmost importance to avoid the chances of a "pump failure" [62].

Patch Pumps

The barriers associated with infusion set have led to the development of "patch pumps." These pumps are free of infusion sets, small, lightweight, and attached to the skin through an adhesive. Patch pumps also offer additional comfort and flexibility to users, especially while traveling. Insulet introduced OmniPod, the first tubeless insulin pump in 2011. It consists of an integrated infusion set and automated inserter that converses wirelessly with an integrated BG meter. The Omnipod patch pump provides complete freedom to the users to engage in routine activities [63]. The specific simplified patch pump models available on the market are V-Go (Valeritas) and PAQ (CeQur) [64]. The second-generation Omnipod, which is smaller and more compact was launched in 2013. This version of the patch pump has modern features such as "human factor screens" and improvements in both correction and meal boluses for insulin dose calculation [65].

Continuous Intraperitoneal Insulin Infusion (CIPII)

Continuous intraperitoneal insulin infusion (CIPII) is considered to permit the infusion of insulin into the peritoneal cavity. The advantage of this method is that it more closely coincides the physiology than the other conventional therapies [66]. Two different technologies have been developed in CIPII: implanted intraperitoneal pumps such as MiniMed MIP2007C (Medtronic) and a percutaneous port attached to an external pump such as the Accu-Chek Diaport system (Roche Diabetes Care). The MIP 2007C is implanted under the subcutaneous tissue in the lower abdomen, and from this subcutaneous pocket, the peritoneum is opened, and the tip of the catheter is carefully inserted and directed towards the liver. After implantation, at least every 3 months the pump reservoir is refilled in the outpatient clinic with concentrated insulin transcutaneously. The Accu-Chek Diaport system permits insulin infusion into the peritoneal cavity through an Accu-Chek insulin pump and an infusion set. CIPII has been proven as a viable option for T1D patients with skin problems and unable to securely or efficiently control their diabetes with subcutaneous insulin [67].

The drawbacks of this route of insulin administration include the invasive nature, cannula blockage, higher cost, portal vein thrombosis, and peritoneal infection. Medtronic announced the worldwide termination of the implantable insulin pump in 2007.

Sensor-Augmented Pump Therapy (SAP)

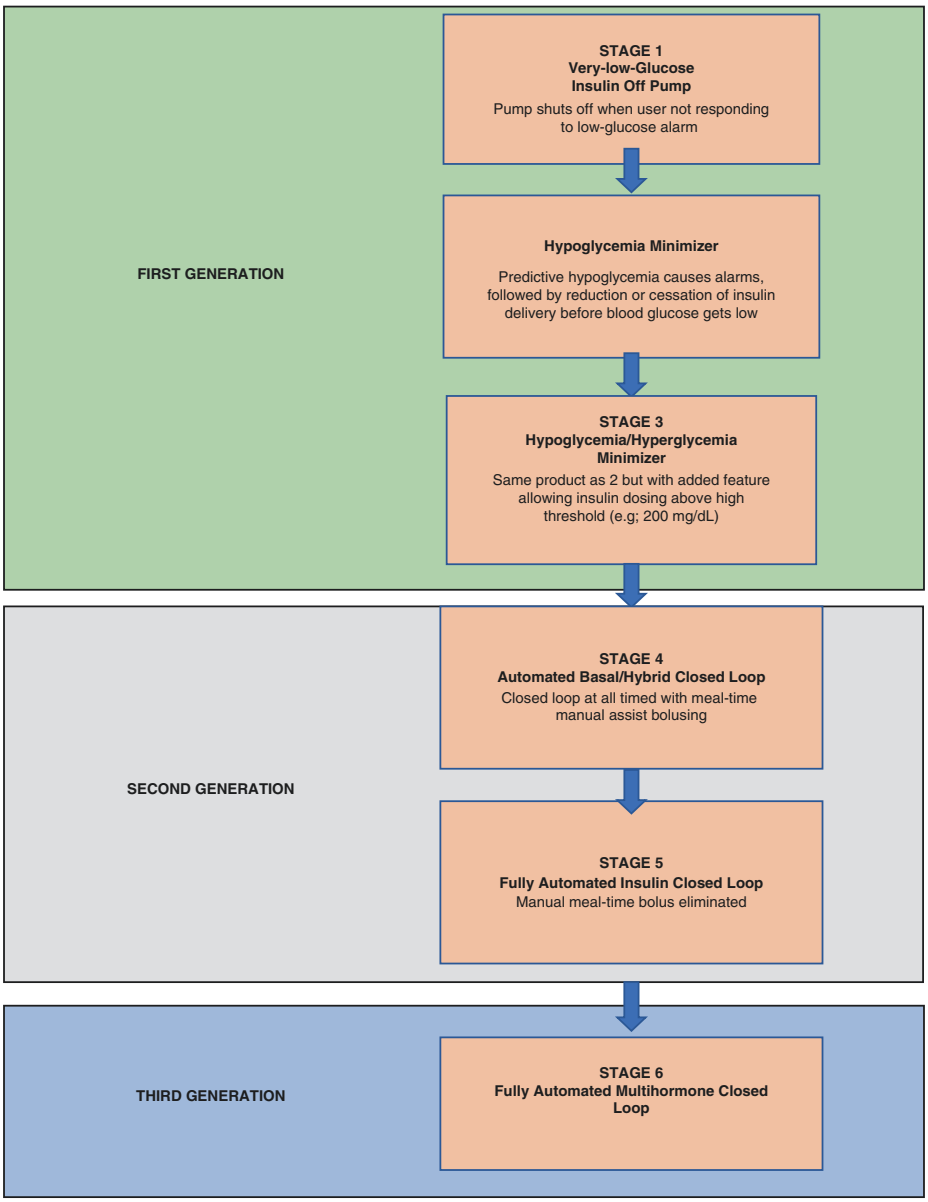
The new generations of CGMs are more accurate, smaller in size, and shown to improve glycemic control in patients with T1DM [68]. When CGM readings are used to adjust insulin

delivery through an insulin pump, it is known as sensor-augmented pump (SAP) therapy [69]. In patients with T1DM, SAP reduces A1c by 0.7–0.8% compared to baseline or MDI therapy. The introduction of real-time, sensor-augmented insulin pumps is considered a major turning point in the development of "closed-loop" insulin delivery or an artificial pancreas (AP) [1]. SAP therapy produces higher-level results in reducing hypoglycemia and achieving glycemic control to conventional therapies [70, 71].

Medtronic launched the MiniMed Veo System in 2009, with a Low-Glucose Suspend feature that automatically halts insulin delivery when sensor glucose levels reach a preset low threshold. This device has been considered the first stepping stone to an AP system [72].

The pump provides more accurate dosing, avoids the need for multiple daily injections, and thus provides convenience and a flexible lifestyle. They can also store a plethora of data that can be transmitted to computer programs or bolus insulin calculators and further analyzed to make insulin dose adjustments. The limitations of pump therapy are technical problems associated with the infusion set and higher acquisition costs. Patients also complained of skin irritations and infections at the insertion sites. Technical issues such as kinking, bending, or crimping of inserted cannulas and leakage of infusion sets have also been observed [61]. SAP requires patient involvement for using CGM glucose readings to adjust insulin pump delivery. This makes SAP susceptible to human errors.

Automation of Insulin Pump



Artificial Pancreas (Closed Loop)

MiniMed 530G with an Enlite sensor has been acknowledged as a first-generation artificial pancreas (AP) device system with Threshold Suspend automation. In 2013, this device was approved by the FDA for diabetes patients >16 years of age [55]. In 2015, Medtronic introduced the MiniMed 640G system, which has been taking one step closer to the artificial pancreas system. This system has integrated smart characteristics such as active insulin tracking, a bolus progress bar, and predictive battery life [73] (Fig. 69.8).

Since the conception of CSII, the main aim was to design an artificial pancreas that mimics exquisite sugar control with minimal human interference. An artificial pancreas or a "closed-loop" is a compilation of progressive technologies to engage automation to achieve glycemic targets. Generally, AP links three devices [74]:

1. A sensor like CGM that measures BG and sends data to a computer algorithm
2. A control algorithm to analyze the data and calculate the required insulin dose
3. An insulin infusion pump to deliver insulin as per the computer instructions

Fig. 69.8 A new-generation insulin pump: MiniMed 640G insulin pump system by Medtronic

Since 2016, safety and efficacy studies have been conducted on the combinational use of the predictive low-glucose suspension algorithm (PLGM) (commercially, "SmartGuard technology") with the MiniMed 640G insulin pump that automatically suspends insulin delivery based on the prediction of low glucose levels [75]. In 2017, the first hybrid closed-loop system, the MiniMed 670G insulin pump with a Guardian 3 sensor, was approved by the FDA (Fig. 69.9). When in auto mode, it functions as a hybrid closed-loop system that automatically controls basal insulin delivery every 5 min based on the CGM values to hold BG levels tightly to the specific target [8]. These systems have been reported to enhance glycemic targets [BG, HbA1c, time-in-range (TIR)] and reduce the incidence of nocturnal hypoglycemia to improve better safety, treatment satisfaction, sleep quality, and cognition in T1D patients [76–78].

In 2018, the FDA approved Insulet's Omnipod Dash System, a CSII system comprising a tubeless, waterproof, Bluetooth wireless technology pump with a capacity of 200 units of U-100 insulin and an advanced personal diabetes manager (PDM) that regulates the pump [79] (Fig. 69.10).

In 2021, Medtronic launched new MiniMed 780G insulin pump designed to work with Medtronic's Guardian sensors to continuously monitor glucose levels throughout the day (Fig. 69.11). Basal insulin adjusts insulin dosage every five minutes as needed based on glucose levels. Bolus is delivered automatically up to every 5 min if maximum auto basal delivery is reached or if glucose level is above 120 mg/dL. This pump helps to achieve the Time in Range goal of >70% and HbA1c goal of 7.0%.

Future steps in the evolution of the artificial pancreas will be [80]:

1. Use of predictive algorithms to minimize hypoglycemia even before hypoglycemia occurs.
2. Use of algorithms to keep blood sugar in target range (hypoglycemia/hyperglycemia minimizer).
3. Automated basal and/or hybrid closed-loop.
4. Fully automated (insulin).
5. Dual (insulin + glucagon) hormonal closed-loop.

Fig. 69.11 MiniMed 780G System

Alternate Controller-Enabled Infusion (ACE) Pumps

Another modern technology in this area has been the arrival of alternate controller-enabled (ACE) infusion pumps. Despite the conventional stand-alone pumps, ACE pumps can be interoperable: used jointly with different components of diabetes technologies, permitting custom-made diabetes management for patients according to individual device preferences. The ACE insulin pump can be combined with automated insulin dosing (AID) systems, CGMs, BG meters, and other electronics. In 2019, the FDA approved the first interoperable t:Slim X2 insulin pump for subcutaneous insulin delivery for children and adults with diabetes [81]. The FDA approved a new-generation, interoperable, control-IQ artificial pancreas system (tandem diabetes) in 2020. A clinical trial that revealed that the use of the control-IQ AP system was linked with a greater percentage of TIR, over the use of SAP, paved the way for this approval [78].

Do-It-Yourself Artificial Pancreas (DIY-APS)

People affected by T1DM have been expecting an affordable and efficient solution for the management of this chronic disease for decades. Lack of accessible and actionable data, unaffordability of the current systems, and long timeline of

medical device development cycles have led to general annoyance in the T1DM community. The first Diabetes Mine D-Data Exchange gathering at Stanford University spotlighted the sentiments and frustrations of patients with T1D and their families/caregivers gathered online under the hashtag "#WeAreNotWaiting" in waiting for their needs to be addressed in 2013. This event marked the beginning of the DIY-APS movement. A major dimension of the #WeAreNotWaiting initiative was that the tech-savvy diabetes followers started self-building their closed-loop systems, also known as "looping." These automated insulin delivery systems are generally known as a "Do-it-yourself" artificial pancreas (DIY-APS) [82, 83]. The basic components of DIY-APS are:

(a) A real-time CGM.
(b) An insulin pump.
(c) A minicomputer or smartphone app.

The diabetes community shared DIY diabetes device-related projects on digital and social media platforms such as Facebook, Twitter, NightScout, and GitHub, which led to the merging of these projects [84]. Through a gradual and systematic method of assembling, merging, and processing data from patients' devices to deliver significant actionable information, there has been a rush in the propagation and convergence of DIY diabetes device-related projects. Dana Lewis, Scott Leibrand, and Ben West launched the OpenAPS project, providing the instructions and outline of a DIY patient-built artificial pancreas system (APS) in 2014. In 2015, the open-source version, also known as OpenAPS, was launched [85]. On January 31, 2020, more than 1776 PWD around the globe have implemented various layouts of DIY-APS [86]. DIY-APS uses individually made unauthorized algorithms to convert CGM data and calculate insulin doses, FDA approved communication devices and insulin pumps. Since it involves the use of unauthorized algorithms, these systems are not FDA approved, commercialized, or regularized. In 2017, another innovation in the DIY-APS evolution was "RileyLink," designed by Pete Schwamb for his daughter Riley, who had T1D. It is a translator device that allows easy communication between the insulin pump and iPhone. This device is considered more user-friendly, and it is easy to set up and maintain procedures [87]. Real-life experiences from patients and caregivers, unscientific data, and published reports from selected cohorts have highlighted the clinical benefits and reductions in self-management burden with DIY-APS [88].

In India, Jazz Sethi, a 26-year-old professional dancer from Ahmedabad, who has been living with T1D since the age of 13, is the first user of Do-It-Yourself (DIY) artificial pancreas. *Diabetes and Metabolic Syndrome: Clinical Research and Review* has narrated her experience with this breakthrough technology, why she decided to use the system, and how the device has produced significant improvement in her quality of life and management of T1D [89].

There are mainly three types of DIY-APS:

1. OpenAPS
2. AndroidAPS
3. Loop

OpenAPS

OpenAPS is a safe, powerful, and easily understandable system that proposes to adjust insulin dosage to manage the BG levels in the recommended range, overnight and between meals. The first Open APS was developed by Dana Lewis, Scott Leibrand, and Ben West, and the code written with the help of Chris Hannemann was on a Raspberry Pi computer and a communication stick to connect to an old Medtronic pump.

Generally, an OpenAPS consists of an insulin pump, a CGM system, and an algorithm running on a microcomputer. The algorithms used in OpenAPS are oref0 (OpenAPS Reference Design Zero), Adjusting for unexpected BG deviation, and Bolus snooze. Recently, an "Advanced Meal Assist (AMA)" feature has been integrated into the OpenAPS algorithm. AMA gives an extremely adaptable algorithm for securely dosing insulin after meals, regardless of broadly differing meal types, and the high variations in rates of digestion between individuals, making it the most widely used postprandial insulin dosing algorithm. The ultimate aim of the OpenAPS system is to completely automate insulin dosing in all situations. In that regulation, an oref1 algorithm has been developed that utilizes small "supermicroboluses (SMB)" of insulin at mealtimes and ensures more rapid and secure insulin delivery in response to BG rises [90].

OpenAPS reads the CGM data every 5 min and queries the insulin pump every few minutes for recent settings and activities such as current and maximum basal rates, recent boluses, insulin on board (IOB), insulin sensitivity factor (ISF), carb ratio (CR), duration of insulin acting (DIA), and BG target/ range. Based on the communication from the insulin pump, OpenAPS updates the bolus wizard calculation and decides upon whether to cancel or supply a temporary basal. OpenAPS accomplishes this function through a physical piece of hardware called a "rig" that implement a sequence of commands to collect the CGM data, runs it through Oref0, and performs the dose calculations based on the pump setting values. The system can guide on changes in insulin to carbohydrate ratios and ISF settings through either Autosens (checking back 8–24 h) or Autotune (check back either 24 h or a user-specified period). However, this was the first developed system; recent users have been preferring AndroidAPS which offers more combinations of compatible devices and in-warranty pumps.

AndroidAPS

AndroidAPS is an open-source app with all properties of OpenAPS but runs on Google Android smartphones. The smartphone receives data from a CGM and transmits it with the insulin pump via Bluetooth. In 2017, the first AndroidAPS was developed in Europe by Milos Kozak and Adrian Tappe and it works with modern in-warranty pumps with Bluetooth capability. The algorithms used here are Oref0 and Oref1. The app is available in different versions particular to geographic locations and languages. The basic elements of the profile include basal rates (BR), ISF, CR, and DIA. AndroidAPS supplies multiple possibilities for remote monitoring of adults and pediatric patients with T1D. NSClient app can be used to check the relevant data by parents and caregivers of kids with T1D on their Android phones. Features like alarms using the xDrip+ app in follower mode, remote monitoring and control with SMS commands, and remote profile switch and temperature targets through the NSClient app provide the kid-friendly convenience of this system.

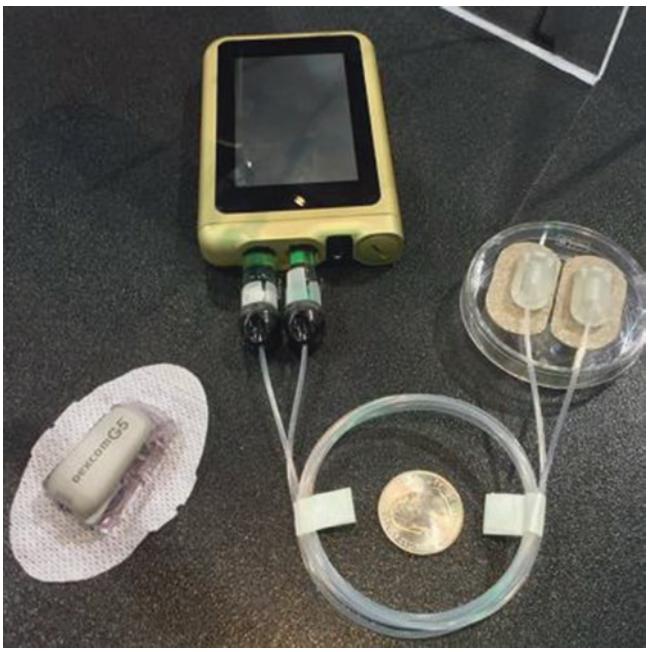

Fig. 69.12 iLet Bionic Pancreas

Loop

The Loop algorithm is different from OpenAPS and runs on an iOS operating system. The Apple iPhone receives CGM data and communicates with the insulin pump via Bluetooth. In 2016, the first loop was developed by Nate Racklyeft and a D-Dad, Pete Schwamb. Loop makes use of a free application, Xcode, to convert the raw code into an iOS application and install it on an iPhone. Loop documentation is available on GitHub and the builders need to register as Apple developers to install the necessary software. The loop makes a forecast using BG values every 5 min from 30 min ago and integrates between that value and the current glucose value to make adjustments in insulin dose and to provide bolus recommendations and temporary basal rates. The app communicates with a small translator device called RileyLink that ensures interaction between the pump, iPhone, and CGM [90]. It is almost the size of a tic-tac box and needs to be carried with you at all times. In a loop system, the pump speaks via radio language and the iPhone speaks via Bluetooth, and RileyLink acts as a translator to loop these parts together.

Bionic Pancreas (BP)

The "bionic pancreas" is a type of closed-loop system consisting of two infusion pumps (separately for insulin and glucagon) and connected to a CGM via a smartphone app. In 2015, the first bionic pancreas, "iLet" (Beta Bionics), exclusively for T1D treatment, was innovated by Dr. Edward Damiano. In this system, based on the appraised CGM data automated dosing assessments of insulin and glucagon levels are made every 5 min (Fig. 69.12). These data are transmitted to pumps to control insulin or glucagon delivery [91]. In 2019, the FDA approved iLet BP as the "breakthrough device designation" [92].

D-Dads

D-Dads are fathers whose fatherhood has been challenged by T1D. Unsatisfied with the disruption and unpredictability of diabetes care, some D-dads thought "outside the box" to ease the burden of diabetes management.

Dr. Edward R. Damiano, a professor of biomedical engineering at Boston University, was determined to develop a bionic pancreas when his 11-month-old son, David, was diagnosed with T1D. Frustrated with the absence of reliable technologies, he created a bionic pancreas with the help of physicians and researchers [93]. The US Food and Drug Administration (FDA) conferred "breakthrough device designation" to the iLet bionic pancreas in 2019 [94]. Pete Schwamb, a software engineer, made innovatory contributions in the field of diabetes technologies. Pete's effort to gain access to the insulin pump data of his 6-year-old daughter, Riley, led to the development of RileyLink, a translator device used to communicate between the insulin pump and iPhone. Later, he developed the first iOS-based automated insulin delivery system, "loop," in association with Nathan Racklyeft [95]. Bryan Mazlish, a Wall Street quantitative analyst and one of the cofounders of Bigfoot Biomedical, made a fully functional homebrew artificial pancreas to manage

his son's T1D. Being a hacker by profession, he has been recognized as a standard-bearer for the DIY-APS hacking mission [93]. Jeffrey Brewer, a past president of the Juvenile Diabetes Research Foundation (JDRF), also known as "the father of the artificial pancreas," has commenced research projects on automated insulin delivery systems. Later, he co-founded Bigfoot Biomedical accompanying Bryan Mazlish to develop its own closed-loop system, the Bigfoot smartloop system [96]. John Costik, the father of a 4-year-old boy, Evan, who had T1D, designed a code to hack his son's CGM, to upload the values into the cloud and remotely acquire those data using a web-based or android interface. He later made the code available as open-source and initiated "Nightscout CGM in the Cloud Project" for wider dissemination of the technology [85, 97]. Lane Desborough, D-Dad of Hayden is the name of an engineer from Medtronic, one of the so-called D-dads in diabetes technology by Nightscout CGM in the Cloud. He was a chief engineer at Medtronic and was one of the advocates of the #WeAreNotWaiting movement. Lane was the first person to get involved in the DIY-APS movement from the industry and later co-founded Bigfoot Biomedical [98]. Tidepool, a non-profitable organization was started by the D-Dads Howard Look and Steve McCanne and has been creating a regulated loop version of DIY-APS. Tidepool is currently on a venture to release a regulated version of the DIY-APS in collaboration with Omnipod and Dexco [99, 100].

D-Dads have been making significant contributions to turn the artificial pancreas dream into reality while focusing on its equitable access and affordability.

Bolus Calculator Apps

Bolus calculator/bolus advisor mobile apps are used for insulin dose calculation available in smartphones. These can function independently or can be integrated into pumps to calculate the accurate insulin dose by incorporating expected carbohydrate intake, measured blood glucose values, and previous insulin doses [101]. The most commonly used bolus calculator apps are Diabetes: M, mySugr (Roche), and PredictBGL. Bolus wizards are built-in automated bolus calculators specific to insulin pumps for insulin dose recommendations. The use of bolus wizards has been correlated with better glycemic control and treatment satisfaction [102]. In 2016, Endocrine Society Clinical Practice Guidelines have strongly promoted patients to use suitably adjusted built-in bolus calculators in CSII to improve glycemic control [103].

Implanted Pancreas

Another novel AP technology was the implanted artificial pancreas, a fully implantable insulin delivery device, which is under development at De Montfort University. It is a gel-based system that responds to BG variation by changing the insulin delivery rate. The performance of this system in glycemic control is well tested in a diabetic domestic pig [104]. It reduces hourly management and human interference to improve user acceptance and quality of life in diabetes patients [105].

Insulin Inhalers

Insulin delivery to the lungs was the first reported substitute for subcutaneous injection. It has long been estimated that insulin delivery by aerosol reduces blood glucose [106]. Insulin inhalers permit patients to breathe fine-inhalable insulin (pulmonary insulin) (either dry powder-based formulations or solution) into their lungs [12].

Advantages of the pulmonary route include a broad and well-perfused absorptive surface, the absence of certain peptidases that are present in the gastrointestinal (GI) tract that breaks down insulin, and the ability to bypass the "first-pass metabolism" [107]. Although the exact mechanism of insulin absorption across the pulmonary epithelium remains unclear, it is believed to involve transcytotic and paracellular mechanisms [106].

When introduced to the market, inhalable insulin was considered a remarkable innovation to address needle phobia and incorrect insulin injection techniques pertained to systemic insulin delivery methods [108]. In 2006, the first inhaled product Exubera® was approved by the US FDA. Exubera® was a dry power formulation available as 1 mg and 3 mg doses to be taken with the help of an Inhance™ inhaler device [109]. Exubera® was found to have pharmacokinetic and pharmacodynamic (PK/PD) properties similar to insulin aspart with a faster onset of action (10–15 min) [110]. In clinical trials in patients with uncontrolled T1DM and T2DM, Exubera® was found to reduce postprandial blood glucose and A1c markedly [111] although Exubera® was contraindicated in smokers as it increased the risk of hypoglycemia due to greater absorption compared to nonsmokers [112]. Along with this, patients were required to undergo pulmonary function tests before treatment initiation, after 6 months, and annually thereafter [109, 112]. This product did not flourish well commercially despite the noninvasive route possibly due to higher cost, the bulky delivery device, concerns related to decline in pulmonary function, and less preference by the patients and physicians. In 2007, this product was withdrawn from the market due to poor sales volume.

Another promising inhaled insulin is Afrezza (Sanofi and MannKind) based on Technosphere® dry powdered formulation. The onset of action of Afrezza inhaled insulin is 15 min and duration is 2–3 h, which is ideal for postprandial blood glucose control [113]. Initially, the common side effects are transient non-productive cough and a modest

reduction in lung function [114]. In 2014, Afrezza got FDA approval for prandial insulin therapy [115]. The delivery system of Afrezza is small, handy, and displays the dose in units [116]. The use of Afrezza has provided remarkable glycemic control and reduction of hypoglycemia in T1DM patients [117, 118]. The recognition of inhalable insulins is further limited by insurance barriers, safety concerns, and competing products [116].

Jet Injectors

Another possible innovation to the market could be jet injectors, a type of syringe that dispenses insulin subcutaneously with the use of a high-pressure air mechanism. In the 1860s, Pioneer jet injector technology was introduced. Later, it was reintroduced in the 1940s as the "Hypospray," focusing on patients' self-management of insulin. In the 1950s, the US military designed a high-speed system, "Ped-O-Jet" (Keystone Industries), in the category of a multiuse nozzle jet injector (MUNJI) for mass vaccination programs. In 1997, the Ped-O-Jet was discontinued as a result of contamination issues built with the use of MUNJI [119]. During the 1990s, the new-generation, disposable-syringe jet injectors (DSJIs) with disposable dose chambers (insulin cartridge) and nozzles were launched. Even though the idea is not firsthand to the market, the wider acceptance of these devices has been interrupted by the cost, low absorption with the repeated use, and high contamination rates of the previous systems [120]. The jet injectors are a solution for patients with needle phobia [121]. Recent safety and feasibility studies have assessed the treatment efficiency and pharmacokinetic and pharmacodynamic (PK-PD) profiles of the insulin administered by the new-generation jet injectors [122].

Oral Insulin

The oral route of insulin administration may be the most patient-friendly way of taking insulin and it could more closely imitate physiological insulin delivery (more portal insulin concentration than peripheral) [123]. Despite this, the limitations in making oral insulin include inactivation by proteolytic enzymes in the GI tract and low permeability through the intestinal membrane due to the larger size and hydrophobicity of insulin resulting in poor bioavailability. Several pharmaceutical companies are engaged in developing carriers to protect insulin from GI degradation and facilitate intestinal transport of insulin to deliver insulin to the circulation with sufficient bioavailability.

Natural and synthetic nanoparticles have been used as a carrier or vehicle for insulin such as chitosan, liposomes, polymeric nanovesicles, polylactides, poly-ε, poly-alkyl cyanoacrylate, and various polymeric hydrogels [124–129].

Certain oral insulin preparations such as Capsulin, ORMD-0801, IN-105, oral hepatic directed vesicles, and Eligen have undergone phase 1 and phase 2 trials with promising results [130].

Colonic Insulin Delivery

Oral colon delivery is currently considered of importance not only for the treatment of local pathologies, such as primarily inflammatory bowel disease but also as a means of achieving systemic therapeutic goals. The large intestine is preferably not suited for absorption processes for drugs but it has certain advantages over the small intestine like long transit time, lower levels of peptidases (prevent the destruction of peptides), and higher responsiveness to permeation enhancers. Accordingly, it has been under extensive inquisition as a possible strategy to enhance the oral bioavailability of peptide and protein drugs. Oral delivery systems intended for colonic release of insulin were devised according to microflora-, pH-, and time-dependent strategies [131].

Bioavailability and pharmacological availability data are generally still far from being reliable in terms of magnitude, onset, duration, and above all, consistency for this route of administration and it is under investigation and despite its progress, there is still a long way to go before these products will be available on the market.

Nasal Insulin

In theory, intranasal delivery has several advantages over oral (bypass GI peptidases), subcutaneous (noninvasive and painless), and inhalation route (no issue with lung function) which makes this route appealing for the delivery of insulin. However, intranasal delivery has disadvantages such as limited permeability of a large molecule through the nasal mucosa and rapid mucociliary clearance resulting in variable absorption [132].

Significantly, intranasal delivery with early porcine and bovine insulins was studied in patients with T1DM [133, 134]. Currently, two technologies are under investigation: Nasulin™ (CPEX Pharmaceuticals) and nasal insulin by Nastech Pharmaceutical Company Inc. Both insulin preparations have a bioavailability of about 15–25% with the onset of action approximately 10–20 min [135, 136]. The substances such as bile salt, surfactant, and fatty acid derivatives are being investigated to improve mucosal permeability of insulin but they increase the risks for local irritation, nasal secretion, sneezing, or burning sensation [137].

Nasal insulin crosses the blood-brain barrier since it has a hypothesized effect on memory function [138]. Treatment with intranasal insulin improved memory, preserved caregiver-rated functional ability, and preserved general cog-

nition without any remarkable hypoglycemic event. These improvements in cognitive functions were combined with changes in the Aβ42 level and in the tau protein-to-Aβ42 ratio in cerebrospinal fluid [139]. Based on these, investigations are ongoing to evaluate the usefulness of this agent for the treatment of Alzheimer's disease.

Buccal Insulin

Buccal delivery of insulin has similar efficacy as oral insulin with the advantage of bypassing GI degradation. In addition, the relatively large surface area results in better bioavailability [140]. Initially, Generex Biotechnology developed Oral-lyn™ which is a liquid formulation of short acting insulin that is administered using Generex's metered dosage aerosol applicator (RapidMist™). Eli Lilly and Generex conducted phase 1 and phase 2 trials in patients with T1DM and T2DM with favorable results [141]. Another fragment being developed by Shreya Life Sciences Pvt. Ltd., India, is oral Recosulin® [142].

Another technique for the delivery of insulin is fast dissolving films as a substitute to oral tablets for rapid drug delivery [143]. The Monosol Rx (Pharm Film Drug delivery technology) in collaboration with Midatech Company developed Midaform™ insulin, which is delivered by buccal route.

Transdermal

Transdermal insulin delivery terminates the problems associated with needles and injections and the large surface area of the skin makes it an appropriate route for insulin delivery. Although the perforation of insulin is halted by the stratum corneum, the outermost layer of the skin, numerous methods have been explored to overcome the barrier of the stratum corneum [144].

There are several strategies insulin can be delivered transdermally such as:

(a) Iontophoresis, the technique that uses small electric currents [145].
(b) Sonophereis or phonopheresis uses ultrasound waves [146].
(c) Microdermal ablation by removing the stratum corneum [147].
(d) Electroporation utilizes high voltage pulses that are applied for a very short time [148].
(e) Transfersulin is the insulin encapsulated in transferosome, an elastic, flexible vesicle, which squeezes by itself to deliver drugs through skin pores [149].
(f) Insupatch™, a device developed as an add-on to an insulin pump that applies local heat to the skin in order to increase the absorption of insulin [150].
(g) Recombinant human hyaluronidase (rHuPH20) to increase insulin absorption from subcutaneous tissue [151].

Moreover, microneedles with a 1 μm diameter and of various lengths can deliver insulin in an effective, accurate, and precise manner [152]. Microneedle technology also can be combined as a transdermal patch.

The transdermal insulin delivery techniques are limited by skin injury, burn or blister formation, and rarely significant pain and discomfort.

Other Non-conventional Routes

Ocular Route

No human trial has been reported with this route and an animal study failed to achieve significant plasma insulin concentration [153].

Rectal Route

Rectal gels [154] and suppositories [155] showed fair results. However, this route is not commercially viable.

Intra-Tracheal

In 1924, the administration of insulin was reported [156] but is not practical so not taken up for further development.

Conclusion

There is a long history of research focusing on recognizing a route of administration for insulin that is minimally or non-invasive, effective, safe, convenient, and cost-effective for patients. Each route and delivery method has its own potential advantages and disadvantages. There has been a high-speed evolution in diabetes technologies to improve the quality of life and to extend the endurance of subjects with diabetes. Though there were commendable developments in the currently available devices, many of those were prohibitively expensive. Additionally, there were serious issues associated with cannula blockages, infusion set handling, Bluetooth connectivity, and user-friendliness. As the search for more accurate and user-friendly methods continues, advances in pumps, CGMs, and predictive algorithms can

make the closed-loop system as physiologic as possible with >90–95% TIR and the least time spent in hypoglycemia. Some of the promising experiences are shared by subjects using DIY-APS. The DIY revolution has prompted all device manufacturers to introduce ACE pumps and compatible sensors. The ultimate dream is to develop an artificial pancreas capable of 100% TIR and 0% time below range and affordable to everyone. Even though the mission demands enormous commitment and time, it has the potential to transform diabetes therapy.
