Preface to the Second Edition

For Andy and Ashley, lighthouses of my life

The first edition of *The Diabetes Textbook* was the result of more than three decades of endeavors in outpatient diabetes management, starting with the creation of a diabetes clinic in a public hospital in Mexico City in 1990. Shortly afterwards, we met Dr. Donnell Etzwiler and his colleagues from the International Diabetes Center in Minneapolis. Don was an advocate of structured diabetes care using a scientifically based, cost-effective and patient-centered approach [1]. He was also aware of the need to improve the quality of diabetes care based on principles established by Shewhart, Deming, Juran, and many other brilliant minds in the history of quality in industry. Don was a highlight in our efforts to develop and implement an outpatient diabetes model that has benefited thousands of people with diabetes, mostly from undeserved communities. Starting in 1991, we have presented an international diabetes conference in which we have assembled a large faculty of experts from all over the world, including basic science, public health, and clinical management. Many of them became longtime friends, collaborators of *The Diabetes Textbook*, and strong supporters of its creation. We have come to understand that communication, collaboration, and hard work are crucial to confront "the largest epidemic in human history" in the words of Professor Paul Zimmet [2]. The COVID-19 pandemic has confirmed the crucial link of globalization and social determinants of health in outcomes and prognosis; diabetes is a clear example of the persisting consequences of health disparities [3].

The second edition of *The Diabetes Textbook* recognizes the importance of multidisciplinary management. I am extremely grateful for the contributions and enthusiasm of almost two hundred experts from five continents. Their expertise in the most diverse professional areas reflects the complexities of diabetes care and the multiple needs for its management. New chapters have increased the scope and enriched the previous edition, and comprehensive updates have been carried out in the original version. All the coauthors are kindly and forever recognized, but special thanks are directed to Sanjay Kalra and Maggie Powers, and very especially to Victoria Serhiyenko, who in the midst of a national tragedy provided her invaluable support. Above all, this book is devoted to persons with diabetes and their families [1]. The burden on suffering continues to be huge, and every day we honor our commitment to support them to achieve a successful life with diabetes.

Part IX Chronic Complications

Preface: A New Disease?

1

Joel Rodriguez-Saldana

At the Scientific Sessions of the American Diabetes Association in 1992, Professor Gian Franco Bottazzo delivered the Banting Lecture, in which he announced that diabetes was "a new disease," based on criteria originally described by Mirko D. Grmek in his classical book about the history of AIDS:

Criteria to define a new disease [1, 2]:

1. Previously nonexistent
2. Previously existent but rare
3. Only occurring in regions
4. Only occurring in animals

Grmek reflected that "a disease can appear to be new in at least five different settings: (1) when it already existed but was unrecognized as a clinical entity; (2) if it already existed, but did not appear until changes occurred in its manifestations; (3) if it did not exist in one region of the world; (4) if it did not exist in humans; (5) if it is absolutely new [2, p. 108]". Diabetes has been recognized as a clinical entity since early times, but its magnitude worldwide and its phenotype have remarkably changed over the last few decades.

The ancient history of diabetes started in Egypt, Asia, and Arabia 3500 years ago [3–5]. The first recorded description appeared in 1552 BC in the Ebers papyrus, the oldest and most complete medical record from ancient Egypt. In the second century AD, Arateus from Cappadocia in Greece coined the term "diabetes" to describe polyuria as the most common symptom of the disease, "a melting down of the flesh and limbs into urine," and he also gave the most detailed account of diabetes ever published (Bliss, Galmer). In the fifth to sixth centuries AD, Sushruta and Charuka in India described the sweetness of urine, the use of ants to diagnose the urine of a person with diabetes, and the distinction of two types of diabetes, one affecting thin, young individuals and another type in the obese elderly (Galmer).

Reports of persons with diabetes were scarce in the ancient period, but despite arising worldwide interest, Hippocrates made no mention of it, and Galen regarded diabetes as a kidney disease ("diarrhea of the urine") associated with "dipsakos" (violent thirst) [5]. In those days, Galen admitted that it was a very rare disease, which he had only observed twice, but at the same time proposed tasting the urine as probably the first diagnostic method in the world (Tattersall). The contributions to the study of diabetes from Avicenna in Arabia are multiple: he gave an accurate description of its clinical features; he listed some of its vascular and infectious complications, including sexual dysfunction, gangrene, carbuncles, and tuberculosis; he noted that when the urine evaporated, it left a residue like honey; and he recommended treatments based on mixtures of seeds with mild hypoglycemic activity [3]. Advances in the diagnosis of diabetes started to appear centuries later in Europe, including the description of a powderlike deposition in the urine of diabetic persons by Paracelsus in the sixteenth century, the sweet taste of urine in people with diabetes by Thomas Willis in the seventeenth century, the measurement of glucose in urine by Dobson in the eighteenth century, the description of excess sugar in the blood and urine by Rollo, who first used the term "mellitus" as the Latin and Greek root for honey, and the identification of glucose as the type of sugar in the blood and urine of people with diabetes in the nineteenth century by Chevreuil [3–6].

Diabetes was still a rare disease in this period, and like almost all other patients, people with diabetes received more harm than good from doctors' orders, including bleeding, blistering, and doping with opium, which was still in use in the early twentieth century and was very difficult to discontinue (Bliss). In the absence of effective glucose-lowering medications, therapeutic interventions were limited to diet, exercise, and "behavior," including eating large quantities of sugar (Piorry), reducing food intake and exercising (Bouchardat), starvation dieting (Allen), or specific types of carbohydrates (von Noorden), and even isolating patients under lock and key to obtain "sugar freedom" (Cantoni and

Naunyn) (Bliss, Galmer, Hurley, Tattersall). Despite all these efforts, life expectancy for people with diabetes was very low, especially in children.

The etiology of diabetes started to be pursued in the nineteenth century. Proposed factors were multiple and disparate, including "grief," "chills," and "excess of venery" (Elliotson), "exposure to cold," "rheumatism and gout," "mental anxiety and distress" (Prout), "sexual excess," and "hereditary predisposition." Based on his assumption that sugar was formed in the stomach from vegetables, Rollo made one of the first proposals of a diabetic diet in which greens were eliminated and consisted mostly of animal food, emetics, ammonia, and narcotics [4] (Tattersall). A "thunderbolt" in the physiological world disclaiming these assumptions occurred when Claude Bernard showed that blood glucose levels are regulated not just by the absorption of dietary carbohydrates but also by the liver from glucose and non-glucose precursors, its storage as glycogen, and the involvement of the central nervous system in controlling blood glucose concentration [4]. In persons with diabetes, he stressed that the cause of the disease was a disequilibrium between sugar formation and disintegration.

The site of diabetes. Early speculations about the source of diabetes located the disease in the stomach, frequently in the kidneys, or systemically as a derangement of the central or autonomic nervous system [3–5] (Farmer, Hurley, Tattersall). Originally considered a supportive cushion in which the surrounding visceral organs rested, anatomic dissection allowed the identification of its ducts and their role in digestion [5]. Advances in "the experimental period in the history of diabetes" included the microscopic description of the pancreas by Langerhans and the endocrine function of the islets by Laguesse [3]. Cawley was the first to suggest a relationship between the pancreas and diabetes, and Minkowski and Mering confirmed the role of the pancreas in diabetes when they showed that pancreatectomized dogs developed "real permanent diabetes, which corresponded in every detail to the most severe form of the disease in man," and which could be reversed by subcutaneous implantation of pancreatic fragments [4, 5]. The race to isolate the hypothesized glucose-regulating hormone which in 1909 was named insulin by Jean de Meyer (Tattersall) was on. Between 1900 and 1921, at least five investigators came close to its discovery, including Nicholai Paulescu from Romania, who described a pancreatic extract that cured diabetes in pancreatectomized dogs in 1916, but for lack of resources, he could not produce it in large quantities.

The Discovery of Insulin and the Start of a New Era. The discovery and purification of insulin by Banting and Best from bovine pancreases with the support of MacLeod and Collip, and the first injection on a human being on January 11, 1922, "was (and still is) one of the most dramatic events in the history of the treatment of the disease (Bliss)," the crowning event of the race started by Mering and Minkowski in 1899 [5, 6] (Tattersall). At 2:00 AM on October 31, 1920, Frederick G. Banting, a surgeon practicing in Canada, conceived the idea to isolate the internal secretion of the pancreas. The following week, he met with John JR McLeod in Toronto to develop a research plan. By August 1921, Banting and his student assistant Charles H Best had prepared an effective extract from a canine pancreas, and in January 1922, James B Collip isolated insulin that was sufficiently pure for human use; for the first time in January 1922, Leonard Thompson, a 14-year-old with type 1 diabetes[7]. On October 25, 1923, Banting and McLeod received the Nobel Prize in Physiology or Medicine for the discovery of insulin, which started a new era of hope for people with diabetes [7].

Therapeutic use of insulin quickly spread around the world and became a remarkable example of the rapid translation of basic science into a benefit for patients [6]. Unfortunately and beyond its landmark achievement, the discovery of insulin has still not solved the problem of diabetes (Bliss). Initially, there were expectations that insulin would allow the islets of Langerhans to recover completely, so diabetes was cured [8]. The burden of microvascular complications was not recognized until the late 1930s and early 1940s in persons who had been saved by insulin. The emergence of chronic complications generated a debate about the possible causes of their origin: the metabolic disorder or its consequences [8].

Almost one century afterwards, countless advances in the understanding of normal glucose metabolism, the pathogenesis of diabetes, and the discovery of many effective therapies to treat hyperglycemia and its complications have occurred [3, 6]. Controlled clinical trials have shown the benefits of glycemic control and traditional cardiovascular risk factors (blood pressure, lipoproteins) in reducing the risk of macrovascular and microvascular complications in type 1 and type 2 diabetes [9–12] and confirmed that the targets recommended in 1923 were identical to the conclusions of the Diabetes Control and Complications Trial 70 years later [8]. After one century of scientific advances, large discrepancies prevail between randomized clinical trial findings and implementation "in the real world" [13]. At the same time, the magnitude of diabetes as a worldwide health problem has reached epidemic levels. The "diabesity" (obesity and type 2 diabetes) epidemic is likely to become the largest epidemic in human history [14]. The burden of suffering and death is unprecedented; many nations are unable to satisfy the increasing demand for services [15]. The impact achieved by scientific discoveries reaches a minority of people with diabetes due to a variety of factors.

The Ascent of Diabetes Mortality and Associated Factors. The first measure of the burden of diabetes was of mortality, through the gathering of death certificates in

Europe and America in 1850 when diabetes was still "a rare disease" [16]. For example, in 1866, the death rate from diabetes in New York City was 1.4 per 100,000 residents, and Charles B. Brigham found only 40 death reports from diabetes between 1854 and 1866 (Hurley). Diabetes started to ascend as a relevant cause of death worldwide until the twentieth century. In the United States, diabetes was the 27th cause of death in 1900, and 45 years later, it had become the eighth cause despite the fact that insulin was prolonging life for hundreds of thousands of patients [17, 18]. The average duration in years of life of persons with diabetes in successive eras of treatment, before and after the discovery of insulin, remarkably increased, advancing from 4.9 years in 1897–1914 to 14.4 years in 1944–1949; the age of death had risen from 44 to 64 years, and life expectancy for each group of all cases was approximately 75% that of the general population of similar age [19, 20]. Albeit "it seemed as if the diabetes problem had been solved," an upward continuing trend was documented, except for a drop in 1918–1919 attributed to the influenza pandemic and the sharp fall in death rates after the discovery of insulin from 1922 to 1924 [21, 22]. In developed countries, the incidence of deaths due to diabetic coma has steadily decreased from 86% in the pre-insulin era to 9.6% since 1944, while the frequency of cardiovascular and renal disease has steadily increased [20]. Deaths from infection also declined due to antibiotic therapy, but longer life expectancy increased the risk of cancer mortality [23, 24]. Long-term complications affecting the vascular and nervous systems were present before insulin was available, but their impact was unappreciated because of the short life expectancy after the onset of diabetes [21]. The average age at death of patients with cardiovascular and renal complications was 64 years, which was diagnosed late in life [21].

International standardization and the creation of the mortality data system by the World Health Organization raised awareness about the importance of diabetes as a cause of death and documented differences in mortality rates in different countries and regions [16]. In 1943, the last year in which statistics for the United States were available before World War II, the number of recorded deaths due to diabetes was 36,314, or 35,000 on average per year [24]. One of the best sources of information about diabetes mortality was assembled by E.P. Joslin and his colleagues through collaborations with the Metropolitan Insurance Company and the Massachusetts Department of Public Health [16]. In several reports, they showed increases in the age of death associated with improvements in survival, refinements in the registration of causes of death, and rates of cardiovascular disease and glomerulosclerosis [1–22]. Starting in the 1960s, multiple studies about mortality and its causes in persons with diabetes appeared in the United States, Scandinavia, England, Asia, Africa, Japan, and Germany [16, 25, 26]. These studies reported similar findings in terms of factors predisposing to death (early age of onset, albuminuria, microvascular complications, high glucose levels) and rates of cardiovascular disease and renal failure [25, 26]. At the same time, factors related to long survival were identified, including (1) regular contact with a personal physician, (2) periodic blood glucose measurement, (3) glucose monitoring (initially in urine), and (4) patient support: longevity of parents and grandparents [27].

Estimating the mortality due to diabetes continues to be challenging because more than one-third of the countries in the world have no reliable data, and routine statistics underestimate diabetes deaths resulting from cardiovascular disease, renal failure, or infection [28]. Variations in death certification practices could explain differences in diabetes mortality between countries and distort international comparisons in which countries with more accurate coding practices report higher mortality rates [29]. Despite limitations in the availability and quality of information, diabetes mortality continues to advance at alarming rates, particularly in middle-income countries [28]. In Mexico, for example, only 368 deaths attributed to diabetes were reported in 1922, representing one death per 1000 people dying [30]. These numbers continued to increase in the second half of the twentieth century, reaching 105,500 deaths in 2016 with no decrease in sight, even during the COVID-19 pandemic [31]. In the United States, the number of deaths resulting from diabetes increased by 21.4% in 5 years, from 79,535 in 2015 to 101,106 in 2020, and the excess deaths estimated from diabetes during the COVID-19 pandemic were 2.1–6.5% above the annual percentage change, probably as a result of delayed care or health crises [32, 33].

By comparison to people without diabetes, having diabetes increases the risk of mortality, even in developed countries like Germany, where 21% of all deaths are attributable to diabetes and 16% correspond to type 2 diabetes [34, 35]. In the ninth edition of its Diabetes Atlas, the International Diabetes Federation (IDF) estimated that 4.2 million people aged 20–79 years died from diabetes and its complications in 2019, accounting for 11.3% of the global all-cause mortality in this age group [15].

The Burden of Disease: Prevalence and Costs in 1943. The estimated diabetes prevalence was 3.5 per 1000 [16]. Before 1946, all available estimates were based on interviews or testing of selected groups, but the first surveys from the United States showed that diabetes was not uncommon [17]. Rates of glycosuria in men were above 2.0% among recipients of life insurance from New York in 1909, but mass screening started to be carried out after World War II in the United States and Europe [16]. In 1947, Wilkerson and Krall published the results of the first series of mass screening and detection enterprises in Oxford, Massachusetts, the birthplace of E.P. Joslin, a native-born resident of the town who supported and sponsored them [16, 36, 37]. Seventy-five

years ago, the prevalence of diabetes in this region of the United States was 1.65% [16], and surveys from Europe reported similar prevalence rates in the range of 0.5% to 2–4% [38]. Even in those years, higher prevalence rates, above 30%, were reported among aboriginal subpopulations, like the Nauru, the Pima Indians, and other American Indian tribes [39, 40]. Beyond the challenges involved in collecting accurate data, the prevalence of diabetes has literally soared worldwide. The report of the Non-Communicable Disease Risk Factor Collaboration is eloquent: global age-standardized diabetes prevalence increased from 4.3% in 1980 to 9.0% in men and from 5.0 to 7.9% in women [41]. Accordingly, the number of adults with diabetes in the world increased from 108 million in 1980 to 422 million in 2014 [41]. Estimates from the IDF put the number of people with diabetes at 463 million adults aged 20–79 years in 2019, with the projection that almost 20.4 million live births to women were affected by some form of hyperglycemia in pregnancy [15]. In conclusion, diabetes directly affects approximately half a billion people worldwide, probably twice as many relatives, inflicting a non-precedent personal and economic burden estimated at $1.31 trillion USD, or 1.8% of the global gross domestic product in 2015 [42]. The direct costs of illness are important drivers, but indirect costs account for 34.7%, ranging from one-fifth to almost three-fifths of the total economic burden [42]. Large disparities prevail between high-, middle-, and low-income countries with total health expenditures in high-income countries exceeding those in low-income countries [43].

Trends in diabetes prevalence are increasingly heterogeneous: they are lower in Africa (3.9%) and Europe (8.9%) and higher in North America and the Caribbean (13.3%) [15], but the sustained increase in the largest populated countries is of great concern. In China, for example, the prevalence of diabetes ascended from 0.67% in 1980 to 10.9% in 2013, and the prevalence of prediabetes increased from 2.09% in 1994 to 15.5% in 2008 [44, 45]. In the United States, the prevalence and incidence of diabetes increased by 90% in the first decade of the twentieth century and tripled in some states [46]. Between 2002 and 2012, the adjusted annual incidence of type 1 diabetes increased by 1.8% per year, and the incidence of type 2 diabetes increased by 4.8% per year [47]. The prevalence doubled from 3.5% in 1990 to 7.9% in 2008, while the incidence increased from 3.2/1000 persons in 1990 to 8.3/1000 persons in 2008 [48]. Despite reaching a plateau since 2008, national trends among African-American and Hispanic subpopulations continue to increase [48, 49]. Data from the National Health Interview Survey based on self-report estimated that 0.55% of U.S. adults had been diagnosed with type 1 diabetes, representing 1.3 million adults, and 8.6% had been diagnosed with type 2 diabetes, representing 21 million adults; the weighted percentage of type 1 diabetes was 5.6% and for type 2 diabetes was 91.2% [50, 51]. Interestingly, the percentage of type 1 diabetes was higher among younger adults with a higher education level and a lower body mass index (BMI), while the prevalence of type 2 diabetes was higher among older adults, non-Hispanic Asians, and people with a low education level and a higher BMI [51]. Despite limitations of self-report, validation, and overestimating type 2 diabetes, this study provides information to track the prevalence by type of diabetes, assess the burden of disease, and address the huge challenge of education and prevention programs [50, 51]. In 2019, the estimated number of adults with diabetes in the top ten countries—China, India, and the United States—was 224.4 million, representing 48.4% of the total population with diabetes in the world [15]. In recent years, remarkable discrepancies in the worldwide incidence of diabetes have been observed: since 2006, increasing trends were reported in 33% of populations, 30% had stable incidence, and 36% reported declining incidence [52]. According to the authors of this systematic review, diabetes has continued to rise in developing countries and has plateaued or even declined in developed countries [52]. Contributing factors to these trends represent one of the main challenges faced by diabetes and chronic disease management.

"The New Disease" in Children and Adolescents. To complicate the scenario, the face of pediatric diabetes has undergone striking changes during the last decades, and the incidence of type 1 and type 2 diabetes in children and adolescents is increasing worldwide, along with its consequences, with wide variations in absolute risk (Hurley) [52–55]. At the start of the twentieth century, type 1 diabetes was rare and rapidly fatal; children affected were thin and usually of white race ethnicity, and type 2 diabetes was not considered a pediatric disease [52]. For example, in the United States, the incidence of type 1 diabetes increased at a rate of 1.4% annually, from 19.5 cases/100,000 youths per year in 2002–2003 to 21.7 cases/100,000 youths per year in 2011–2012, but the incidence of type 2 diabetes more than doubled in the same period at 7.1% per year [53]. Over the last decade of the twentieth century, several reports confirmed the association of type 2 diabetes in youth with obesity, especially in minorities; the face of pediatric diabetes has changed [52].

Over two decades, the incidence of type 2 in persons younger than 20 ascended from 9.0/100,000 in 2002–2003 to 12.5/100,000 in 2011–2012 [54]. Having diabetes in youth elevates the risk of complications at earlier ages: Amutha and colleagues in India showed that the frequency of hypertension and hypercholesterolemia and the incidence of retinopathy, nephropathy, neuropathy, and ischemic heart disease are 2.1 times higher in patients with type 2 diabetes [55]. The results of this study are concerning and suggest that 60% of the participants would develop one or more complications of diabetes in one decade and therefore may lose 15 years of

remaining life expectancy [55]. Younger age at diabetes diagnosis is associated with a higher risk of mortality and vascular disease [56]. Young people with type 2 diabetes have a more aggressive form of the disease, including a worse response to glucose-lowering medications, greater insulin resistance, and a higher risk of complications [57]. Venkat-Narayan accurately claims that some countries are winning battles against diabetes [58], while others are losing the war, and some are unable or unwilling to do anything about it [59].

The "Wrong" Lifestyle. The drivers of the diabetes epidemic have been described for decades and involve genetic and environmental risk factors which induce inflammation, autoimmunity, and metabolic stress [60]. Beyond the genetic background of every type of diabetes, the prevalence of type 1 and type 2 diabetes is increasing globally at rates that surpass genetic variation and reveal the key role of environmental factors in both types of diabetes [61]. The pioneering work of David J.P. Barker challenged the idea that chronic diseases like diabetes are explained by bad genes and unhealthy adult lifestyles and proposed that their roots lie in the early life environment [62–64]. Using old birth records, he showed that people of lower birth and infant weight had higher rates of cardiovascular disease, impaired glucose tolerance, beta-cell dysfunction, and diabetes in middle age and proposed a thrifty genotype hypothesis, in which type 2 diabetes is the outcome of the fetus and early infant having to be nutritionally thrifty as a result of impaired growth of beta cells [63, 64]. His statement was visionary: "As long as the individual persists in the undernourished state, there is no need to produce much insulin. However, a sudden move to good or overnutrition exposes the reduced state of beta-cell function and results in diabetes [64]". Further reports have refined Hales and Barker's hypothesis and demonstrated the role of environmental factors in the etiology of obesity, type 1 and type 2 diabetes, and current strong data supporting a genetic-epigenetic predisposition in type 2 diabetes [65–68].

A New Disease in a Changing Environment. Despite remarkable reports showing stabilization and even decline in some countries [69, 70], worldwide trends in overweight and obesity in children [71], adolescents, and adults continue to rise [72, 73]. From 1975 to 2016, the global age-standardized prevalence of obesity increased from 0.7 to 5.6% in 2016 in girls and from 0.9 to 7.8% in boys [71]. From 1975 to 2014, the age-standardized prevalence of obesity increased from 3.2% in 1975 to 10.8% in men and from 6.4 to 14.9% in women, and the prevalence of morbid obesity continues to ascend [72]. Rising trends in children's and adolescents' body mass index have stabilized in many high-income countries, especially at high socioeconomic levels, but have accelerated in east, south, and southeast Asia [71]. Contrary to the dominant paradigm, more than 55% of the global rise in mean body mass index from 1985 to 2017 and more than 80% in some low- and middle-income regions has been due to increases in BMI. If post-2000 trends continue, the bad news is that moderate and severe infant underweight will be surpassed by obesity in 2022, and the analysis of nationally representative data from the United States clearly shows an alarming picture of an obesity epidemic in the future with its related challenges [72–75].

The New Faces of an Old Disease. As a result of changing trends in the epidemiology and phenotype of diabetes over the last two decades, traditional clinical paradigms for type 1 and type 2 diabetes, described as early as 500–600 BC by Indian physicians Sushruta and Charaka and adopted in the first classifications of the 1970s, are being challenged in every age group [76, 77]. Today, diabetes is recognized as a complex and heterogeneous disease that can affect people at different life stages, and the classic phenotypes that were useful to define the types of diabetes are far less useful clinical indicators [76]. In addition to their role in the pathogenesis of type 2 diabetes, obesity, and insulin resistance have become remarkable determinants of type 1 diabetes microvascular, macrovascular, and foot complications [78, 79]. Increasing childhood growth and weight gain augments peripheral insulin demand, which could place greater stress on beta cells and make them more vulnerable to autoimmune attack; reduction in type 1 diabetes is a potential additional benefit of preventing childhood obesity [78, 79]. Metabolic syndrome is particularly useful for cardiovascular risk stratification in younger people, with progressively less impact with increasing age, and while type 1 diabetes is caused by autoimmune destruction of the beta cells, its association with insulin resistance was described as early as 1986 [80]. The unprecedented influence of obesity on the phenotype of type 1 diabetes has resulted in double diabetes, "a new clinical entity" in which clinical features of metabolic syndrome overlap in children and adolescents with type 1 diabetes [76, 81].

On the opposite side of the spectrum, the longtime recognized heterogeneity of type 2 diabetes and its classification has been critically reassessed [82–87]. Metabolic differences suggesting heterogeneous pathways among ethnicities with high risk for diabetes and widely different distributions of BMI support the existence of different molecular mechanisms leading to diabetes presentation and the need to break down patients traditionally classified with type 2 diabetes into new "clusters" or subgroups in order to translate the new subclassification of type 2 diabetes into the clinic with the objective that in a not too distant future, our genetic code will be part of patient records to support clinical decisions and precision medicine [83, 88].

The Bottom Line: Syndemics and Diabetes. Far fewer people globally are underweight than are becoming obese. As economic inequalities have increased worldwide, so have

inequalities in weight and an interplay between genes and the environment [89, 90]. Beyond violence and substance abuse, social inequalities create syndemics: aggregations of two or more diseases or health conditions in populations with some level of the deleterious biological or behavioral interface that exacerbates the negative health effects of any or all of the diseases involved [91]. The syndemics framework was described by Merrill Singer in the mid-1990s and refers to the adverse interactions of all types of diseases (infectious, chronic noncommunicable, mental health, behavioral, from toxic exposure and malnutrition) which emerge under conditions of health inequality caused by poverty, stigmatization, stress, or structural violence [92]. Three elements interact to produce syndemics: disease concentration (genetic predisposition), disease interaction (obesity and insulin resistance, for example), and the large-scale social forces that give rise to them [92]. Syndemics provide an innovative and important alternative to interpret the co-occurrence of noncommunicable diseases like obesity and diabetes, addressing the importance of social conditions in the emergence and medical outcomes [93]. The concept of syndemics departs from traditional medical approaches that treat diseases as distinct entities, detached from the social context of the people suffering from them [94]. It moves beyond the common medical conceptualization of comorbidity and concerns the consequences of disease interaction and the social, environmental, or economic factors that cluster with the diseases and shape their interaction [92]. The role of syndemics in persons with diabetes was brilliantly described by Emily Mendenhall in 2012 in a study about the social context of clustering of diabetes and depression among Mexican immigrant women in Chicago, in which she demonstrated the parallelism between syndemics and the embodiment construct, which states that "we literally incorporate, biologically, the material and social world in which we live (Mendenhall, Krieger)."

The Social Determinants of Health and Diabetes. Beyond the undeniable role of genetic traits in the pathogenesis of diabetes, environmental and social determinants have become preeminent in their ascent and the response at every level, including people with diabetes, providers, and society. In a highly cited study, Christakis and colleagues analyzed the possible contribution of the person-to-person spread of obesity in a densely connected social network of 12,067 people assessed as part of the Framingham Heart Study from 1971 to 2003 [93]. The results showed that clusters of obese persons were present in the network all the time, albeit not solely attributable to the formation of social ties [93]. Among the obese, a person's chances of becoming obese increased by 57% if he or she had a friend who became obese, and if one friend became obese during a given time interval, the other friend's chances of following suit increased by 171% [93]. By comparison, if one sibling became obese, the chance that the other would become obese was 40%, 20% lower [93]. This study highlights the fact that social networks are even more important than genes in determining a person's risk of becoming obese and became a milestone in the story of network medicine [95]. The revolutionary work of Albert Barabasi has shown the existence of networks pervading all aspects of human health [95]. Network-based systems may account not only for the genetic but also for the environmental and social influences of disease [95]. The increasing rates of obesity and diabetes have led the WHO and the scientific community to describe them as epidemics [14, 96]. Traditionally and until today, diseases like obesity and diabetes have been described as "noncommunicable," but current evidence indicates that this formulation is inaccurate [97]. As the study of social networks has demonstrated, behavioral risk factors are acquired through social mechanisms and are thus communicable [97]. A report from the Israeli IDDM Registry Study Group showed that between 1997 and 2014, familial cases of type 1 diabetes increased by 1.9% per year, while sporadic cases decreased by 0.2% per year in the same period [98]. The authors state that the rapid rise in the proportion of familial cases of type 1 diabetes suggests that environmental factors impose higher diabetogenic pressures on patients with susceptible genetic backgrounds [98].

The Social Environment of Diabetes. The inverse care law states that the availability of good medical care tends to vary inversely with the needs of the population served [99]. Social and geographical inequalities in morbidity and mortality persist worldwide, with direct effects on the lifestyle and outcomes of persons with diabetes. The hardships of people with diabetes in achieving effective, multidisciplinary care have been repeatedly documented, even in developed countries, in every age group. For example: (1) children with diabetes in Canada have worse levels of glycemic control if they live in areas of the highest neighborhood index, defined by indicators evaluating economic, social, environmental, and lifestyle factors [100]; (2) lower socioeconomic status and medical insurance are strong predictors of diabetic ketoacidosis readmissions in adults with diabetes in the United States [101]; also in the United States, albeit mortality rates from diabetes decreased from 23.5 person-years in 1997–2001 to 18.1/1000 person-years in 2007–2011, socioeconomic disparities were associated with greater mortality rates in each time period [102].

Food insecurity, defined as the limited or uncertain availability of nutritionally adequate and safe foods owing to cost or distance, is associated with increased consumption of inexpensive food alternatives, which are frequently calorically dense and nutritionally deficient, and increases the risk of obesity and diabetes [103–105]. Compared to people living in food-secure households, food insecurity increases the risk of poor glycemic control (A1c >9.0%), hospitalizations, and visits to emergency departments in adults with type 1

and type 2 diabetes and, through the stress associated with it, negatively affects the ability of patients to perform self-care behaviors [106, 107]. Persons with diabetes and food insecurity have worse glycemic control compared to people who are food secure, and it is likely that multiple factors at the community and individual levels negatively influence diabetes control in the setting of food insecurity [108, 109]. Food insecurity affects all stages of diabetes prevention and control, and people with this condition are at a higher risk of having undiagnosed diabetes [110].

The Preeminence of Context and the Social Determinants of Health. Daneman and the realities of clinical practice confirm that the most common cause of death in youth with type 1 diabetes worldwide continues to be a lack of access to insulin [111]. Despite one century since the discovery of insulin, the life expectancy of children with type 1 diabetes continues to be reduced, and scarcity and costs also affect persons with diabetes from every age group [111, 112]. The five fundamental requirements for diabetes care (availability of food and clear water, availability of insulin and glucose or urine testing, prevention of hyper- or hypoglycemia, and protection against harm) [111] are still—and increasingly—unavailable to a large number of people with diabetes from every age group [112, 113]. Availability and affordability of insulin remain a challenge in many parts of the world [113], and beyond the evidence about their effectiveness, the costs of new therapeutic classes like GLP-1 analogues and SGLT-2 inhibitors are prohibitive for many patients, even in developed countries. Lower socioeconomic profiles are associated with poor glycemic control among children and young adults with type 1 diabetes and with the outcomes, including increased diabetes-related hospitalizations, emergency department attendances, missed outpatient appointments, and a higher risk of complications in patients with type 2 diabetes, but are not part of routine diabetes or clinical assessment [114–118]. Lower socioeconomic position continues to be a risk factor for diabetes and its complications all over the world [114, 118]. Due to the importance of understanding and mitigating the impact of the social determinants of health (SDOH) on the creation of "intractable patterns of higher risk of diabetes, diabetes complications, and mortality" and the role of social inequalities on the vulnerability of people during the COVID-19 pandemic, several professional organizations have published statements on SDOH and calls to action to ameliorate these determinants at the individual, organizational, and policy levels [119, 120].

The Disease, the Illness, and the Predicament. Diabetes is perceived and approached from multiple perspectives including those of patients, their families, physicians, and health professionals. The most important, nevertheless, is from people with diabetes and their families. In 1979, David C. Taylor brilliantly described three different ways of "being sick": (1) diseases, physical entities discernible through diagnostic tests; (2) illnesses, or the experience of being sick; and (3) predicaments, or the complex of psychosocial ramifications, contacts, meanings, and ascriptions which bear on the individual [121]. In our personal and professional experience, we confirm the truth behind these words every day.

The predicament and the positive or negative way in which it is confronted by persons with diabetes and their families are crucially linked to the outcomes. Bob Anderson described it as "the personal meaning of diabetes" and illustrated his statement with five levels of personal responsibility, from absolute denial to total commitment, that every individual has the option to assume [122]. Tinetti and Fried eloquently claimed that:

"Time has come to abandon disease as the focus of medical care. The changed spectrum of health, the complex interplay of biological and nonbiological priorities render medical care centered on the diagnosis and treatment of individual diseases at best out of date and at worst, harmful…clinical decision-making should attainment of individual goals and identification and treatment of all modifiable biological and nonbiological factors, rather than solely on the diagnosis, treatment, or prevention of individual diseases [123]."

A Long Way to Go. Although the conversation has seemingly shifted, paternalism in health care has not changed [124]. Health care systems continue to focus on engaging patients in behaviors that are desirable from a biomedical perspective, with no space left for patient (concerns) goals, needs, desires, abilities, and backgrounds that make humans so rich and diverse [125]. Declining trust in health care has come partly from structural contradictions in health systems in many countries [126]. Health care organizations and providers should consider using language more appropriate for their role in the user's care such as coach, guide, counselor, or advocate, and recognize that despite technological, economic, and political changes, trust in health care fundamentally begins with healing relationships between patients and physicians [125, 126]. Reductionist approaches seek to build holistic constructs for disease etiology, pathophysiology, epidemiology, and therapeutics without including the multiple insertion points of the social world and reduce the "whole person" to pieces that can be coded into data and fed into network analysis [125]. In the twenty-first century, biomedical research and clinical practice have begun to shift from the close examination of disease parts (beta cells, endothelium) toward a "personalized approach" that focuses on the whole person as a unit of analysis [125]. At the same time, medical organizations worldwide have called for a renewed sense of professionalism among physicians based on the overriding principles of patient welfare, patient autonomy, and social justice [127]. These tasks will be complex, time-consuming, and arduous but essential to the advancement of medicine [125, 127].

New Approaches to an "Old" Disease. Diabetes has changed in many ways, each representing a challenge. The "old disease" described in Egypt 35 centuries ago in small numbers of patients has become a worldwide health problem, affecting directly one-sixth of the general population and indirectly at least another sixth of siblings and relatives [128]. The social distribution of the disease leads to large inequalities in management; most of even the "reasonably" expected benefits go to a small fraction of the patients, the ones who have access and can afford it [129–131]. A huge mismatch exists between countries and regions with the largest diabetes burdens and sites of research and clinical excellence [58, 130, 131]. Individuals with suboptimal versus optimal control differ significantly in terms of health care coverage, comorbidities, diabetes-related complications, health care utilization, and cardiovascular risk factors [132]. Even people with economic resources have to endure individualistic, vertical physician approaches and low-quality services. Improvements in the quality of diabetes care [129] and reductions in complication rates among people with type 2 diabetes in the United States and high-income countries [133] are exemplary and contrast with the inability of countries like Mexico, where despite high levels of obesity and diabetes, glycemic control continues to be poor, diabetes is associated with a far worse prognosis than in high-income countries, and complications continue to ascend [134]. Achievements in the science of diabetes are unprecedented, and the future looks even more promising [135–137]. The paradox is unprecedented: never before has there been so much knowledge and resources about diabetes, but never before has there been so much suffering.

The Road Ahead. With the advent of the twenty-first century, science and technology were expected to be formidable forces that would improve population and well-being, but most of the global response to the coronavirus disease 2019 pandemic was unable to realize these hopes. On July 22, 2019, six months before the announcement of the COVID-19 pandemic, a brief communication by Colin Carson and Emily Mendenhall appeared in the Lancet [138]. In their prophetic letter, Carson and Mendenhall warned about three major global challenges: (1) proliferation of closely related emerging viruses, (2) co-occurrence with endemic infections, and (3) interactions with other aspects of health, including noncommunicable diseases (like diabetes), mental health, and stigma, and he made an urgent call to "plan for syndemics of the future [138]." The arguments to establish diabetes as a syndemic are clearly represented and instrumental in advancing the burden of suffering. The COVID-19 pandemic has exposed, once again, longstanding drivers of health inequities, including precarious and adverse working conditions, growing economic disparities, and antidemocratic (and ineffective) political processes and institutions, which exacerbated the vulnerability of societies [139]. From social determinants of health perspective, global economic trends create enduring health hazards for the general population and for people with diabetes, chronic diseases, and comorbidities [139].

A "cascade of care" proposed by Ali and colleagues is a powerful tool to visualize gaps and disparities across groups to improve engagement and the quality of diabetes care, including awareness and the effectiveness of prevention programs for people with prediabetes [140]. Frank Vinicor proposed a Decalogue in which he summarized the challenges facing the future of diabetes [141]. Besides new medicines, it is essential: (1) to continue the improvements in diabetes care, (2) to recognize the complexities of diabetes management, (3) to improve the system of care, (4) to broaden the definition of "medical office" and the delivery of services, (5) to address the dual impact of the diabetes epidemic, through improvements in management and primary prevention, (6) to recognize the role of "non-health forces" influential on diabetes prevention and control, (7) to look for special opportunities for health professionals, (8) to empower patients, (9) to achieve a balance between individuals and communities, (10) to accept and embrace globalization [141]. The challenge is formidable, and the multiple stakeholders involved are required to address the role of the social determinants of health to reduce the persisting and increasing inequalities in diabetes access and quality of care.

Magnitude of the Problem from an Individual and Social Context

The Dynamics of Diabetes Prevalence, Morbidity, and Mortality

2

Danilo de Paula, Paula Bracco, and Edward W. Gregg

Introduction

Diabetes mellitus has caught the attention of the world as a major public health problem due to the explosive increases in prevalence that have occurred, affecting virtually all regions of the world and, within regions, affecting all age and demographic subgroups and across the full range of socioeconomic status [1–3]. The estimated global prevalence for 2021 is 536 million, with 10.8% of men and 10.2% of women affected. The highest regional prevalence was registered in the Middle Eastern and North African region (18.1%), while the lowest was in the African region (5.3%). The countries with the highest prevalence were Pakistan (30.8%), French Polynesia (25.2%), and Kuwait (24.9%) [1]. This growth has included both type 1 and type 2 diabetes, although between 90 and 95% of the cases and the predominant increase in prevalence have been driven by type 2 cases [4]. Dozens of individual-level genetic and environmental factors have been prospectively associated with type 2 diabetes, but the increases in prevalence in most societies have likely been driven by a smaller set of trends, including the increasing prevalence of overweight and obesity, declining levels of physical activity, poor-quality carbohydrate in our diets, sugary drinks, increased fast food and portion sizes, aging and a longer lifespan, and increasingly diverse socioeconomics [5, 6]. There is also increasing recognition of heterogeneity in diabetes types, even within the classic categories of type 2 and type 1 diabetes, that likely have different patterns of risk factors that may further vary by region and context [7].

The growth of diabetes prevalence has ominous implications for numerous health and economic-related reasons. Ultimately, diabetes places an enormous burden on individuals, families, health systems, and societies because of the treatment required, the acute and chronic complications, the demand for health services, the direct impact on quality of life, and the loss of years of life [8, 9]. Apart from the already established macrovascular and microvascular complications, reductions in cardiovascular and all-cause mortality are leading to a shift in the morbidity profile and causes of death of those living with diabetes [10–12].

While the growth of diabetes is most apparent in prevalence trends, there are numerous dynamics in the epidemic underway, with important implications for the clinical and public health priorities that follow. We have synthesized primary findings from population studies of the burden and trends in prevalence, incidence, morbidity, and mortality, with a particular focus on the status in North America and Latin America.

Current Burden of Prevalence and Incidence

Prevalence

Countries of the Americas tend to be around the median of the worldwide prevalence of adult diabetes, now estimated at 10.5%, with almost one-in-two adults with diabetes being unaware that they have the condition [1]. The highest estimates from the Americas region come from the Caribbean Islands and Belize, where, except for Aruba, prevalence ranges from 8.7% in the British Virgin Islands to 16.1% in Saint Kitts and Nevis, making it one of the higher diabetes prevalence regions in the world. Similarly, the Central America region contains countries with a particularly high prevalence (Guatemala, the Dominican Republic, Nicaragua, and Puerto Rico), ranging between 9.3% and 13.3% [1]. Prevalence estimates for subregions of the Americas from the Global Burden of Disease Study are generally highest in Mexico, the Caribbean, Central Latin America, and high-income North America, and lowest in Southern Latin

America, Tropical Latin America, and Andean South America. Other estimates within the past ten years suggest that prevalence is similar for Canada (6.7% diagnosed diabetes in 2014 and an additional 3% undiagnosed in 2007-2009) and Brazil (6.6%) but higher for Mexico (8.9% diagnosed in 2012) and Colombia (12.3% diagnosed in 2016-2017) [13–15]. Prevalence is strongly associated with age, ranging from 2% to 7% across subregions among young adults (age 15-49 years), from 8% to 25% in adults aged 50-69, and from 12% to almost 30% in those aged >70 years.

In the USA, 11.2% of adults have diagnosed diabetes, and 3.4% have undiagnosed diabetes, for a total of 14.6% [16]. The national prevalence in the USA conceals considerable geographic variation, ranging from less than 5% in low prevalence areas of the USA to greater than 16% in high prevalence areas, including areas of concentration in the Mississippi Valley and Deep South, the Appalachian Mountain chain, and selected areas of the West and Midwest corresponding to Native American lands [17, 18]. Prevalence is also notably high in areas corresponding to areas of high concentration of Native Americans and, in Canada, in areas with large populations of First Nations residents.

In the USA, diabetes prevalence is similar across genders but increases steeply with age, such that young adults (age 18-44), middle-aged (45-64), and older (≥65 years), have a prevalence of 2.4, 12.2, and 20.7, respectively. Prevalence also has a strong association with race and ethnicity in the USA, as compared to white women, American-Indians, Alaska Natives, and non-Hispanic blacks have a prevalence that is about twice that of whites, while Hispanics and Asians have a prevalence that is about 80% higher than whites [16, 19]. Education level is also a key factor, as adults with less than a high school education have a prevalence rate of 19.6% that is about 67% higher than that of those with a college or higher education (11.6%) [16]. Within Latin America, indigenous populations have historically had a low prevalence but now represent the populations with the greatest magnitude of recent increase, as evident in indigenous populations in Brazil and Chile [20].

Undiagnosed Diabetes

Because early stages of diabetes are usually without symptoms, many individuals have several years with the disease before detection and diagnosis, and thus a large proportion of the population with diabetes is undiagnosed. In the USA, the prevalence of undiagnosed diabetes is about 3.4%, representing 23.3% of the adult population with diabetes [16]. Older adults, Mexican Americans, and persons with lower education are somewhat less likely to be diagnosed. Although it is commonly believed that awareness and detection of diabetes are increasing over time, changes in the proportion of the population with undiagnosed diabetes converting to the diagnosed state have been relatively unchanged over time, with the exception of recent improvements in detection in older adults, non-Hispanic whites, and wealthy individuals and worsening detection in Mexican-Americans [16, 21, 22]. Few other studies in the Americas have reported undiagnosed diabetes. Considerably higher proportions of cases remaining undiagnosed have been documented in many other regions of the world. Although diagnostic definitions and time periods vary across studies, the proportion of undiagnosed diabetes has been reported to range from 20 to 53% in the South and Central American regions [1]. However, national data from Mexico suggests that up to 50% of cases remain undiagnosed, and in Canada, 20%-40%, depending on the glycemic definition [23].

Incidence

Incidence, or the rate of new cases per population, is less directly affected by mortality rates than is prevalence and is thus a more sensitive indicator of the trajectory of the epidemic. The current adult incidence of diagnosed diabetes is about 6 cases per 1000 adults per year. The incidence is higher for men, with incidence rates of around 7 per 1000 adults, while women had an incidence of 6 cases per 1000 adults in 2019. race-ethnic patterns that parallel the estimates for prevalence [19]. Like prevalence, incidence increases steeply with age, from 4 per 1000 in young adults (age 18-44) to 10 per 1000 in middle age (45-64 years), but there is no further age-related increase thereafter, as incidence is 7 per 1000 among persons aged ≥65, reflecting the age-related incidence peak in the early 60s; Incidence estimates from population-based studies only include the detected cases and thus do not reflect true incidence. When undiagnosed cases are included, estimates in the USA approach 1% per year, and can be used as a general benchmark of the risk of a population, as subpopulations with different designations of prediabetes, such as impaired fasting glucose and impaired glucose tolerance, have incidence estimates that range from 1 to 5% per year [24].

Prediabetes

Estimates of prediabetes vary considerably with the definition used, which remains an area of debate because of the high degree of discordance that exists across different glycemic markers, including fasting plasma glucose, post-challenge glucose response, and HbA1c. Using the American Diabetes Association-like prediabetes definition of fasting plasma glucose or elevated HbA1c, 35% of adult Americans have prediabetes, with estimates ranging from 24% among

young adults (age 18-44) to 47% among adults aged ≥ 65 years [22]. It is noteworthy that, while only about 15% of persons with prediabetes are aware of their risk status, this represents a 50% increase from the last estimates of 10%. Since the risk of progression from prediabetes to diabetes with the ADA definition is relatively low, the Center for Medicare and Medicaid Services (CMS) has adopted a definition of FPG > 110 mg/dl or HbA1c > 5.7%.

Trends and Trajectories in the Epidemic

Prevalence and Incidence

The prevalence of diagnosed and total diabetes has been increasing in most regions for as long as population-based estimates have existed [2, 25, 26]. From 1990 to 2019, worldwide prevalence among adults (20 years of age or older) increased from 4.8% to 8.7% in men and from 4.6% to 7.8% in women, corresponding to an increase in total numbers from 143 to 418 million adults [27]. Diabetes prevalence increased in virtually all regions of the world, with the greatest absolute increases in the Middle Eastern and North African region [27]. Although the growth of mega-urban areas in low- and middle-income countries is often regarded as an accelerator of the diabetes epidemic, large increases have also been observed in rural areas [28].

In the United States, national-level prevalence was first recorded in 1960 at less than 1% of the population and grew steadily in the 1960s through the 1980s to about 3.5% in 1980 (Diabetes in America, 1995) [29–31]. However, in the 1990s, prevalence and incidence increased more rapidly, with a dramatic 50% increase in prevalence from 1990 to 2010 and a continued increase until a peak incidence of 9 per 1000 in 2008 [19]. The increase in prevalence continued from 2009 up to 2018, with total and diagnosed cases being responsible for the trend, while undiagnosed cases remained stable. These trends followed large increases in the prevalence of overweight and obesity occurring during the same period. Throughout this period, the increases in prevalence were paralleled by increases in incidence, from around 4 cases per 1000 per year in the 1980s and early 1990s to almost 10 cases per 1000 adults in 2009 [19, 32].

Prevalence increased in both men and women and in all age groups; the greatest relative increases were observed in youth and young adults, while the greatest absolute increases occurred in older adults [33, 34]. However, the greatest increase in total numbers was observed among middle-aged adults, driven by the USA's baby boom generation, born between 1945 and 1965, reaching the ages of peak diabetes incidence. The increases in diagnosed diabetes increased in virtually all other demographic subgroups of the population, but were particularly notable in those of low education and socioeconomic status, leading to a particular widening of prevalence by social class [32, 35]. This is also evident in geographic trends, where the poorest areas of the USA saw the greatest increase in diabetes prevalence [36].

Impact on Lifetime Risk and Years of Life

The enormous increases in incidence, combined with large decreases in mortality, described in more detail below, have had a large impact on the lifetime risk of diabetes, or the probability of developing diabetes before death, and the number of years spent with and lost due to the disease. Considering Latin America, those metrics have so far have been estimated only for Mexico and Brazil. In Mexico, the lifetime risk through life for women was estimated at 57.7%, whereas for men it was 48.8% [15]. In Brazil, the lifetime risk of diabetes for a healthy 35-year-old woman was 23.8% for those who self-reported as white and 32.2% for those who self-reported as brown or black, the same pattern was observed among men, with a 23.0% and 29.3% risk, respectively. On average, a Brazilian woman diagnosed with diabetes at the age of 35 will lose 2 years of life, whereas a man will lose 4 years [37]. Although this changing burden is a function of both increasing incidence and declining mortality in the diabetic population, the increases and sustained incidence are the predominant factor, underscoring the continued need for effective prevention strategies at the policy, community, clinical, and individual levels.

A Turn of the Tide?

Following the large increases in prevalence in the 1990s, 2000s, and 2010s, data from the U.S. National Health Interview Survey described a peak at an incidence level of 8.5 per 1000 in 2008, followed by a 28% decline to 6.1 per 1000 in 2019 [19]. In contrast with incidence, the prevalence of total and diagnosed diabetes increased from 2009 up until 2018. The prevalence of undiagnosed cases had no significant changes during the period. Similar trends have been reported in state-level prevalence from a separate survey (the Behavior Risk Factor Surveillance System), confirming the encouraging reduction in incidence observed in the NHIS. The reductions appear to have generally affected all major subgroups of the population [33]. Youth and young adults stand out as remaining areas of concern, however, as prevalence and incidence continue to grow in these subgroups [38, 39]. Findings from the SEARCH Study (SEARCH for Diabetes in Youth) revealed a 4.8% yearly increase in the incidence of type 2 diabetes from 2003 to 2012. The increases in incidence were greatest for American Indians and Alaska Natives (8.9% increase), Asian or Pacific

Islanders (8.5%), non-Hispanic Blacks (6.3%), and Hispanics (3.1%), as whites were the only group with no change. Follow-up studies covering the period up to 2015-2017 showed the same annual percent change of 4.8% for both incidence and prevalence of type 2 diabetes, but a change in the most affected subpopulations was observed. In this time period, yearly increases in incidence were greatest for Asians and Pacific Islanders (7.7% per year), Hispanics (6.5% per year), Blacks (6.0%), and American Indians and Alaska Natives (3.7%), and Blacks (3.7). Whites were still the only group with no increase [39–41]. The increases in type 2 diabetes incidence were also accompanied by increases in type 1 diabetes incidence of about 2% per year from 2002 to 2015, and 1.4% from 2009 to 2017, paralleling concerning trends observed in other areas of the world [39, 40].

The continued increases in prevalence and incidence in youth are a discouraging harbinger for the future, given the implications of such early diabetes diagnosis on long-term cumulative diabetes-related complications.

Several explanations for the reduction in incidence have been raised, ranging from true reductions in the rate of the disease due to declining underlying risk in the population, to measurement biases stemming from changes in detection, diagnosis, or definitions of diabetes [32]. Midway through the past decade, surveillance reports also described peaks and decreases in total dietary intake, sugared beverage intake, and plateaus in the prevalence of obesity and physical inactivity. The 2010 American Diabetes Association recommendation to use HbA1c for the diagnosis of diabetes is another potential factor because the HbA1c threshold of 6.5% selects fewer people than the fasting glucose threshold of 126 mg/dl. Thus, a shift from FPG to HbA1c for diagnostic purposes would lower incidence and prevalence [42]. However, if health care providers use both tests, it could actually increase prevalence and incidence. As no surveillance systems measure the actual rates of diagnostic testing or the method of diagnosis, it is unclear how testing or changing awareness of diabetes is affecting incidence rates.

The Burden and Trends in Diabetes Complications

Prevalence and Incidence

Diabetes is notorious for its systemic effect on a diverse array of diabetes-related complications, including macrovascular, microvascular, neuropathic conditions, and infections with coronary heart disease, stroke, foot ulcers, vision loss, kidney failure, amputations, and death regarded as many of the most feared outcomes [43–45]. Diabetes is also increasingly associated with nontraditional complications, including cancers, liver disease, dementia, disability, and other geriatric syndromes [43, 46]. The etiology of diabetes is believed to be multifactorial, with genetic and environmental influences and a key influence of level of glycemic and blood pressure control on most complications.

Diabetic retinopathy is recognized as the signature complication of diabetes and, being the complication that is most specific to diabetes, has been used to guide diagnostic thresholds for diabetes. The prevalence of any diabetic retinopathy has been estimated at 28.5% of the adult diabetic population in the USA, with 4.4% of them having vision-threatening retinopathy [47]. However, no nationally representative estimates of retinopathy exist within the past decade. While it is conceivable that the reductions in incidence of diabetes complications (described in detail below) have served to reduce the prevalence of retinopathy, it is also possible that the concomitant reductions in mortality have resulted in the maintenance of similar or even higher levels of retinopathy.

Chronic kidney disease and coronary heart disease are prevalent at similarly concerning levels in the adult diabetic population, with 19% of adults having stage 3 or stage 4 chronic kidney disease and 18.3% of adults having coronary heart disease [48]. CKD is notably higher in African Americans than in whites, and although coronary heart disease prevalence is similar across race and ethnic groups, a strong gradient with education level has been noted for coronary heart disease, wherein persons with less than a high school education have a prevalence that is 8% points higher (26%) than those with more than a high school education (18%). Although recent estimates of CKD represent a reduction relative to the early 2000s, when prevalence was around one-fourth, there has been no significant reduction in prevalence between 2003-2004 and 2011-2012. Finally, estimates of the prevalence of specific complications do not reveal the full burden of diabetes-related morbidity; when the prevalence of the full range of vascular, musculoskeletal, neurologic, and cancer conditions is considered, most persons with diabetes have multiple chronic conditions present, and the mean number of comorbid conditions is already 3 at the time of diagnosis [49].

Trends in Complications

Despite the high prevalence of morbidity among patients with diagnosed diabetes, there have been large reductions in the incidence rates of diabetes complications over recent decades [29]. In a report of nationally representative data from 1990 to 2010 in the USA, there were substantial declines in a diverse spectrum of diabetes complications, including myocardial infarction, stroke, lower extremity amputation, end-stage renal disease, and hyperglycemic death, resulting in an overall halving of rates of complications for the average U.S. adult with diagnosed diabetes

[29]. The magnitude of decline was greatest for myocardial infarction, declining 68% to draw even with stroke, which also declined by 53%. Rates of amputation declined by 51%, end-stage renal disease by 28%. Rates of death due to hyperglycemia, which were less common in absolute terms, also declined substantially. These reductions in complications generally included men and women and both whites and non-whites. However, the declines in complications were substantially greater in older adults (age > 65 years), moderate in middle-aged adults, and either modest or non-existent in young adults. Although no national data exist on rates of diabetic retinopathy, the prevalence of vision impairment in the USA declined by 25%, from 24 to 18%, paralleling the other improvements in rates. From 2017 to 2019, following a redesign of the survey, the prevalence of visual impairment for all age groups was estimated at 26% [19]. Improvements in diabetes-related complications of a similar magnitude have also been observed for hospitalizations due to vascular disease, amputations, and diabetes in the UK [10].

While the long-term perspective on trends in diabetes complications has clearly been encouraging, more recent reporting of results from the 2010 to 2016 period from the U.S. National Diabetes Surveillance System suggests that the improvements in complications have stalled, and in young adults, even increased [50]. Rates of lower extremity amputations increased overall, particularly among men and the middle-aged population, and were potentially driven by an increase in amputations of the toe, as trends in amputations above the foot have been stable. Similarly, trends in myocardial infarction, stroke, and end-stage kidney disease appear to have plateaued [19, 50–52]. It remains unclear whether such apparent shifting trends are related to changing characteristics of the population with diagnosed diabetes, changes in self-care, risk factor management or treatment, health policy effects, or even broader secular trends in the health of the population.

The encouraging trends in incidence of diabetes-related complications described above take the perspective of the average risk for a person with diagnosed diabetes. When trends in diabetes-related events are expressed as the absolute number of events, wherein the increases in diabetes prevalence over time are permitted to influence rates, the trends have been less encouraging [29]. From this general population burden perspective, rates of diabetes-related MI and mortality declined by 32% and hyperglycemic death declined by 42%, perhaps reflecting the impressive gains that have been made in smoking and the management of hypertension and hyperlipidemia in recent decades. However, trends in amputation stroke have been flat and ESRD has increased when viewed from this population perspective, reflecting the continued wave of new diabetes cases and perhaps an indication that there has been less success in reducing microvascular disease risk than macrovascular disease risk in many countries.

Despite the large reductions in the incidence of diabetes complications, the excess rates of complications associated with diabetes remain substantial, and areas of important disparities remain. Relative risks for lower extremity amputation and ESRD were 10.5 and 6.1, respectively, and adults with diabetes still have an 80% increased risk of myocardial infarction and a 60% increased risk of stroke, respectively [29]. Considerable disparities still exist across subgroups, as non-Hispanic blacks still have more than three times the risk of ESRD, a 50% higher incidence of amputations and stroke, Hispanics have a double incidence of ESRD, and Asians have a 30% higher risk of ESRD than Whites [19]. In addition, compared to women, men have 50% higher rates of ischemic heart disease and more than twice the rate of lower extremity amputation.

Limited population-based data on trends in other areas of the world exists to confirm whether the encouraging trends from the USA are also occurring elsewhere. Although reviews of international data have revealed reductions in rates of lower extremity amputations in numerous settings, these data generally come from Canada, Europe, and Australia. There is limited data on the trends in complications in the Americas or the remainder of middle- or lower-income countries around the world.

Diabetes and Mortality

Adults with diabetes in the USA, Canada, and several countries in Europe have been shown to have overall mortality rates that are approximately 60-80% higher than those of equivalent-aged adults without diabetes [11, 53]. However, data from a Mexico City cohort finding a considerably higher relative risk of death, ranging from 1.9 in persons aged 75-84, to 3.1 in those aged 60-74, to 5.4 for adults aged 35-59 years, serves as a reminder that there may be considerable variation across populations in excess mortality associated with diabetes [54].

Cardiovascular disease is the leading cause of death among adults with diabetes in the United States, accounting for 34% of the total, followed by cancer (20%), diabetes itself, and renal disease. In addition to the five most common causes of death described above, diabetes is associated with an increased risk of several other causes, including unintentional injuries, lower respiratory diseases, sepsis, influenza, and liver diseases. Comprehensive data from the Emerging Risk Factors Collaboration reveals several other specific causes of death that are notably increased in adults with diabetes, including cancers of the liver, pancreas, ovary, and colorectum [53]. These differential rates likely reflect multiple factors, including the chronic hyperglycemia associated

with diabetes as well as the underlying risk factors, including hypertension, insulin resistance, and inflammation commonly recognized in persons with diabetes.

The association of diabetes with mortality varies considerably by demographic subgroup. For example, the relative risk of all-cause, CVD, and renal disease mortality decreases steeply with age. In the USA, among young adults (age 20-44) and middle-aged adults (age 45–64), diabetes is associated with about three times the death rate of those without diabetes. Among those age 65-74, diabetes is associated with twice the death rate and about a 25% increased rate among adults age >75 years. The lower relative risk among older age groups likely reflects several factors, including the possibility that type 2 diabetes onset in young adulthood is a more severe form that is more difficult to manage for physiological as well as environmental and behavioral reasons.

A Diversification of Long-Term Diabetes Associated with Diabetes

Several dynamics in the diabetes epidemic may be leading to relative shifts and diversification in the character of diabetes-related complications [29]. First, the proportionately greater declines in diabetes complications among older adults mean that proportionately more diabetes-related complications now occur in middle age than in previous decades. This is particularly evident in the United States, where adults age 45-64 accounted for only one third of amputations in 1990 and now account for more than half. Second, this may be further compounded by the greater relative increase in diabetes incidence in youth and the earlier exposure to long-term hyperglycemia and the development of diabetes-related complications [55, 56]. The large reductions in cardiovascular disease events and related mortality may be responsible for the relative persistence of end-stage renal disease, as people with diagnosed diabetes are living longer to develop renal disease. Similarly, the reduction in cardiovascular disease mortality observed in most populations with diagnosed diabetes is now accompanied by a proportional increase in deaths due to other causes. Among the US population with diabetes, the proportion of total deaths that were due to cardiovascular causes declined from almost 50% in the early 1990s to 33% in 2010. A similar shift in the specific causes of death has recently been reported in the UK, consistent with the observation of the gradual diversification of the **CVD** types of morbidity associated with diabetes [12]. During the same period, deaths due to cancer in the population with diabetes stayed stable around 18%, and deaths due to all non-CVD, non-cancer causes increased from 33% to 50% of the total. This latter group of "other causes" included several causes, including influenza, pneumonia, sepsis, renal disease, and chronic liver disease, that have an increased association with diabetes. For these latter causes, there has been no improvement or even an increase in the rates in recent decades.

Primary Conclusions and Implications

This synthesis of the epidemiology and trends of diabetes and its complications reveals the following general observations:

1. Changes in the underlying risk of most societies have led to large increases in the incidence and prevalence of diabetes over recent decades, leading to an enormous burden for individuals, families, health systems, and societies.
2. Signs of a peak in the epidemic are apparent in the USA and selected other countries of the world, with recent decreases in incidence and a plateau in prevalence. However, the explanations for these trends are unclear, and the encouraging news is offset by continued increases in diabetes incidence in youth.
3. Diabetes leads to an extensive and diverse array of morbidity, including macrovascular, microvascular, and neuropathic complications and the health outcomes that result.
4. Rates of diabetes-related complications have declined in the USA and other selected countries, likely due to improved risk factor management and organization of care.
5. The disproportionate reduction in cardiovascular disease mortality and increasing lifespan among adults with diabetes, combined with the continued growth of diabetes prevalence in youth, is fueling a diversification of diabetes-related complications and continued population-wide exposure to hyperglycemia that will drive high rates of diabetes-related morbidity into the figure.

ECP: Estimated crude prevalence referes to non-adjusted prevalence of a disease
WNH = white non-Hispanic
BNH = black non-Hispanic

Multiple-Choice Questions

1. The global prevalence of diabetes is currently estimated to be:
   (a) 278 million
   (b) 324 million

(c) 435 million
(d) **536 million**
(e) 612 million

2. The region with the highest worldwide prevalence of diabetes:
   (a) **Middle East and North Africa**
   (b) Europe
   (c) North America
   (d) Africa
   (e) South Asia
3. Increases in diabetes prevalence are likely driven by:
   (a) By autosomal dominant genetic traits
   (b) By Mendelian inheritance
   (c) **By increasing the prevalence of obesity and overweight**
   (d) By aging and having a longer lifespan
   (e) By socioeconomic factors
4. Current estimated prevalence of adult diabetes in the Americas:
   (a) 5.7%
   (b) 6.8%
   (c) 8.3%
   (d) **10.5%**
   (e) 12.1%
5. The percentage of undiagnosed cases of diabetes among those with diabetes is:
   (a) **23.3%**
   (b) 19.8%
   (c) 16.4%
   (d) 12.5%
   (e) 10.9%
6. Estimated prevalence of persons with prediabetes aware of their risk status:
   (a) 65%
   (b) 50%
   (c) 35%
   (d) 20%
   (e) **15%**
7. Greatest relative increases in diabetes have been observed:
   (a) In newborns
   (b) **In youth and young adults**
   (c) In pregnant females
   (d) In middle-aged adults
   (e) In the elderly
8. The incidence of diabetes in the USA has peaked:
   (a) In the late 1980s
   (b) In the late 1990s
   (c) **In the late 2000s**
   (d) In the late 2010s
   (e) Is still increasing, no observed peak so far
9. Lifetime risk of developing diabetes before death for a 35-year-old woman is:
   (a) 73.2%
   (b) 61.4%
   (c) **57.7%**
   (d) 44.4%
   (e) 38.1%
10. The signature and most specific complication of diabetes:
    (a) Coronary heart disease
    (b) Renal failure
    (c) **Diabetic retinopathy**
    (d) Diabetic foot
    (e) Stroke

The Economic Costs of Diabetes

3

Joel Rodriguez-Saldana

Paradigms of Medical Care

- "We must do everything, no matter the cost."
- "We must do everything at the lowest possible cost."
- "We must add value to resources."

Introduction

The Value of Health Care. Achieving high value for patients must become the main goal of health care delivery, with value defined as the health outcomes achieved per dollar spent [1, 2]. For a medical condition like diabetes, no single outcome captures the results of care [1]. Outcomes in health care are multidimensional and interactive. Clinicians traditionally are concerned with the clinical outcomes of treatment (Bootman et al. 1996); many of them conceive that economic resources are nonlimited or at least should be and that patients' views and opinions are secondary to their wisdom and expertise. During the last three decades, health care payers and administrators have focused on the economic outcomes of health care decisions, and patients are becoming increasingly knowledgeable and involved in health care (Bootman et al. 1996). They want to know how their quality of life will be affected or about the satisfaction of other patients with the proposed treatment. Clinical, economic, and patient outcomes are closely linked. The true value of health care interventions and programs can only be assessed if all three dimensions of outcomes are measured and considered (Bootman et al. 1996). When aligned and measured, the three outcomes represent health politics [3].

The intrinsic desire to improve patients' perspectives contrasts with the reality of translating the results of evidence-based medicine to all patients and their involved costs. Diabetes costs include the costs of disease at several levels: from individuals to the family, health providers, payers, institutions and society, and the clinical, economic, and patient outcomes obtained by glucose and metabolic control on the natural history of disease. Above all, the patient's vision prevails, as does their longing to receive timely medical care to satisfy their needs for physical and emotional support.

Economics in Health Care: The Basics

Economics is about getting better value from the deployment of scarce resources [4]. Since the 1960s, economists have turned their attention to health services and have considered the economic aspects of different alternatives in the financing, planning, and management of health care [4]. Costs are important in economics, but not more than benefits. Cost is a measure of sacrifice in that since resources are finite, deploying them means a lack of availability for other purposes [4]. Clinicians are usually not aware of the economic resources they consume and the cost of those resources [4]. Health economics is about opportunity cost and benefits because keeping costs down means maximizing the benefits and efficiency of health care [4]. From this perspective, the view that health services (diabetes care in this case) should be about meeting total needs results in confused thinking and romanticism in health care planning [5]. There are not and never will be enough resources to cover all the costs of diabetes care [6]. If this notion of scarcity of resources is accepted, the logic of comparing the costs and benefits of an intervention is more appealing [6]. Resources devoted to an intervention mean less resources available to another. From this perspective, costs should be addressed in terms of benefits sacrificed for the best alternative use of resources: opportunity costs [6]. In some cases, a cost analysis can provide useful information

J. Rodriguez-Saldana (✉)
Multidisciplinary Diabetes Center Mexico, Mexico City, Mexico

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_3

but does not consider the relative effectiveness of treatment alternatives, and a cost-benefit approach should be advocated, weighing the benefits and costs of different patterns of care [5]. In other cases, when scarce resources should be devoted to one intervention rather than another, a cost-benefit analysis should be undertaken [6]. One final issue of health economics is ethical: clinical practice requires resources for diagnosis, monitoring, and treatment. The inevitability of considering cost can be perceived for resources over which clinicians have control, but it is not easy when several categories (sources of resources) are not available [7]. Allocation of scarce resources is an everlasting problem despite any utopian dreams of unlimited care for everyone and a variety of efforts and proposals assuming that that dream will become a reality [8]. This issue involves moral questions about justice and equity and implications for quality of life [8, 9]. To summarize, Drummond et al. proposed a series of basic notions of health economics for clinicians wishing to acquire a grasp in the field, including [10]: (1) human wants are unlimited but resources are finite, (2) economics is about benefits, but it is also about costs, (3) health care delivery is only one way of improving the health of the population, (4) choices in health care should always involve value, and (5) reducing inequality always comes with a price [10].

Economic analysis has become an integral component of health programs all over the world. In 2021, the World Health Organization (WHO) reported that global spending on health more than doubled in real terms over the last two decades, reaching 8.5 trillion USD in 2019, or 9.8% of the global gross domestic product [11]. In the same report, the WHO describes the inequalities in the distribution of economic resources: high-income countries account for 80%, of which 70% comes from the government, while low-income countries are highly dependent on out-of-pocket spending (44%), and external aid (29%) [11]. Most concerning is the fact that the share of health in government spending increased in upper-middle and high-income countries, stagnated in lower-middle-income countries, and declined in low-income countries [11]. Out-of-pocket spending is a financial burden for people with diabetes, even in developed countries [12, 13], and is largely unaccounted for in studies about diabetes costs. The high frequency of comorbidities will increase the financial burden of people with diabetes and discourage the continued use of medications that prevent disease progression [14].

To summarize, economic analysis of costs is essential for the following reasons:

1. They are limited and finite, even in developed countries.
2. In countries like the United States, health expenditures have surpassed inflation rates without accompanying reductions in the burden from the leading causes of morbidity and mortality.
3. The competing demands of other programs influencing health (education, employment, nutrition).
4. Persistent deficiencies in the use of economic resources and waste despite scarcity. Increasing resources does not necessarily result in improvements in the quality of health care; it may also reduce it.

Interestingly, developed countries pioneered the design of methods to estimate the costs of disease, measure the results of interventions, and devise strategies to contain the ascending costs of health care.

Economic Analysis and Financial Analysis. Economic analysis consists of the estimate of the net value (the direct and indirect costs) of diseases, whereas financial analysis refers to the comparison of alternative resources, or the "opportunity cost." From the medical and patients' perspectives (when not out-of-pocket), costs would be irrelevant. In the "real world" of limited resources, administrators or payers have to decide. To make these decisions, it is essential to have information about the consequences (outcomes) of different interventions, in terms of not only clinical but also economic effectiveness.

Costs. Medical care involves three types of costs: (1) direct medical costs: directly attributed to the disease and its management, involving screening, prevention, diagnosis, and treatment and including medical visits, medications, and hospital admissions; (2) direct nonmedical costs; (3) indirect morbidity and mortality costs to patients, their families, and society; and (4) intangible costs, short-term and long-term consequences of disease for patients, their families, and society (years of life lost, loss of opportunity for spouses and children [15].

Types of Economic Analysis

Economic evaluation is about costs and consequences (Drummond et al. 2015). It provides a framework to make the best use of clinical evidence through an organized approach to the available alternatives on health, health care costs, and other valuable effects. Economic and clinical evaluations are not alternative approaches; they are essential components to achieving the desired outcomes (Drummond et al. 2015). The evaluation of new or existing health care interventions involves five steps: (1) efficacy: the capacity to achieve its stated goals in optimal circumstances, (2) effectiveness: the demonstration that an intervention does more good than harm, (3) efficiency or cost-effectiveness: the combined assessment of the effectiveness of the health care

intervention and the economic resources required to deliver the intervention, (4) availability: matching the supply of services to the persons who require them, (5) distribution: examination of who gains and who loses by choosing to allocate resources to an intervention instead of another [16].

Efficiency Measures

Three methods are used to assess the economic consequences of interventions: cost-benefit analysis (CBA), cost-effectiveness analysis (CEA), and cost-utility analysis:

Cost-benefit analysis is defined as all of the costs required to achieve a benefit (a clinical outcome) [15, 17]. A main challenge in cost-benefit analysis is the ability to account for all the costs and benefits in monetary units.

Cost-effectiveness analysis is defined as a series of analytical and mathematical procedures that support selecting an intervention [15, 17]. It can be measured in monetary units or clinical outcomes. The main challenge consists of establishing the magnitude of the clinical benefit.

Cost-utility analysis is defined as the total cost to achieve a unit of quantity or quality of life. Measurement units are quality-adjusted life years (QALYs) and disability-adjusted life years (DALYs) [15, 17]. The rationale for using QALYs is that it allows for comparisons of different therapies regardless of health problems or diseases [9].

The Study of the Costs of Diabetes. Every disease involves three types of costs: direct costs, resources used for prevention, screening, diagnosis, and treatment; indirect costs from loss of productivity, absenteeism, early retirement, disability, and early death; and intangible costs from the effect of disease on the quality of life of people. The study of the financial costs of diabetes has covered two complementary fields: (1) cost of illness studies, which initially focused on comparisons of direct costs between people with diabetes and without diabetes and which increasingly include outcomes and (2) comparative analysis of interventions. Costs of illness studies are descriptive, cross-sectional, or longitudinal, relate all costs to a specific disease, and involve two approaches: top-down, or burden of disease, and bottom-up, or person-based. Top-down studies include the direct costs of illness (inpatient, outpatient, nursing home) between people with and without diabetes and have particularly focused on the progressive and lifetime costs of complications and comorbidities. Bottom-up studies involve societal costs and quality-of-life measures. Cross-sectional studies have confirmed the impact of direct diabetes costs on a country's gross domestic product and per capita and the large proportional impact of diabetes on health systems, while incidence-based studies have shown the incremental medical care costs of diabetes before and after diagnosis, showing that the rise in medical spending associated with diabetes begins well in advance of the diagnosis of diabetes, accelerates as diagnosis approaches, immediately after diagnosis, and steeply increases for patients with complications. The study of the financial consequences of diabetes is a recent topic that started with cost-of-illness studies and moved forward to include cost-effectiveness analyses of individual interventions, economic analyses of randomized controlled trials, and systematic reviews. The first studies about the cost of illness were carried out in Sweden, the United Kingdom, and the United States in the 1980s. The initial studies about the cost of diabetes complications started to appear in the 1990s along with evidence about the benefits of metabolic control on the risk of microvascular and macrovascular complications. In the last two decades, the number and scope of studies about diabetes have escalated to include cost-of-disease and cost-effectiveness studies. Table 3.1 depicts a chronological summary of studies about the costs of disease in diabetes, starting with the classical report by Jönsson in Sweden. Beyond depicting the direct and indirect costs of diabetes, over the years, cost of illness studies have been enriched by the inclusion of other relevant variables in the outcomes, like comorbidities, avoidable hospital admissions, and patient outcomes:

The Economic Burden at the Global Level. Measuring the global costs of diabetes confirmed the magnitude of the problem and revealed persistent limitations in objective measurement [66–68]. In 2015, a systematic review by Seuring et al. reported large variations in methods and cost estimates and the absence of control groups in most studies, resulting in large differences in direct and indirect costs. In their review, direct costs ranged from $242 USD on out-of-pocket expenditures in Mexico to $11,917 USD for direct costs in the United States. Indirect costs show similar variations: from $45 USD in Pakistan to $16,914 USD in the Bahamas [66]. Interestingly, and in stark contrast with high-income countries, a substantial part of the cost burden comes out-of-pocket. Regression analysis revealed that direct costs are positively associated with the gross domestic product of each country and that the United States has particularly high costs [66]. In 2017, Bommer et al. published the results of the first global cost-of-illness study building on the methods of the IDF Diabetes Atlas, in which the estimated cost of diabetes in 2015 amounted to $1.31 trillion USD, or 1.8% of the world gross domestic product (GDP) [67]. In their report, indirect costs represented 34.7% of the total, due to labor-force dropout (48.5%), absenteeism (3.9%), presenteeism (2.1%), and death [67]. Morbidity-associated factors dominate in high-income countries, whereas premature mortality

Table 3.1 Studies about the costs of diabetes

Year and country	Author and reference	Type of study	Results
1983 Sweden	Jönsson [18]	Inpatient statistics from 19 county councils in 1977	Total economic costs in 1978: 1300 million SEK
			Institutional care: 2/3; noninstitutional care: 1/3 of direct costs
			Direct costs: 43% of the total
			Indirect costs: 57%, dominated by permanent disability: 60%
			Higher share of direct costs for diabetes than for cancer, cardiovascular or musculoskeletal diseases
			Total number of bed days: 656,000
			Hospital discharges: 25,700
			A slow decrease in admissions for acute care since 1970, an increasing number of bed days in long-term care
			Years lost from retirement: 8000
			Total loss of production caused by early retirement: 438 million SEK
			Direct costs from management: 313 million SEK
			Direct/indirect costs from complications: 1004 million SEK
			Total loss of production caused by premature death: 176 million SEK
1989, UK	Gerard et al. [19]	Cost of illness study, including: (1) direct costs, (2) indirect costs, (3) welfare effects from disability or distress	Total direct costs: £238.9
		Estimation as the sum of inpatient, outpatient and primary care costs	Total indirect costs: £343.0 million
1989, USA	Huse et al. [20]	Estimations based on the prevalence of diabetes, microvascular and macrovascular complications and mortality in people with type 2 diabetes	Total costs in 1986: 19.8 billion USD
			Direct costs: 11.6 billion USD
			Indirect costs including disability and premature death: 19.8 billion USD
1991, France	Triomphe [21]	National estimation extrapolated from a sample of 109 patients with type 1 and type 2 diabetes	Average medical costs: type 1, 12,178 FFr; type 2, 6908 FFr
			Distribution of costs:
			Type 1 Diabetes
			Hospitalizations: 33.9%
			Laboratory tests: 4.9%
			Medical visits: 5.5%
			Medications: 44.7%
			Other: 11.0%
			Type 2 Diabetes
			Hospitalizations: 40.1%
			Laboratory tests: 5.7%
			Medical visits: 8.1%
			Medications: 34.3%
			Other: 11.8%
			Hospital admissions: 144,936; percent of the total: 2.2%
			Hospital costs of diabetes in 1987: 195,500 billion FFr; percent of the total: FFr: 1.7%

1991, USA	Jacobs et al. [22]	Cost of illness study	Hospital admissions in excess of those occurring in the general population in 1987: 786,903; 2.0% of the total
		Data from the National Hospital Discharge Survey to estimate the cost of hospitalizations from chronic complications	Total cost of inpatient care: $5091 million
			Cardiovascular complications: 74%
			Renal disease: 10%
			Neuropathy: 3.6%
			Ophthalmic disease: 1.5%
1992, USA	Rubin et al. [23]	Cost of illness study	Hospital admissions from acute complications: 372,000
		Data from the National Medical Expenditure Survey 1987	Emergency visits: 647,000
			Hospital admissions from chronic complications: 731,000
			Medical visits: 15.700 million
			Visits to dietitians: one million
			Glucose monitors: 9.4 million
			Prescriptions of antidiabetics and insulin: 41 million
			Direct costs: 45.2 billion USD
			Economic expenditures per capita
			People with diabetes: $9493.00 USD
			People without diabetes: 2604.00 USD
			Percentage of expenditures devoted to the management of complications: 50% of the total
			Percentage of the total health expenditure devoted to diabetes: 15%
1996 Finland	Kangas et al. [24]	Cost of Illness study	Total health expenditure per patient:
		30,266 questionnaires receiving medications through pharmacies in Finland in 1989	With diabetes: $3941 USD
			Without diabetes: $1326 USD
			Total costs represent 5.8% of the total health expenditure, were three times higher than the average health costs for people without diabetes, and were distributed as follows:
			Inpatient care: 81%, 13% of all available hospital beds in the country
			Medications: 9%
			By comparison, the cost of ambulatory care and resources for self-care is lower, amounting to 8% and 2%, respectively
1998, Sweden	Henriksson and Jönsson [25]	Cost of illness study	Economic burden of diabetes in Sweden in 1994: 5746 million SEK
			Direct costs: 2455 million SEK, 43% of the total
			Indirect costs: 3291 million SEK
1998, USA	American Diabetes Association [26]	Cost of illness study	Total medical expenditures in the United States in 1997: $77.7 billion USD, $10,071 USD per capita
		National Health Care Survey Data	Direct costs: $44.1 billion
			Acute care costs: $7.7 billion
			Chronic complications: $11.8 billion USD
			Excess prevalence of general medical conditions: $24.6 billion USD
			Proportional costs: Inpatient care: 62%
			Outpatient care: 25%
			Nursing home care: 13%
			Indirect costs: $54.1 billion USD; from premature mortality: $17.0 billion USD, from disability: $37.1 billion USD

(continued)

Table 3.1 (continued)

Year and country	Author and reference	Type of study	Results
1998, USA	O'Brien et al. [27]	Cost of disease study	Direct medical and indirect expenditures attributable to diabetes in 1997: $98 billion USD
		Data from multiple sources to estimate direct medical costs on managing type 2 diabetes chronic complications and hypoglycemia	Hospital costs: 62%
			Ambulatory costs: 25%
			Nursing home care: 13%
			Average event costs:
			Acute myocardial infarction: $27,630 USD
			Cerebrovascular events: $40,616 USD
			End-stage renal disease: $63,659 USD
			Blindness: $3486 USD
			First low extremity amputation: $26,894 USD
			Second low extremity amputation: $27,132 USD
			Hypoglycemia: $188 USD
			Indirect medical costs increased from $46.6 billion in 1992 to $54.0 billion in 1997 due to an increase in the number of people with disabilities from diabetes
			With a prevalence of 3.0%, total expenditures for diabetes comprised 8% of health care expenditures in 1997, a more than fourfold difference compared with people without diabetes
1999, USA	Brown et al. [28]	Analysis of clinical data from 11,768 patients with type 2 diabetes to assess the progressive costs of complications	Per-person costs increased from baseline:
			Variable from primary to specialized care
			By more than 50%, from $1087 USD to $2033 USD over 9 years after initiation of a cardiovascular drug
			By 360% after a major cardiovascular event
			By 65% with abnormal renal function
			By 195% with advanced renal disease
			By 771% with end-stage renal disease
			Greatest cost savings would be achieved by preventing major cardiovascular events and progression to stage 3 renal disease
2000, Sweden	Henriksson et al. [29]	Cross-sectional, cost of disease study	Total annual direct costs in Sweden in 1998: 7 billion SEK, 6% of the total health care expenditures, more than four times higher than a previous national estimate
		Estimate the direct costs of type 2 diabetes and the influence of complications	Annual per patient cost: 25,000 SEK, 42% from hospitalizations
			Hospitalization costs: 2.7 billion SEK
			Hospitalization cost per patient: 10,599 SEK
			Ambulatory costs: 2.161 billion SEK
			Ambulatory costs per patient: 7719 SEK
			Medication costs: 1.8 billion SEK
			Medication costs per patient: 6665 SEK
			Costs in patients with macro and microvascular complications:
			Hospitalization: 29,555 SEK
			Ambulatory care: 11,053
			Medications: 9520 SEK
			Average costs for patients without complications: 24,983 SEK
			Average costs for patients with complications: 50,128 SEK
			Difference: 25,145 SEK
			Higher costs with longer duration of disease, from 20,977 SEK with less than 5 years to 22,059 SEK between 5 and 10 years

2000, USA	Nichols GA et al. [30]	Cost of disease study	An economic burden from impending diabetes is apparent for at least 8 years before diagnosis, beginning with outpatient and pharmacy services ranging from $156 to $245 USD/year
		Review of electronic records of a large health maintenance organization to describe and analyze medical care costs 8 years before the diagnosis of type 2 diabetes	The single class of drugs with the highest incremental costs were antihypertensives
			Incremental costs averaged $1205 USD per type 2 diabetes patient per year, including $1913 USD each year for the 3 years preceding diagnosis
2001, Sweden	Norlund et al. [31]	Cost of disease study	Physical dependence increased from 1.3% in people younger than 65 years to 14.6% in those aged 80 years or older
		1677 people with diabetes from the catchment area of Southern Sweden, 2.4% of the total population	Leading diabetes complications included:
		Interview and physical examination to establish physical dependence and comorbidities	Retinopathy, proliferative: 32.9%
		Health depreciation as a capital asset as a result of illness and death	Foot problems: 31.3%
			Ischemic heart disease: 22.1%
			Congestive heart failure: 14.5%
			Cerebrovascular disease: 11.3%
			Foot ulcers: 8.4%
			Total direct and indirect costs per person with diabetes in SEK: 61,738 Total direct costs: 36,173
			Distribution:
			Home-help hours: 11,315
			Inpatient days: 11,294
			Retirement home: 4795
			Nursing home: 3085
			Nurse visits: 1984
			If no monetary value was assigned to home help by relatives, the total average cost would be reduced by 10%
			Total indirect costs: 25,565
			Distribution:
			Early retirement: 19,610
			Sick days: 5955
			Incremental use of resources in 1 year by people with diabetes was 1.2 more medical visits and 5.3 more nurse visits
			Compared with people without diabetes, the incremental losses in production amounted to 9.4 sick days
			Frequency of early retirement: 14.2% higher
			When diabetes-related complications are included, the cost of disease is 2–3 higher
			The incremental costs are more than double for the population
			Diabetes generates high costs to society

(continued)

Table 3.1 (continued)

Year and country	Author and reference	Type of study	Results
2003, USA	American Diabetes Association [32]	Cost of illness study	Total medical expenditures in the United States in 2002: $132 billion USD
		Based on an estimate of 12.1 million people in the United States in 2002 diagnosed with diabetes, an increase of 1.8 million (1.7%) from year 1997 estimates	Health care expenditures: $92 billion
			$13,243 USD per capita
			Direct costs: $91.8 billion, 52% for people ≥65 years
			Hospital inpatient care: $40,337 billion USD, 31% of the total
			Nursing home care: $13,878 billion USD, 11%
			Outpatient care: $20,130 billion USD, 13%
			Proportional costs: Inpatient care: 31.0%
			Emergency visits: 2%
			Outpatient care: 15.0%
			Nursing home care: 11.0%
			Indirect costs: $39.8 billion USD
			Lost productivity from disability: $7.5 billion USD
			Premature mortality: from diabetes: 21.5 billion USD
			The estimates are conservative and probably underestimate the true costs of diabetes
2004, Mexico	Arredondo and Zúñiga [33]	Cost evaluation method based on instrumentation and consensus techniques	Comparing the economic impact in 2003 vs. 2005, a 26% increase in financial requirements was observed
			Total costs: $317,631.206 USD
			Direct costs: $140,410.816
			Indirect costs: $177,220,390
2010, Mexico	Rodríguez Bolaños et al. [34]	Cost of illness study	Total direct costs: $452,064,988 USD, 3.1% of operating expenses
		Review of medical charts from 497 patients from a social security institution treated at secondary and tertiary medical care units from 2002 to 2004	Annual average cost per patient: $3193.75
			Cost per patient without complications: $740.34
			Cost per patient with complications: $3550.17 USD
			It is essential to identify possible savings, redistribute economic resources, and improve medical care at the early stages of the disease
2011, UK	Simmons and Wenzel [35]	Cross-sectional, retrospective 12-month audit in a single teaching hospital to assess mortality, bed day per year and diabetes attributable hospitalization cost	4864 diabetes hospital admissions, 12.9% of the total
			Bed occupancy: 13.9%
			Risk of death among people with diabetes: 18.1% higher
			Mean bed days:
			Men with diabetes: 10.9 vs. 6.3 in men without diabetes
			Women without diabetes: 11.4 vs. 5.9 in women without diabetes
			Mean costs
			People with diabetes: £5835
			People without diabetes: £3706
			Diabetes attributable hospitalization cost: 46.5%, an HbA1c >10% was associated with excess hospitalization
			Approaches known to reduce hospitalization through the improvement of primary diabetes care are urgently required

2011, USA	Nichols, Vupputuri, Lau [36]	Cost of diabetes study to estimate the direct medical costs of patients with type 2 diabetes and hypertension by the level of proteinuria to evaluate differences between patients with and without nephropathy progression	Patients with normoalbuminuria who progressed to microalbuminuria experienced an annualized change in baseline costs that was $396 USD higher than those who maintained normal albuminuria ($902 vs. $506)
			Among patients with microalbuminuria, progression was significantly associated with a $747 USD difference in annualized change in outpatient costs compared with no progression ($1056 vs. $309)
			Among patients who progressed, costs were 37% higher following progression from normoalbuminuria to microalbuminuria ($10,188 vs. $7424), and 41% higher following progression from microalbuminuria to macroalbuminuria ($12,371 vs. $8753)
			Progression of diabetic nephropathy is strongly associated with higher subsequent medical care costs in hypertensive patients with diabetes
			Preventing progression from normo- to microalbuminuria and micro- to macroalbuminuria may reduce the economic burden of diabetic nephropathy
2013, USA	Zhuo, Zhang, Hoerger [37]	Cost of disease study	Lifetime direct costs of treating type 2 diabetes and complications according to the age of diagnosis in men:
		Type 2 diabetes simulation model to simulate disease progression and direct medical costs among a cohort of newly diagnosed type 2 diabetes patients based on the 2009–2010 National Health and Nutritional Survey	25–44 years: $124,700 USD
			45–54 years: 106,200 USD
			55–64 years: $84,000 USD
			≥65 years: 54,700 USD
			Lifetime direct costs of treating type 2 diabetes and complications according to age of diagnosis in women:
			25–44 years: $130,800 USD
			45–54 years: 110,400 USD
			55–64 years: $85,500 USD
			≥65 years: 56,600 USD
			Effective interventions that prevent or delay type 2 diabetes and diabetic complications might result in substantial long-term savings in health care costs
2014, Spain	Arrieta et al. [38]	Cost of illness study from a descriptive, cross-sectional analysis of a sample of 3268 patients with type 2 diabetes	From an estimated population of 390,944 people with diabetes, 172,406 will experience macrovascular complications and 212,283 will experience microvascular complications during their lifetimes
			The mean cost of complications per patient is estimated at EU 4121.54, 66% from macrovascular complications
			Total costs from diabetes complications: EU1.611 billion, EU1.065 billion from macrovascular complications, 545 million from microvascular complications
			The economic impact of diabetes complications will increase with higher diabetes prevalence

(continued)

Table 3.1 (continued)

Year and country	Author and reference	Type of study	Results
2015, USA	Ozieh et al. [39]	Cost of illness study from 2053 adults with diabetes registered in the 2011 Medical Expenditure Panel Survey	Percentage of patients with self-reported chronic kidney disease (CKD): 9.7%
			By comparison of a $9689.49 USD expenditure in people without CKD, the unadjusted medical expenditures from CKD amounted to $20,726 USD
			Adjusted mean expenditures were $8473 USD higher
			Estimated unadjusted total expenditures for CKD: more than $43 billion USD in 2011
			CKD is a significant contributor to the financial burden for people with diabetes, minorities, and the uninsured experience barriers in accessing care
2016, Iran	Davari et al. [40]	Cost of illness study	Mean total costs
		Retrospective observational study	Public fees:
		Analysis of medical records of 2898 people with Type 2 diabetes from a tertiary care center to estimate 1-month direct costs	Laboratory tests: $20.4 USD
			Medications: $65.9 USD
			Medical visits: $17.9 USD
			Private fees:
			Laboratory tests: $52.4 USD
			Medications: $67.8 USD
			Medical visits: $35.6 USD
			Outpatient direct costs for diabetes increased 14.6 times over 10 years
			Medications are the main component
			Estimated national direct costs of diabetes: $810 million USD
2016, Denmark	Sortso et al. [41]	Cost of disease study	Total health care costs: EUR 1.64 billion
		To investigate the relationship between costs, with and without complications in a National Diabetes Register	Cost per person-year: EUR 5509
			On average, a person with diabetes without complications consumes twice as many health care resources as a person without diabetes
			With complications, a person with diabetes consumes three times the health care resources with higher gradients among younger patients, men than women, and for secondary care
			From no complications to minor or major complications, increased health care costs ranged from EUR 1782 to EUR 7534
			Productivity loss amounted to EUR 1.77 billion
			Patients with diabetes received on average a lower income than people without diabetes
			Additional costs were estimated to be EUR 761 million
			Total costs of diabetes in 2011: EUR 6.67 billion
			Diabetes costs increase with increased complications, providing an economic rationale for secondary prevention
2016, Mexico	Lugo-Palacios, Cairns [42]	To estimate the financial and health burden of diabetic ambulatory care sensitive hospitalizations (ACSHs) from public general hospitals at a national level, 2001–2011	Over one decade, 195,778 ACSHs were identified, accounting for one-fifth of total ACSHs for any cause
			Total ACSHs due to diabetic complications increased >130% over 10 years
			The estimated financial costs due to diabetes complications increased 125%
			Diabetic foot hospitalizations showed an increasing trend, growing by 160% and surpassing renal failure
			Estimated DALYs increased by 112%; renal failure had the highest health burden
			Despite promotion and prevention efforts to improve the control of diabetes across the health system, the financial and health burden of ACSHs associated with diabetes complications increased dramatically
			Given the WHO cost-effectiveness criterion, it would have been cost-effective to spend $1.146 billion USD on primary care interventions to avoid the DALYs associated with diabetes complications

2016, Mexico	Lugo-Palacios, Cairns, Masetto [43]	To estimate the financial and health burden of diabetic ambulatory care sensitive hospitalizations (ACSHs) in a large social security institution 2007–2014	Over 7 years, 322,977 ACSHs were identified, of which kidney failure and diabetic foot represented 78%
			Diabetes complications increased 10.3% over this period
			Multiple admission for the same complications occur in 15% of patients
			Diabetes costs increased by 8.4% in 7 years, with kidney failure as the most important cause, accounting for 43% of costs
			Estimated DALYs decreased by 13.6%, representing more than 50% of the estimated total
			Timely and effective primary care could reduce the burden of preventable hospitalizations
			Resources used to treat avoidable hospitalizations could be used to fund more and better primary care
2017, Israel	Porath, Fund, Maor [44]	Cost of illness study in a large health maintenance organization	Median annual cost in cost units (CU): 4420
		Retrospective analysis, 1 year duration	Differences between costs for people with diabetes and people without diabetes accounted for 85% of people 35–44 years old and 24% of people 75–84 years old
			Medical costs increased similarly for patients with controlled and poorly controlled diabetes and with comorbidities
			Costs were significantly impacted by kidney disease
			Leading factors affecting costs were HbA1c level, male gender, chronic diseases, diabetes complications, disease duration, and stage of renal failure
			Early treatment of diabetes and its complications is cost-effective
2017, Hong Kong	Jiao et al. [45]	Cost of disease study to estimate medical costs associated with diabetes complications from the Hospital Authority Clinical Management System through modelling	Expected baseline cost of a 65-year-old person without complications: $1521 USD
			Stroke and foot ulcers had the highest incremental costs
2017, Germany	Jacobs et al. [46]	Cost of illness study based on a random sample of all German people with statutory health insurance	Per capita costs for people with type 2 diabetes: EUR 4957 in 2009, EUR 5146 in 2010
			People with diabetes had 1.7-fold higher health expenses than people without diabetes, with the largest expenses in medications and inpatient treatment
			Medical care for people with diabetes accounts to 10% for total health insurance expenses
2017, USA	American Diabetes Association [47]	Cost of illness study from national surveys, Medicare standard analytical files and claims databases for the commercially insured population	Total estimated direct costs of diabetes in 2017: $327 billion, including $237 billion in direct medical costs and $90 billion in reduced productivity, accounting for one in four health care dollars
			Average medical expenditures per year: $16,750 USD
			Medical expenditures for people with diabetes are 2.3 times higher than expenditures for people without diabetes
			Indirect costs include increased absenteeism ($3.3 billion USD), reduced productivity at work ($26.3 billion USD), reduced productivity for people outside the labor force ($2.3 billion USD), inability to work because of disease-related disability ($37.5 billion USD), and loss of productivity due to premature death ($19.9 billion USD)
			After adjusting for inflation, the economic costs of diabetes increased 26% from 2012 due to the increased prevalence of diabetes and the increased cost per person with diabetes
2018, USA	Squires et al. [48]	Cost of illness study	Diabetes costs increased from $37 billion USD in 1996 to $101 billion in 2013
		Estimates extracted from a health metrics database from 1996 to 2013	In 2013, the greatest amount of health care spending occurred on medications (57.6%), followed by ambulatory care (23.5%)
		Disease burden was extracted from the Global Burden of Disease 2016 Study	Between 1996 and 2013, pharmaceutical spending increased by 327%, especially by 144% increased pharmaceutical spending between 1996 and 2013

(continued)

Table 3.1 (continued)

Year and country	Author and reference	Type of study	Results
2018, USA	Shresta et al. [49]	Cost of illness study using data from three national 2013–2014 databases to estimate direct costs and a human capital approach to estimate indirect costs	The estimated median state economic costs were $5.9 billion USD, ranging from $694 billion to $55.5 billion in total
			The estimated cost per person with diabetes was $18,248, ranging from $15,418 to $30,915 per person with diabetes
			The estimated direct medical costs ranged from $2.8 billion to $8.5 billion, and indirect costs ranged from $3.0 billion to $9.6 billion
			Indirect costs were larger than costs from mortality
			Economic costs for diabetes vary extensively across U.S. states, and are not associated with the size of the population
2018, Germany	Kähm et al. [50]	Cost of disease to estimate costs associated with diabetes complications using statutory health insurance data from 316,220 patients with type 2 diabetes in 2013–2015	Base case estimated total costs for the example of a 60- to 69-year-old man: diabetic foot EUR1293, amputation EUR14,284, retinopathy EUR671, blindness EUR2933, nephropathy EUR3353, end-stage renal disease EUR22,691, fatal stroke EUR11,176, nonfatal myocardial infarction/cardiac arrest EUR8035 EUR, nonfatal ischemic heart disease EUR6548, fatal ischemic heart disease EUR20,942, chronic heart failure EUR3912, angina pectoris 2965, retinopathy EUR6130
2018, Ireland	O'Neill et al. [51]	Cost of illness study from a nationally representative sample of 8107 adults aged ≥50 years	Incremental cost from diabetes: EUR 88,894,421
			Compared with people without diabetes, diabetes was associated with 1.49 additional visits to general practitioners annually, with an 87% increase in outpatient visits, a 52% increase in hospital admissions, and a 33% increase in accident and emergency department attendances
			Diabetes is associated with substantial health services use and costs; costing of hospital admissions was EUR60,002,421, accounting for more than two-thirds of the cost burden
			Areas for potential cost savings include a shift in routine management to primary care and improved access to effective ancillary services such as foot care and dietetic interventions
			These findings outline the urgent need to invest in the prevention and management of diabetes
2018, France	Charbonnel et al. [52]	Cost of disease study from a random sample of 600,000 patients registered in a national health insurance database	Extrapolating the results to the whole population with type 2 diabetes in France, the total estimated direct costs amounted to EUR8.5 billion in 2013, corresponding to 5% of all health care expenditure. Per patient medical expenditures were EUR6506 for patients with type 2 diabetes as compared with EUR3668 in the control group
		Cost analysis from a sample of 25,987 patients with type 2 diabetes matched with a control group of 76,406 individuals without diabetes	Cost difference between the two groups was EUR2838 per patient per year, mainly due to hospitalizations (33.2% of the total costs), medications (23.7%) and nursing care (10.9%)
			Total per capita annual costs were lowest for patients receiving metformin monotherapy (EUR4153) and highest for those receiving insulin (EUR12890)
			These results highlight the importance of public health programs aimed at reducing the incidence of type 2 diabetes, preventing diabetic complications through better glycemic control, reducing clinical inertia and improving patient adherence, and developing less costly integrated care programs

2018, USA	Lin, Pope, Zhou [53]	Retrospective observational study on 138,466 privately insured adults newly diagnosed with type 2 diabetes who were classified into five comorbidity groups: (1) concordant only, (2) discordant only, (3) both concordant and discordant, (4) any dominant, (5) none, to investigate the influence of type of comorbidity on health care utilization and costs	Comorbidities were significantly associated with higher health care costs and the magnitude of the association varied with comorbidity type
			Type of comorbidities and costs:
			Discordant only conditions: 27%, $9173 USD
			Dominant conditions and costs: 25%, $38,168 USD
			Concordant and discordant conditions: 24%, $20,401 USD
			Concordant conditions only: 7%, $9000 USD
			No comorbidities: 21%, 3365 USD
			53% of the total costs were attributable to 25% of patients with comorbidities
			Dominant comorbidities and concordant plus discordant comorbidities substantially increase diabetes costs
			Diabetes management must explicitly address comorbidities to address distinctly different health needs and utilization patterns
2018, Mexico	Salas-Zapata et al. [54]	Cost of illness study to estimate the direct costs related to hospitalizations for diabetes and its complications in a social security institution from 2008 to 2013	Hospital discharges during the period of study: 411,302
			Direct costs: $1.563 USD billion, 77.26% for type 2 diabetes, 22.74% for type 1 diabetes
			Magnitude of costs according to complications:
			Renal failure and peripheral arterial disease account for 46% of hospital admissions
			Hospital admissions show an increasing trend in men and in the 15–44 age group, with decreasing amounts in people ≥65 years
			Diabetes management should be multidisciplinary; health institutions should devise strategies supporting diabetes prevention and control
			Costs from hospitalizations could be reduced by delivering optimal primary care
			Essential costs to be addressed include indirect and out-of-pocket costs
2019, USA	Shresta et al. [55]	Cost of illness study to examine changes in diabetes-related preventable hospitalization costs and to determine the contribution of each underlying factor to these changes	During 2003–2014, the estimated total cost of diabetes-related preventable hospitalizations increased annually by 92.9 million USD (1.6%)
		Data from the Nationwide Inpatient Sample for adults to estimate trends in costs in US dollars in total and by condition, including short-term complications, uncontrolled diabetes and lower extremity amputations	Of this 1.6% increase, 75% was due to the increase in the number of hospitalizations
			The cost of short-term complications, lower extremity amputations, and long-term complications increased annually by 4.2, 1.9, and 1.5%, respectively, while the cost of uncontrolled diabetes declined annually by 2.6%
			Total costs associated with preventable hospitalizations increased despite substantial improvements in preventable hospitalizations and reduced lengths of stay, which were offset by increasing costs per day and increases in the size of the diabetes population
2019, USA	Dall et al. [56]	Cost of illness study to estimate the economic burden of undiagnosed diabetes, prediabetes, and gestational diabetes (GDM) in 2017, including state-level estimates from three databases of 5.8 million, 2.8 million and 7.1 million records from 2013 to 2015, in addition of data from the U.S. Census Bureau, the Centers for Disease Control and Prevention and Centers for Medicare & Medicaid Services	Direct costs associated with diabetes, undiagnosed diabetes, prediabetes, and gestational diabetes in 2017: $404 USD billion
			Distribution
			Diagnosed diabetes: $327.2 billion
			Undiagnosed diabetes: $31.7 billion
			Prediabetes: $43.4 billion
			Annual burden per case
			Diagnosed diabetes: $13,240 USD
			Gestational diabetes: $5800 USD
			Undiagnosed diabetes: $4250 USD
			Prediabetes: $500 USD
			The economic burden of diabetes for each US citizen in 2017: $1240 USD
			It is urgent to adopt more comprehensive approaches and better prevention and treatment strategies

(continued)

Table 3.1 (continued)

Year and country	Author and reference	Type of study	Results
2020, USA	Crossen et al. [57]	Retrospective analysis of type 1 medical costs 2012–2016 from a comprehensive database of 9445 individuals aged ≥18 years and ≥13 months of continuous enrollment	Mean annual cost increased 35%, from $11,178 USD in 2012 to $17,060, mainly because of a 48% increase in the cost of insulin and a 48% increase in the cost of diabetes technology
			The study indicates that the cost of type 1 diabetes care is driven by mounting insulin prices (9.6% per year) and diabetes technology (also 9.6% per year)
			It is possible that short-term costs will be offset by future savings!
2020, Taiwan	Chen et al. [58]	Cost of illness study from 802,429 adults with newly diagnosed type 2 diabetes identified during 1999–2010 and followed until death or December 2013	Annual health care costs for a male or a female diagnosed with type 2 diabetes <50 years, without comorbidities, antidiabetic treatments, or complications: $281 and $298 USD
			Depression was the costliest comorbidity, increasing costs by 64% and 82%, respectively
			Antidiabetics increased costs by 72–126%
			Costs for retinopathy: 36%
			Costs for heart failure: 49%
			Costs for stroke: 202%
			Costs for the five leading costly nonfatal complications increased by 201–599% for end-stage renal disease, 37–376% for stroke, and 13–279% for limb amputation
			Fatal complications increased costs by 1784–2001% and 1285–1584% for cardiovascular or other causes
			The economic burden of vascular complications and death is compelling over time and the impact of depression cannot be ignored
2020, Netherlands	Janssen et al. [59]	Cost of illness study from 2915 individuals who were classified normal glucose tolerance, prediabetes or diabetes based on fasting and 2-h glucose levels, through resource-use and a quality of life questionnaires	Diabetes costs per individual with diabetes: EUR3006
			Health care costs for individuals without diabetes: EUR1377
			People with diabetes had 2.2 times higher societal costs than people with normal glucose tolerance and lower quality of life
			Total costs were 1.6 higher for people with type 2 diabetes and one complication, and 4.8 higher for people with two or more complications
			Higher age, being female, and having two or more diabetes complications resulted in higher costs and lower quality of life
2020, Scotland	McMeekin et al. [60]	To compare costs for three groups of people with type 2 diabetes: (1) at high risk of cardiovascular disease, (2) without cardiovascular disease, (3) with established cardiovascular disease, and for those with established cardiovascular disease, to compare costs incurred by people with type 2 diabetes with an incident cardiovascular disease, with people who remained incident-free over 3 years from a national diabetes registry	Mean annual costs for people at low cardiovascular risk and without established cardiovascular disease: £2500
			For people at high risk: £3300
			For people with established cardiovascular disease:
			£6900
			Costs for people without an incident cardiovascular event: £2100
			Costs of an incident cardiovascular event: £16,700
			Cumulative costs: £4200 and £21,500, respectively
			Cumulative costs by year 3: £5900 and £25,000
			Cardiovascular disease places a significant financial burden on people with diabetes and the global economy
			The results of the study emphasize the financial consequences of cardiovascular disease prevention strategies

Table 3.1 (continued)

Year and country	Author and reference	Type of study	Results
2020, Sweden	Hellgren et al. [61]	Cost of disease study about the economic and clinical burden associated with poor glycemic control, from a national registry of 77,932 people with type 2 diabetes	People with poor glycemic control
			HbA1c ≥7.0%:19,477 (24.9%)
			HbA1c ≥7.5%: 11,753 (15.08%)
			Even short delays in achieving glycemic control have substantial impact on costs and small effects on life expectancy and quality of life
			Benefits were more pronounced over longer-term horizons and versus longer delays in achieving glycemic control
			For people with HbA1c ≥7.0% and ≥7.5% immediate glycemic control was associated with population-level cost savings of SEK 39 and 38, 50 and 77, and 113 and 107 million, respectively, at 3 and 10 years and lifetime, compared with a 1-year delay in achieving control
			Immediate glycemic control was also associated with improvements in population-level life expectancy of 136 and 118, 467 and 470, and 1305 and 928 years, respectively, in the periods
			Population-level life expectancy also increased to 117 and 129, 915 and 858, and 2590 and 2257 years, respectively
			The economic burden of poor glycemic control in individuals with type 2 diabetes is substantial but could be considered reduced by early and effective treatment to achieve and maintain targets
2021, USA	Khan et al. [62]	Cost of illness study of 17,207 subjects without diabetes 5 years before and diagnosed in 2014 from a commercial claims database	Newly diagnosed patients spent $8941 USD more than control subjects over 5 years, approximately $4828 in the year of diagnosis
			The difference gradually widens over time and is greatest in the year of diagnosis
			The compound annual growth rate is 9% higher
			The rise in medical spending associated with diabetes begins in advance of the diagnosis and supports the need to encourage physicians to implement timely identification and prevention efforts to reduce the economic burden of the disease
2021, Germany	König et al. [63]	Cost of illness study of 325 individuals with diabetes and 4490 people without diabetes from a national health survey for adults	Total excess costs: EUR 927 of which EUR 719 were attributable to direct and EUR 209 to indirect excess costs
			Medication costs were 88% higher and had the largest share in excess direct costs
			Direct excess costs:
			For 4–10 years of diabetes duration: EUR 203
			For diabetes complications: EUR 1405
			Indirect excess costs:
			For >10 years duration: EUR 544
			For high education: EUR 995
			Holistic care approaches like disease management programs might be beneficial for people with type 2 diabetes
2021, Canada	Choi et al. [64]	Cost of illness study from a retrospective cohort study of 41,934 patients with diabetes admitted to seven general internal medicine beds between 2010 and 2015	Compared with patients without diabetes, hospital admissions were more frequent and costly for:
			Soft tissue and bone infections (CAN $8794 vs. CAN $5845)
			Urinary tract infections (CAN $5442 vs. CAN $4427)
			Stroke (CAN $8270 vs. CAN $6992)
			Electrolyte disorders (CAN $4422 vs. CAN $3679)
			Nearly one-third of hospital admissions are related to diabetes
			A preventive strategy focused on reducing hospital admissions secondary to soft infectious complications, stroke, and electrolyte disorders would be cost-saving

(continued)

Table 3.1 (continued)

Year and country	Author and reference	Type of study	Results
2022, Ireland	Sharma et al. [65]	Cost of illness study from secondary data sources	Total diabetes costs: EUR129 million in 2018
			Direct costs: EUR81.5 million, 63% of the total
			Indirect costs: EUR47.5 million, 37% of the total
			Costs per capita
			Direct costs: EUR3994
			Indirect costs: EUR2326
			Potential for cost-effective improvements in type 1 diabetes practices that may reduce the health and economic burden

accounts for most of the indirect costs in middle-income and low-income countries [68]. Substantial regional variations were observed in the economic costs of diabetes: North America had the largest absolute burden, sub-Saharan Africa had the lowest costs, and South Asia was in the middle. High-income countries contribute the most of the economic burden of which 36.5% are indirect costs, and low-income countries bear the lowest burden with an average of 0.7% of GDP [68]. Last but not least, in 2020, the International Diabetes Federation updated its report about global direct diabetes expenditures based on prevalence estimates, United Nations population estimates, World Health Organization health expenditure per capita, and ratios of health expenditure for people with diabetes and without diabetes [68]. The global cost of diabetes for 2019 in adults aged 20–79 years was estimated at 760 billion USD, with 68.7% of the spending on people aged 50–79 years, and is expected to grow to $825 billion USD by 2030 and $845 billion USD by 2045 [68]. Like in previous reports, wide variations in expenditures were observed. The United States has the largest expenditure estimated at $294.6 billion, followed by China and Brazil with USD $109.0 billion and USD $52.3 billion, respectively, and afterwards by Germany (43.8), Japan (23.5), Mexico (17.0), France (16.9), the United Kingdom (14.1), Canada (12.3), and the Russian Federation (10.6) [68]. The main drivers of higher direct costs are poor glycemic control, medications, ambulatory care, hospitalizations, diabetic foot ulcers, cardiovascular disease, end-stage kidney disease, and individual characteristics, including the number of medical visits and the number of comorbidities. In the United States, for example, diabetes costs reached $404 billion USD in 2017. People with diabetes have medical expenditures 2.3 times higher than people without diabetes, accounting for one in four health care dollars. Accurate and comprehensive information on the global economic burden of diabetes will assist clinicians and policy makers in making informed decisions, obtaining resources for activities to prevent or slow its progression, and evaluating the benefits of these interventions [68]. Cost-of-illness studies have been very useful to confirm the increasing economic burden of diabetes at a health-system, national and global level, but do not provide an indication of the value obtained for the money spent [69]. Strategies to analyze the effectiveness of interventions are needed.

Cost-effectiveness of Interventions. Except for politicians and clinicians, it is universally recognized that the economic resources available to meet the demands for health care are limited [70]. Measuring effectiveness in clinical practice should be outcome-oriented, with length and quality of life as the ultimate objectives [70]. Economic analyses are used to describe the costs of health care programs and to ensure that value is obtained for the money spent [71]. The economic analysis of interventions in diabetes started in the 1990s and evolved from economic models to compare the costs and benefits of medications in delaying the progression of advanced complications [72], cost-effectiveness analysis of controlled clinical trials like the Diabetes Control and Complications Trail (DCCT) [73, 74], the United Kingdom Prospective Diabetes Study (UKPDS) [75–81], the Steno-2 Study [82], and comparisons of health care use and costs between real and simulated cohorts of patients with good glycemic control and patients without improvement [83–90].

The evidence collected from clinical trials about intensive therapy has been shown to reduce the risk and advance of diabetes complications [74]. Economic analysis and models have been used to evaluate the cost-effectiveness of intensive therapy for people with type 1 and type 2 diabetes [73–90]. An economic analysis of the DCCT estimated the costs of therapy to be two to three times higher than those of conventional therapy [74]. The results of a Monte Carlo simulation model showed that intensive therapy could reduce 41% the risk of blindness, from 34 to 20%, the risk of end-stage renal disease by 71%, from 24 to 7%, and 43% the risk of amputations, from 7 to 4% [73]. The final analysis compared additional costs from intensive management with savings resulting from preventing or delaying chronic complications: $2000.00 USD per patient with blindness per year, $31,000.00 USD per patient with amputation per year, $45,000.00 USD per patient with end-stage renal disease per year. According to the DCCT, intensive therapy for type 1 diabetes delays 15.5 years in the occurrence of chronic complications and would extend 5.1 years the life expectancy of these patients [73]. Implementing intensive rather than conventional therapy for all the people with type 1 diabetes in the United States would result in a gain of 920,000 years of sight, 691,000 years free from end-stage renal disease, 678,000 years free from lower extremity amputation, and 611,000 years of life at an additional cost of 4.0 billion USD over the lifetime [73]. These were the estimated costs to deliver intensive diabetes care in 1996. The question is if they are affordable in 2022 with the increasing prevalence of type 2 diabetes and the escalating costs of treatment for type 1 diabetes (see below)?

Economic analysis was not initially included in the study design of the UKPDS. However, data were collected throughout the study and were supplemented by cross-sectional surveys of non-patient health care use and quality of life [75]. The evaluations of tight versus less tight blood pressure control [76, 77], intensive versus less conventional blood glucose control [78, 79], and metformin [80] showed that each intervention was highly cost-effective and that all could be provided at modest total costs. Estimation of the cost of all

consultations, visits, hospital admissions, and procedures showed that diabetes complications are associated with substantial immediate and long-term health care costs, not only in the year in which an event occurs but also in permanently raising the average level of inpatient and outpatient costs in subsequent years [81]. In the Steno-2 study, an intensified multifactorial approach was compared with a routine multifactorial intervention for 7.8 years in high-risk individuals with type 2 diabetes and microalbuminuria [82]. At the end of follow-up, individuals randomized to intensified therapy survived for a median of 7.9 years longer, and incident cardiovascular disease was delayed by 8.1 years with a relative risk reduction of 45% and an absolute risk reduction of 20% [82]. The risk of nephropathy, retinopathy, and heart failure was significantly reduced in the intensified therapy group [82]. Information on direct health care costs was retrieved from health registries, and the costs in two groups of 80 patients each were compared. No statistically significant differences were found in total direct costs between the two groups during a 21-year follow-up period. In the intensified therapy group, yearly expenses for prescription drugs were higher than in the conventional therapy group, while in contrast, yearly expenses for primary care and hospital admissions were lower in the intensified therapy group. The difference was driven by the increased costs for admissions related to cardiovascular disease [82]. After 8 years, the yearly costs per individual increased steeply in the conventional treatment group but remained unchanged in the intensified treatment group, albeit after 15 years, the yearly costs in the conventional treatment group started to increase [82]. The results of the study reflect that cardiovascular disease and mortality are delayed by about 8 years in the intensified therapy group, which increases life expectancy by 7.9 years and postpones the occurrence of cardiovascular disease by 8.1 years [82].

Simultaneous reports about the benefits of improving glycemic and overall diabetes control confirmed that they were cost-saving and cost-effective. A historical cohort study conducted in 1992–1997 in a health maintenance organization from the United States showed that mean total costs were $685 to $950 USD less each year in the improved cohort for 1994–1997 [83]. Cost savings in the improved cohort were statistically significant among patients with higher baseline HbA1c levels, and beginning in the year following improvement, the use of services was consistently lower in the improved cohort [83]. In England and Wales, a summary of characteristics of patients with type 2 diabetes from the National Diabetes Audit was used to assess the impact of achieving treatment targets for HbA1c, total cholesterol, and blood pressure on clinical outcomes and health care costs across general practitioner practices [84]. Using the UKPDS Outcomes to estimate long-term health outcomes and health care costs, achieving HbA1c, cholesterol, and blood pressure targets led to a lower incidence of diabetes-related complications, in addition to 0.4–0.6 QALYs and 0.6 years of life gained over a lifetime for each additional target met [84]. The projected health care cost savings arising from fewer diabetes complications as the result of achieving one, two, or three targets compared to none were £859, £940, and £1037 over a patient's lifetime. Interestingly, a typical patient in the lowest-performing decile was projected to gain between 201 and 231 years of life if all patients achieved all three targets [84].

The cost-effectiveness analysis of a hypothetical cohort of people with type 2 diabetes showed that the incremental cost-effectiveness ratio for intensive glycemic control was $41,384 USD per QALY; for intensified blood pressure control, the cost-effectiveness ratio was −$1959 USD per QALY; and the cost-effectiveness ratio for reduction of serum cholesterol level was $51,889 per QALY and increasing with age [85]. Individualized control is cost-saving, primarily due to lower medication costs and decreased life expectancy due to an increase in complications, but also produces more QALYs due to fewer episodes of hypoglycemia and medications [86].

The Evidence about Cost-Effectiveness in Diabetes Management. Starting in 2000, 2010, and 2020, three systematic reviews in which diabetes interventions were stratified confirmed their positive impact in the following categories: (1) clearly cost-saving, including preconception care, intensive hypertension control with ACE inhibitors or angiotensin receptor blockers to prevent end-stage renal disease, comprehensive foot care and patient education to prevent and treat foot ulcers, telemedicine for diabetic retinopathy screening compared with office screening; (2) clearly cost-effective interventions included intensive lifestyle interventions to prevent type 2 diabetes, universal opportunistic screening in high-risk populations, intensive glycemic control (targeting HbA1c <7%) as implemented in the UKPDS study, multicomponent interventions involving behavior change/education and pharmacological therapy for hyperglycemia, hypertension, dyslipidemia, microalbuminuria, nephropathy/retinopathy, secondary prevention of cardiovascular disease with aspirin, early detection of complications and bariatric surgery for individuals with type 2 diabetes, statin therapy for secondary cardiovascular prevention, diabetes self-management education and support, counseling and treatment for smoking cessation, screening every 3 years for type 2 diabetes, integrated, patient-centered care, self-monitoring of blood glucose three times per day among people using insulin, intensive glycemic management for type 2 diabetes, collaborative care for depression [87–89]. The last frontier in cost-effectiveness analysis is the estimation of the health utility impact of diabetes complications [90]. Neuwahi et al. combined the Health Utilities Mark 3

data on 15,252 patients with type 2 diabetes from the Action to Control Cardiovascular Risk in Diabetes (ACCORD) and Look AHEAD (Action for Health in Diabetes) trials, classified complications and estimated utility decrements [90]. The largest, statistically significant health utility decrements reported were for stroke, amputation, congestive heart failure, dialysis, reduced glomerular filtration rate, angina, and myocardial infarction [90]. Health utility estimates can be used to improve population-based models and to inform policy makers about the benefits, costs, and cost-effectiveness of type 2 screening, prevention, and treatment programs [90].

The Economic Burden of the Disease on Persons with Diabetes and Their Families

The opening statement of the classic article by Ed Wagner's group about chronic disease is probably one of the few "permanent paradigms" in medicine, and an inescapable truth: "in chronic illness, day-to-day responsibilities (including costs) fall most heavily on patients and their families" [91]. The indirect and intangible costs of diabetes are underestimated, their burden increases over the years, and comorbidities impose additional charges. The costs of chronic care, for cardiovascular diseases and cancer, are becoming a serious burden for patients [92]. Diabetes is not an exception, and patients are increasingly suffering signs of financial strain as out-of-pocket costs ascend [92]. The burden of financial hardship from medical bills among individuals with chronic disease results in financial distress, food insecurity, and cost-related medication nonadherence [93], but it is largely unaccounted for in the analysis of diabetes costs. Berkowitz et al. published the results of a cross-sectional analysis of data from 9696 individuals with a variety of chronic diseases including diabetes, in which 23.4% reported cost-related medication underuse, 18.8% reported food insecurity, and 11.0% reported both [94]. The high overall prevalence of food insecurity and cost-related medication underuse highlights one of the main barriers to successful diabetes management [94], but these realities are vetoed in academic forums, where the advantages of new and costly medications are championed regardless of their costs. The ugly reality has to be recognized and addressed: national spending on glucose-lowering medications among adults with diabetes increased 240% by $40.6 billion from 2005–2007 to 2015–2017 in the United States of which insulin and noninsulin medications contributed $26.6 billion (169%) and $12.0 billion, respectively [95]. For insulin, the increase was mainly associated with higher expenditures from analogs (156%); for noninsulin medications, the increase was the result of higher costs of new medications (88%), while the cost of older medications decreased by 34% [95]. Most importantly, the increase in insulin spending came from higher costs per user (out-of-pocket costs) [95]. Having to use multiple insulin doses, the status of people with type 1 diabetes is more alarming [57]. A retrospective analysis of direct costs for children and adolescents with type 1 diabetes showed that mean annual costs increased from $11,178 USD in 2012 to $17,060 USD in 2016, driven primarily by the increase in the costs of insulin, from $3285 USD to $6255 USD, and technology, from $1747 USD to $4581 USD [57]. The authors of this study conclude that the short-term burden of costs could be offset by future savings and that cost-effective analyses should be undertaken to support optimal care [57]. The bottom line is that within 5 years, the direct costs for children and adolescents with diabetes increased by 34.5%, or 7% per year, by comparison with the average annual inflation rate of 1.96% [57]. As already mentioned, the costs of insulin were mainly responsible, increasing by 52.5% in 5 years, or 10% per year!

Considering the acute and long-term health risks of poor glycemic control, it is vital that people with type 1 (and type 2) diabetes have uninterrupted access to insulin (and antidiabetics), yet millions of people with diabetes around the world still struggle to procure medications [96]. Patients are clearly aware of and conceptualize the experience of being without insulin as a "life or death" emergency and have described multiple insulin access barriers including unaffordable health care, institutional unresponsiveness, and personal life transitions [96]. In the face of these adversities, patients resort to several strategies, including omitting medications, asking for lower-priced medications, or self-treatment [97, 98]. Unable to consistently rely on the health care system to facilitate insulin access, patients turn to non-traditional and dangerous alternatives [96]. The negative consequences of these actions have been confirmed but are inexorably linked to the preeminence of social determinants of health in the continuity of diabetes management over a lifetime. The situation is even worse in many low- and middle-income countries which are unable to provide "comprehensive diabetes care" established by international guidelines, and consequently, diabetes care is delivered at a minimal level [99]. To address this reality, Gregory et al. developed a 30-year type 1 care model that looked at the onset of complications, mortality, financial costs, and quality-of-life measures associated with achieving HbA1c levels for "minimal" and "intermediate" care in six countries with varying income levels and geographic locations (Mali, Tanzania, Pakistan, Bolivia, Sri Lanka, and Azerbaijan) [99]. Minimal care was defined as receiving human insulin once or twice per day, two syringes per week, routine clinical care and hospital admissions, and no screening for complications [99]. Intermediate care consisted of a basal bolus regimen for human insulin delivery, 2–3 capillary blood glucose testing per day, point-of-care HbA1c test-

ing, screening for complications, diabetes education, and 24-h emergency call services [99]. The expected outcome for minimal care was an HbA1c range of 12–14% and from 8.0 to 9.5% for intermediate care [99]. According to their model, the cumulative 30-year incidence of complications was much lower for "intermediate" care than "minimal care" [99]. For many people with diabetes all over the world, even intermediate diabetes care is inaccessible or unaffordable.

Conclusions Achieving glucose, cholesterol, and blood pressure targets in patients with diabetes leads to substantial gains in clinical outcomes, a lower incidence of diabetes complications, and quality-adjusted life years (QALYs). Randomized clinical trials significantly increase direct costs but substantially reduce the risk and cost of complications and increase the time free of complications. Underlying factors driving the rising costs of diabetes include deficiencies in health systems, changing demographics associated with increased life expectancy and aging, and the persistence of the status quo. Simmons and Wenzel accurately claimed that in many cases, diabetes inpatients are a case of lose, lose, lose [35]. Health systems unable or unwilling to reinforce multidisciplinary outpatient management can only expect to see increases in the financial and health burden of preventable hospitalizations [36]. To make matters worse, many patients with diabetes struggle to pay medical bills or to pay them at all. To reduce the out-of-pocket costs of prescription drugs, patients resort to several strategies including self-treatment, avoiding taking medications, or asking doctors to prescribe lower-priced medications with negative consequences for their health. Clinical trials have shown that diabetes interventions are cost-saving or cost-effective; achieving these results in the real world is a great challenge. Albeit limited in scope, the study of diabetes costs confirms the increasing impact of the disease on people with diabetes, their families, national health systems, and societies, and represents a call for action to respond in a comprehensive manner to all phases in the natural history of the disease at the prevention level (primary and secondary), at the health care level, and stress the importance of improvements in disease management. The crisis of diabetes costs is worsening; the time to act is now [100].

Multiple-Choice Questions

1. Value of health care is defined as:
   (a) Health care at the highest cost
   (b) Health outcomes appreciated by pharmaceutical companies
   (c) Health outcomes appreciated by physicians
   (d) **Health outcomes achieved per dollar spent**
   (e) Health outcomes achieved per dollar saved
2. The true value of health care can be assessed:
   (a) Only if clinical outcomes are considered
   (b) Only if economic outcomes are considered
   (c) Only if patients' outcomes are considered
   (d) None of the above
   (e) **All of the above**
3. Health economics is about
   (a) Getting better value from the deployment of endless resources
   (b) **Getting better value from the deployment of scarce resources**
   (c) Learning about the use of economic resources
   (d) Saving resources at all cost
   (e) The use of resources to obtain the most advanced technology and medications
4. Opportunity costs are defined
   (a) **As benefits sacrificed for the best alternative**
   (b) As benefits obtained for the most expensive alternative
   (c) As benefits obtained for the most clinically effective alternative
   (d) As risks avoided for the best alternative
   (e) As risks avoided for the future scarcity of an intervention
5. By comparison with people without diabetes, direct health care costs in people with diabetes
   (a) Are equal
   (b) Are lower
   (c) Are one time higher
   (d) **Are two to three times higher**
   (e) Are ten times higher
6. Out-of-pocket spending:
   (a) Is higher in developed countries
   (b) Is the same all over the world
   (c) Is lower in low-income countries
   (d) **Is higher in low-income countries**
   (e) Is irrelevant
7. Indirect medical costs include:
   (a) Medical visits, medications, hospital admissions
   (b) **Patients and family expenditures**
   (c) Years of life lost, loss of opportunity for spouses and children
8. Direct medical costs include:
   (a) **Medical visits, medications, hospital admissions**
   (b) Patients and family expenditures
   (c) Years of life lost, loss of opportunity for spouses and children
9. Intangible medical costs include:
   (a) Medical visits, medications, hospital admissions
   (b) Patients and family expenditures
   (c) **Years of life lost, loss of opportunity for spouses and children**

10. Cost-effectiveness analysis is defined as:
    (a) All the costs required to achieve a clinical outcome
    (b) **Analytical and mathematical procedures supporting an intervention**
    (c) Total costs to achieve a unit of life saved
    (d) Total costs to achieve a unit of quality of life
    (e) The cost to achieve a medical outcome as appraised by clinicians

Glossary[1]

Cost The value of resources engaged in a service.

Cost-benefit analysis An analysis to consider the economic and social costs of medical care and the benefits of reduced loss of net earnings for preventing death or disability. A method for comparing the value of the outcome of all resources consumed (costs) by an intervention against the value (benefits) of the outcome.

Cost-effectiveness analysis A method designed to assess the comparative impact of expenditures on different health interventions. Identifying, measuring, and comparing the significant costs and consequences of alternative interventions to determine the degree to obtain the desired objectives or outcomes.

Cost-effectiveness ratio A comparison between alternatives, the difference in cost divided by the difference in effectiveness.

Cost-utility analysis Economic evaluation in which the outcomes of alternative interventions are expressed in single "utility-based" units of measurement. The most appropriate approach when quality of life is an important outcome.

Direct costs Diagnosis and treatment costs borne by the health system, the community, and patient families.

Health economics Monetary or humanistic trade-offs between wants, needs, and the scarcity of resources to fulfill these wants.

Incremental costs Difference between marginal costs of alternative interventions.

Indirect costs Lost productivity caused by disease to the individual, the family, the society, or the employer.

Intangible costs Costs of pain, grief, suffering, loss of leisure time, years of life lost.

Outcomes The results and value of medical interventions. Multidimensional and dependent on three perspectives: clinical, economic, patients'. The true value of health care interventions can only be assessed if all three dimensions of outcomes are measured and considered.

Pharmacoeconomic research Identification, measurement, and comparison of costs (resources consumed) and consequences (clinical, economic, humanistic) of pharmaceutical products and services.

Pharmacoeconomics Description and analysis of the costs of drug therapy to health care systems and society.

Quality-adjusted life years Adjustment measure that reduces life expectancy, reflecting the existence of chronic conditions causing impairment, disability, and/or handicap as assessed from health surveys, hospital discharge data, or others.

Total costs All costs incurred in producing a set of services.

The Ecological Approach to Self-Management in Diabetes

4

Edwin B. Fisher, Paul Bloch, and William Sherlaw

Whether our lives are directed by events around us or events within us, "not in our stars, but in ourselves,"[1] is of concern not only in ethics, aesthetics, law, or religion (the Old Testament of laws and the New Testament of "faith as a mustard seed"[2] within us) but also, of course, in behavioral science, biology, and health. The present paper emphasizes the importance of "events around us," of ecological, social, organizational, community, and policy contexts in health and health behavior. It also describes social, community, and policy approaches to addressing contexts and considers all of these with reference to the challenges of diabetes prevention and management.

Broad Patterns of Social and Ecological Relationships with Health

Connections between contexts and health are many and often manifest as health disparities. Since the middle of the twentieth century in many high-income countries, smoking has evolved from a privilege of the well-to-do to a problem among those who are poorly educated, poorly paid, and/or burdened by a variety of personal and psychological problems such as depression, schizophrenia, or divorce [1]. In the United States, African Americans, Latinos/as, and American Indians are about twice as likely to have diabetes as the rest of the population. Internationally, infectious diseases, especially HIV/AIDS, are much more prevalent in poor nations and, within all nations, among poor people. Diabetes, along with other noncommunicable diseases, is also socially stratified. Socioeconomic factors, along with the production, marketing, and drawing profit from the sale of food, all contribute to the sharply increasing levels of obesity both within the United States and globally [2]. At the same time, health problems can have enormous impacts on the social and economic environment, as shown by the impact of HIV/AIDS in many countries in Africa. Most recently, of course, worldwide COVID has wreaked its greatest impacts among groups and countries with the fewest resources. By affecting most people with other health vulnerabilities, it has revealed those vulnerabilities and the contextual factors, including poverty and racism, that lie behind much vulnerability.

The "social determinants of health"—the circumstances in which people are born, grow up, live, work, and age have received great attention in recent decades. Differences in health may be revealed and characterized through statistical analysis linking health and illness, disease and death, to latent variables of social inequity such as income, education, and socioeconomic status. Social gradients show that higher levels of income, education, or social economic status are associated with better health status and lower levels of mortality and morbidity across a range of diseases.

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_4

Along these gradients, causality may occur in both directions, such that poor health may also lead to lower socioeconomic status, income, or education, so-called "health selection." Nevertheless, the overriding tendency and bulk of evidence tend to show that social position determines population health status. For this reason, we may speak of social determinants of both health inequities and health status.

Cross-national analyses support the view that disparities in health reflect variability in the socioeconomic characteristics of countries [3]. Michael Marmot's analysis of this global variability in health extends, however, beyond socioeconomic status *per se*. For example, the populations of the United States, Greece, Costa Rica, and Cuba have life expectancies ranging from 76.5 years (Cuba) to 78.1 years (Greece). However, their 2016 GNPs in US dollars range much more widely, from $7815 per person (Cuba) and $11,825 (Costa Rica) to $57,808 (US) [4]. Marmot interprets such data as indicating that, along with income poverty and material conditions, other social factors must also play roles in the development of health risks and the paths of infectious disease transmission. Key social determinants include stress, early life circumstances, social exclusion, unemployment, poor education, a lack of social support, and various addictions [5]. If obesity and other risks such as smoking and hypercholesterolemia and hypertension are the proximal biological causes of noncommunicable diseases, then these social determinants are among the "causes of the causes" [5]. Attention to these poses the possibility of reducing the population's disease burden.

Articulating a Broad View of Experience and Environment: Ecological Perspectives

Before considering social, community, and policy determinants of health and avenues for its betterment, it is helpful to consider broad conceptual models of how contexts, biology, and behavior all influence each other and our health. Certain approaches underline the importance of proximal factors (lifestyles and behaviors), while others place greater emphasis on distal fundamental or structural determinants such as socioeconomic conditions [6]. Whitehead and Dahlgren, for instance, famously represent "the main determinants of health as a set of concentric arcs around the individual" [7]. Health is represented as "the outcome of a web of social influences" [8].

In ecological approaches [9–11], the behavior of the individual is viewed as guided by layers of influences, including the family, proximal social influences such as social networks or neighborhoods, organizational influences such as worksite or community systems or health care systems, and larger social influences such as government, policy, or large economic structures.

Different models may specify different layers of influence and different components of each, but they share two important emphases: (1) that the behavior of the individual reflects the influence of all the layers; and (2) that the layers interact in their influence so that, e.g., communities may influence families, but families may also influence communities [12].

Habitually there has been a tendency to think of social determinants of health acting at different levels in a cascade, with the distal impinging on intermediate factors and finally on individuals through proximal factors. But as Krieger has argued, it is important to understand that interventions at nonadjacent levels may have direct impacts. A new national law restricting or granting rights or cutting or attributing welfare taken at the macro-governmental level may have immediate implications for individuals subject to it. Furthermore, different factors may operate at different levels simultaneously in consort. This is especially evident in the case of the accumulation of disadvantages within vulnerable or marginal groups and individuals. The same factors may differ in their impact at different moments in the life course, and unexpected effects may emerge. Such impacts on health and well-being do not occur in a vacuum but are mediated through the wielding of political and economic power. Discussing Pierre Bourdieu's rich but complex sociology, Ghassan Hage speaks of a "political economy of being" [13]. We may consider that different groups and individuals through social, economic, and cultural capital may have the possibility to deploy their social being to a lesser or greater extent. Here lies the real meaning of accessibility for disabled people, for example. When services and resources in the community are less easily accessible, it will be difficult for disabled people and indeed other marginal groups to fully deploy their social being, that is, to be able to exert choices which they value. Such capabilities, defined as "the substantive freedoms" a person "enjoys to lead the kind of life he or she has reason to value" [14], are dependent on political and economic power, which both enables and obstructs the choices of groups and individuals.

Relationships Among Influences: The Example of Genetic Expression and the Environment

Gene-environment interactions illustrate well how interactions among levels of ecological models are fundamental to health and well-being. Many think of genes as causes that obviate other influences on behavior. Old controversies as to whether one or another condition, e.g., schizophrenia, is ***either*** genetic ***or*** learned presumed that the one trumps the other. The reality is that genetic, other biological, behavioral,

and environmental variables interact in complex ways to lead to behaviors and health states [15].

The importance of the environment in determining whether or not a gene will have any effect is illustrated in the work of Michael Meaney and his colleagues with rat pups and their dams. It turns out that the frequency with which rat dams lick their pups and other maternal behaviors influence the expression of genes related to stress response in adults. "Epimutations" (specific changes in methylation of cytosines on genes) mediate the relationship between rearing and adult stress response [16]. A large number of studies by Meaney and his colleagues and other groups show that this epigenetic structuring of gene expression is the result of a series of intracellular processes that can be set in motion by external contextual influences such as maternal nurturance [17]. The expression of a cell's genes is thereby dependent on the environment within the cell, an interdependence between genes and the intracellular environment that sets a model for gene X environment interactions at the levels of whole animals and populations.

The role of central nervous system serotonin in cardiovascular disease illustrates well the complexities surrounding gene X environment interactions. As contributed to and summarized by Williams and his colleagues [18, 19], there is considerable evidence that long and short alleles of the serotonin transporter gene promoter polymorphism appear to affect CNS serotonin activity in ways that impact CVD risk. But this is not a simple relationship in which, for example, one or the other allele lowers serotonin and raises CVD risk. Among Rhesus monkeys reared by their parents, for example, there is no difference between those with long and short alleles in CNS serotonin levels. However, among those reared among peers, the short allele is associated with reduced CNS serotonin and greater risk [20].

Socioeconomic and social factors surely influence the pathways from the serotonin transporter gene to CVD risk. For example, overstressed parents or neighborhood crime may be analogous in humans to the levels of a rat dam's nurturance or to the peer vs. parental rearing that moderates gene expression in monkeys. There are also several broad contextual factors that influence the pathway from genotype to CVD risk. The prevalence of the long-allele genotypes varies by country of origin, from less than 30% in China and Japan to over 70% among populations originating in Africa [21].

But what is most interesting and most illustrative of the complexities of gene X environment interaction are perplexing inconsistencies regarding the serotonin transporter gene. It turns out that the same genotype can have both advantageous and disadvantageous effects. In some studies, the long alleles are the "bad actors" [22, 23]; those with one or two long alleles have significantly greater blood pressure responses to stress and greater CVD risk. However, in a longitudinal study of depression among young adults, the number of *short* alleles (either one or two) was related to greater likelihoods of depression and suicidality [24].

If we think of genes as conferring a simple advantage or vulnerability to some disease or condition, it is confusing that a particular genotype is associated with benefit in some studies and vulnerability in others. Williams and his colleagues have suggested another way of framing these influences as conferring a greater or lesser *sensitivity* to environmental influences [19, 25]. Thus, in a study of depression among young adults, those with two short alleles of the serotonin transporter gene reported greater depression than those with other genotypes *if* they had been exposed to early adversity in childhood or recent negative life events. Among those exposed to a positive early environment or recent events, on the other hand, those with two short alleles reported the least depression [26]. It seems that the two short alleles confer no advantage or disadvantage, *per se*, but greater responsiveness to the environment, for good or ill.

Others have noted a similar pattern of greater sensitivity to the environment. In one study, observers' measures of poor home and neighborhood quality during adolescence predicted lower self-esteem in young adulthood among those with short alleles. In contrast, there were no effects on home and neighborhood quality among those with two long alleles [27]. In a study of those exposed to a series of hurricanes in Florida in 2004, county-level indices of joblessness and crime moderated the effects of the transporter gene in a remarkable interaction. In counties with high crime/high unemployment, the short allele was associated with higher levels of post-traumatic stress disorder, but in counties with low crime/low unemployment, the short allele was associated with lower risk of post-traumatic stress [28]. Putting these findings together, it seems that short alleles confer greater sensitivity to environmental influences, either positive or negative. That is, sensitivity to the environment may be, itself, influenced by genetic variation. Thus, the genotype is far from destiny, independent of context. Rather, sensitivity to context is itself embedded in some genotypes—no doubt further influenced by other contexts in the external, phenotypic, and intracellular environments.

What Meaney and Williams and their colleagues point out at the level of the cell is parallel to what others have called "reciprocal determinism" [29] in the relationships between human behavior and its environmental surroundings. Just as the cell phenotype acts as an environment that influences the expression of the cell's genetic material and the further emergence of the cell's phenotype, our environment governs our actions, which, in turn, exert influence on the environment that will govern our next actions. Continuing up the ladder of complexity, one can see the same kind of reciprocity in the influence of:

- the group on the individual and the individual on the group

- the organization on the division and the division of the organization
- policies on organizations and organizations on policies.

This pattern of the reciprocal influence of surround on agent and of agent on surround appears to be an important dynamic across living systems. It poses an important counterpoint to more primitive models such as those which get lost in the debate over whether genes ***or*** environment are important, models that seek a single cause, and in which a single thing can be only a cause or an effect but not both.

The Illusion of the Fundamental.

It is worth noting that we can see either party to a reciprocal relationship as fundamental. We might say the work unit is the fundamental determinant of employee performance as moderated by the organization, or we might say that the organization is the fundamental determinant, as moderated by the work unit. Both may be equally true. Both illustrate the illusion of "fundamental" amidst the reality of multiple, multilevel, interacting determinants. Diabetes provides a classic example. Pima Indians in the United States show "the highest prevalence of type 2 diabetes mellitus…of any population in the world" [30]. Yet, Pimas living in Mexico have relatively low levels of diabetes. Ample evidence links genetics to diabetes *within* the Pima population [30]. Thus, the relationships among genes, environment, and diabetes among the Pimas can be stated in either of two ways:

- Genetic factors associated with membership in the Pima population have a strong influence on the prevalence of diabetes among a population exposed to the obesigenic environment of US diet and food distribution
- The obesigenic environment of the United States has a strong influence on the prevalence of diabetes among a population such as the Pima, who are genetically predisposed to high rates of diabetes

Genetics as a Model for Analyzing Social and Ecological Influences

In genomics, causal relationships are frequently identified through cluster analysis and related statistical techniques that compare differences in probabilities of hundreds or even thousands [31] of genes among those with varied phenotypes. In such analyses, no one gene is the cause or indicator of the phenotype. Instead, the relationship between phenotype and all the genetic markers in the analysis is probabilistic, not all or none.

This approach to characterizing genetic influences is descriptive but persuasive as to the likely causal relationship between profiles and outcomes. To what extent does it provide a model for making judgments about causal influences in a multilevel approach to complex behavior, such as might be arrayed by genetic, personal, social, organizational, and geographic influences?

From the perspective of the individual, we can envision complex webs of influence including genetic and other individual characteristics as well as, outside the individual, the ecological layering of family, neighborhood, community, worksite, government, and policy, all arrayed in a spatial analysis. These multilevel complexes could be examined as they explain, for example, the likelihood of smoking and its relationship with rates of cardiovascular disease and cancer, or BMI and its relationship with diabetes, obesity, and other related diseases.

Ecological Analysis and Diabetes

Consider adults with diabetes. Even if they spend 6 h a year in a professional's office—certainly more than average—that still leaves over 8760 h a year they are "on your own." The ecological perspective provided a basis for program planning for the Diabetes Initiative of the Robert Wood Johnson Foundation, which demonstrated the successful implementation of diabetes self-management programs in "real world," ethnically and economically diverse primary care and community settings around the United States [32, 33]. To guide program development across 14 different project sites, an ecological perspective was used to identify the resources and supports for self-management that people with diabetes need to take care of their disease in their daily lives. These include (1) continuity of quality clinical care, (2) individualized assessment, (3) collaborative goal-setting, (4) opportunities to learn skills both specific to diabetes (e.g., measuring blood sugar) and for addressing challenges, including negative emotions, that may interfere with management, (5) ongoing follow-up and support, and (6) community resources such as for regular physical activity and a healthy diet [32–34]. The last two, ongoing follow-up and support, and community resources, especially illustrate the contributions of an ecological perspective to diabetes management.

Sustaining Health Behaviors: Follow-Up and Support

Sustaining diabetes self-management is of key importance. We all have great respect for intervention studies that include follow-ups for 1, 2, or 3 years. Consider now that the average

individual with type 2 diabetes will live 20, 30, or 40+ years with the disease. How do we make the extension from studying the maintenance of change over a year or 2 to developing systematic ways of supporting individuals who need to maintain changes for decades?

Major guidelines [35] of the American Diabetes Association, American Association of Diabetes Educators, and the American Dietetic Association distinguish between diabetes self-management education, the results of which often deteriorate by 6-month follow-up, and diabetes self-management support to "assist the individual…to implement and sustain the ongoing behaviors needed to manage their illness." This reflects reviews in diabetes self-management that showed that the length of time over which intervention is maintained is the best predictor of changes in blood sugar control [36].

The importance of sustained contact is not limited to diabetes. It was recognized, for example, in early meta-analytic reviews of research on smoking. In their 1988 review, Kottke and colleagues noted that "Success was…the product of personalized smoking cessation advice and assistance, repeated in different forms by several sources over the longest feasible period" [37]. More recent reviews have continued to document the importance of duration of the interventions in smoking cessation [38]. In research on weight loss and weight management as well, the duration of interventions emerges as a key predictor of success [39–41].

The *Diabetes Initiative* of the Robert Wood Johnson Foundation came to recognize that the most important characteristic of type 2 diabetes and self-management of it is that it is "for the rest of your life" [42]. It sounds simple, but it is striking how this consideration reframes thinking about self-management programs. As an example, consider the goals of working with a 45-year-old adult whose diabetes is under poor control. Is the goal to get that control improved in the next 3 months? Or, is the goal to establish an approach to living with diabetes that will help the individual attain the best possible control over the next three or four decades? Does the choice of goal have implications for the approach to helping the individual? Clearly, the lifespan is an important context of behavioral medicine and one we are just beginning to grasp [43].

In 1968, early leaders in the field of behavior modification, Donald Baer, Montrose Wolf, and Todd Risley noted that maintenance of behavior changes needed to be arranged or planned, as they put it, to be "programmed rather than wished for or lamented" [44]. A December 2021 search of PubMed for papers with "diabetes" (or "diabetic") and self-management in their titles or abstracts yielded 6536 responses. A subsequent search with these terms and cognates of "sustain" or "maintenance" yielded only 782, 12.0%.[3] A parallel search just of "self-management" yielded 22,931 while that with "self-management" as well as cognates of "sustain" or "maintenance" yielded 2776, again 12.1%. Clearly, a major challenge remains the relative dearth of research on maintaining or sustaining changes brought about by self-management.

From the perspective of "programming" maintenance of behavior, contexts take a central role. Behavior will be sustained to the extent that the daily lives of individuals provide opportunities for the behavior, facilitate it, and reinforce it. It is the contexts of neighborhoods, workplaces, communities, families, and friends that must sustain the healthy behaviors that prevent or manage the disease and enrich lives.

The content of follow-up may include continued assistance in refining problem-solving plans and skills, encouragement in the face of challenges, assistance in responding to new problems that may emerge, and assistance that may entail linking patients back to primary care providers or other parts of the disease management team. The Diabetes Initiative grantees identified a number of strategies for providing follow-up and support [42], including nurse follow-up by telephone [45–50] as well as through community health workers, lay health workers, *Promotoras*, or health coaches [51–54].

The structure of clinical care may also contribute to ongoing support through group medical visits [55, 56]. In these, all patients in a particular category (e.g., those with diabetes, cancer survivors, or, perhaps, those with any of several chronic diseases) are scheduled for a group visit in a 2- or 3-h block of time. Physicians and other staff carry out individual medical visits within this group visit that also includes educational and supportive discussions or other activities.

In spite of the importance of sustaining key behaviors, *ongoing* follow-up and support for *good self-management* is not always recognized as an important service. Among those with diabetes, for example, ongoing support for self-management may be made available for those whose indices of blood sugar control exceed some criterion (e.g., hemoglobin A1c > 8%), but not for those who are below that criterion, but to help them maintain their relatively good management. Our systems of providing health care are still slow to recognize what Baer, Wolf, and Risley noted in 1968: that maintenance of changes in behavior "…needs to be programmed rather than wished for or lamented" [44].

[3]Search syntax: ((diabetes [tiab] OR diabetic [tiab]) AND self-management [tiab]) AND (sustain* [tiab] OR maintain* [tiab] OR maintenance [tiab]). Date of search: 29 December, 2021.

Community Resources Access to Healthy Food

An early study examined the distribution of supermarkets and fast food restaurants in St. Louis, Missouri, in the United States [57]. Supermarkets were audited and sorted into tertiles according to their offering of fresh fruits and vegetables and lean, low-fat, and fat-free meat, poultry, and dairy products. Of 21 supermarkets in census tracts with a greater than 75% African American population, none were in the highest tertile. In contrast, 17 of 30 (57%) census tracts with less than 10% of the population below the poverty level and more than 75% white population were in the top tertile.

Do neighborhood resources make a difference? Obesity rates vary between neighborhoods within cities such as New York. A range of factors would seem to be involved, including the presence of supermarkets and food stores and the area's income [58]. Earlier research examined the relationships between obesity and supermarkets and convenience stores in neighborhoods [59]. After adjusting for gender, race, age, income, education, and physical activity, it turns out that the presence of supermarkets in a census tract was associated with a lower prevalence of obesity (prevalence ratio = 0.83 relative to census tracts with no supermarkets), while the prevalence of convenience stores was associated with a higher prevalence of obesity (prevalence ratio = 1.16 relative to neighborhoods with no convenience stores). Those in census tracts with only convenience stores were 1.45 times as likely to be obese as those in tracts with only supermarkets.

This is an area in which the view of self-management as the individual's own responsibility can be especially damaging. The benefits of teaching about physical activity and a healthy diet are compromised if people live in neighborhoods in which it is dangerous to walk alone, in which food sellers offer little healthy food, and with little public transportation to access better resources. Studies indicate that such deprivation of community resources is more common in low-income and minority neighborhoods [57].

The Ecology of Professionals

A critical feature of the application of the ecological model is to recognize that it applies as much to providers as to recipients of care. For example, the network analyses of the influences of social networks and ties on obesity [60], cigarette smoking [61], depression [62], and other features of health and quality of life have been extended to physicians' prescriptions of medications [63]. This leads to recognition of the importance of systems that facilitate good clinical care and professional services, not just the training and commitment of individual providers.

Wagner's Chronic Care Model articulates the organizational and system features that support the integration of Resources and Supports for Self-Management with key components of clinical care [64]. One health system instituted a comprehensive approach to improving a range of diabetes care services, including handouts and manuals, outpatient programs, web-based programs, telephone/nurse case management, financial incentives for physicians' meeting testing guidelines, and patient incentives for annual eye exams. These were followed by improvements in a variety of outcomes [65]. But the emphasis on such integration of comprehensive clinical and self-management services is not widely shared in health care. Audits of health plans utilized by major companies [66] show little support for such elements of care, and 60–70% of patients with diabetes report not having received self-management interventions [67].

Another ecological approach to systems of care is the patient-centered medical home (PCMH). A review of evaluated demonstration projects showed encouraging evidence for the benefits of PCMH in diabetes care [68]. At the organizational level, the PCMH includes resources such as electronic medical records, evidence-based algorithms and care plans, and ties to referral sources and other community-based resources for patients. In many presentations of the patient-centered medical home, the interdisciplinary, collaborative team—i.e., the social or organizational level of the ecological model—is emphasized as its central characteristics.

A Social Strategy: Peer Support

The chapter now turns to three areas of the application corresponding to three key levels of the ecological model: the social, community, and policy levels. At the social level, peer support programs—known by varied terms, e.g., "community health workers," "*promotores de salud*," "lay health advisors," "health coaches"—are widespread and supported by a diverse literature [69–75]. There are many ways in which peer supporters can encourage health. Among these are helping individuals sustain important health behaviors.

Peer support is an especially promising approach to providing ongoing support for disease management and sustained changes in health behaviors, such as smoking cessation and weight management. To begin, peers have time, a critical ingredient in all of health care [76]. Whether volunteer or paid staff, nonprofessionals trained to assist and encourage ongoing efforts at disease management and prevention can also be readily available to those they help and spend time with them to get to know them and their circumstances.

Additionally, the credibility of peers' assistance is enhanced by being "like me." Research shows that individuals rely on experts to understand what is important and set

priorities, but turn to peers and "peer coping models" [77] to gain confidence that they, themselves, can implement a plan. Adding to their credibility, peer supporters oftentimes have the advantage of having the health problem with which they are assisting. Also, they often come from similar neighborhoods, so they share the perspectives and experiences of those they are seeking to help.

Extending the advantages of time and similarity, peer supporters can work with individuals on the details of implementing important health behaviors. For example, it is one thing to set an objective of physical activity for 150 min a week. It is another thing to work out exactly what activity, where and how often, and how an activity will fit in with other responsibilities and daily routines. In a report of qualitative analyses of peer support aptly titled "*Teaching How, Not What*" [54], a participant noted that, whereas her doctors and nurses helped identify *what* to do, her peer supporter "taught me a lot about *how* to control my diabetes, *how* to eat healthy, and *how* to do my exercise" (emphases added).

A 2014 review in the *Annual Review of Public Health* [78] identified the contributions of community health workers to basic health needs (e.g., reducing childhood undernutrition), to primary care and health promotion, and to disease management. Another review [79] included peer support interventions from around the world that addressed a wide variety of prevention and health objectives entailing sustained behavior change (in contrast to relatively isolated acts such as cancer screening). It identified papers from the United States (34 papers), Canada (7), Bangladesh, England, Pakistan, and Scotland (4 each), and Australia, Brazil, Denmark, Ireland, Mozambique, New Zealand, South Africa, and Uganda (1 each). The health issues papers addressed included pre- and postnatal care (17 papers), cardiovascular disease (10), diabetes (9), asthma (6), HIV (6), mental health (8), cancer (4), substance use (3), and chronic fatigue syndrome and chronic obstructive pulmonary disease (1 each). Across all 65 papers, 54 (83%) reported significant between-group or pre-post changes showing the benefits of peer support. Among the 48 papers reporting RCTs, 39 (81%) reported significant between-group or pre-post changes. The review also included a summary of 19 other reviews of peer support interventions. Across these 19 reviews, a median of 64.5% of papers reported significant effects of peer support.

Nineteen papers reviewed provided pre- and post-intervention measures of hemoglobin A1c (HbA1c) as a measure of glucose control [80–93]. Using the individual publication as the unit of analysis, the average HbA1c declined by 0.76 points (e.g., from 8.76% to 8.00%; $p = 0.001$). In diabetes, a reduction of HbA1c by half a percentage point, e.g., from 8.5% to 8.0%, is generally considered clinically meaningful. The average reduction across these 19 studies of 0.76 points is thus very striking and adds considerably to the evidence for the benefits of peer support in diabetes management [79].

Peers for Progress (peersforporgress.org) is a program at the University of North Carolina-Chapel Hill (led by co-author EF) that is dedicated to promoting peer support in health, health care, and prevention [94]. In 2009, it funded fourteen projects on peer support in diabetes in nine countries—Argentina, Australia, Cameroon (2 projects), China, England, South Africa, Thailand, Uganda, and the United States (5 projects). In addition to effectiveness, the fourteen showed real-world applicability. All were able to be implemented, often in under-resourced settings and/or with disadvantaged populations. Based on data provided in progress reports, the average baseline HbA1c in the fourteen was 8.71%; clearly, the projects were not "cherry picking." Across peer support interventions, projects retained 81.9% of their participants, again quite impressive, especially considering the underserved settings and disadvantaged populations of many of the projects. The average among site reports of reductions in HbA1c was 1.18 points, well above the 0.5-point reduction generally considered clinically meaningful. Other indicators of benefits included reduced hospitalizations [95]. Two years after the end of funding from Peers for Progress, group programs in Uganda and South Africa continued and reported *increased* participation and attendance. Similarly, a private, not-for-profit health care company, adopted the program as routine care for diabetes in all of its U.S. clinical sites [96].

Across 7 of the Peers for Progress sites, documentation of participants' contacts with peer supporters enables analyses of both predictors and effects of contacts. In structural equation modeling, lower levels of available support for diabetes management, higher depression scores, and older age predicted any vs. no contact with peer supporters. That is characteristics indicative of greater need for assistance were associated with greater receipt of peer support. Any contact, in turn, predicted lower levels of final HbA1c. Additionally, no, low, moderate, and high contacts showed a significant linear, dose-response relationship with final HbA1c [97].

Strategic Advantages of Peer Support

Peer support is especially beneficial for people with diabetes with high needs and for those who are hardly reached by conventional health care services. Two meta-analyses have shown an association between higher baseline HbA1c and a larger effect size [98, 99]. Compared to usual care, peer support is an effective strategy for improving glycemic control for underserved, low-income minority populations [100–102]. For example, a program for ethnic minority patients of safety-net clinics in San Francisco reported significantly greater reductions in HbA1c with peer support in addition to

usual care, compared to usual care alone [103]. These benefits of peer support were significantly greater for patients categorized as *low* on medication adherence and self-management at baseline [104]. Similarly, in support exchanged within dyads of US veterans with diabetes, improvements in blood glucose relative to controls were greatest among those with initially low levels of diabetes support or health literacy [85]. In an underserved Chicago population, a low-intensity, home-based community health worker intervention was more effective at decreasing HbA1c among participants that had lower levels of diabetes self-care at baseline [105]. These are important observations: intervention worked across all individuals, but worked especially well relative to controls for individuals whose diabetes management was in most need of improvement (as suggested by various indicators). This pattern of peer support reaching and benefitting those whom we would expect to be most difficult to reach and the benefit was sustained in a systematic review of peer support programs across a variety of health conditions [106]. Therefore, peer support is a viable strategy to address one of the major challenges in population health management: benefitting high-need groups that experience disproportionate burdens and costs of care.

Peer support has also demonstrated strong potential to address diabetes and co-morbidities [100, 107]. The co-occurrence of diabetes and depression is quite common; people with diabetes are twice as likely to be depressed as those without diabetes, and symptoms of depression are present among almost one-third of people with diabetes [108]. Psychological problems, from heightened distress to serious psychopathology, compromise self-management behaviors and exacerbate disease. Among people with diabetes, depression is associated with poor glycemic control and decreased adherence to medical treatments [107]. Peer support directly mitigates depressive symptoms by providing social and emotional support through regular, affirming contacts. Even if recipients of peer support do not change their behaviors, they still experience emotional benefits from having someone with whom to talk [109]. Additionally, peer support addresses diabetes and depression together by helping people with diabetes overcome socioeconomic barriers and teaching common skills to cope with both conditions. Peer supporters can help identify safe places to exercise and ways of buying affordable food, as well as coach people with diabetes to develop healthy coping skills when facing stressful situations and setbacks. For example, a CHW stress management intervention for U.S. Latinos with type 2 diabetes found a dose-response relationship between attendance at stress management sessions and improvements in HbA1c and diabetes distress [110].

In some cases, psychological improvements have been observed as a by-product of peer support programs designed principally for diabetes. With support from *Peers for Progress*, the PEARL project in Hong Kong examined the impacts of peer support on diabetes-related distress [111]. PEARL was designed to assist in diabetes management, not necessarily to reduce emotional distress. At baseline, however, about 20% of participants exceeded norms for depression, anxiety, or stress on the Depression, Anxiety, and Stress Scale (DASS) [112]. Among this 20%, the DASS scores of those randomized to receive peer support were significantly reduced relative to those randomized to control. Among controls, those with elevated DASS scores also experienced disproportionately high rates of hospitalization, whereas those randomized to PEARL showed hospitalization rates comparable to those without elevated DASS scores. Perhaps because of the social support intrinsic to the PEARL peer support intervention, it achieved substantial effects on distress and associated hospitalizations.

Another example of the distress-reducing benefits of peer support is the REACH program, a diabetes lifestyle intervention for African Americans and Latinos with type 2 diabetes in Detroit [113]. Although the intervention was not intended to reduce symptoms of psychosocial problems, it was able to reduce diabetes-related distress by encouraging positive lifestyle changes and coping skills that could be applied to both diabetes and psychosocial challenges.

A Community Strategy: Community Action

Recognition of the diverse types and levels of influence on behavior and health can leave one discouraged as to the possibility of changing such influences as the built environment, culture, or social networks. Surely interventions in such arenas are challenging. Nevertheless, promising approaches have been developed. Here, we focus on broad community campaigns to combat cardiovascular disease (CVD), smoking cessation, and diabetes prevention. These provide models for community approaches to diabetes management but ones that have been too little pursued.

North Karelia: CVD Risk Reduction in Finland

The North Karelia project [114, 115] set a strong example for the incorporation of multiple channels and intervention approaches, from mass media to cooperation with agricultural, dairy, and food merchandising groups to improve the availability of healthy foods such as low-fat milk [114]. Because of unusually elevated cardiovascular disease and risk factors within the region, the program was developed through the Department of Epidemiology of the National Public Health Institute within North Karelia, with field offices at the level of county departments of health and local advisory boards. The project ran in North Karelia from 1972

to 1977 and then was extended to the rest of Finland, with increased national government and policy support, through its formal end in 1997, after 25 years.

Community organizations in North Karelia included collaboration with existing official agencies and voluntary health organizations so that "the new health service activities initiated by the project became part of formal public health activities in the area" [114, p. 166]. In addition to extensive health education materials, mass media interventions interacted with local newspapers, community organizations, and campaigns. Training activities included not only doctors and nurses but also social workers, representatives of voluntary health organizations, and informal opinion leaders. Training was organized through county-level or other local organizations. Training and development of treatment guidelines in the health system included reorganizing screening and treatment for hypertension and care following myocardial infarction. Cooperation with other local organizations included not only the voluntary health agencies but also the critical food industry (e.g., including dairies and sausage factories) and grocery stores [114, pp. 166–167].

Nationwide impacts to which it contributed included an 80% reduction in the use of butter on bread, reduction in the prevalence of smoking among men from 60% to 16% in 2016, sharp decreases in salt intake with corresponding reductions in systolic blood pressure from 149 to 134 mmHg in women and 153 to 127 among men, 20% reduction in serum cholesterol, and an 80% reduction in cardiovascular mortality among men aged 35–64 [115]. In comparison with other parts of Finland, the North Karelia campaign led to significant reductions in cardiovascular risk factors [116] and mortality [117] as well as reductions in cancer risk factors [118].

Two characteristics appear critical in the North Karelia community organization: (1) the variety of activities and channels included, and (2) the attention in all areas to implementation through and in collaboration with local organizations. In a 2020 review of the project [115], its leader, Pekka Puska, and a co-author emphasized its community organization: "…the project catalyzed, trained, and coordinated the work that was carried out by numerous community and nongovernmental organizations" (p. 496). They also emphasized the breadth of approaches the program included: "…far beyond health services and providing health information… practical priority targets of change…provided change skills…social and environmental support…grassroots approach…local community organizations, schools, workplaces…application of lifestyle changes…mass media… television, pamphlets, and newspaper articles…National level health policy and legislation affecting changes in the food industry and tobacco use…" so that "Health had become the conversation of Finland" (p. 498).

Since the days of the North Karelia project, numerous population- and community-based interventions on health promotion and diabetes prevention have emerged in many countries around the world, and important learnings and recommendations for optimizing intervention and evaluation processes have been published [119].

A Danish research group (co-author PB and colleagues) has developed a conceptual framework, the supersetting approach, to integrate the breadth of community resources, including citizens and professional stakeholders, for social action and health promotion. It involves the coordinated engagement of multiple stakeholders in multiple community settings to implement multiple actions at multiple levels [120]. The supersetting approach includes five principles: (1) *context* to ensure that everyday life challenges of citizens and professionals are respected and considered in planning activities, (2) *participation* to ensure that people are motivated to take ownership of processes of developing and implementing interventions, (3) *action competence* to ensure that people acquire skills and competences to express and act on their visions and aspirations, (4) *integration* to ensure that activities are implemented across the boundaries of specific settings, and (5) *knowledge* to ensure that scientific knowledge is used to inform action and produced from the action. Moreover, the supersetting approach includes three highly participatory, structured, and research-based phases: (1) describing the context, (2) developing and implementing the intervention, and (3) conducting the evaluation. These phases have been optimized methodologically through iterative processes of co-creation with citizens, social workers, health professionals, and researchers. Although it is generally acknowledged that complex interventions are difficult to evaluate [121], there is now sufficient evidence from meta-analyses of intervention studies on community engagement to conclude that they may positively impact a range of health outcomes [122].

An important extension of community approaches is their integration with life course perspectives. Type 2 diabetes provides a case in point, as conventional approaches targeting high-risk adults will not efficiently ameliorate this growing disease burden. It is therefore essential robustly to identify determinants across the entire life course and, subsequently, appropriate interventions at every stage to reduce an individual's disease risk [123]. A life course approach has the potential to prevent noncommunicable diseases, from before conception through fetal life, infancy, childhood, adolescence, adulthood, and into older age. Epidemiological research in cardiovascular disease has shown health benefits resulting from the cumulative effects of health behavior over an individual's lifetime, not from a change in lifestyle [124]. On this basis, it is also important to involve children and youth in decisions pertaining to the shaping of the social and built environments of their everyday lives. This was done

within the framework of a large community-based intervention project in Denmark by addressing schoolchildren's perceptions and visions for a socially and physically improved school environment [125]. Guided by an everyday-life perspective and applying participatory action research methods including social imagination and visual techniques, the study observed that children were very capable of articulating their thoughts, ideas, and visions for a better and healthier school environment. Identified challenges and solutions varied widely and represented a broad perspective of health including social, physical, environmental, and emotional aspects. The paper concluded that children can be visionary and creative stakeholders and important agents of change in community development efforts if methods to include them are interactive, participatory, and carefully adapted to the age of the target group. Thanks to the collective dedication and action of schoolchildren, teachers, and management, the aspirations of the children resulted in the commencement of environmental, structural, and organizational change processes, which still continue today, years after project termination [126].

Integrating Community and Peer Support in Shanghai

Community approaches and peer support share a recognition of the importance of social influences around us. Additionally, community approaches offer the potential of expanding the base and organizational resources for peer support and other initiatives. This interplay of peer and community has emerged in work on diabetes management, advanced under the aegis of the "Shanghai Integration Model" [127]. This model brings together specialty/hospital care with primary/community-based care for people with diabetes. This provided the setting for the development of peer support programs in nine community health centers that serve, on average, communities of about 100,000. Peer leaders encouraged those with diabetes to adopt good health habits, which included adherence to prescription medications, a healthy diet, physical exercise, seeking community support for emotional well-being, and attending routine primary and specialty care. They did this by leading neighborhood activities, co-leading meetings on diabetes management, and following up with individuals and families. This resulted in significant changes in HbA1c, other clinical markers, and diabetes distress among 1284 participants from the start of the program to the end of the active program at 12 months. Changes were especially pronounced among those with poor baseline status, e.g., HbA1c reduction from 9.09 to 8.50% among those ≥8% at baseline [128].

Two research staff blinded to outcomes rated each community health center's implementation of the peer leader program. From these ratings, more extensive implementation of the program was associated with reduced HbA1c and diabetes distress and increased neighborhood support. In particular, ratings of the extent to which programs linked with community resources and utilized neighborhood committees were associated with improved HbA1c, indicating the value of peer support programs including community resources.

Summarizing the study of nine Community Health Centers, it showed improvements in clinical and quality of life measures initiated through peer leaders promoting diabetes self-management as part of the Shanghai Integration Model, especially among those with elevated measures at baseline and among those in high implementation sites. However, assessment of the implementation showed that not all centers implemented equally, that level of implementation was related to outcomes, and that engagement of community organizations enhanced impacts. This suggested that a way to address variable implementation among community health centers is to broaden the programmatic base to include community organizations.

Following the strategy of broadening the programmatic base, the current phase includes both health centers and other organizations in the community to bring further support for the program. These include community health promotion offices and citizen-led "Community Self-Management Groups," of which there are more than 5000 in Shanghai. Additionally, support for the program comes from the Shanghai government, which designated peer support as a key strategy for achieving 2030 goals for self-management of diabetes and other chronic diseases.

To evaluate program implementation with this expanded, community base, project records, semi-structured interviews, and an implementation assessment have characterized processes of adaptation of standardized materials, examined the extent to which the program was implemented, and identified key success factors and challenges. Communities took standardized intervention components and adapted them to meet their needs. They also assumed responsibility for the implementation of different components of the program based on their community's available capacity. Additionally, community innovations occurred that were then standardized for dissemination in future iterations of the program. Key success factors included cooperation and collaboration among varied partners within and across communities.

COVID not only interrupted the later stages of the program and delayed the final evaluation but also illustrated the benefit of the community organization approach. With the capacity developed among the collaborating community groups and peer leaders, they were able to assist in the implementation of control provisions within their neighborhoods,

such as by assisting older adults in obtaining food and other supplies, while also maintaining diabetes support activities such as social networking with WeChat, the dominant social networking base in China. Given Community Health Centers' need to focus on clinical management and prevention of COVID, the peer leader program would likely have dwindled without its expansion to include other community organizations. Instead, including other community organizations provided an additional base not only to sustain the diabetes support program but also to assist in pandemic control.

Cigarette Smoking

Although apparently a simple behavior, cigarette smoking illustrates well the broad range of contexts emphasized in this chapter. As detailed in an integrative review in 2004 [1], influences on smoking range from the brain physiology of nicotine addiction to broad economic factors. At the individual level, addiction to nicotine and genetic factors contribute to long-term smoking [129, 130]. Psychological conditioning is also important. The average smoker of a pack a day for 20 years has inhaled over a million times, establishing diverse conditioned associations of smoking with work, relaxation, drinking coffee, and other routines, and various moods like anxiety and depression [1].

Research from Scotland and France [131] shows that people at the lower end of the social gradient are more likely to smoke and smoke longer than those from higher up on the social gradient. However, it is not only social position that will determine whether one becomes a smoker and one's smoking habits. These will also depend on which neighborhood one lives in. It has been shown that the practice of smoking is favored by the proximity and density of points of sale for tobacco. These are often concentrated in deprived areas. Van Lenthe and Mackenbach have also found that people from deprived communities are more likely to smoke but even more so if they live in stressful neighborhoods. Stressors included "physical quality (decay), required police attention, noise pollution from traffic, and population density in neighborhoods." Similarly, objective and perceived measures of neighborhood crime have also been correlated with smoking.

Smoking also illustrates well the reciprocal and complex relationships among influences. As lower socioeconomic status may incline people to smoke, so better economic and social prospects and the associated better health, increased life expectancy, and security that goes with them provide incentives for quitting smoking or not taking it up in the first place [131].

Other determinants among the broad range of social and environmental influences on smoking include:

- Parents' and peers' smoking are major predictors of youth smoking [132]
- Marketing and advertising—Cigarettes are one of the most heavily marketed consumer products in the United States. According to the American Lung Association [133], the five largest US tobacco companies spent $8.401 billion on marketing in 2018, even with restrictions on electronic, print, and billboard ads. Youth with the greatest exposure to tobacco marketing are more likely to start smoking and to become frequent smokers [134]
- Influence on government regulations through contributions to candidates' campaigns for office [135] and influence on media coverage of the risks of smoking through advertising in major media [136], all driven by the profitability of cigarettes

The many determinants of smoking across multiple levels of influence illustrate well the concept that influences at different ecological levels interact with each other. For example, the genetics of nicotine metabolism and the addictive nature of nicotine create strong markets for cigarettes. Profitability of selling cigarettes drives both (a) enormous advertising and marketing campaigns that promote the anxiety-reducing and mood-elevating benefits of nicotine as well as (b) political contributions to control restrictions on harmful tobacco products. The cycle continues as the success of addicting large numbers of smokers and keeping them addicted ensures the profitability of the cigarette business.

Comprehensive Intervention Programs to Reduce Tobacco Use Smoking rates among adults in the United States have declined from 42% in 1965 to 14.0% in 2019 [137]. This reduction in smoking rate has been achieved through the best example of multilevel population-based health behavior interventions to date. Highlights at the several ecological levels include individualized smoking cessation programs, nicotine replacement therapy, and counseling by health professionals (intrapersonal level), workplace and community-based programs as well as programs tailored to reach different groups (social and cultural level), clean indoor air restrictions (physical environments), news coverage, government reports, anti-smoking campaigns of various health agencies (population-level mass communication), and restricting access to cigarettes and raising taxes on their sale (policy level) [1]. Clearly, interactions among these levels are numerous. For example, clean indoor air policies have driven changes in the physical environment of smoking as well as workplace programs. As another example, the creation of the desire to quit through mass communication and social marketing has cre-

ated markets for the development of improved individual cessation interventions.

There has been considerable development of organizational and community-level interventions to promote nonsmoking. At the organizational level, reductions in smoking have been reported through programs restricting smoking at the workplace [138]. Community-based studies that emphasized community participation in program development have been successful in low-income city neighborhoods and at the county level [139, 140]. COMMIT was a large trial of community organizations designed to improve access to numerous options for smoking cessation throughout entire cities. It achieved appreciable impacts among light and moderate smokers but failed to show benefits among heavy smokers [141, 142]. Commentaries that accompanied the publication of these results noted the importance of broad, public health approaches to reducing population prevalence of smoking [143] as well as ways in which intervention planning might have more broadly and effectively engaged communities, their organizations, and leaders [144].

Extending beyond the organization or community, comprehensive statewide programs have created substantial reductions in smoking. These programs embody broad campaigns of public education, including "counter-marketing" TV advertisements and billboards, increased taxes on cigarettes, support services for cessation, smoking prevention programs for youth, and multicultural approaches, all coordinated through community coalitions [145]. The scope of tobacco policy has expanded to include international initiatives such as the World Health Organization's Tobacco Free Initiative and Framework Convention on Tobacco Control (www.who.org).

Amidst the many contributors to reductions in population smoking, Livingood, Allegrante, and Green have also suggested that mass communication on the harms of cigarettes has had a role to play in this irrefutable "culture change of accommodation to intolerance of smoking" seen in the United States [146]. This is seen to operate through indirect effects through secondary transmission within groups of people rather than being attributed directly to the influence of mass campaigns. This reinforces the message from North Karelia that multilevel and diversity of interventions contribute to bringing about such a change in norms and indeed behavior change.

Finally, the broad ecological approach to smoking cessation is underscored by the recognition that no one type of smoking cessation intervention is reliably effective for 50% or more of those to whom it is delivered [1], and only a small proportion of smokers ever participated in a formal program. Tobacco use is a social and public health problem, not just an individual behavior. Smoking reductions *require* an ecological perspective; population-level changes reflect the aggregate of the many influences promoting nonsmoking, not a single "magic bullet."

Community Organization for Diabetes Prevention in India

The Kerala Diabetes Prevention Program (K-DPP) was a cluster RCT conducted in 60 polling areas of Neyyattinkara sub-district in Trivandrum district, Kerala state in India [147]. Polling areas are well-defined and identifiable locations demarcated with landmarks such as hills, roads, etc. Participants included those at risk according to age, family history, low level of physical activity, and waist circumference as included in the Indian Diabetes Risk Score. The intervention extended over 1 year and included group sessions held on weekends in community settings. After an introductory meeting, two, half-day sessions led by local experts covered key information about prediabetes, diabetes, and ways to prevent it. Trained peer leaders were chosen among group members. They then led meetings to discuss how to apply the information about diabetes prevention to their daily lives. These discussions were held twice in the first month and then monthly for the remainder of the 12-month intervention. Sessions lasted 60–90 min and included 10–23 participants with family members also encouraged to attend.

At the 24-month follow-up, the incidence of diabetes was 17.1% among participants from control polling places who received an educational booklet and advice for lifestyle change, and 14.9% in the intervention polling places (RR = 0.88, $p = 0.36$). The two groups differed significantly, however, in several important areas. Those from the intervention polling places achieved greater reductions in the Indian Diabetes Risk Score ($p = 0.022$). Most notably, incidence among those with impaired glucose tolerance, the primary outcome of the major efficacy studies of diabetes prevention in China [148], Finland [149], and the United States [150], was significantly lower in the intervention than control sites (relative risk = 0.66, $p = 0.03$). Further analyses showed that K-DPP also reduced risks for cardiovascular disease [151]. It was also cost-effective in terms of cases of diabetes-prevented and quality-adjusted life years and from both health system and societal perspectives [152].

The community base of the K-DPP was apparent in an evaluation of its implementation [153]. In addition to the structured sequence of educational and discussion sessions, participants were encouraged to participate in a variety of group activities to support healthy lifestyles and diabetes prevention. These included yoga groups that 31% of participants attended, walking groups—41%, and kitchen gardens—40%. Additionally, the organization of the program at the local, community level of polling places facilitated casual contact between peer leaders and group members. Indeed, 75% of participants reported contact with their peer leaders outside the structured group sessions. Through these contacts, peer leaders provided encouragement for

individuals' prevention plans, information about missed sessions, reinforcement of progress, and the opportunity to share and discuss other questions or concerns of participants. Finally, commitment from political leaders in districts and sub-districts facilitated the high uptake of the program.

As with the North Karelia program and the Shanghai diabetes project, K-DPP drew on substantial community input in its implementation. In a low/middle-income country, it then replicated the results of major international efficacy trials, reducing the incidence of diabetes among those with impaired glucose tolerance.

A Policy Strategy: Health in All Policies

To markedly improve population health in an equitable way, it will be necessary to orient policy towards the non-health sector such as housing, and to take into account the environment, especially the built environment, in which people live, work, and play. Social, economic, and cultural conditions should be considered a significant part of our environment. The bulk of evidence from social determinants research and informed practice suggests that in order to improve health and reduce health inequities, it is necessary to act on areas of life and activity lying beyond the health sector [154, 155].

The idea of Health in All Policies (HiAP) is not new. The first article of the Alma Ata declaration proclaims that "…the attainment of the highest possible level of health is a most important worldwide social goal whose realization requires the action of many other social and economic sectors in addition to the health sector." Similarly, the 2010 Adelaide Statement [156] argued strongly for intersectoral action for health. This stressed how cross sector collaboration and joined-up government not only was a key to better health and equity but also may be linked to sustainable development, citizen participation, and more efficient economies. The Adelaide Statement identified a broad range of non-health sector areas and issues: economy and employment, security and justice, education and early life, agriculture and food, infrastructure, planning, and transport, environments and sustainability, housing and community services, land, and culture. As can be easily appreciated, all these areas are related to social determinants of health and tackling inequities. The logical policy follow-up to such initiatives, "Health in All Policies," highlights the necessity for intersectoral initiatives including the health sector.

Table 4.1, from a World Bank report [157], indicates how different sectors such as education, finance, urban planning, agriculture, industry, transport, and health itself may have a significant role to play in reducing risk factors for chronic and noncommunicable diseases.

Healthy Cities

Perhaps the best examples of health in all policies and a "beacon of hope" may be seen in the WHO Healthy Cities movement [158]. Its evolving agenda and philosophy initiated in 1986 incorporate health into urban policy and planning to create healthy, sustainable, and economically prosperous environments and just communities. The Working Cities movement is epitomized by the WHO European Healthy Cities Network, which involves some 100 flagship cities and 31 national networks across the WHO European region [159], This comprises some 1500 cities (some 90 in France alone). Twenty networks have been accredited formally by WHO. These represent 1137 local governments and a population of 156 million people. Healthy Cities endeavor to foster health in all policies by highlighting the importance of improving leadership for health, participatory governance, intersectoral collaboration, and upstream action at the local level to improve population health and tackle health inequities [160]. Different cities and their municipal councils fix priorities and initiate projects in a wide range of environmen-

tal and health domains. In France, these include projects on radon and indoor air pollution, physical and sporting activities to tackle obesity, school transport schemes encouraging walking to school or environmentally friendly vehicles, healthy nutrition, and carrying out a Health Impact Assessment in order to inform decisions about such initiatives. Healthy Cities teaches us that such initiatives need long-term vision and planning. It may take 30 years to reverse the taken-for-granted dependency on cars. Planning may involve thinking, participation, and the implementation of policy changes in successive phases to reach long-term goals [158, 161].

A study of the members of the French Healthy Cities Network investigated how health was taken into account by city authorities through different non-health sectors such as transport, green spaces, social action, youth, education, culture, sport, and housing. Although it featured less strongly within some sectors, e.g., housing policy, health featured prominently in connection with green spaces policy, urban design, and transport and active travel or mobility policy. There is now good evidence that such urban policies prevent disease and impairment, and, important for sustainability, save energy, money, and lives.

City of Well-being: A radical guide to planning [158] provides a wide range of evidence suggesting that "spatial arrangement of towns can influence active travel and recreational activity to a significant extent—and in certain situations it can influence diet" [158]. Walkable, safe environments, and in particular distance from stores and services are key factors in fostering walking and cycling. The fact that this varies substantially from country to country and city to city and neighborhood to neighborhood indicates that urban design taking into account spatial factors and distance can influence norms and reduce dependency on cars. Thus, a joint Canadian and American study [162] cited by Heritage [160] suggests that people living in neighborhoods adapted to walking and in proximity to stores move four times more than those living in areas adapted to cars. However, living in a walkable district or a car-friendly area may not always be a matter of individual choice.

Evidence cited from the United States, China, and India suggests that cycling rather than driving can reduce obesity, diabetes, and hypertension significantly [158]. It is estimated that increasing cycling in the Paris area to 4% of all travel will produce benefits in terms of mortality 20 times greater than the risks due to accidents or accidents caused by cyclists or the effects of air or noise pollution and stress [163].

WHO recently championed a system for assessing the economic impact of changing urban mobility patterns. The Health Economic Assessment Tool (HEAT) which may contribute to broader assessments of health impact allows municipalities to make estimates of the amount of money and lives saved that could be gained through switching from driving to cycling and walking. The value of a statistical life is fixed at 4 million Euros for France, but it is also possible to simply reflect on benefits in terms of the number of lives saved [164]. As an example of such estimates, the French city of Nantes hopes that 12% of all journeys in 2030 will be by bike. If this is achieved, the HEAT calculation shows that 67 lives will be saved each year, or 670 over 10 years. In monetary terms, an estimate is made that 2,682,000,000€ will be saved over the next 10 years if the 12% target is reached. Currently this stands at 4.5% in the Nantes metropolitan area. This in itself represents a saving of some 1,005,000,000€ and 260 lives over 10 years.

In addition to walking and cycling, urban planning may consider the distances needed to walk to stores and services. Other effective policies include car sharing/pooling promoted through strategically placed car pooling parks, transport zoning with 20 and 30 km zones coupled with the designation of cycle lanes, bike parks with credit card renting of both regular and electric bicycles (especially important in hilly cities), chaperoned walking of children to their local school by volunteer parents, signage indicating not distance but the time necessary to walk from one point to another, and general interchangeability in public transport so that transfers from bike, to rail, to bus are cost-free. Coupled with encouraging active mobility, there are also parallel efforts made to render all public places and spaces accessible to physically disabled people using wheelchairs or parents pushing baby carriages, tactile paving guidelines and studs in foot pavement for blind people, traffic signals equipped to give oral cues, and even instructions to blind people guided by personal GPS controllers. If well-planned, cities will not just favor more walking but also chance encounters with people from the neighborhood, thus fostering social support and community ties and benefitting mental health.

Behavior change is not just about education and providing information to individuals but is also about creating new physical, sociocultural, and attitudinal environments which favor healthy behaviors and habits. The healthy cities movement embodies this idea well and illustrates how a holistic view of health and health promotion such as in the following statement of the International Union of Health Promotion and Education that may reap great benefits if applied with intelligence:

> Health is a basic human need. It is fundamental to the successful functioning of individuals and of societies … The main determinants of health are people's cultural, social, economic and environmental living conditions, and the social and personal behaviours that are strongly influenced by those conditions [165].

As much as research may guide and show the value of HiAP and related approaches, evaluation such as through Health Impact Assessment can never be a substitute for political decisions. It will never replace the necessity for politi-

cians to take difficult decisions and have the vision and political will necessary to tackle sources of disease in our environment to develop opportunities for health and well-being, especially where these would seem to run counter to short-term institutional prerogatives or market opportunities [166]. Barton and his co-workers have put forward a Settlement Health Map [158, 167] to explain and analyze the interplay of different factors impacting on health and well-being in the built environment. As Barton suggests this offers a useful tool for generating discussion and debate, thus situating different stakeholders' responsibility within the urban environment, and for shaping intersectoral and multi-stakeholder involvement in creating healthier conditions for urban living [158]. Health Impact Assessment and other evaluation approaches may provide data for consideration in such processes, but they cannot replace them.

Globalization

Globalization and the trends associated with it provide an important context for HiAP. Globalization typically describes changes in production and its organization associated with neoliberalism, the free circulation of information, capital and goods, and the primacy of financial markets over other aspects of the economy [168]. However as Scholte argues [169], it should not be conflated with liberalization as such because other economic policy agendas could be pursued which would highlight the positive benefits of globalization and supraterritorial relations. These are according to Scholte "social connections that substantially transcend territorial geography": [169] a new way of configuring and handling social space. In recent years, such suprateritoriality is epitomized by the Internet and by the fact that local events may become instantly global and have global consequences. This may be seen in communication campaigns such as the response to terrorism "Je suis Charlie" or the current "Me Too" campaign, which denounces sexual violence towards women. Trans-world travel and migration and how business, financial operations, and markets are organized globally working as a network also highlight that we are living in a supraterritorial world. Territorial space can also be bridged, for example, in telemedicine or online trans-world training such as through "massive open online courses" (MOOCs).

Arguably, globalization is not new. There has always been a movement of goods and labor, but distances are being shrunk and travelling times across the world have grown progressively shorter. Current global connections are characterized by transplanetary flows with simultaneity and instantaneity. The premier property of successful modern commerce is its capacity to create universally transferable objects which circulate through frontiers and borders with utmost ease. This aligns well with a neoliberal agenda which espouses the free movement of information, goods, and financial capital, together with the nonintervention of states in the economy and private and business affairs. After some resistance from nonaligned developing countries, this agenda has been taken up by an overwhelming majority of countries in both the developed and developing worlds that now organize or have to organize their economies in conformity with such neo-liberal principles [168]. It is associated with changes in management, work organization, and practices. It has led to the delocalization of industry, reduced wages, and wage costs for multinational companies within a globalized economy.

Geertz [170] has noted that, along with globalization, people living in different communities are also subject to an opposing movement emphasizing the uniqueness of nations, nationalistic ideologies, regions, local products, customs, and beliefs, perhaps as a bulwark against threats to local identities. Thus, people from different countries may not only find similar globalized goods, modes, and beliefs in their countries but also be united by a sense that they must respect their local traditions and ways of doing things. Again, people may strive to be as connected to the contemporary as possible while at the same time falling back on and upholding tradition. Recent political changes may confirm this dialectic and the current move towards political isolationism and a backlash against free trade and political cooperation, e.g., Brexit in the United Kingdom, or the recent emphasis in the United States on "America First." Such apparently contradictory movements (which may be harnessed politically) nevertheless uphold the idea that ultimately, we live in both globalized and localized worlds.

Locality and local cultures should not be opposed to globality and universalism, since both are intermeshed and interact with each other to produce new forms of social organization, space, and sociocultural being. Thus, it is more fruitful in line with the overall socio-ecological model of this chapter to avoid dichotomies and to conceptualize social space as not being made up of discrete entities but incorporating both the global and the local and similarly characterizing the people living in them as having plural identities influenced through both their global and local cultures. Furthermore, it is also wise not to demonize globalization since it also allows the quick transfer of knowledge and experience to enable and emancipate people.

We live in a global world on one planet, and ultimately, we are all affected by planetary factors such as global climate change, migration, widening inequities, the emergence of infectious disease, and noncommunicable disease epidemics. The latter, for instance, are associated with the spread of tobacco and obesity. These however are driven not by globalization as such, but rather by the neo-liberal harnessing of this phenomenon for private profit.

Globalization and Health

Bearing such complexities in mind with respect to different contexts, globalization has been argued to produce both positive and negative impacts on health [171, 172]. In 2001, Feacham claimed that "Globalisation is good for your health, mostly" [173]. Dollar maintained that "the higher growth that accompanies globalization in developing countries generally benefits poor people … globalization has indirect positive effects on nutrition, infant mortality, and other health issues related to income" [171]. Among the negative aspects cited were the spread of disease (AIDS) due to increased migration and travel as well as the impact of tobacco through free trade [171]. Huynen et al. [174] citing Fidler [175] suggest that the World Trade Organisation has more influence on the governance of global health than the WHO and that it is unclear whether World Trade Organization agreements may protect health.

Globalization appears to have affected some countries, such as Asian countries, more positively than others (African, Latin American, and Eastern European countries). On the one hand, slow and uneven growth was associated with stagnation in health indicators, and on the other, economic crises in middle-income countries such as the former Soviet Union produced economic instability, sharp rises in unemployment, and dramatic effects on health and life expectancy. Additional negative claims have included that globalization has had deleterious impacts on health and has worsened health inequities, especially in poor developing countries and among poor households [176–178]. Of particular interest with respect to health and inequity is the observation that "high income inequity reduces the pace of growth and of poverty reduction" [172].

Income Distribution and Other Effects of Globalization

Recent work on austerity shows that recessions can impact people's health not only negatively, as one would intuitively suspect, but also positively [179]. This may largely depend on whether support from social protection systems is maintained or cut. Ironically however recession in itself may have less effect than the austerity measures taken to combat it, measures that arguably are bad for health and kill massively [180].

"Population health tends to be better in societies where income is more equally distributed. Recent evidence suggests that many other social problems, including mental illness, violence, imprisonment, lack of trust, teenage births, obesity, drug abuse, and poor educational performance of schoolchildren, are also more common in more unequal societies" [181]. The measure of inequity taken is how much richer the top 20% are than the bottom 20% in each country. Significantly, in richer countries, what counts is not absolute wealth but whether the wealth is distributed more or less equally. As Wilkinson has stressed [181], it makes little difference how a degree of equality is achieved. Countries such as Sweden and Japan are vastly different in many respects and have different social protection and fiscal systems, but their relatively low degree of income inequity correlates well with health and may be contrasted with the situation in less equal societies. The situation with respect to inequity and health and other social indicators seen between countries is also mirrored among states in the United States with the highest degree of inequity also have high levels of poor social outcomes including health.

Of particular importance is the labor market. Bambra [182] reminds us that "work (paid wage labor) and worklessness (lack of paid work) are not the discrete activities of individuals, but are essential parts of the way in which the totality of society is politically, socially, and economically organized." Being in work is an important condition for health, having an income and for social inclusion, but can also lead to bad health through the impact of an adverse physical or indeed psychosocial working environment. These risks follow a social gradient, with lower-paid workers being more vulnerable to workplace hazards and accidents as well as having less control over their work and related stress in the workplace.

Supranational Policy

One example of the influence of European policy on national policy is the regulatory context of urban planning and environmental health in the European Union (E.U.). The Green Paper and the Leipzig Charter put forward an integrated sustainable urban development to overcome demographic, social, and environmental problems in European cities. Two EU Directives have been implemented to address the issues related to ambient air quality (2008/50/EC) and environmental noise (2002/49/EC). The Parma Declaration (5th Ministerial Conference on Environment and Health in 2010) [183] described the way forward in the work of environment and health in Europe. It set out concrete targets to tackle key urban environmental risk factors, paying special attention to children's health, inequities, and emerging environmental health challenges.

The influence of supranational policy agendas sets the scene for national legislation and implementation and can have both positive and negative effects on health. This can easily be seen in another important non-health field within Europe, namely agriculture and food policy. The Common Agricultural Policy provides a strict regulatory framework and subsidies for farmers in Europe. This has important

impacts on land use, the form of agriculture practiced, its impact on employment and the environment, and the type and price of food available, favoring either health or disease [184]. Thus, on the one hand, subsidizing beef and dairy production favors high saturated fat intake, and on the other hand, the lack of support for fruit and vegetables favors comparatively high prices and lower consumption, all with obvious implications for health. Consequently recommendations have been made for public health policy and agricultural policy goals to be aligned to favor higher and more equitable consumption of fruit and vegetables and less sugar, dairy produce, and meat [184, 185].

Interactions Among Determinants and Sectors

A central point of most writing in these areas is that different environmental or contextual determinants often interact in their influences on health. Good examples include the relationships between air pollution and poverty. Irrespective of the levels of exposure, there is a correlation between being poor and the resultant harmful effects of pollution. This would seem to be related to the second mechanism of differential susceptibility. Through having been exposed to repeated insults of their environment during certain periods of their lives (windows of exposure) [186] poorer populations have developed a greater susceptibility to the resultant health effects. As Deguen and Zmirou conclude, in the case of ambient air quality, long-term multipolar urban planning and diversity-sensitive housing policy may be the best way to tackle environmental and social inequities and to mitigate differential health impacts [187].

Examples: Housing and Urban Life

To further the discussion of HiAP, we will now take a more detailed look at two of the most important non-health sector areas: housing and urban planning and development, and how these impact on people's lives.

National and local government policy with respect to issues such as mortgages, local housing taxes (rates), and rent fixing will largely determine whether the supply of social housing is high or low. Access to social housing (housing owned and rented out by local authorities to people with low incomes or specific needs) will for the most part be determined by residence in the community and recognized needs, such as being a lone woman with children. In France, a country with a tradition of strong social policies, it is estimated that more than 500,000 people do not have a home. Among those, 133,000 are actually homeless; others are living on the sofas of friends, in hostels, squats, etc. [188]. If the number of people living in very "difficult housing" (chronic overpopulation, dangerous buildings, lack of basic amenities) is added, the number rises to 3.6 million, more than 5% of the French population. Another 5 million people are considered to have a very fragile housing situation (lack of house maintenance, large unpaid rents, etc.), and nearly 3.5 million face fuel poverty [188].

Even if appropriate and affordable housing has been heralded as a fundamental human right, it remains one which is far from being upheld in many developing and developed countries alike. The WHO "Closing the gap in a generation" report warns that "One of the biggest challenges facing cities is access to adequate shelter for all. … This crisis (of housing) will worsen social inequities in general and in health in particular" [189]. A 2009 Call to Action from the US Surgeon General asserted that "To improve the nation's overall health, we must improve the health of the nation's homes and ensure that safe, healthy, affordable, accessible, and environmentally friendly homes are available to everyone" [190].

Closely related to housing, indoor air pollution can be caused by both chemical and biological sources. Interventions directed at these can be effective, however. Lead hazard control in the United States has been shown to be a very effective intervention, decreasing dust lead levels by 78% over a 3-year period [191]. In France, exposure to radon is the second leading cause of lung cancer after tobacco, causing up to 2900 deaths per year [192]. Radon mitigation is effective in reducing individuals' risk of lung cancer and is cost-effective compared to other health care and environmental interventions [191].

Examples: Urban Environmental Impacts, Planning and Development

More than half of the human population worldwide now lives in towns and cities. This is likely to increase to 60% by the year 2030. In Europe and the United States, 75% and 80% of people, respectively, live in urban areas [193, 194]. In the developing world, this is likely to lead to megacities in Asia and Africa with 2 billion people living in slum conditions worldwide. Thus, it is important to draw lessons from the healthy cities movement to prepare for an increasingly urban world [195].

From a physical perspective, the urban environment has also assumed considerable importance due to its high population density, the size of buildings, and the existence of a considerable technical infrastructure coupled with diverse industries that have a high potential for different kinds of environmental pollution impacting human health. These may aggregate or intensify the chemical and biological hazards associated with housing described above. Noise provides a good example. An increase of 10 dB in sound intensity is

associated with an increase in prescribed sleeping pills, and cardiovascular disease medications [196].

The Chicago, 1996, and French, 2003 heatwaves illustrate how the urban environment may also exacerbate risks to health. Built-up environments lacking trees, hedges, bushes, and other plants tend to conserve heat (or cold). The impact of such events on mortality and morbidity is exacerbated by vulnerable isolated members of the population being trapped in veritable islands of heat within the urban environment [197].

The design of the neighborhood and the provision of urban green spaces have an impact on health risks by influencing aesthetic perceptions, determining physical constraints, and determining the degree of social mixing. Poorly maintained and deteriorated urban environments are associated with lower levels of physical activity and increased rates of overweight, partly explained through people's perception as a reaction to the aesthetic impression, which also affects mental health and social isolation. The presence of accessible municipal services, public gathering places, and green areas can counteract some of these effects. In addition, environments mimicking natural conditions (green corridors, parks, etc.) help reduce ambient air pollution, cool urban areas, provide a barrier against noise, and may even have an influence on preventing the development of some forms of cancer [198]. A 2020 study found that these considerations include the proximal urban environment. A comparison of the proportion of streets and green spaces within 400 m of homes found that the proportion of streets was associated with overweight or obesity, higher media use, less outdoor activity, and more emotional problems among children and youth, while the proportion of green spaces was associated with more outdoor activity during the winter months [199].

Capabilities go beyond achieving a set goal to encompass the idea that what matters is possessing the freedom to envisage and choose from a range of possibilities in relation to the projects and life plans that people have reason to value. Neighborhoods structure the health practices that people engage in, notably through the unequal distribution of resources. The idea of resources may be widened to include not just physical resources but also intangible resources which may be seen as relational processes. Neighborhoods are not just passive geographical spaces but also living dialectics of structure and agency in which people adapt to constraints and embrace freedoms in different domains over time; they are places where individuals and communities engage in practices producing health on a daily basis [200].

Given that low-income populations are disproportionately found in environments with worse urban features (less green spaces, poor urban design, etc.), many different approaches have been developed in the last decades to address health inequities by changing the neighborhood characteristics of low income people. One approach to changing neighborhood characteristics is to move people from high- to low-poverty neighborhoods. Moving neighborhoods can improve mental health, reduce obesity, and impact positively some wider determinants of health [201]. Several studies have examined the effects of giving people housing vouchers to change homes and neighborhoods. "Moving to Opportunity" permitted families to move from public housing in high-poverty neighborhoods to private housing in lower-poverty or non-poor New York neighborhoods. Moving out of the public housing/high poverty neighborhoods was associated with lower distress among parents and lower anxious/depressive and dependency problems among their sons [202]. Similarly a randomized environmental experimental intervention carried out in Chicago [203] has shown that obesity and diabetes risk may be reduced by moving to different neighborhoods. Three groups were constituted. One group was offered housing vouchers, provided they changed addresses and moved to another neighborhood. Another group was offered the equivalent sum but was given no instructions or advice on moving, and a third, control group was offered neither advice nor money. Over a 7-year period, there was no significant difference between the latter two groups, but the objectively measured risks of developing obesity and diabetes were reduced in the group who moved home. Positive effects were seen 10–15 years later in the prevalence of obesity and diabetes [203].

Evaluation of the effects of moving inhabitants out of unhealthy neighborhoods shows benefits that might be achieved but not a feasible approach for general application. Urban regeneration programs aiming at the whole neighborhood level are argued to be more cost-effective than the movement of individuals to better areas, including because they benefit the community as a whole [204]. Yet the evidence supporting this idea is still weak. A systematic review in the United Kingdom [201] found small positive impacts on socioeconomic determinants of health but potential negative impacts as well. Mixed tenure has also been promoted in many European countries as a means to tackle social exclusion and create sustainable communities. However, the evidence is inconclusive on whether it actually promotes social cohesion, residential sustainability, or improves people's perceptions of the neighborhood. Nor has it been found to provide better job opportunities or changes in income mix [204].

Other interventions that have the potential to improve health and health inequities include: the demolition of distressed housing and relocation of residents; universal design standards to favor the elderly and people with disabilities; crime prevention through environmental design; smart growth and connectivity designs; zoning (regulating how land or a site may be or not used for certain purposes, e.g., prohibiting alcohol outlets near schools); and interventions concerning green space around housing [205].

Urban environments are already home to two-thirds of people with diabetes. This makes cities the front line in the fight against type 2 diabetes. In 2014, three global partners, Novo Nordisk, Steno Diabetes Center Copenhagen, and

University College London, launched the Cities Changing Diabetes (CCD) program to accelerate the global fight against urban diabetes. Today, the program has established partnerships with key stakeholders in 41 cities around the world to address the social, cultural, and environmental factors affecting type 2 diabetes vulnerability among citizens living in the cities [206]. The CCD partners have modeled that it will take a 25% reduction in obesity from 2017 levels to hold the rise in diabetes prevalence at 10.0% globally. This is CCD's long-term global target for 2045. Tingbjerg Changing Diabetes in urban Copenhagen is an example of a long-term strategic engagement which is carried out within the framework of CCD. Tingbjerg Changing Diabetes is a multilevel intervention to promote health and social development while preventing diabetes in urban Copenhagen by using the supersetting approach to mobilize citizens and public, private, civic, and academic stakeholders for collective action across sectors [207].

Although the incidence of type 2 diabetes has not yet declined in the neighborhood, the initiative has, by the end of 2021, managed (1) to establish a strong and dynamic alliance of dedicated stakeholders working with the shared purpose of strengthening community cohesion in Tingbjerg while supporting its residents to adopt healthy lifestyles; (2) to establish vibrant physical settings where residents engage collectively in the social development and health promotion of the community by organizing initiatives such as urban gardening, food and craft workshops, restaurants, and mentor-based support to health systems navigation; (3) to promote participation and engagement in joint activities among residents of all ages, genders, cultural affiliations, and ethnicities; (4) to mobilize and retain socially marginalized residents; (5) to strengthen the commitment of a wide and flexible network of frontline workers to support activities and projects in the neighborhood [208].

Neighborhood Design and Social Isolation

A rapidly emerging area of research that epitomizes the ecological perspective is that regarding the impact of our physical and built environment on our social relationships and behavior. As background, there is ample evidence about the association among mortality, health, and social isolation.

A meta-analysis of 148 studies involving 300,000 persons documented that individuals with strong social relationships had a 50% increased likelihood of survival over an average study period of 7.5 years compared to individuals with weak social relationships [209]. Moroever, associations between social isolation and type 2 diabetes have been documented in several studies [210, 211].

Research suggests that architectural design impacts social isolation and integration. Among older adults in Chicago, Illinois, in the United States, social isolation was more common in dilapidated, run-down areas [212]. In addition, elderly people who lived in high-rise public housing buildings were less likely to venture into neighborhoods than those who lived in low-rise public housing buildings (after controlling for other environmental aspects and personal characteristics) [212].

The complications among the effects of policies are illustrated, for example, by the influence of neighborhood design not necessarily following the influence of neighborhood economic status. In Singapore, almost 90% of residents reside in Housing Development Board public housing, which functions as a neighborhood block in which residents are able to access social support services for the elderly and children along with public spaces such as playgrounds, markets, and cafes [213]. The remaining 10% with higher household incomes reside in private housing. In a cross-sectional study among approximately 4500 Singaporeans over the age of 60 [213], Wu and Chan found that the strongest predictors of lower isolation were residence in housing board public housing and daily social participation in housing board neighborhood events. Accordingly, they hypothesized that the housing board built environment functioned as a community and encouraged social care, social support, and social interaction among residents. In contrast, those who resided in private condominiums or gated communities were at greater risk for social isolation because of less frequent social interaction and lower proximity to others [213].

As the built environment may discourage social interaction, several features have also been linked to increased social interaction. In particular, indoor and outdoor common spaces have been shown to support social ties among older individuals [214]. By offering opportunities for informal face-to-face contact, common spaces allow individuals to foster and maintain casual social relationships that have been found to be associated with health, including among older adults [215]. In a study of older individuals aged 60–90 in Chicago public housing buildings [214], those who lived in the closest proximity to trees and vegetation experienced higher levels of social support and integration than those with little nearby vegetation. Moreover, in a study of 273 Hispanic elders living in East Little Havana in Miami, Florida [216]. researchers found that architectural features such as porches and stoops encouraged greater person-to-person contact and were positively associated with perceived social support and negatively associated with psychological distress.

One might expect that architectural features that make housing pleasant, such as windows, might allow for broader observation of the surrounding area and increase a sense of connection. But in one study, such windows actually removed individuals from close person-to-person contact and resulted in lower levels of perceived social support. Along with the observation from Singapore about the socially isolating effects of private housing for wealthy citizens, this suggests the importance of critical appraisal of environmental, architectural, and urban design. What may seem pleasant or even

luxurious may, in actuality, be isolating or unhealthful. Common spaces that actually encourage individuals to engage with others are necessary to increase social connections and support [216].

In addition to common spaces and architectural design, social interaction may also be influenced by the perceived accessibility of resources. Richard and colleagues [217] conducted a study to assess neighborhood correlates of social participation among older adults living in an urban environment in Montreal, Quebec. They found that a significant predictor of social participation was perceived accessibility to key resources, in that greater access to key resources within a 5-min walk was associated with increased social participation. This has been confirmed by several other studies, which have found that higher levels of participation occur in places where people hold a positive image of their environment [212, 218]. For instance, Bowling and Stafford [218] conducted a cross-sectional study of perceptions of neighborhood infrastructure and social engagement among older adults. They found that perceptions of poor local facilities in the area, particularly poor facilities for people aged 65 and older, were associated with a greater likelihood of low social activities. This suggests that the accessibility of social resources, services, and facilities is an important determinant of social participation and interaction. This emerging field of evidence thus points to an association between the built environment and social support, whereby neighborhood design, architectural features, and perceived accessibility of resources influence individuals' levels of social support and participation. However, research is still needed to document how these components can be manipulated in existing settings to reduce social isolation.

HiAP and Community Organization

It has been argued that HiAP approaches are distinguishable from other intersectoral initiatives to advance health equity in two important ways [219]. First, because they emphasize health in all *policies*, HiAP approaches are coordinated primarily by the formal structures and mechanisms of governments that are responsible for policies. Second, initiatives adopted under HiAP approaches are explicitly linked to structural or long-term governmental policies or agendas, rather than focusing on specific problems. While recognizing the importance of applying the HiAP approach at the governmental level, it has also been argued that intersectoral collaboration and action should also be nurtured at more local levels. The Sundsvall Statement on Supportive Environments for Health, which emerged from the third International Conference on Health Promotion in Sundsvall, Sweden, in 1991, thus recommended the building of alliances and strengthening cooperation between health and environment campaigns and strategies to advance supportive environments at the community level [220]. Health in All *local* Policies is thus a meaningful concept in the context of local community development when referring to the policies and strategies of all stakeholder organizations involved in decision-making and agenda setting, and not just local government institutions [221]. The meta-message of this chapter clearly applies here. Because of the multiple layers and sectors of multiple determinants of health behaviors and health, the broadest possible range and diversity of sectors and influences should be brought into campaigns to address important health problems and challenges. We should reject analyses or rhetorics that privilege one or another approach.

A Key Change in Perspective

Increasing emphasis on non-health policy flies in the face of representations of health that are taken for granted in the general population. Health is often reduced to health care, and this is how governments and citizens traditionally represent health, dividing up the world into health and non-health. Similarly, health is often viewed as determined by individual characteristics—e.g., "good genes"—and individual choices. This may lead to viewing the individual as responsible for her/his own health [222]. In contrast, the ecological perspective casts such views as imposing an unreasonable attribution of responsibility to the individual—a sort of victim blaming—by ignoring the diversity of forces that shape each individual's behavior. Some may see such "robbing" the individual of responsibility as a reduction of individual and human dignity. This concern about dignity may represent a Western view that individual dignity and recognition of external influence are somehow opposed. In other cultures, influence of the environment is assumed and not seen as detracting from the dignity of the individual [223].

A 2015 French study [224] suggests that local stakeholders involved in a community project may perceive health more broadly than might have been anticipated. They were described as seeing health "as a global resource for life, determined by a large number of factors (behaviors, social life, work conditions, education, transportation, etc.), and for which every local actor has a responsibility." Similarly, the success of a Healthy Cities initiative in Portland, in the U.S. state of Oregon, shows that such policies can be acceptable and effective outside of Europe's strong tradition of social and health protection.

The example of Penwerris, in Falmouth, Cornwall, in the United Kingdom, provides a model for changing perspectives and achieving intersectoral collaboration at the community level. In 1995, this socially deprived area had the highest number of poor households, the highest proportion of children in households with no wage earners, and the second highest number of lone parents. More than 50% of homes lacked central heating, and the illness rate was 18% above the

national average [225]. Community health nurses, known as "Health Visitors" pinpointed 20 residents who they felt could work constructively on the estate's problems with the authorities. Five agreed to participate. The health visitors went on to initiate intersectoral action, inviting the representatives of health, social services, education, local government, and the police to a series of meetings. Most importantly, in parallel with an injection of funds following a successful application for an energy improvement grant for the area, a shift in power was granted by the authorities to allow the community partnership to fix priorities and take decisions about their own community and lives. Problems were discussed and "discovered" between the actors, with different solutions being explored. This was not based on classical needs analysis carried out from above, but emerged and relied on local knowledge, ideas, and initiative. Regeneration was not planned from outside but emerged from within [225].

Five years later, the situation had undergone a spectacular and radical transformation. Improvements in a whole series of community indicators had occurred including a 50% drop in crimes, a 42% fall in child protection registrations, and a 70% drop in postnatal depression. Furthermore, there were no unwanted teenage pregnancies, educational achievement had hugely improved, and the unemployment rate had fallen by 71% for both men and women [225]. Interviews and two focus groups to understand the process of change suggested that, in line with complexity theory, the downward spiral of social deprivation and urban decline was reversed through acting at a critical point, developing trust and self-confidence, favoring self-organization within the community, and leading to a reconfiguring of social relationships among residents, different statutory agencies, and new actors. This success has led to similar initiatives with other deprived communities based on similar principles of trust and self-organization being set up in other urban areas in the United Kingdom [226].

Implicit in the emphases on ecological determinants and, especially, Health in All Policies is a focus on general health and well-being, not one or a particular disease. As agricultural policy, for example, will affect diet and all the diseases that nutrition influences, the breadth of impacts on health will be necessary to justify proposals to alter policies not directly related to health. Surely a proposal for major changes in national agricultural policy to benefit a small number of people with a specific disease would have much less likelihood of adoption than one that may be justified as benefitting all children and adults in a society. So too and consistent with considering the many determinants of health, it is important to consider health beyond the prevention of disease and incorporate salutogenesis and resources for health and well-being, favoring a sense of coherence and quality of life [227–229]. Again, the broader focus makes excellent conceptual and policy sense and also recruits additional reasons in support of policy proposals that may emerge from it.

Extension to Diabetes

We have presented a range of ways non-health sector factors and policies may impact human health. We have also sketched a number of different policies that may reduce or mitigate deleterious health impacts. We have also stressed that health should be seen positively and that the physical and sociocultural environment have the potential to promote and improve health. Increasingly non-health policy is taking up the gauntlet and addressing a number of these issues at the macro and micro levels. At the macro level, this has been tackled notably through adapting recommendations from Health in All Policies within national and supranational government policy agendas. At the micro or local level, numerous initiatives tackle proximal lifestyle issues and at the local level the practice of carrying out systematic health impact assessments on new infrastructure development projects. Also, at the community and city level, collaborative community organization such as the supersetting approach has been shown to be effective.

As a way of summarizing the many topics the chapter has addressed, Table 4.2 sets out the advantages or contributions several of the approaches can make towards diabetes prevention and management.

Table 4.2 Examples of application to diabetes prevention and management of multilevel, multi-sectoral interventions

Peer support	A major approach to dissemination of the Diabetes Prevention Program in the United States is group-based, implemented by trained nonprofessionals [230]
	Substantial evidence for the benefits of group, individual, and dyad-based peer support in diabetes management [79]
Community organization	Kerala Diabetes Prevention Program [147]in rural communities in India utilized community engagement in program development and implementation and replicated the results of major diabetes prevention programs [148–150] while reducing CVD risk
Health in All Policies	Urban, agricultural, housing, economic, transportation, and business policies of local, regional, national, and international governments all influence activity levels, diet, stress and emotional well-being, as well as access to care and adherence to preventive and treatment regimens for diabetes and other chronic diseases
Multi-sector, multilevel engagement	The global prevalence and burdens of diabetes in terms of health impacts, complications, quality of life, and costs of care for the disease and its many complications all justify the engagement of all sectors of society and government in prevention and improving its treatment
	Tingbjerg Changing Diabetes is an example of a long-term multilevel engagement to promote health and social development while preventing diabetes in urban Copenhagen, Denmark, by using the supersetting approach to mobilize citizens and public, private, civic, and academic stakeholders for collective action across sectors [207, 208]

Concluding Thoughts

In contrast to old oppositions of nature vs. nurture, genetics vs. environment, or biology vs. psychology, twenty-first century science is clear that causes of health, illness, and well-being are complex, multidimensional, and interactive. Those with serious diseases need good medical care, but it is also clear that economics, policies, environments, organizational and social factors, personality, and a host of other contextual features play major roles in the etiology of health problems, their prevention, and their management. Moreover, despite frequent pessimism as to population trends in health, a broad range of community, health education, and health promotion approaches addressing community, policy, economic, social, and personal factors can be successful in reducing populations' health problems, such as cigarette smoking in the United States [1, 143] or cardiovascular disease in Finland [114, 116, 117].

At least since Villermé's writings of the nineteenth century [231], we have known that the places where we live are not equal as regards health, well-being, and indeed death. Here we have emphasized social, community, and non-health policies over clinical care. In line with Health in All Policies, it will become more and more necessary for government, policy makers, and indeed stakeholders to accept that all these segments have important parts to play in making the world a healthier and safer place. Such a realization however is also linked to our values and views on the sources of inequity and health. It is clear that inequity is a major source of poor health and disease. It is also abundantly clear that the social, community, and non-health sectors could have a substantial role in righting such inequities. In *t*he field of environmental health, a sea change has occurred through the recognition that we all live in the same world with finite resources, and this has opened the way for greater sustainable development and more friendly environmental policy. We believe it will be necessary for a comparable change of representations to occur, accepting that the health and welfare of individuals are deeply tied to the circumstances and environments in which they work, live, and play.

The time has perhaps come when it will become habitual to think of people as being embedded in sociocultural and economic contexts with habitual practices rather than as decontextualized individuals within statistical populations with free choice of behaviors and free choice of dwelling and neighborhood [232]. Once this way of thinking has become normative, then the determining role of the social, community, and non-health sectors and the necessity for different sectors and the health sector itself to work together will be very apparent. Furthermore, the idea that insalubrious, rundown, unhealthy, unsafe, non-accessible, or segregated environments are acceptable will become unthinkable and a thing of the past.

Multiple-Choice Questions

1. Reduction in income, education, and socioeconomic status is associated with:
   (a) Improved health and decreases in mortality and morbidity
   (b) No changes in health, mortality, and morbidity
   (c) Better health and increases in mortality and morbidity
   (d) **Worse health and increases in mortality and morbidity**
   (e) Worse health and decreases in mortality and morbidity
2. Social determinants of health:
   (a) Are irrelevant in the development of health risks
   (b) **Play key roles in the development of health risks**
   (c) Can be corrected with the use of new medications
   (d) Are important, but only secondary to genetic traits
   (e) Are irrelevant in the paths of infectious disease transmission
3. Epimutations refer to:
   (a) **The relationship between rearing and the adult stress response**
   (b) Abnormalities resulting from environmental factors
   (c) Acute changes in DNA methylation
   (d) Prenatal disorders of genetic development
   (e) Major causes of stillbirth
4. Socioeconomic and social factors:
   (a) Are irrelevant to CVD risk
   (b) Probably are related to CVD risk, but it has not been documented
   (c) **Influence the pathways from the serotonin transporter gene to CVD risk**
   (d) Are the leading contributors to CVD risk
   (e) Are not influential on health status at all
5. Resources and supports for self-management that people with diabetes need to manage their disease in daily life include all of the following except:
   (a) Continuity of quality clinical care
   (b) Individualized assessment
   (c) Collaborative goal-setting
   (d) Community resources
   (e) **Access to the latest, most expensive medications**
6. Sustaining diabetes self-management:
   (a) Is secondary to the level of professional expertise of health providers
   (b) **Is a component of key importance in the ecological approach**
   (c) Is not important because interventions studies include follow-up of 1–3 years
   (d) Is based on a 1-week admission to a specialized diabetes center
   (e) Has negative consequences in the physician-patient relationship

7. Diabetes self-management support:
   (a) Is exactly the same as self-management education
   (b) Is exclusively provided by specialists in the medical office
   (c) Is provided by other patients with expertise
   (d) **Is the ability to assist the individual to implement and sustain ongoing behaviors needed to manage their illness**
   (e) Is unnecessary in diabetes management
8. The best predictor of changes in blood glucose control:
   (a) Medical expertise
   (b) Number and cost of medications
   (c) Absolute compliance with the doctor´s orders
   (d) **Length of time over which interventions are maintained by patients**
   (e) Self-monitoring of blood glucose
9. The most important characteristic of type 2 diabetes and self-management:
   (a) **It is "for the rest of your life"**
   (b) It is impossible to achieve
   (c) It has to comply with protocols for randomized controlled trials
   (d) It is feasible for all patients
   (e) It is totally dependent on new technologies
10. Patients rely on peers:
   (a) To learn how to implement care management plans developed with their clinical team
   (b) To gain confidence to implement a plan of action
   (c) To understand what is important and set priorities
   (d) To gain support in coping with the distress chronic diseases often pose.
   (e) **Peer support may contribute in each of the ways noted.**

Social Determinants of Health and Diabetes Outcomes

5

Hideki Hashimoto

The following section presents a short review of the existing evidence regarding the societal distribution of diabetes morbidity and mortality. In the third section, theoretical frames relevant to explaining the societal distribution of the disease, including the concept of "social determinants of health," are introduced. The section also articulates the negative impact caused by social stigma on people with diabetes that may interfere with effective self-care and treatment of diabetes. The section further describes the important role of professional circles as public advocators to effectively address due policy and social change. The fourth section discusses how the social determinants of diabetes could be translated into policy interventions to countermeasure the disparity in the burden of diabetes across populations. The chapter concludes with some policy and research implications of the social determinants of diabetes.

This chapter focuses mainly on type 2 diabetes mellitus (T2DM), although type 1 diabetes has also been the subject of social disparity in terms of mortality, morbidity, access to high-quality diabetes care, and effective self-care among people with different occupational classes, educational attainment, and income levels [1]. The mechanism through which type 1 diabetes affects people with lower socioeconomic positions more seriously remains open to academic and clinical debate, and whether the mechanism of the disparity is distinct from that of people with T2DM is unclear. Although access to quality health care is suspected to contribute, some have argued that the "opportunity costs" of properly conducting self-care management, in terms of psychological, economic (including time), and social costs, may be higher for those with lower socioeconomic positions, and this likely prohibits them from effectively protecting their own health. We return to this point later in the chapter.

Social Disparity in the Diabetes Burden

A large body of evidence has been accumulated on the unequal distribution of the incidence, comorbidity, and mortality of T2DM among people, depending on income level, occupational class, educational attainment, gender, race/ethnicity, and the economic development stage of the country where they live [2]. Of these factors, socioeconomic position, measured as household income, occupational class, educational attainment, or the combination of these attributes, has been the most widely studied in terms of its association with diabetes outcomes. In general, diabetes incidence, or the population rate of new development of diabetes, is consistently reported to be higher among those with lower socioeconomic positions in developed countries, and limited empirical findings indicate that this is possibly also the case in middle-low-income countries [3].

It is important to note that the association may vary by gender. A study using data from a European cross-country panel survey of the aged population showed no consistent association between diabetes incidence and education among men, but a significant negative association between these variables among women, which remained even after adjusting for body mass index and lifestyle-related behaviors such as physical activity [4]. Another cross-country study of existing cohorts in European countries found a consistently higher diabetes incidence rate in subgroups with lower education for both genders; this effect remained significant but was substantially attenuated by including body mass index in the analytic model [5]. A study using data from the Canadian Community Health Survey also found an education gradient in diabetes incidence that was clearer among women than among men and was partially explained by body mass index [6]. A nationally representative study using the US National Health and Nutrition Examination Survey also showed a stronger relationship between diabetes incidence and education among women than among men [7]. An exceptional result was reported in a recent Chinese population-based survey, which revealed a negative rela-

tionship between diabetes incidence and education among men, but not among women [8].

Regarding mortality due to diabetes, a US study showed that lower income and lower education were related to higher diabetes-related mortality [9]. In a similar vein, a number of studies in developed countries showed that lower socioeconomic position was related to a higher chance of diabetes-related comorbidities (e.g., retinopathy and nephropathy) [10–12].

Turning to diabetes prevalence, or the proportion of current people with diabetes among the general population, several studies in middle-low-income countries have demonstrated that subpopulations with higher socioeconomic positions have a higher prevalence of diabetes [13, 14], whereas reports from high-income countries have consistently shown that diabetes prevalence is higher among those with lower socioeconomic status [4, 15, 16]. In Ghana, the associations of diabetes prevalence with socioeconomic positions have been found to differ between urban and rural regions [17, 18].

Mixed results for diabetes prevalence by socioeconomic position could be explained by the associations of socioeconomic position with diabetes incidence and mortality varying across regions and countries by level of economic development. Where the higher incidence of diabetes among those in lower socioeconomic positions has been overwhelmed by the higher mortality of diabetes in that stratum, it may lead to a lower diabetes prevalence among those in lower socioeconomic positions. If the disparity in mortality by socioeconomic position is compensated for by better access to diabetes care and the survivorship of patients in lower socioeconomic positions is relatively improved, it may result in a higher prevalence of diabetes among those in lower socioeconomic positions, simply reflecting the higher incidence of the disease among that subpopulation. Clarification of how the different survivorship across socioeconomic positions contributes to the patterns of socioeconomic disparity in the incidence and prevalence of diabetes requires detailed cross-country population-based cohort studies.

Some studies have focused on socioeconomic conditions in early life. A review of ten existing studies indicated that experiencing low socioeconomic conditions during early childhood was related to current diabetes morbidity, though the association varied by gender and conditional adult risk factors (e.g., obesity) [18]. Very few studies showed a protective effect of low childhood socioeconomic position on adult diabetes status [18].

More recently, a United States-based cohort study reported that early socioeconomic position predicted current diabetes (measured as blood glucose and HbA1c), and the association was significantly mediated by current waist circumference, physical activity, and depressive symptoms [19]. Along the same lines, a population-based study in the Netherlands found self-reported economic difficulties during childhood and parental educational attainment to be significantly associated with current diabetes status, although these associations were attenuated after adjustment for current socioeconomic conditions [20]. Taken together, these results imply that early socioeconomic hardship may increase the risk of diabetes-related risk factors in adulthood through life-course trajectories and critical windows during childhood for the later onset of diabetes in adulthood.

Other studies have explored the association between child abuse experiences and diabetes outcomes in adulthood. A study using data from the Canadian Community Health Survey showed that the experience of childhood abuse was related to self-reported diabetes status, and the association was substantially mediated by diabetes risk factors such as obesity and smoking [21]. Similar findings were obtained in the US Nurse Health Study, in which the participants were registered nurses and therefore relatively homogeneous in their current socioeconomic position. Despite the relatively higher and more homogeneous educational attainment of the study participants, adverse experiences during childhood showed a significant impact on diabetes incidence [22].

These observational studies indicate that the development, disease control, and subsequent prognosis of diabetes are highly dependent on the social context in which people are situated throughout their lives.

Supposed Mechanism of Social Disparity in Diabetes

Individual risk factors for diabetes are related to lifestyle behaviors (e.g., obesity and physical activity), and the control of diabetes requires healthy modification of these behaviors. Indeed, observed socioeconomic disparities in diabetes incidence, morbidity, and mortality were substantially explained by socioeconomic differences in lifestyle behaviors—especially obesity [3, 23]. However, this does not yet explain why such differences in lifestyle behaviors by socioeconomic position and gender occur at all, or how they are translated into disparities in the burden of diabetes.

Brown et al. proposed a model to help us comprehend the complex mechanism of diabetes development within a social context. In this model, lifestyle behaviors, access to care, and the process of care are set as proximal causes that link socioeconomic conditions and diabetes outcomes [24]. Brown et al. further advocated the inclusion of an individual's health literacy, psychological stress, demands competing with self-care activities (e.g., time constraints), and availability of social support as mediating factors linking socioeconomic conditions to lifestyle behavioral choices and effective negotiation with health care professionals for diabetes care. In addition, environmental factors such as the local availability of healthy food, walkability, and safety may also influence whether people

make healthier behavioral choices. However, the most recent review on T2DM and environmental risk factors [25] and other related review articles on obesity [26] and nutrition [27] concluded that, although the built environment (e.g., food access and walkability) is potentially associated with the chance of having diabetes and related risk factors, the strength of the evidence is currently limited because of heterogeneity in measurement and study design, which needs to be addressed by more rigorous research on this important theme.

As described earlier in this chapter, several studies have indicated that socioeconomic conditions affect the access to and the process quality of diabetes care [10–12]. Notably, the majority of these reports have come from countries with universal public health insurance coverage, suggesting that universal health insurance coverage may not be enough to close the socioeconomic gap in diabetes outcomes. Indeed, a study using the United Kingdom-based cohort of the Whitehall II study found that universal health insurance coverage may not be enough [23]. Among civil servants in the United Kingdom, the study found that the socioeconomic gradients in diabetes-related morbidity and mortality were substantially mediated by cardiovascular risk factors such as blood pressure and smoking. Most striking was the finding that such socioeconomic gradients in diabetes outcomes were found even among civil servants, who had relatively good job security, and even in the United Kingdom, where public health care is widely available without an out-of-pocket co-payment.

Social relationships in the family and community are powerful structures that influence the distribution of obesity in society [28]. Social networks are supposed to provide norms about obesity, psychological support, conflict-influencing behaviors, and/or social selection processes where "birds of a feather flock together" [29].

Recent studies have further focused on the social influence of the stigma faced by people with diabetes [29–33]. People living with diabetes are often stereotyped as lazy and undisciplined, and they are blamed for their own diabetes condition. Prevailing social stigma, even among health care professionals, causes psychological and social isolation and excludes people with diabetes from social participation and effective self-care management. Given the seriousness of health care professionals' influence on social stigma, the position statement by Diabetes Australia and the subsequent guidance issued by the National Health Service England advocate that health care professionals should ensure proper use of their words during interactions with people with diabetes [34, 35].

Culture is another aspect of the social context that hinders effective communication and shared decision-making between people with diabetes and health care professionals. Although studies focusing specifically on cultural aspects of people with diabetes are scarce, the existing literature suggests that cultural norms about the body, food, and physical activity influence people's lifestyle-related choices [24].

In addition to macro-social mechanisms, biological mechanisms also need to be understood to see the whole picture of how social context gets "under the skin." The most influential biological mechanism may be the intrauterine programming and thrifty phenotype hypothesis (also known as the Barker Hypothesis) [36]. This hypothesis views exposure to low nutrient intake during the fetal stage as causing adaptation for survival, which, in turn, causes diabetes in adulthood when the nutritional environment becomes richer. Several epidemiological studies have supported this idea because those who experienced poor nutrition during early life had higher risks of obesity, insulin resistance, and diabetes [37–39]. Recent epigenetic research has further investigated how the early environment becomes inscribed on the epigenome as "metabolic memory" that reveals itself later in life as metabolic dysfunction [40].

Another series of studies has suggested the possible role of chronic inflammation. A United Kingdom-based longitudinal survey revealed that about 50% of the excess risk of T2DM incidence associated with a low socioeconomic position was explained by lifestyle behaviors, whereas a quarter of this excess risk was explained by chronic inflammation markers such as C-reactive protein and interleukin-6 [41, 42]. The role of chronic inflammation may indicate a biological mechanism that translates social stress related to low socioeconomic position into a pathological path leading to insulin resistance and beta cell dysfunction.

As described in our review thus far, no single theory can tell the whole story about how social context gets "under the skin" and results in differential diabetes outcomes. This is why two larger frameworks are needed to comprehend diabetes as a social challenge—namely, the ecological perspective and the life-course perspective.

The ecological perspective regards individuals as nested within families, which are further nested within communities, which are further nested within larger social contexts, such as states (Fig. 5.1) [43]. All of these levels (individual, family, community, society) interact with each other. For example, an individual's behavioral choices may be enhanced if he/she has a supportive relationship with his/her family

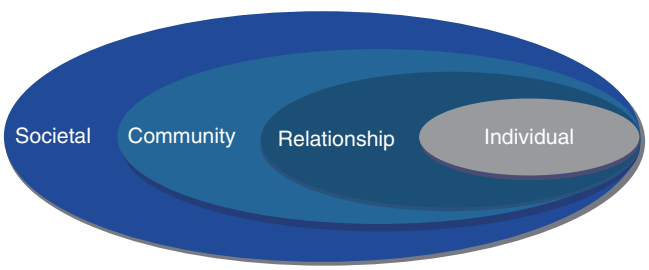

Fig. 5.1 Ecological structure. (Source: Centers for Disease Control and Prevention. The Social-ecological Model: A Framework for Prevention. Downloaded on 15 June 2018 from https://www.cdc.gov/violenceprevention/overview/social-ecologicalmodel.html)

and community. A supportive relationship is more likely to be available if the community environment is safe and has relatively less deprivation—factors that will be further determined by a nation's economy and social policies.

The life-course perspective examines the sequence of life stages from the fetal period to childhood, adolescence, young adulthood, midlife, and later stages of life. Each stage exhibits a unique window with specific vulnerabilities to biological, behavioral, and psychosocial risk factors for chronic diseases, and the impact of a certain stage will echo in the later stages [44]. For example, life difficulties in the early stages affect an individual's chances of getting diabetes in later life through biological programming, reduced opportunities to nurture health literacy, and smaller chances of obtaining a secure job and income, which will further impede access to necessary health care resources.

Bridging the ecological and life-course perspectives is the concept of "social determinants of health." This concept sees health as determined not only by medical systems but also by daily life conditions where people are born, live, learn, and work [45]. The concept of the social determinants of health can be applied to diabetes [46]. As the above review shows, to achieve equity in diabetes outcomes, it is important—but not sufficient—to provide equal access to quality health care. The social determinants of health concept indicate that changes should be made in the root causes of the biological, behavioral, psychosocial, and socioeconomic causes of health gaps (Figs. 5.2 and 5.3 [45]). For this purpose, the social determinants of health concept require interventions that are multilevel, multidomain, and longitudinal.

Health care sectors are important, but are not the only institutions that can enable a reduction in health gaps. For example, a study from Scotland based on a nationwide clinical database reported that diabetes incidence declined from 2004 to 2013 in all socioeconomic strata except for the lowest decile—the most deprived group. This group showed a resurgence in diabetes incidence beginning in 2010, after the global economic shock, resulting in a widening socioeconomic disparity in diabetes incidence, especially among women [47]. Apparently, macroeconomic policy is a strong social structural determinant of health. Attention to the social determinants of health calls for inter-sectorial collaboration across health, finance, labor and industry, education, civil engineering, and other sectors in government and global institutions [45, 46].

It should be noted, however, that a recent conceptual review on social determinants of diabetes criticized the existing literature on socioeconomic conditions and diabetes outcomes for focusing too much on individual-level factors, such as behaviors and literacy, and emphasized the significance of the larger social context, such as the health care system and the legal and social policy frames that shape an

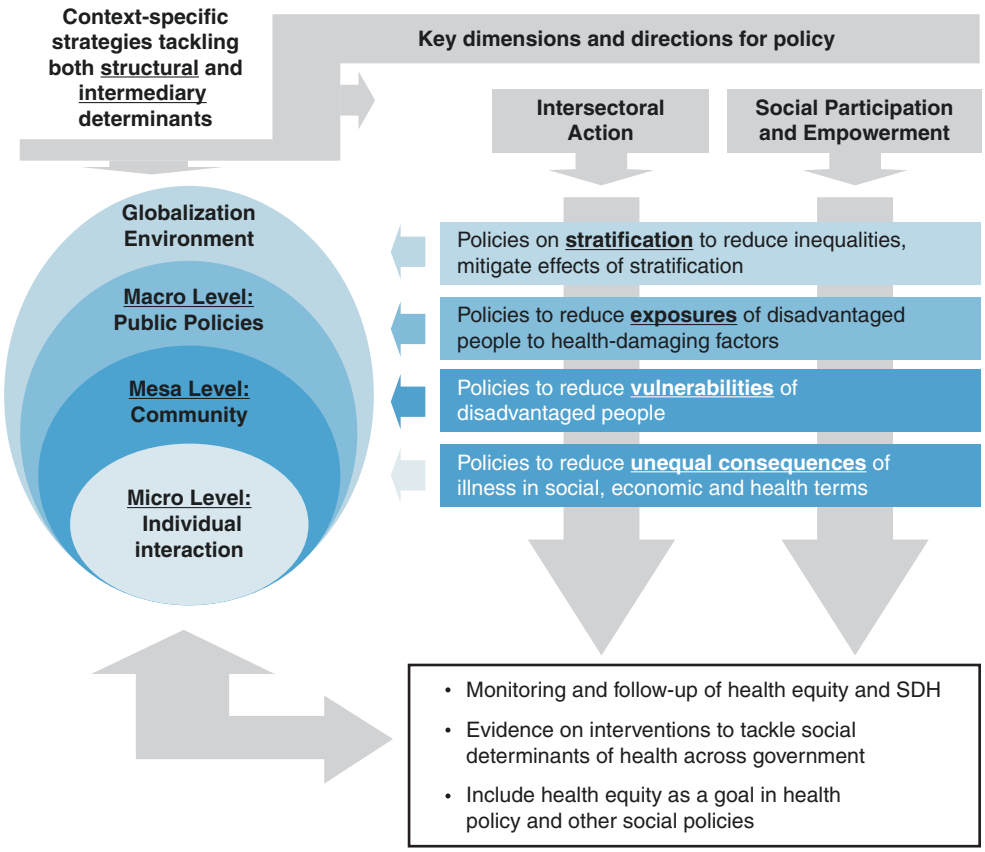

Fig. 5.3 Levels of policy to address social determinants of health. (Source: World Health Organization (2010) [45]. Conceptual Framework of Social Determinants of Health, Paper 2, Fig. B, p. 8)

individual's likelihood of engaging in diabetes-related risk behaviors [46, 48].

This notion logically indicates the importance of social change through policy advocacy, as well as the impact of health educational intervention and psychosocial support for individuals with diabetes. The International Diabetes Federation and other organizations have been leading the advocacy to influence policy, both domestic and international, to improve health care and social conditions for people with diabetes and enable them to exercise better control over their lives [49]. Although the importance of advocacy activities has gradually begun to be recognized among health care professionals, it remains challenging and controversial whether social and political activities should be added to the traditional physicians' code of "scientific neutrality" [50].

Social Determinants of Diabetes Interventions to Close the Social Gap in Diabetes Outcomes

What can be done to close the social gap in diabetes outcomes? A good quality of diabetes care should be available to all people, regardless of socioeconomic status, ethnicity/race, or gender. The introduction of universal health coverage is a high-priority policy for closing the gap [51, 52]. However, this is not sufficient; quality care availability may help to close the gap in diabetes mortality, but it will do little to prevent the gap in diabetes morbidity and, especially, incidence.

Lifestyle and related behaviors are strong risk factors for diabetes outcomes, and the provision of information through community education to support people in making healthier choices is promising. Indeed, a large randomized clinical trial showed that intensive health education can have a significant preventive impact on diabetes incidence if the intervention is properly prepared [53]. However, a longer follow-up of the same randomized clinical trial revealed that the difference originally observed between the treatment and control groups gradually declined over time [54]. This decline was not simply because the program's effectiveness attenuated over time after the intervention ended; rather, it was because behavioral change among the control group patients caught up with that of the treatment group patients over time, suggesting that factors other than the educational program influenced behaviors among patients with prediabetes afterward. Social changes in the norms about healthy diet and habitual exercise, improvements in access to supportive information, and environments facilitating the maintenance of behavioral modifications are the suspected explanations. This supports the idea that behavioral choices are not completely volitional; instead, behaviors are influenced by social,

economic, cultural, and other structures. Creating supportive environments for behavioral modification toward healthier lifestyles is promising. However, existing reviews on the effectiveness of policy interventions such as the development of walkable cities and improving access to healthier food in the community concluded that the current evidence is mixed, and further research on the effectiveness of environmental architecture and other interventions on the social determinants of diabetes is required [25, 26, 48].

Among the possible policy interventions, accumulating evidence has begun to show that a sugar tax, or the taxation of sugar-sweetened beverages, is a promising policy for obesity prevention [55]. The sugar tax and the subsequent price increase of sugar-sweetened beverages are expected to provide disincentives for consumers' purchasing decisions. By nature, this intervention is expectedly regressive: the disincentives have a stronger influence on the poor, who have lower income, suggesting that the impact of the sugar tax on obesity prevention should be largest among the poor, who are also at higher risk of obesity.

Currently, the policy has already been introduced in several countries, including Mexico, where the consumption of sugar-sweetened beverages has been considered a major target for reducing caloric intake for obesity prevention, especially among children and poor adults. In April 2014, the Mexican government enacted a policy to incur a 1 peso-per-liter excise tax on all sugar-sweetened beverages. This has resulted in a reduction in the consumption of sugar-sweetened beverages, and, as expected, the impact was observed to be larger among low-income households and those in rural regions than among high-income households and those in urban locations [56–59].

Although the Mexican policy seems to have achieved early success, the introduction of taxes for health promotion is not simply effective. Recent assessments found that weight reduction was observed only among girls in rural areas, and those with obesity at baseline, while no reduction was visible among boys [60]. Another study found that the reduction in sugar-sweetened beverages was accompanied by substitutional increases in cholesterol and saturated fat intakes, resulting in no change in calorie intake [61]. These recent observations indicate that such a "sin tax" for health promotion should be accompanied by alternative healthy choices at affordable prices for the vulnerable population. Furthermore, the implementation of the sugar tax was challenged by business sectors and lobbying parties with vested interests and was under threat for political feasibility [62–64].

Despite its challenges, the sugar tax can be taken as a good example of the "proportional universalism" approach, or the universal inclusion of people in health promotion, with resource allocation proportional to needs or risks [65]. Because people with diabetes are vulnerable to social stigma, high-risk approaches that target people with high diabetes risks (e.g., targeted educational interventions for patients with prediabetes) often induce discrimination and subsequent social exclusion among targeted vulnerable people. Instead, universalism approaches can provide a wider range of community members with the opportunity for self-management of their own health without selection. In addition to offering community campaigns to reduce social stigma by providing precise information on the etiology and control of diabetes, health care professionals should be aware of the significance of structural interventions for changing the social environment, and take active roles to help people achieve healthier lifestyles in a socially inclusive manner.

Conclusion

Epidemiological and clinical studies have convincingly demonstrated that the disease burden of diabetes is disproportionally distributed across society because the incidence, mortality, and morbidity of diabetes are influenced by the socioeconomic and environmental determinants of diabetes. Lifestyle behaviors such as diet and exercise are significant factors in diabetes control, and they are shaped not only by individual capacity but also by the social environment surrounding individuals. Interventions to improve diabetes control among selective high-risk groups through lifestyle modification have been shown to be effective. However, this selective approach may run the risk of inducing social stigma toward people with high diabetes risk, which may seriously hinder effective self-care. As an alternative, structural interventions to change the social environmental determinants of diabetes are promising, although they require further research and policy evaluation to effectively translate the concept into actions that help people to overcome the social challenges of diabetes. Furthermore, health care professionals specialized in diabetes care should take on more active roles to help people with diabetes overcome the challenges of the disease through improvements in policy and social environments.

Multiple-Choice Questions

1. Which of the following statements best fits the concept of the social determinants of diabetes? (Choose one that fits best.)
   (a) Patients' rights to quality diabetes care should be addressed.
   (b) Patients are responsible for modifying their lifestyles to improve diabetes control.
   (c) The government health sector should provide community education to improve knowledge about diabetes risks.
   (d) **All social, economic, and health policies related to people's life-course experiences should be consid-**

ered in terms of their potential leverage to close the gap in the diabetes burden among people.

(e) None of the above.

2. What determines the prevalence of diabetes? (Choose one).
   (a) Genomic predisposition.
   (b) Local availability of healthy food.
   (c) Education.
   (d) Motorization (transportation by car driving).
   (e) **All of the above.**
3. Which subpopulation is susceptible to a higher diabetes prevalence? (Choose one).
   (a) Richer men.
   (b) Poorer men.
   (c) Richer women.
   (d) Poorer women.
   (e) **It depends on the local stage of economic and social development.**
4. Which of the following options describes a policy intervention that is in the frame of the social determinants of diabetes? (Choose all correct responses.)
   (a) Research and development of genetic treatments for diabetes.
   (b) Patient education to improve adherence to diabetes care regimens.
   (c) **Introduction of a sugar tax.**
   (d) **Improvement of health literacy among community dwellers.**
   (e) **Civil engineering to design a walkable city.**
5. Why is the incidence of diabetes higher among people with lower socioeconomic status in low-middle-income countries as well as in high-income countries? (Choose all correct responses).
   (a) **Limited availability of healthy food.**
   (b) **Limited affordability of resources to sustain healthy lifestyles.**
   (c) **Lower health literacy to support healthy lifestyles.**
   (d) **Early life experience with deprivation and related physical manifestations.**
   (e) **Social influence of close peers with poor diets and prevalent smoking.**
6. Which of the following statements fits the ecological model of health and diabetes? (Choose one).
   (a) An individual's dietary habits are influenced by family and close friends.
   (b) Walking habits are facilitated if the community is safe and walkable.
   (c) Healthy diets are discouraged if the availability of fresh vegetables is limited in the community.
   (d) The national economy affects an individual's chances of having suitable resources to protect their own health.
   (e) **All of the above**.
7. How does the social stigma of people with diabetes affect their self-management of the disease? (Choose one).
   (a) Social stigma blames people with diabetes, considering them responsible for their own disease.
   (b) Social stigma socially excludes people with diabetes from necessary social support.
   (c) Social stigma discourages self-esteem and self-efficacy related to self-management among people with diabetes.
   (d) People with diabetes are forced to conceal their diabetes status in public out of fear of stigmatization.
   (e) **All of the above**.
8. Which of the following options best fits the concept of the "proportionate universalism" approach to tackling social disparity in the diabetes burden? (Choose one).
   (a) Screening for obesity to provide publicly subsidized education programs for behavioral modification.
   (b) Targeting people with low incomes or low educational attainment to provide free vouchers for fresh and healthy food.
   (c) **Introduction of a sugar tax on sweetened beverages to reduce sugar intake in the general population.**
   (d) Free provision of diabetes care for people living in targeted communities, with means testing.
   (e) All of the above.
9. What are the strengths and weaknesses of the population approach compared with the high-risk approach? (Discuss).

ZnT8	Zinc transporter 8

Objectives

- The aim of this chapter is to delineate the definition of diabetes mellitus and its diagnostic criteria. Following a brief discussion on the evolution of the current diagnostic criteria, the recent ADA criteria and recommendations for screening will be discussed.
- The section on the diagnostic criteria for gestational diabetes compares and contrasts the various criteria recommended by different professional bodies and their merits. This section will also discuss the utility and fallacies of HbA1C as a measure of glycemic status.
- The section on the classification of diabetes lists the various etiologies of diabetes mellitus based on the pathophysiology or common mechanisms for better understanding. Few subsections like "endocrinopathies" and "drugs causing diabetes" are discussed in brief.

Definition

The word diabetes is derived from its Greek root, which means "to pass through," referring to polyuria—the hallmark symptom of diabetes mellitus (DM). The word mellitus means "from honey," denoting glycosuria, differentiating it from its close mimic, diabetes insipidus [1].

DM is defined by the World Health Organization (WHO) as a metabolic syndrome characterized by chronic hyperglycemia resulting from any of the several conditions

L. P. Nandhini · S. Kamalanathan · J. Sahoo (✉)

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_6

that cause defective insulin secretion and/or action. Prediabetes is a state characterized by metabolic abnormalities that increase the risk of developing DM and its complications.

Diagnostic Criteria

The diagnostic criterion for DM has undergone a sea change over the last several decades with improved understanding of its pathophysiology and complications. Though the association between chronic hyperglycemia and its complications is well established, the specific cutoff points for diagnosing DM still remain a matter of intense debate.

The WHO, in the year 1965, published the first guidelines for diagnosing DM [2]. The National Diabetes Data Group (NDDG) proposed a criterion based on the observation of the bimodal distribution of plasma glucose (PG) in Pima Indians and Nauruan populations and the risk of progression to DM and the development of complications. The NDDG also recognized an intermediate group of individuals with raised PG above normal, but not satisfying the criterion for diagnosing DM. This group faced a risk of progression to DM at a rate of 1–5% annually and also had higher prevalence of atherosclerotic disease. The terminology "impaired glucose tolerance (IGT)" was introduced to identify this important group of persons in whom early intervention could avert DM and its complications [3].

The subsequent modifications of the diagnostic criteria by WHO saw a revision of the fasting and 2-h post glucose load venous PG thresholds to 7.8 mmol/L and 11.1 mmol/L, respectively, based on the observations that complications of DM rarely occurred below these PG levels.

In 2003, the American Diabetes Association (ADA) made a controversial change to its existing guideline by reducing the cutoff point for defining the upper limit of fasting plasma glucose (FPG). This modification was based on data from four population-based epidemiological studies which showed that the ideal FPG cutoff point fell between 5.22 and 5.72 mmol/L and the cutoff of 5.55 mmol/L was arbitrarily chosen [4].

Glycated hemoglobin (HbA1c) was included as a modality to diagnose DM by the ADA in 2010 and the WHO in 2011.

The latest ADA criteria for diagnosing DM are given below: in asymptomatic individuals, these tests need to be repeated on another day for the confirmation of the diagnosis [5].

- FPG ≥7.0 mmol/L. Fasting is defined as no caloric intake for at least 8 h.
- or
- 2-h PG ≥11.1 mmol/L during an oral glucose tolerance test (OGTT). The test should be performed as described by the WHO, using a glucose load containing the equivalent of 75-g anhydrous glucose dissolved in water.
- or
- HbA1c ≥6.5% (48 mmol/mol). The test should be performed in a laboratory using a method that is National Glycohemoglobin Standardization Program (NGSP) certified and standardized to the Diabetes Control and Complications Trial (DCCT) assay.
- or
- In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random PG ≥11.1 mmol/L.

ADA Criteria for Diagnosis of Prediabetes

In addition to fasting and post-glucose load PG levels, HbA1c is also recommended as a screening test for prediabetes.

The cutoff points recommended for the diagnosis of prediabetes are given below:

1. FPG—5.6–6.9 mmol/L [impaired fasting glucose (IFG)]
2. 2-h PG in the 75-g OGTT—(7.8–11.0 mmol/L) (IGT)
3. HbA1c 5.7% (39 mmol/mol)

It should be noted that WHO defines the IFG cutoff at 6.1 mmol/L.

Criteria for Screening for Diabetes or Prediabetes in Asymptomatic Adults

The ADA 2017 guidelines have laid down certain risk factors for screening for diabetes and prediabetes. These include:

1. Overweight or obese (body mass index (BMI) ≥25 kg/m^2 or ≥23 kg/m^2 in Asian Americans) adults who have one or more of the following risk factors:
   (a) First-degree relative with diabetes
   (b) High-risk race/ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islander)History of cardiovascular disease
   (c) Hypertension (≥140/90 mmHg or on therapy for hypertension)
   (d) High-density lipoprotein cholesterol level ˂0.90 mmol/L and/or a triglyceride level ≥2.82 mmol/L

(e) Women with polycystic ovary syndrome
(f) Physical inactivity
(g) Other clinical conditions associated with insulin resistance, e.g., severe obesity and acanthosis nigricans

2. HbA1c ≥5.7% (39 mmol/mol), IGT, or IFG on previous testing.
3. Women who were diagnosed with gestational diabetes mellitus (GDM).
4. HIV
5. For all patients, testing should begin at age 45.
6. If results are normal, testing should be repeated at a minimum of 3-year intervals, with consideration of more frequent testing depending on initial results (e.g., those with prediabetes should be tested yearly) and risk status.

Screening for Prediabetes and Diabetes

Prediabetes is an intermediate state of hyperglycemia characterized by elevated PG levels above normal but not qualifying for the diagnosis of DM. Its significance lies in the fact that 5–10% of patients can progress to develop DM annually without intervention [6, 7]. The dreaded complications of DM are also observed in this group of patients, stressing the need for early recognition and reversal of this state.

According to the WHO, prediabetes constitutes two distinct entities, namely, IFG and IGT. Different pathogenic mechanisms are believed to underlie these two distinct entities, and persons with a combination of both abnormalities have more advanced metabolic abnormalities than those with either of the two. Similar to the increasing prevalence of DM globally, the prevalence of prediabetes is also expected to rise, with an estimated 472 million people expected to be affected by this condition by the year 2030 [8]. Although a significant proportion of people progress to develop DM, several remain static, and many go on to revert to a normal state, although the rate of conversion has been reported to be different in various studies [7, 9].

It is well recognized that beta cell dysfunction and insulin resistance are already present in patients at the time of detection of prediabetes [10, 11]. It thus represents a phase in the continuum of worsening beta cell dysfunction and insulin resistance. Insulin resistance is a feature of both IFG and IGT, though the site of resistance varies. IFG is characterized by hepatic insulin resistance, while in IGT, resistance is mainly at the level of skeletal muscles. The beta cell dysfunction is however seen in both [10, 12]. This difference in the pathophysiology is reflected in the PG changes following a glucose load with persons with IFG demonstrating impaired early response in contrast to those with IGT who show impairment of both early and late phases of insulin secretion [12–14].

The ADA recommends screening for DM and prediabetes in asymptomatic people, including those who are obese or overweight and have one or more additional risk factors as listed above. For all others, testing should begin at 45 years of age, and repeat testing in those with normal results is to be done at a minimum interval of 3–5 years [5].

Diagnostic Methods

Glycated Hemoglobin

With sustained exposure to hyperglycemia, proteins undergo nonenzymatic glycation. Hemoglobin A (HbA), the predominant fraction of hemoglobin in normal adults, also undergoes a similar modification. Three minor fractions of glycosylated hemoglobin are known to occur, namely, HbA1a, HbA1b, and HbA1c, based on their elution properties during electrophoresis. The HbA1c fraction that has been widely employed as a diagnostic test has a hexose moiety attached covalently to the NH_2-terminal valine residue of the β-chain of HbA [15]. Several methods have been used to separate this fraction from the nonglycated hemoglobin. These techniques exploit the differences in structure (affinity chromatography and immunoassay), charge (ion-exchange chromatography, high-performance liquid chromatography [HPLC] electrophoresis, and isoelectric focusing), or chemical nature (photometry and spectrophotometry) of the various fractions. HbA1c is a measure of average plasma glucose levels over the preceding 3 months [16]. There are several advantages to measuring HbA1c over plasma glucose. HbA1c estimation can be done regardless of the time of day or fasting status. It also shows less day-to-day variability and analytical stability [17]. HbA1c also predicts the development of micro- and macro-vascular complications of DM, as observed in clinical trials like the DCCT and the United Kingdom Prospective Diabetes Study (UKPDS). However, it is not free from limitations and can be influenced by other non-glycemic factors (Table 6.1). Diseases affecting the red blood cell turnover rate can result in imprecise values. Compared with FPG and $HbA1_C$, the 2-h PG value diagnoses more people with prediabetes and diabetes.

Table 6.1 Factors affecting HbA1c estimation

	Change expected
Physiological characters	
Age	HbA_{1c} increases by approximately 0.1% with every 10 years of age—not relevant clinically
Race	Variably reported
Hematological conditions	
Iron deficiency anemia [18, 19]	Falsely elevated in most studies Mechanism—not clear
Hemolytic anemia	Falsely low due to the shortened life span of RBCs
Hemoglobin variants (HbF, HbS, HbD, HbE) [20]	Variable based on assay methodology
Analytical interference	
Hyperbilirubinemia	Variably reported interference [20, 21]
Hypertriglyceridemia [20]	Falsely low
Others	
Malaria	Falsely low [22]
Transfusions [23]	Falsely low
Splenectomy	Increases life span of RBC in conditions like hereditary spherocytosis, resulting in elevated HbA1c after splenectomy [24]
Renal failure	Falsely low due to shortened erythrocyte life span, frequent blood transfusions, erythropoietin-promoted erythrocytosis, and drug-induced anemia [25]
Alcohol abuse	Falsely low [26]
Aspirin [27]	Modest increase—not clinically relevant

Standardization of HbA1c

The clinical utility of HbA1c largely hinges on the quality of the analytical method used. A plethora of tests are available today for estimating HbA1c. In order to establish uniformity in testing, reporting, and interpreting the HbA1c results, the American Association of Clinical Chemistry (AACC) and the NGSP (National Glycohemoglobin Standardization Program) developed a protocol to standardize the HbA1c test results to those of the DCCT [28].

In 1995, the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) sought to establish a true reference method for HbA1c estimation instead of standardizing it to a comparison method like the NGSP. Here, hemoglobin is digested using enzymes that cleave a hexapeptide off the amino terminal of the β-chain. The glycated and non-glycated hexapeptide components are then separated and quantified. HbA1c was calculated as the ratio of two fractions and reported as a percentage [29]. This method is expensive and laborious, making it unsuitable for routine analysis of samples.

Classification of Diabetes Mellitus

It is prudent to try and classify the type of DM in order to identify the best management plan, screen for associated complications and comorbidities, and also screen other members of the family. However, this may not be straightforward in all scenarios. DM can be classified based on the underlying pathogenic mechanisms into the following categories: type 1 DM, type 2 DM, GDM, and secondary DM (Table 6.2) [5, 30].

Table 6.2 Secondary causes of diabetes mellitus

A. Genetic defects of β-cell function
Maturity-onset diabetes of the young (MODY) 3 (HNF-1α)
MODY 1 (HNF-4α)
MODY 2 (glucokinase)
Other rarer forms of MODY
Transient neonatal diabetes
Permanent neonatal diabetes
Mitochondrial DNA
B. Genetic defects in insulin action
Type A insulin resistance
Leprechaunism
Rabson-Mendenhall syndrome
Lipoatrophic diabetes
C. Diseases of the exocrine pancreas
Pancreatitis
Pancreatectomy
Neoplasia
Cystic fibrosis
Hemochromatosis
Fibrocalculous pancreatopathy
D. Endocrinopathies
Acromegaly
Cushing's syndrome
Glucagonoma
Pheochromocytoma
Hyperthyroidism
Somatostatinoma
Aldosteronoma
E. Drug or chemical induced
Glucocorticoids
Thiazides
Statins
Antipsychotic medication
Antiretroviral therapy
Phenytoin
Thyroid hormone
F. Infections
Congenital rubella
Cytomegalovirus
G. Other genetic syndromes
Down syndrome
Klinefelter syndrome
Turner syndrome
Wolfram syndrome
Friedreich ataxia
Huntington chorea

Type 1 Diabetes Mellitus

Type 1 DM is characterized by complete cellular-mediated destruction of the β-cells, resulting in insulinopenia and insulin replacement therapy for survival. Majority of patients present with the constitutional symptoms of DM, namely, polyuria, polydipsia, and polyphagia. One-third of the patients can present with diabetic ketoacidosis as the first manifestation [31]. The disease is believed to be precipitated by an environmental insult in a genetically predisposed individual. Type 1 DM, including latent autoimmune diabetes in adults (LADA), is known to be strongly associated with human leukocyte antigen (HLA)-DR3-DQ2 and HLA-DR4-DQ8 haplotypes, alone or in combination [32, 33]. Some HLA haplotypes can offer protection from type 1 DM [34]. In addition, several other putative genes like cytotoxic T-lymphocyte-associated antigen 4, protein tyrosine phosphatase, non-receptor type 22, and insulin variable number tandem repeat affecting disease susceptibility have been identified [35]. Autoantibodies against islet antigens like glutamic acid decarboxylase 65, insulin, insulinoma-associated antigen 2 and 2β, and zinc transporter 8 are seen in the majority of patients [36, 37]. The number of antibody positivity correlates with the rate of progression of β-cell failure with 70% of children with two or more antibodies progressing to develop DM [38]. Three distinct stages of type 1 diabetes can be identified: presymptomatic with normoglycemia, presymptomatic with dysglycemia, and symptomatic with hyperglycemia [5]. In addition to islet cell autoimmunity, these patients are also predisposed to the development of other autoimmune disorders like Hashimoto's thyroiditis, Graves' disease, Addison's disease, celiac disease, vitiligo, autoimmune hepatitis, myasthenia gravis, and pernicious anemia [5].

A number of environmental triggers have been studied, including cow's milk, certain viruses, and gut microbiota, although none have been conclusively identified to influence the pathogenesis of type 1 diabetes mellitus [39–43]. A minority of patients with a clinical picture consistent with type 1 DM do not have evidence of autoimmunity. This is particularly common in patients of Asian and African ancestry and is not HLA-associated [44]. Ketosis-prone diabetes is an example of such a type of diabetes. There is currently a lack of accepted and clinically validated screening programs for type 1 DM outside of the research setting.

Type 2 Diabetes Mellitus

In contrast to type 1 diabetes, type 2 DM is characterized by relative insulin deficiency due to β-cell dysfunction and resistance to the action of insulin in target tissues. Unlike patients with type 1 DM, patients with type 2 DM, at least initially, are amenable to oral hypoglycemic agents. Beta-cell loss occurs progressively and can result in treatment failure with oral hypoglycemic agents and the requirement of insulin for the control of hyperglycemia, especially in younger individuals [45]. The global epidemic of type 2 diabetes mellitus parallels that of its prime risk factors—obesity, physical inactivity, and lifestyle modifications. Excessive abdominal adiposity, prior history of GDM, and certain ethnicities (like Asian, African American, Hispanic) are other strong risk factors for developing type 2 DM [5]. The ADA diabetes risk test (score ≥5) is an additional option for assessment to determine the appropriateness of testing for diabetes or prediabetes in asymptomatic adults (available on diabetes.org/socrisktest) based on age, gender, family history of diabetes, hypertension, GDM, physical inactivity, and obesity [5].

Gestational Diabetes Mellitus

GDM has traditionally been defined as any degree of glucose intolerance that is first detected during pregnancy, regardless of whether the condition may have predated the pregnancy or persisted after the pregnancy [46]. This definition of GDM, which is based on the PG level alone, does not distinguish the underlying pathological process. Hence, this heterogeneous group comprises women with preexisting insulin resistance and insulin deficiency worsened by deteriorating glucose homeostasis in pregnancy and women with short-term alterations in glucose homeostasis resulting from pregnancy-related physiological changes. Irrespective of the etiology, the management of these patients remains more or less the same, though women with pregestational diabetes need screening for long-term complications of dysglycemia, which can worsen further as pregnancy progresses [47].

The very first diagnostic criterion for GDM was proposed by O'Sullivan and Mahan in 1964. The authors had suggested a 50 g, 1-h glucose challenge test (GCT) for screening and follow-up of women with a 1-h post glucose load exceeding 140 mg/dL with a confirmatory test. A 100 g, 3-h OGTT was suggested to confirm the diagnosis. The cutoff levels were validated for the risk of the mother developing diabetes in the future and not for pregnancy outcomes [48].

This criterion was subsequently modified by the NDDG in the United States and later by Carpenter and Coustan to account for the changes in the methodology of glucose estimation and for using plasma samples instead of whole blood [3]. This modified criterion was widely accepted and endorsed by professional bodies like the ADA and WHO, until the International Association of Diabetes and Pregnancy Study Groups (IADPSG) criterion was proposed, following the results of the path-breaking hyperglycemia and pregnancy outcomes (HAPO) study. The American College of

Obstetricians and Gynecologists (ACOG) still recommends the Carpenter and Coustan criterion [49].

HAPO was a large multinational, multicenter study which included over 23,000 pregnant women of diverse ethnicities. The OGTT was administered between 24 and 32 weeks of gestation using 75 g of glucose. A linear relationship was noted between PG levels following OGTT and several primary (umbilical cord-blood C peptide level, birth weight, neonatal hypoglycemia, and rate of cesarean delivery) and secondary outcomes (delivery before 37 weeks of gestation, shoulder dystocia or birth injury, need for intensive neonatal care, hyperbilirubinemia, and preeclampsia). The outcomes were directly related to FPG level and independently to 1-h and 2-h PG values [50].

Based on the results of the HAPO trial, IADPSG suggested a single-step, 75 g OGTT be performed in all pregnant women at 24–28 weeks of gestation. The defined diagnostic cut points for diagnosing GDM were those levels at which odds for adverse outcomes reached 1.75 times the estimated odds of these outcomes at the mean fasting, 1-h, and 2-h PG levels of the study population. A single value above the suggested cutoff was enough to make a diagnosis of GDM, unlike the two-abnormality criteria earlier followed [51].

Universal implementation of the stringent IADPSG criteria is likely to increase the prevalence of GDM as many women with mild GDM are likely to be included. The cost-effectiveness of this approach and its impact on improving maternal and fetal outcomes have been questioned. A few studies have however shown that the additional patients diagnosed using the IADPSG criterion when compared to other criteria are at risk for GDM-related complications [52–54]. The IADPSG also recommends diagnostic cutoff values to diagnose GDM in the first trimester. This recommendation was not based on any hard data and was an extrapolation of the results of the HAPO study. In 2011, the ADA also adopted the IADPSG criteria.

The NICE in 2015 published its guidelines for diagnosing GDM and suggested higher FPG cutoff values when compared to those of the IADPSG. The prime reason quoted for choosing higher FPG levels was to reduce the economic burden imposed by the application of a lower FPG cutoff on the health-care system. Though this criterion strives to strike a middle ground, it has not been tested clinically, and its impact on maternal and fetal health will be seen in the coming years [55]. The cutoff values for diagnosing GDM using the one-step and two-step strategies according to the ADA are given below [5].

One-Step Strategy

75-g OGTT is recommended with PG measurement when the patient is fasting and, at 1 h and 2 h, at 24–28 weeks of gestation in women not previously diagnosed with overt diabetes. The OGTT should be performed in the morning after an overnight fast of at least 8 h. The diagnosis of GDM is made when any of the following plasma glucose values are met or exceeded:

- FPG: 92 mg/dL (5.1 mmol/L)
- 1-h PG: 180 mg/dL (10.0 mmol/L)
- 2-h PG: 153 mg/dL (8.5 mmol/L)

Two-Step Strategy

Step 1

Perform a 50-g GCT (non-fasting), with PG measurement at 1 h, at 24–28 weeks of gestation in women not previously diagnosed with overt diabetes. If the PG level measured 1 h after the load is ≥130, ≥135, or ≥140 mg/dL (7.2, 7.5, or 7.8 mmol/L), proceed to a 100-g OGTT. The ACOG recommends either of the commonly used thresholds of 130, 135, or 140 mg/dL for the 1-h 50-g GCT.

Step 2

The 100-g OGTT should be performed when the patient is fasting. The diagnosis of GDM is made if at least two of the following four plasma glucose levels (measured at fasting and 1, 2, 3 h after the OGTT) are met or exceeded. However, the ACOG notes that one elevated value can be used for diagnosis:

- FPG: 95 mg/dL (5.3 mmol/L)
- 1-h PG: 180 mg/dL (10.0 mmol/L)
- 2-h PG: 155 mg/dL (8.6 mmol/L)
- 3-h PG: 140 mg/dL (7.8 mmol/L)

Screening for GDM

Recommendations for choosing the target population for GDM screening are shrouded by controversies and a lack of uniformity among the existing guidelines. The WHO and ADA recommend universal screening of all pregnant women, while the NICE guidelines recommend a selective screening strategy [55, 56]. The selective screening approach is likely to miss a significant proportion of women who develop GDM in the absence of traditional risk factors [57, 58]. The ADA recommends screening for diabetes in women with risk factors for diabetes at the first prenatal visit using its standard diagnostic criteria. Those who are not known to have diabetes are to be screened at 24–28 weeks of gestation using a one-step or a two-step approach [5].

Screening for Persistent Diabetes After Pregnancy

The majority of women diagnosed with GDM will revert to normalcy in the immediate postpartum period, leaving a small proportion with continuing hyperglycemia. The lifetime risk

of developing type 2 DM is as high as 50–70% [59]. The immediate postnatal period provides a window of opportunity to identify this precarious cohort of at-risk women. The ADA recommends screening at 4–12 weeks postpartum using the OGTT and advises lifelong follow-up and screening at least every 3 years [5]. The NICE guidelines recommend using FPG or HBA1c after 13 weeks, and annual testing with HbA1c is recommended if the first test is normal [55].

Specific Types of Diabetes Due to Other Causes

This heterogeneous group includes monogenic forms of diabetes and others with an underlying genetic defect affecting insulin secretion and action, diseases affecting the pancreas, diabetes associated with endocrine disorders, drug-induced diabetes, and posttransplantation diabetes.

Monogenic Diabetes Syndromes

Single gene defects causing β-cell dysfunction constitute around 1–2% of all cases of DM [60]. MODY is characterized by defective insulin secretion with intact insulin action. Thirteen different genetic loci have been identified so far and are inherited in an autosomal dominant fashion [5]. The most commonly reported types include MODY 2, MODY 3, and MODY 1. There is wide variation in the severity and clinical course of the disease among the various types. Some forms show excellent response to sulfonylurea, and certain subtypes require insulin therapy for management. Identification of additional malformations or multisystem involvement helps in arriving at a diagnosis and also necessitates a multipronged approach to the management of these patients.

Neonatal Diabetes

Infants developing DM within the first 6 months of life should undergo genetic testing to identify potential genetic defects. Neonatal diabetes can be transient or permanent, and patients who have an initial transient presentation can develop DM later in life. Making the correct diagnosis in these patients cannot be overemphasized, as switching to oral hypoglycemic agents is possible in a subset of them with potassium inwardly rectifying channel, subfamily J, member 11 (KCNJ11), and ATP-binding cassette, subfamily C, member 8 (ABCC8) mutations, thus greatly reducing the burden of management on the afflicted family [61, 62].

Diabetes Mellitus Secondary to Pancreatic Disorders

Acute and Chronic Pancreatitis

Acute pancreatitis often results in defective glucose metabolism at presentation. In many patients, this defect is transient. However, the risk of developing DM is increased during the follow-up of these patients. Chronic inflammation and destruction of pancreatic tissue can occur due to several etiologies, including cystic fibrosis-related diabetes. Although the islets are more resistant to the destructive process in the earlier stages, significant β-cell loss eventually ensues, resulting in varying degrees of dysglycemia.

Fibrocalculous Pancreatitis

Tropical chronic pancreatitis, or fibrocalculous pancreatic diabetes (FCPD), is a specific form of chronic pancreatitis which is encountered in several tropical countries, as the name suggests. The etiology of this condition is elusive, and a number of hypotheses exist to explain its occurrence. The earlier popular theories linking the consumption of cassava with FCPD have been challenged [63]. Familial clustering of cases makes genetic predisposition a plausible risk factor. Several candidate genes have been explored in this context, with the most prominent ones being serum protease inhibitor Kazal type 1 (SPINK1), cationic trypsinogen (PRSS1), anionic trypsinogen (PRSS2), and chymotrypsinogen C [64, 65]. Increased oxidative stress has also been reported in patients with FCPD [66].

Almost 90% of patients develop diabetes eventually due to β-cell destruction [67]. Although defective insulin secretion is a cardinal defect, the development of insulin resistance is also known [68]. Defects in the shifting of glucose transporter 2 (GLUT2) into the hepatocyte membranes during the postabsorptive phase have been shown in animal models of chronic pancreatitis. This can result in postprandial glucose excursions [69]. Also, pancreatic polypeptide secreted by the islet cells plays a role in the expression of the insulin receptor gene in the liver. Deficiency of pancreatic polypeptide, along with insulin deficiency, could contribute to the development of diabetes [70]. Glucagon levels, on the other hand, have been postulated to be relatively unaffected or even elevated in a few studies, indicating selective destruction of the islet cells [71, 72]. However, not all studies corroborate this theory, and it needs further analysis.

In patients presenting with symptoms of chronic pancreatitis, typical large ductal calcifications and dilatation of the pancreatic ducts visualized on imaging point to a diagnosis of FCPD. Diabetes in this scenario is generally ketosis-resistant with most patients requiring insulin therapy [68, 72]. Most patients also have evidence of exocrine pancreatic insufficiency at the time of diagnosis, and enzyme replacement therapy can worsen glycemic control by improving malabsorption.

Pancreatic Ductal Adenocarcinoma

The relationship between pancreatic ductal adenocarcinoma (PDAC) and DM is complex. DM is believed to be a risk factor for developing PDAC, while the malignancy per se

has been postulated to affect glucose homeostasis. Around 85% of patients with PDAC have IGT or DM [73]. A meta-analysis of 36 studies indicated that the risk of developing PDAC is twofold higher in patients with DM [74]. Also, studies show that 25–50% of patients with PDAC develop diabetes in the preceding 1–3 years of their diagnosis [75]. Pancreatitis related to the tumor, destruction of islets, and the development of insulin resistance are the postulated mechanisms to explain the development of diabetes. Animal studies suggest that the secretory products of tumor cells can impair glucose metabolism [76]. New-onset DM in these patients is known to improve with resection of the tumor, further strengthening the link between the two [73].

Endocrinopathies

Acromegaly

Majority of patients with acromegaly are diagnosed with either prediabetes or diabetes at presentation. The reported prevalence of prediabetes varies between 16% and 46% [77–79], and that of DM is between 15% and 38% [80]. The risk of developing diabetes is strongly associated with higher growth hormone (GH) levels, family history of diabetes, hypertension, increasing age, and disease duration [79, 80]. Identification and appropriate management of diabetes are essential to preventing the increased cardiovascular morbidity and mortality associated with it.

GH plays an important role in regulating intermediary metabolism. It stimulates lipolysis, suppresses lipogenesis, and also antagonizes the insulin-induced suppression of gluconeogenesis, resulting in increased hepatic glucose output [81, 82]. Increased levels of free fatty acids induce a state of insulin resistance in the liver and peripheral tissues [83]. The inability of the β-cells to compensate for this state of insulin resistance results in the development of diabetes. Direct inhibition of insulin signaling by interfering with downstream signaling molecules like insulin receptor substrate-1 (IRS-1) and phosphatidylinositol 3 (Pi-3) kinase also contributes to the development of diabetes [84]. Most patients with acromegaly undergo surgical resection and radiotherapy. Some, in addition, require medical management for ameliorating disease activity. The treatment modality chosen can also influence the glycemic status. Surgical removal of the tumor and subsequent reduction of GH and insulin-like growth factor-1 levels are associated with improvement of glycemic status [85, 86]. Dopamine agonists have a modest effect on reducing PG levels, and the effect of somatostatin agonists (SSA) on glucose metabolism is conflicting [87]. SSA can inhibit insulin and incretin secretion and worsen glucose levels, especially in those with an underlying insulin secretion defect, though this is often offset by the reduction in GH level and improvement of disease status [87]. Among the SSA, pasireotide seems to have a greater propensity to alter glycemic control, and its effect is dose-dependent. This tendency can be explained by its greater affinity for somatostatin receptor subtype 5 expressed in the islet cells when compared to other SSA [88]. Pegvisomant is another agent which can improve glycemic control by containing disease activity. There is a reduction in FPG levels, and improved insulin sensitivity has been noted in most studies [87].

Cushing's Syndrome

Glucocorticoids exert a multitude of effects on the various organs involved in carbohydrate metabolism. It stimulates lipoprotein lipase activity and lipolysis [89]. At the liver, increased glucose output results from an increased rate of gluconeogenesis. These actions, in addition to reduced glucose uptake by muscles and increased proteolysis, result in a state of insulin resistance [90, 91]. Reduced expression of glucokinase and GLUT2 in the pancreatic β-cells results in reduced insulin secretion, which compounds the diabetogenic action of glucocorticoids [92]. Glucocorticoids can interfere with the action of insulin directly by inhibiting downstream signaling molecules like IRS-1 and Pi-3 kinase [93, 94]. Disordered glucose metabolism is seen in 50% of patients with endogenous Cushing's syndrome, with two-thirds of them developing diabetes [95, 96]. Increased prevalence of diabetes and prediabetes is also observed in cases of adrenal incidentaloma associated with subclinical Cushing's syndrome [97]. Glucose metabolism generally improves with cure, though these patients seem to have a continuing greater risk of cardiovascular morbidity. Most drugs used in the management of Cushing's syndrome, like ketoconazole, dopamine agonists, and metyrapone, have a favorable effect on glycemic control. Pasireotide, on the other hand, is known to worsen hyperglycemia [87]. The frequency of hyperglycemia-related adverse effects is lower in patients with acromegaly who are treated with pasireotide long-acting release (57.3–67%) than those with Cushing's syndrome who are treated with the subcutaneous formulation (68.4–73%) [98].

Treatment with metformin is recommended as first-line therapy for patients on pasireotide with persistent hyperglycemia. A dipeptidyl peptidase-4 inhibitor can be added on in patients failing monotherapy with metformin. A glucagon-like peptide-1 receptor agonist should be added in place of the dipeptidyl peptidase-4 inhibitor if HbA1C continues to remain above 7.0%. Insulin is started as a final resort if adequate glycemic control is not achieved with the above measures [98].

Other Endocrine Disorders

Glucagonoma

Islet cell tumors secreting glucagon are rare with a reported incidence of 0.04–0.12 per million per year [99]. They are

exclusively seen in the pancreas with the tail being the most common location [100]. In two-thirds of the cases, the tumor is malignant, and half of them have evidence of metastasis at the time of diagnosis [101]. DM is known to occur in 40–95% of patients, along with other symptoms like weight loss, gastrointestinal manifestations, and neurological symptoms like ataxia, dementia, optic atrophy, and proximal muscle weakness [102, 103]. The characteristic dermatological lesion called necrolytic migratory erythema is seen in 90% of patients. Glucagon increases hepatic gluconeogenesis and also increases lipolysis and fatty acid oxidation [104]. Diabetes mellitus is generally mild and nonketotic.

Somatostatinoma

Somatostatinomas are rarer than glucagonomas and occur in less than 1 in 40 million people [105]. They produce excess somatostatin, which directly suppresses insulin and glucagon secretion, causing diabetes. The most common clinical manifestation is related to mass effects, and metabolic manifestations occur in a minority [103, 106].

Drug-Induced Diabetes Mellitus

Thiazide Diuretics

Studies reporting the incidence of diabetes with thiazide diuretics have been conflicting. A recent meta-analysis of 22 studies showed an increased risk of diabetes with thiazides and beta-blockers when compared to other antihypertensive agents like angiotensin-converting enzyme inhibitors and angiotensin receptor blockers [107]. Hypokalemia caused by thiazides has been linked to impaired insulin secretion in addition to other mechanisms like decreased insulin sensitivity, increased hepatic glucose production, alteration in body fat composition, and stimulation of glucagon [108, 109].

Statins

Statins are widely used as the first choice for their potent low-density lipoprotein-lowering effect. Evidence for their diabetogenic potential was first demonstrated in the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER) trial in which a 32% increased risk of new-onset diabetes was noted in the statin arm [110]. Subsequently, similar risks for diabetes have been reported for other statins, prompting the Food and Drug Administration (FDA) in 2012 to add a warning of the increased risk of diabetes with statin use. A meta-analysis of 113,394 subjects showed a 15% added risk of new-onset diabetes with 80 mg of atorvastatin and 25% with rosuvastatin at a dose of 20 mg [111]. Statins are also known to worsen glycemic control in patients with DM. The risk for DM with statins is more pronounced in those who already have the traditional risk factors. Mechanisms by which statins induce and aggravate diabetes include impaired pancreatic secretion of insulin (by blocking calcium channels), reduced expression of GLUT4 interfering with glucose uptake and disposal by skeletal muscle, and exacerbation of insulin resistance in liver and peripheral tissues [112]. Lipophilic statins like simvastatin and atorvastatin are transported across cellular membranes with ease, explaining their greater propensity to cause diabetes [113].

Beta-Blockers

β-Blockers impair insulin secretion, increase hepatic glucose production, and impair lipoprotein clearance. The risk of diabetes is higher with nonselective beta-blockers [108, 114].

Antipsychotic Medications

Weight gain is a common adverse effect of almost all antipsychotic medications. The magnitude of weight gain varies with the different drugs, and the greatest risk is associated with clozapine and olanzapine [115]. Aripiprazole has a minimal effect on weight gain [116]. Maximum weight gain occurs in the first year of therapy and is related to the duration of exposure. Increased appetite and consequent food intake, reduced satiety, and effects on adipose tissue like increased lipogenesis contribute to weight gain [117, 118].

The risk for diabetes is also greater, especially with second-generation antipsychotics. It is estimated to be 32% higher in this group. Drugs causing increased weight gain are associated with a greater risk for diabetes. In some patients, this effect seems to be independent of the change in body weight. Blockage of muscarinic receptor 3 by antipsychotic medication is known, and this can hamper insulin secretion [119]. Impaired insulin sensitivity in peripheral tissues is also known to occur, possibly by interfering with the functioning of glucose transporters [118].

Antiretroviral Therapy

Risk of new-onset diabetes is a well-known complication of antiretroviral therapy, particularly with stavudine, indinavir, and didanosine. The drugs per se and the lipodystrophy associated with their use contribute to metabolic derangements. PG abnormalities are seen in 25% of patients following the initiation of protease inhibitors. Redistribution of adipose tissue is the key factor contributing to increased insulin resistance. Age, BMI, and waist circumference are additional risk factors [120–122].

Posttransplantation Diabetes Mellitus

Posttransplantation diabetes mellitus describes the presence of diabetes in the posttransplant setting, irrespective of the timing of diabetes onset. New-onset diabetes after transplantation (NODAT) refers to the occurrence of diabetes in previously nondiabetic persons after organ transplantation. NODAT excludes patients with pretransplant diabetes that was undiagnosed as well as posttransplant hyperglycemia that resolves by the time of discharge. Twenty percent to 50% of patients following kidney transplants, 9–21% after

liver transplants, and approximately 20% after lung transplants are diagnosed to have NODAT at 12 months post-transplant [123]. NODAT increases the risk of allograft loss, infections, and mortality in post-renal transplant recipients [124–127]. Patients with NODAT also develop microvascular complications associated with diabetes at an accelerated rate and are at an increased risk for cardiovascular morbidity and mortality [128]. In addition to the traditional risk factors for DM, exposure to immunosuppressive agents, CMV and hepatitis C infection, and acute rejection posttransplantation augment the risk of developing NODAT [129–132].

The ADA recommends screening for hyperglycemia in all patients posttransplantation using OGTT. A diagnosis of NODAT can be made using the standard criteria if the patient is on a stable immunosuppressive regimen and is free from infections [5].

Concluding Remarks

- Diabetes mellitus is a global epidemic and is associated with multiple morbidities and mortality. The importance of adequate glycemic control in order to circumvent these complications has been proven beyond doubt. However, there still exists a controversy over the appropriate diagnostic criteria for diabetes mellitus and prediabetes, which is constantly evolving.
- Diabetes mellitus is the final common outcome of disrupted insulin secretion and/or action. An array of etiologies is known to cause this disruption, ranging from monogenic and polygenic predispositions to endocrinopathies and drug therapy.
- Prediabetes is an intermediate state of hyperglycemia and includes the states of impaired fasting glucose and impaired glucose tolerance. The rise in the incidence of prediabetes globally mirrors that of diabetes mellitus. Screening for and detection of prediabetes is an opportunity to intervene and prevent the progression of diabetes mellitus and its complications.
- Gestational diabetes mellitus is defined as any degree of hyperglycemia that is first detected during pregnancy and encompasses true gestational diabetes mellitus and preexisting diabetes mellitus. There is no universal criteria for diagnosing GDM. Several countries have adopted differing criteria that best meet the needs of their populations.

Multiple-Choice Questions

1. Falsely low HBA1c levels can be seen in all of the following conditions except:
   (a) Hemolytic anemia
   (b) Hypertriglyceridemia
   (c) **Postsplenectomy**
   (d) Renal failure
   (e) Malaria
2. Maturity-onset diabetes in the young is inherited in _____ fashion.
   (a) Autosomal recessive
   (b) **Autosomal dominant**
   (c) X-linked dominant
   (d) X-linked recessive
   (e) Mitochondrial
3. Which of the following treatment modalities for acromegaly can worsen glycemic control?
   (a) Surgery
   (b) Radiotherapy
   (c) Dopamine agonists
   (d) **Pasireotide**
   (e) Pegvisomant
4. Glucocorticoid excess results in diabetes mellitus through which of the following mechanisms?
   (a) Stimulating lipolysis
   (b) Increasing rate of gluconeogenesis
   (c) Inducing a state of insulin resistance
   (d) Interfering with the action of insulin by affecting down-stream signaling molecules
   (e) **All of the above**
5. Which of the following drugs are known to cause or worsen diabetes mellitus?
   (a) Dopamine agonists
   (b) **Thiazides**
   (c) Loop diuretics
   (d) Alpha-adrenergic blockers
   (e) All of the above
6. Genetic syndrome associated with diabetes mellitus is
   (a) **Turner syndrome**
   (b) Edward syndrome
   (c) Patau syndrome
   (d) Cri du chat syndrome
   (e) **Down syndrome**
7. Endocrinopathy associated with secondary diabetes is
   (a) Adrenal insufficiency
   (b) **Somatostatinoma**
   (c) **Hyperthyroidism**
   (d) Hypoparathyroidism
   (e) Insulinoma

8. ADA recommendations to begin screening for diabetes mellitus for all patients at age.
   (a) 40 years
   (b) **45 years**
   (c) 50 years
   (d) 35 years
   (e) 55 years
9. The rate of progression of prediabetes to diabetes mellitus in the absence of intervention is
   (a) 1–2% per year
   (b) **5–10% per year**
   (c) 20% per year
   (d) 40% per year
   (e) 60% per year
10. The HbA1c cutoff recommended by the ADA for diagnosing diabetes mellitus is
   (a) ≥5.7%
   (b) ≥6.7%
   (c) ≥7%
   (d) ≥7.5%
   (e) **≥6.5%**

Glossary

Diabetes mellitus Diabetes is derived from its Greek root, which means "to pass through," and the word mellitus means "from honey." Diabetes mellitus is defined by the World Health Organization as a metabolic syndrome characterized by chronic hyperglycemia resulting from any of the several conditions that cause defective insulin secretion and/or action.

Gestational diabetes mellitus Defined as any degree of glucose intolerance that was first detected during pregnancy, regardless of whether the condition may have predated the pregnancy or persisted after the pregnancy.

Impaired glucose tolerance Defined as an intermediate state where blood glucose levels are above normal but do not satisfy the criteria for diagnosing diabetes mellitus.

Neonatal diabetes Development of diabetes in the first 6 months of life.

NODAT (new-onset diabetes after transplantation) Defined as the occurrence of diabetes in previously nondiabetic persons after organ transplantation.

Prediabetes It is a state characterized by metabolic abnormalities that increase the risk of developing diabetes mellitus and its complications.

7 Homeostasis of Glucose and Intermediate Metabolism: From the Lens of a Clinician

Nitin Kapoor and Madhukar Mittal

Introduction

The key substrate for energy production is blood glucose during all the phases of life. Fasting blood glucose levels remain within a narrow physiological range of 70-100 mg/dL except in the first few days of life and during pregnancy [1]. There are variations in blood glucose levels beyond this range as revealed by continuous glucose monitoring systems, which show levels both high and low (especially post meal excursions being greater), but this change spontaneously reverts to within the normal range rapidly. Both fasting and postprandial blood glucose levels are kept within a tightly controlled range. This glucose homeostasis is the result of a complex interplay of hormones controlling glucose production and glucose utilisation, which include insulin, glucagon, epinephrine, norepinephrine, cortisol and human growth hormone (HGH) [2]. Most of these hormones help maintain blood glucose levels in the fasting state while it is mainly the insulin and the incretin hormones that help regulate levels in the postprandial state. The early line of defence against hypoglycaemia includes glucagon and epinephrine, while cortisol and HGH rise in a more gradual way.

Although Claude Bernard introduced the concept of homeostasis, it was Walter Canon who introduced the term "homeostasis," defining it as "the various physiologic arrangements that serve to restore the normal state, once it has been disturbed" and expanded on the foundations laid by Bernard [3]. Glucose homeostasis, as the name suggests, is the process of maintaining blood glucose levels at a steady-state. After a meal, this is accomplished by an intricately driven and balanced hormonal regulation of glucose absorption, peripheral glucose uptake and hepatic glucose production.

The liver produces glucose through glycogenolysis (breakdown of stored glycogen) and gluconeogenesis (formation of glucose from non-carbohydrate sources such as lactate, alanine and glycerol). Apart from the liver, the kidney also plays an important role as a gluconeogenic organ. This chapter discusses the phases of glucose homeostasis, the various metabolic pathways, glucose transporters, the various organ systems and glucose homeostasis in hypoglycaemic disorders.

In healthy individuals after a meal, the liver is a major site of glucose utilisation (30-60% of the ingested glucose). Glucose uptake in skeletal muscle and in non-insulin-sensitive tissues like the brain, accounts for the rest of the total glucose disposal in the postprandial state. Glucose provides reducing equivalents for fatty acid synthesis, ribose 5-phosphate for nucleotide synthesis and precursors for glycosylation reactions. Glucose enters the liver cells and is phosphorylated to glucose 6-phosphate. Glucose 6-phosphate is like a central hub for carbohydrate metabolism and may follow a number of metabolic pathways, including glycolysis, glycogen synthesis, the hexosamine pathway, the pentose phosphate pathway and oxidative routes based on the nutritional or hormonal status of an individual.

Phases of Glucose Homeostasis

Normal glucose homeostasis after food intake requires the maintenance of the closely coordinated effects of insulin in conjunction with other hormones to stimulate glucose uptake by peripheral tissues, stimulate glucose uptake by the liver, suppress hepatic glucose production, inhibit lipolysis and reduce FFA concentration. The five phases of glucose homeostasis are described below and summarised in Table 7.1 [4].

Table 7.1 Phases of glucose homeostasis

	Phase 1	Phase 2	Phase 3	Phase 4	Phase 5
Origin of blood glucose	Exogenous	Glycogen predominantly	Gluconeogenesis (hepatic) glycogen	Gluconeogenesis (hepatic and renal)	Gluconeogenesis (hepatic and renal)
Time interval	2-4 h	4-16 h	16-48 h	2-5 Days	>5 days
Tissues utilising	All	All except liver	All except liver	Brain, RBCs, renal medulla	Brain at diminished rates
Glucose		Muscle and adipose tissue at reduced rates	Muscle and adipose tissue at reduced rates		
Major fuel for brain	Glucose	Glucose	Glucose	Glucose + ketone bodies	Glucose + ketone bodies

1. Absorptive (Well-fed State)
   (a) Occurs within 2-4 hours of food intake
   (b) Maintenance of euglycemia is dependent on five processes that occur in a simultaneous and coordinated fashion:
   (c) Plasma levels of glucose, amino acids and triacylglycerols increase
   (d) Insulin secretion is stimulated in response to hyperglycaemia
   (e) Hyperinsulinemia along with hyperglycaemia augments glucose uptake by splanchnic (liver and gut) and peripheral tissues (primarily muscle and adipose tissues)
   (f) Hepatic glucose production is further suppressed by insulin and hyperglycemia
   (g) Lipolysis in adipocytes is inhibited by insulin, and the subsequent reduction in FFA further augments muscle glucose uptake and facilitates the suppression of glucose production
2. Early Fasting
   (a) Occurs 4-16 hours after food intake
   (b) Glucose homeostasis shifts from energy storage to production with an accompanying decrease in insulin levels and a rise in glucagon levels that typically occur after an overnight fast.
   (c) This phase predominantly involves glycogenolysis
   (d) Maintains blood glucose levels for 16-18 hours
3. Fasting (Gluconeogenic)
   (a) Occurs 16-48 hours after food intake
   (b) Gluconeogenesis is the predominant pathway to occur in this phase
   (c) The required ATP for gluconeogenesis is provided by fatty acid oxidation of triacylglycerol in this phase
4. Prolonged Fasting or Starvation
   (a) Occurs 2-5 days after food intake
   (b) Decreased gluconeogenesis
   (c) There is splitting of triacylglycerol into fatty acids, which undergo beta oxidation to produce acetylcoA, which subsequently forms ketone bodies
   (d) The presence of ketone bodies prevents muscle proteolysis
5. Prolonged Starvation
   (a) Occurs after more than 5 days of fasting
   (b) Decreased fatty acid oxidation along with decreased ketone body synthesis
   (c) Lysis of muscle proteins: cachexia

From an evolutionary perspective, there has been an adaptation of the physiological processes in humans for survival, even in prolonged periods of fasting. With progressive fasting, there occurs a switch of major fuel for the body's utilisation from glucose, derived from glycogenolysis and gluconeogenesis, to fatty acids and ketone bodies termed the "flipping of the metabolic switch". The hormonal changes mediating these changes include suppression of insulin along with raised concentrations of counterregulatory hormones involving glucagon, cortisol, growth hormone and cortisol.

Depending on the individual's energy expenditure/exercise during the fast, liver glycogen content, the metabolic switch typically occurs in the third phase of fasting, between 12 and 36 hours after cessation of food consumption, and is characterised by the depletion of glycogen stores and accelerated lipolysis, which produces increased fatty acids and glycerol. Free fatty acids are then transported into hepatocytes and metabolised by β-oxidation to produce ketones, namely, beta-hydroxy butyrate, acetone and acetoacetate. These are transported into cells with high metabolic activity and metabolised to acetyl CoA, which then enters the TCA cycle to generate ATP. Hence they function as energy generating fuels, especially in the brain, during periods of prolonged fasting when there is limited glucose availability.

Fasting, initially a survival trait, has since been used as a religious and medical practise with improved nutrient availability for thousands of years. This cuts across geographical landscapes, religions and cultures, with a multitude of durations and formats. The potential benefits of fasting described in literature involve an improvement in insulin sensitivity, a decrease in inflammatory cytokines, an improvement in lipid profiles, weight loss, and a wide variety of other benefits. Case reports have been described utilising fasting for the management of both type 1 and type 2 diabetes. It becomes important, however, to balance out these potential benefits against the downside of extreme fasting and starvation, like nausea, vomiting, alopecia, motor neuropathy, hyperuricemia and urate nephropathy, deranged liver functions, metabolic acidosis and Wernicke encephalopathy.

Glucose Pathways in Health and Disease (Figs. 7.1 and 7.2)

Broadly, the various metabolic pathways can be grouped into four categories as follows [5]:

1. Glycolysis, fructose/galactose metabolism, the tricarboxylic acid (TCA) cycle and oxidative phosphorylation are pathways that release energy
2. Glycogenesis and lipid synthesis are pathways of energy storage
3. Gluconeogenesis, lipolysis, glycogenolysis and protein catabolism occur in states of starvation
4. Pentose phosphate pathway (HMP shunt), urea cycle and cholesterol synthesis are the other pathways

Metabolic pathways maintaining glucose homeostasis (Table 7.2) can be generally categorised as "fed-state" or "fasting-state" based on whether they build energy reserves or release energy for later use.

Glycolysis (Embden-Meyerhof-Parnas Pathway)

Being one of the major metabolic pathways for glucose metabolism, it operates in all the cells of the body. Glycolysis, is unique in that it functions both aerobically and anaerobically. As the name suggests, in glycolysis, there is lysis of the 6-carbon glucose into two 3-carbon compounds: dihydoxyacetone phosphate and glyceraldehyde-3-phosphate. This glyceraldehyde-3-phosphate is then further catalyzed or converted via a series of steps to pyruvate. The fate of pyruvate further depends on the body's needs: In presence of oxygen, pyruvate is metabolised to acetyl CoA and further enters the Krebs cycle and the electron transport chain. In the absence of oxygen, however, it is converted to lactate via lactate

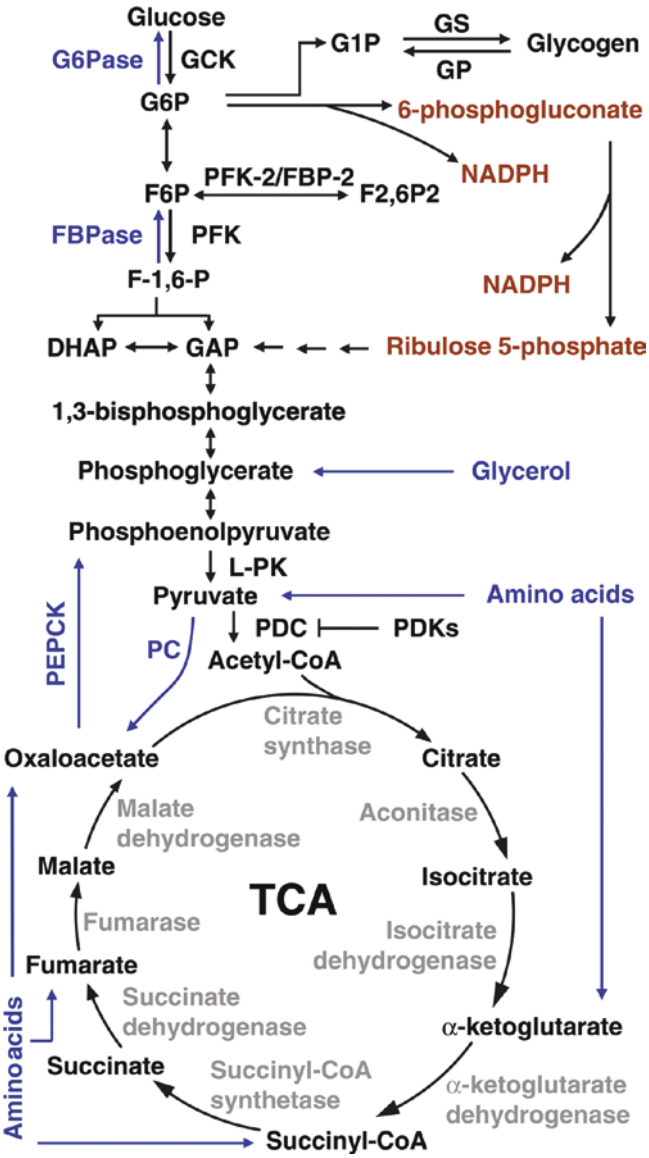

Fig. 7.2 Glucose metabolic pathways

Table 7.2 Metabolic processes in fasting and fed states

Fed state	Fasting state
Glycolysis	Glycogenolysis
Glycogenesis	Gluconeogenesis
Lipogenesis	Lipolysis
Fructose/galactose catabolism	Protein catabolism
	Ketone body metabolism

dehydrogenase. In terms of energetics, aerobic glycolysis leads to the generation of net 7 ATPs in comparison to anaerobic glycolysis which generates net 2 ATPs [6, 7].

Regulation of glycolysis: In the fed state, under the influence of insulin, glycolytic hormones are active due to the presence of insulin, while in the fasting state, enzymes are inactive due to the presence of glucagon.

Clinical Relevance

- In RBCs, due to the absence of mitochondria, anaerobic glycolysis occurs predominantly. Ten percent of glucose entering the RBCs is metabolised via the Rapaport Leubering cycle, where 1,3 BPG is converted to 2,3 BPG via bisphosphoglycerate mutase, which is then converted to 3 PG via phosphatase. No ATP is produced via this pathway, the significance of this pathway, however, lies in the fact that 2,3 BPG shifts the oxygen dissociation curve to the right and helps with oxygen unloading at the tissue level [6].

- In cancer cells, pyruvate kinase M2 (low catalytic activity) converts pyruvate to lactate, in contrast to pyruvate kinase M1, which functions in normal glycolysis. Hence, this consumption of oxygen by cancer cells leading to the generation of lactate is called aerobic glycolysis. This forms the basis of functional PET scanning, where cancer cells will take up all the glucose that is available. Warburg effect: Via Oto Warburg, in 1924, he stated that cancer cells use more glucose and convert it to lactate in the presence of oxygen. He, however, proposed that this was due to a defect in the mitochondrial respiratory chain, while it has now been seen that this effect is due to metabolic reprogramming.
- Inhibitors of glycolysis: arsenate inhibits glyceraldehyde 3 phosphate via decreased availability of inorganic phosphate. Fluoride inhibits the enzyme Enolase, the significance is that when blood is drawn for glucose estimation, the presence of fluoride inhibits glycolysis, preventing a fall in blood glucose levels post collection.

- Deficiency of enzymes of glycolysis leads to hemolysis, Pyruvate kinase deficiency is the second most common enzyme deficiency in humans and its absence leads to hemolysis. Similarly, aldolase An enzyme deficiency leads to hemolysis, while a muscle PFKI deficiency causes exercise intolerance.

Gluconeogenesis

The importance of gluconeogenesis lies during fasting. In the early stages of fasting, that is, from 4 to 16 hours, glycogenolysis predominates and maintains blood glucose levels for 16-18 hours. After 16-48 hours of fasting, gluconeogenesis predominates, which implies the synthesis of glucose from noncarbohydrate substrates. It occurs predominantly in the liver and kidney. The substrates for gluconeogenesis are predominantly alanine, lactate, glycerol and propionyl CoA [6].

- Lactate (Cori's cycle): In skeletal muscle, the glucose is converted to lactate, which in the liver is metabolised to glucose, and this glucose is then metabolised in the muscle.
- Alanine (Cahill cycle): The importance of this cycle occurs in starvation. Glucose in muscle is converted to pyruvate, which is transaminated to alanine, which then enters the liver; alanine is then converted to glucose.
- Glycerol: It is converted to glycerol-3-phosphate which is then converted to DHAP which is then metabolised to glucose.
- Propionyl CoA: It is converted to glucose via methymalonyl CoA and succinyl CoA, which act as intermediates.
- Regulation: In the well-fed state, glycolysis is active. In the fasting state, under the influence of glucagon, gluconeogenesis is switched on. Acetyl CoA is an allosteric activator of pyruvate carboxylase, one of the key enzymes of gluconeogenesis. Fructose- 2,6-bisphosphate is an allosteric inhibitor of fructose-1,6-bisphosphatase and an activator of PFK-1.

Glycogen Metabolism

Glycogen, the storage form of glucose in animals, is composed of glucose residues joined in straight chains by alpha 1,4 linkages and branched at intervals of 4-10 residues by alpha 1,6 linkages.

Glycogenesis

In a well-fed state, insulin stimulates glycogenesis. It occurs in the liver and muscles in the cytosol. The rate-limiting enzyme of glycogen synthesis is glycogen synthase. It occurs with the formation of UDG Glucose which functions as the active glucose donor. Glucose is converted to glucose-6-phosphate via hexokinase, a step common to both glycolysis

and glycogenesis. Glucose-6-phosphate is then converted to glucose-1-phosphate which donates the glucose to UTP, forming UDG Glucose. Glycogenin, a 37 kDa polypeptide with tyrosine residues, functions as the primer for glycogen synthesis. Glycogen synthase, via its alpha 1,4 action, helps to add glucose residues in a linear fashion. For the formation of branching points, alpha 1,4-alpha 1,6 glucan transferase is needed [6].

Glycogenolysis

In the early fasting stage, under the influence of glucagon, glycogenolysis occurs predominantly in the liver and the cytosol. The rate limiting enzyme here is glycogen phosphorylase, which releases glucose as glucose-1-phosphate. Following this, the debranching enzyme, which functions as alpha 1,4-1,4 glucan transferase and alpha 1,6 glucosidase, is produced. Glucose-1-phosphate is converted to glucose-6-phosphate, which is eventually converted to glucose in the liver [6].

Pentose Phosphate Pathway (PPP), Phosphogluconate Pathway or Hexose Monophosphate (HMP) Shunt

The pentose phosphate pathway is an alternative pathway for glucose metabolism, having a useful role in hydroxylation and anabolic reactions, lipid and steroid biosynthesis and in maintaining the integrity of RBC membranes. After the first step of glycolysis, the PPP branches to generate fructose 6-phosphate (F6P) and glyceraldehyde 3-phosphate (G3P) via oxidative and non-oxidative branches.

It is active in the liver, lactating mammary glands and adipose tissue, generating NADPH [reducing power required for synthesis of fatty acids, sterols, nucleotides and non-essential amino acids, cellular antioxidant defenses] and ribose 5-phosphate (R5P) [building block for nucleic acid synthesis] and is especially active during oxidative stress, e.g. this pathway may become more active in diabetes.

Studies have shown a role for the PPP in obesity-related insulin resistance, insulin secretion and chronic diabetic complications. Obesity-induced inflammation can lead to insulin resistance in the skeletal muscle or liver, resulting in systemic insulin resistance. Macrophages surrounding dead adipocytes cause obesity-induced inflammation and secrete pro-inflammatory cytokines, leading to local insulin resistance. Pro-inflammatory macrophages show enhanced glycolysis and PPP flux, which provide more energy and NADPH to trigger inflammatory responses, secrete pro-inflammatory cytokines and recruit more immune cells. The differential activity of the oxidative PPP in macrophages contributes to this functional discrepancy.

The deficiency of the enzyme glucose-6-phosphate dehydrogenase results in X-linked hemolytic anemia, which is common in persons of Mediterranean descent. Patients with G6PD deficiency show decreased insulin secretion. Thus, the PPP might serve as a promising target for modulating obesity-induced inflammation and insulin sensitivity in different tissues [8].

Glucose Transporters or SWEET Proteins

Glucose transporters (GLUT) are proteins coded by the SLC2 (solute carrier family 2) gene. These aid in the diffusion of substances across the concentration gradient. A total of 14 isoforms have been described, including GLUT1-12, 14 and GLUT 13/HMIT (H+/proton myo-inositol transporter) (Table 7.3) [9].

The proteins usually comprise about 500 amino acid residues with 12 transmembrane spanning alpha helices along with a single oligosaccharide attached at the N terminal. There is a large homology between the GLUT transporters, suggesting a similar process of glucose transport across different tissues. Almost all tissues depend on GLUT receptors for the uptake of glucose. The commonly known isoforms, their location and function are summarised in Table 7.3. GLUT4 is said to be the key insulin responsive form and is expressed in all insulin-sensitive tissues. Expression of some of these GLUT isoforms has been shown to be associated with a poor prognosis, e.g. GLUT and GLU14 in gastric adenocarcinomas.

Table 7.3 The location and substrate specificity of commonly known GLUT transporters

Isoform	Location	Substrate specificity
GLUT1	Placenta, muscle, adipose tissue, brain and endothelium, red blood cells	Glucose, galactose, dehydroacetic acid
GLUT2	Pancreatic beta cells, liver, small intestine and renal proximal tubule, hypothalamus	Glucose, fructose, galactose, glucosamine
GLUT3	neurons, small intestine, testes	Glucose, galactose, dehydroacetic acid
GLUT4	Skeletal muscle, cardiomyocytes, adipose tissue	Glucose, galactose, dehydroacetic acid
GLUT5	Small intestine, brain, muscle and adipose tissue, spermatozoa	Fructose
GLUT6	Brain and spleen	Glucose
GLUT7	Intestine and colon	Fructose, glucose
GLUT8	Testes, brain, fat, liver, spleen	Glucose, fructose
GLUT9	Kidney, liver, placenta, colon	Urate/gluose/fructose
GLUT10	Heart, lung	Glucose
GLUT11	Muscle, heart, placenta, kidney. pancreas, adipose tissue	Glucose
GLUT12	Insulin-sensitive tissues	Glucose/fructose
GLUT13/ HMIT	Brain	Myoionisitol
GLUT14	Testes	Like GLUT 3; it has 95% homology to GLUT 3

In addition to GLUT, specific glucose efflux transporters called the SWEET proteins that help to maintain blood glucose levels are equally important. Glucose efflux from the liver is cardinal in maintaining fasting glucose levels. SWEET1 is expressed in humans as a glucose uniporter and is expressed in the oviduct, epididymis, intestine and beta cell lines.

Organ Systems That Help Regulate Glucose Metabolism

Pancreas

The pancreas plays a critical role in maintaining normal glucose levels both in the fasting and postprandial state. five major hormones secreted by the pancreas help regulate serum glucose levels. Moreover, many of the currently available and upcoming pharmaco-therapeutic agents modulate these hormones in isolation or in combination. The four major cell types in the pancreatic islets of Langerhans that secrete these hormones include the beta cells that secrete insulin and amylin, the alpha cells that secrete glucagon, the delta cells that secrete somatostatin, and the PP cells that secrete pancreatic polypeptide (PPY). The understanding of these hormones is helpful from a clinical standpoint, wherein today the reversal of diabetes is possible through the restoration of pathways mediated by these hormones following significant weight loss [10].

Insulin

Insulin secretion is proportional to serum glucose values. The glucose enters the beta cell via GLUT 2, which in turn stimulates the insulin release via K-ATP dependent and independent channels. Postprandial insulin secretion occurs in two phases. The first phase is essentially the release of the preformed insulin, followed by a gradual release during the second phase. Following insulin secretion, glucose regulation occurs at several sites. These include reducing hepatic gluconeogenesis and glycogenolysis, enhancing glycogenesis in the liver and muscle, increasing glucose uptake in the adipose tissue and muscles and also increasing the expression of glucose transports like GLUT1 and GLUT4 in non-hepatic tissues.

Glucagon

Glucagon is a hormone secreted in response to hypoglycemia. Its secretion is activated by the generation of the activation of sodium and calcium ion action potentials stimulated by low blood glucose. It primarily acts on the liver by stimulating glycogenolysis and gluconeogenesis. It also reduces glycogenesis and glycolysis. Glucagon also enhances amino acid uptake in the liver, coupled with enhanced glycerol production by adipose tissue, thereby providing an adequate substrate for gluconeogenesis.

Somatostatin

Somatostatin is known to be produced by several organs, including the delta cells of the pancreas, the intestinal tract and even the central nervous system. Though it has no direct effect on glucose production, its release causes a potent paracrine local inhibitory effect on surrounding alpha and beta cells. The insulin and glucagon levels measured in the portal vein are significantly reduced following somatostatin infusion. The glucose stimulated release of somatostatin is mediated through the calcium channels.

Amylin

Amylin is stored in secretory granules and co-secreted with insulin by the beta cells in response to glucose, akin to insulin. However, it is secreted in a ten-fold lower molar ratio than insulin. Plasma amylin levels increase in the postprandial/postglucose administration and are directly proportional to body fat percentage. Amylin facilitates the inhibition of postprandial glucagon secretion and retards gastric emptying. It is also implicated in improving satiety. Amylin analouges have been used in the treatment of diabetes, but more recent molecules like cagrilinitide have shown to be very effective in the management of obesity [11].

Pancreatic Polypeptide

The pancreatic polypeptide is secreted by the F cells, which are also called the PP cells, and requires an intact vagus nerve for secretion. Like amylin, the pancreatic polypeptide increases following the ingestion of food in a dose-dependent manner. It reduces fatty acid levels and inhibits other pancreatic hormone secretion.

Liver

The liver is regarded as the key organ for glucose metabolism. The glucose uptake in the hepatocytes occurs with the help of GLUT-2 receptors. This glucose is further phosphorylated by the enzyme glucokinase to glucose-6-phosphate, which in turn is further directed to glycogenesis, the pentose phosphate pathway, or glycolysis. This helps the liver maintain glucose homeostasis.

Following glucose intake and subsequent hyperglycaemia along with hyperinsulinemia, the liver homeostasis shifts from a fasting state to a state of storage. Both glycogenolysis and gluconeogenesis are temporarily halted for up to 6 hours, the former more than the latter.

Moreover, up to 90% of all the glucose in the circulation that is not derived from diet is produced by the liver. Following prolonged fasting, exercise or hypoglycemia, glycogenolysis sets in. Furthermore, the gluconeogenic enzymes, namely, phosphoenolpyruvate carboxykinase and glucose-6-phosphatase, are activated. These are promoted by glucagon, cortisol and the interleukin-6 family of cytokines and inhibited by insulin. Glucagon also facilitates the inhibi-

tion of hepatic glucose by the liver to further conserve the low amount of available glucose during these times. The skeletal muscle also facilitates the release of lactate, which can be shuttled back to the liver (Cori's cycle).

Kidney

After the liver, the kidney is regarded as the next key regulator of glucose in the body. It is responsible for the release of glucose into the circulation following gluconeogenesis, the uptake of glucose from the circulation and also reabsorption of the glucose from the glomerular filtrate. However, kidney is unable to produce glucose through glycogenolysis. Gluconeogenesis occurs in the renal cortex and is primarily regulated by insulin and adrenaline. The key substrates used for this are lactate, glutamine and glycerol. The renal medulla helps in glucose utilisation. Following an overnight fast, about 25% of the glucose released in the circulation is derived from the kidneys. Insulin facilitates renal glucose uptake, reduces renal gluconeogenesis and also decreases the available substrates for gluconeogenesis. On the contrary, adrenaline, stimulates renal gluconeogenesis and reduces renal glucose uptake. Glucagon has only been shown to act on the kidneys in animal studies.

Glucose reabsorption from the glomerular filtrate is also very important. With a normal glomerular filtration rate of 180 mL, approximately 160 g of glucose is reabsorbed in a normal individual. This is primarily mediated by the sodium glucose transporters (SGLT) present in the proximal renal tubule. Ninety percent of this is reabsorbed by the SGLT-type 2 receptor, which is present in the convoluted section of the proximal tubule, and the remaining 10% is absorbed by the SGLT-1 receptor, which is present in the straight section of the proximal tubule.

Role of the Hypothalamic Pituitary Axis

The regulation of food intake and energy homeostasis is regulated by the cross talk between the brain and the gastrointestinal system. Though several areas of the brain are responsible for this regulation, the key region is the hypothalamus, which in turn can regulate the autonomic nervous system (ANS). The ANS is helpful for the regulation of insulin and glucagon secretion and also the metabolic activity of the liver, muscle and adipose tissue [12]. This regulation is mediated through a direct effect on the autonomic nerves innervating the pancreas as well as indirectly by altering the catecholamines through the adrenal medulla. The feedback loop is completed by the signals received by the hypothalamus for the various hormones summarised in Fig. 7.3 [13].

The regulation through the hypothalamic pituitary adrenal axis is mediated by corticotrophin-releasing hormone (CRH) production, which further regulates adrenocorticotropic hormone (ACTH) and cortisol production. This has a major impact on glucose metabolism. Cortisol activates glycogen synthase as well as inhibits the phosphorylation of glucose, overall increasing the glycogen synthesis. Glucocorticoids also lead to lipolysis in the adipose tissue and proteolysis in the muscles, resulting in the release of glycerol and amino acids, respectively. These act as substrates for gluconeogenesis. Cortisol also inhibits the actions of insulin at the level of the liver and muscles and thereby stimulates gluconeogenesis at the liver. It also acts at the level of the beta cells to reduce the secretion of insulin. The regulation of the hypothalamus through the hypothalamic-pituitary-thyroid axis is also an important channel to modulate glucose homeostasis. T3 regulates the gene expression of enzymes responsible for glucose and fatty acid oxidation, glycolysis and cholesterol biosynthesis. T3 also directly stimulates basal and insulin medicated glucose uptake in the skeletal muscle through enhanced GLUT-4 expression.

Human Growth Hormone secretion is regulated through the hypothalamic hormones, namely, the Growth hormone–releasing hormone (GHRH) and somatostatin, which also antagonise insulin action, increase the fasting hepatic glucose output and decrease the peripheral glucose utilisation. GnRH-mediated estrogen regulation, is another way the hypothalamus is able to regulate glucose homeostasis. Estrogen enhances insulin action and increases the peripheral expression of glucose transporters. Similarly, testosterone in hypogonadal men helps to reduce insulin levels and improve the capacity of the muscle to enhance glucose uptake.

Gut Regulation of Glucose: Role of Incretin Hormones

The exaggerated insulin release following oral glucose ingestion as compared to intravenous glucose infusion, known as the incretin effect, suggested the vital role of the incretin hormones glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP), in the regulation of blood glucose. While GIP is more potent, GLP-1 is secreted in greater quantities and has gained more recognition in humans [14].

GIP, secreted by the K cells in the duodenum, helps in the stimulation of insulin release and regulates fat metabolism. GLP-1, which is secreted by the L cells in the ileum and colon, also helps in inhibiting glucagon secretion and delaying gastric emptying. The regulation of glucose by GLP-1 is only mediated in the postprandial state in a glucose-dependent manner and not when glucose levels are in the normal or hypoglycaemic range. While GLP-1 blunts the glucagon response in the postprandial state, it does not alter its secretion during an episode of hypoglycemia. The impact of GLP-1 on gastric emptying and gastric acid secretion, is driven by its central actions mediated by the vagus nerve. The plasma half-life of GLP-1 is about 2 minutes, as it is rapidly degraded by the enzyme dipeptidyl peptidase-IV

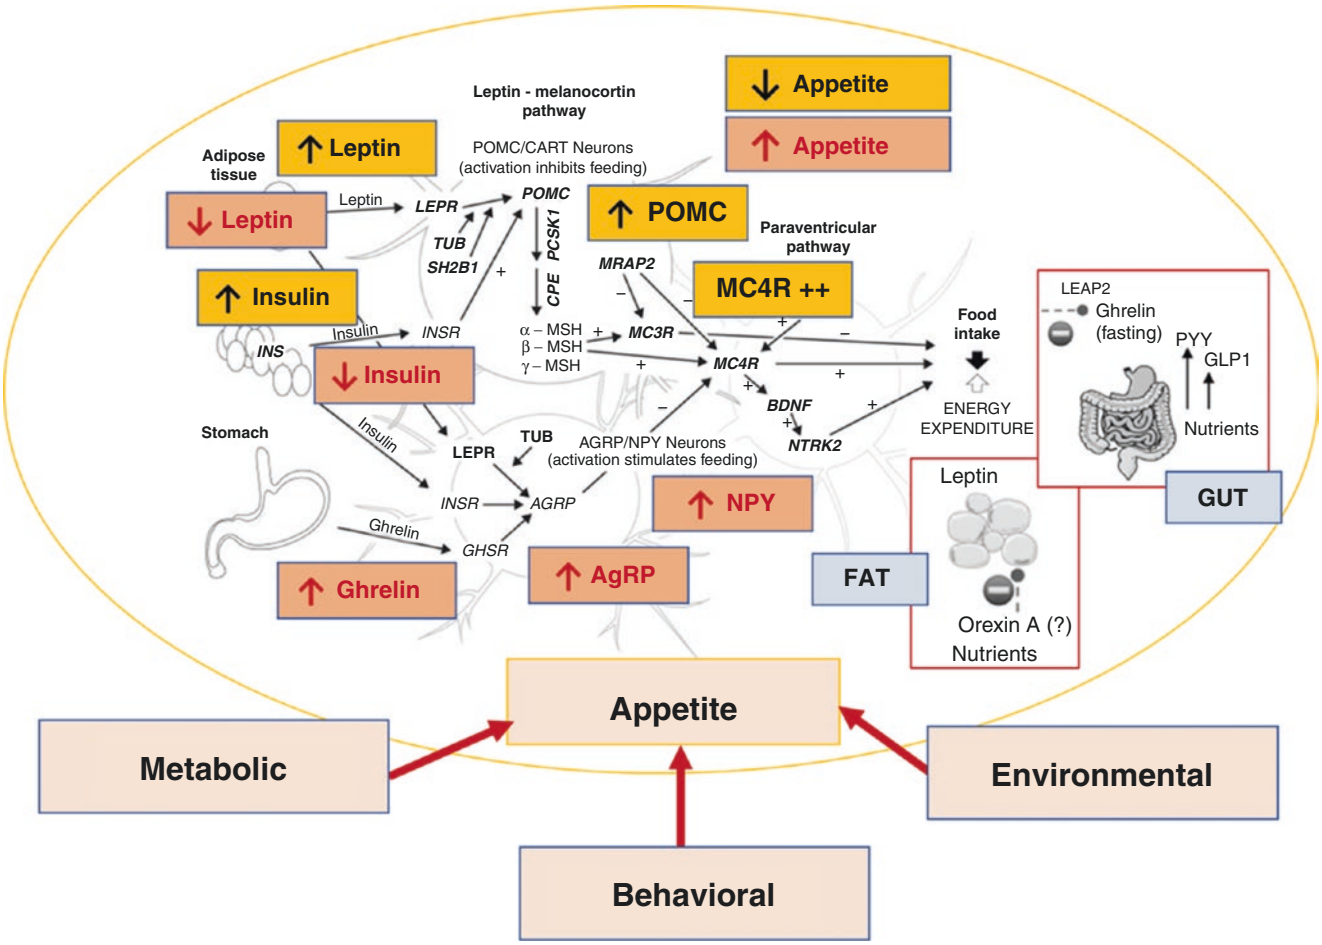

Fig. 7.3 Pathways responsible for the regulation of appetite in the hypothalamus, *AgRP* agouti-related protein; *PYY* peptide YY; *MC4R* melanocortin 4 receptor; *POMC* proopiomelanocortin; *LEAP2* liver-expressed antimicrobial peptide 2; *GLP1* glucagon-like peptide-1

(DPP-IV). GLP-1 levels are significantly reduced in people with prediabetes and established type 2 diabetes mellitus. GLP-1 analogues and DPP4 inhibitors have been used for the management of obesity and diabetes, in clinical practice. There is also an emerging interest in studying the role of GLP-1 in the preservation of beta cell function and proliferation.

Gall Bladder: The New Metabolic Orchestrator

More recently, the gall bladder has been identified as an important regulator of metabolic parameters. This initially emerged from data in patients after cholecystectomy, wherein it was found that the odds ratio of having type 2 diabetes after cholecystectomy increased several fold as compared to those not undergoing cholecystectomy. Though the long-known function of the gall bladder is to store, concentrate and release bile into the gut, more recently it has been described as an endocrine organ. The intermittent release of bile acids and FGF-19 into the circulation through the bile has been shown to have a positive impact on the metabolic profile of a given individual. The loss of this function following cholecystectomy has been implicated in the metabolic disturbances in these patients. FGF-19 is secreted from the gall bladder mucosa into the bile and helps to reduce serum triglycerides, cholesterol and promote glycogen synthesis. FGF-19 has also been shown to suppress insulin-induced fatty acid synthesis in the liver. Large pulses of bile acids in the postprandial state help to increase GLP-1 mediated insulin secretion, reduce gluconeogenesis through FGF receptor 4 (FGFR4) and increase glycogenesis and reduce glycogenolysis through the Farnesoid-X-Receptor (FXR). Though this is still an active area of research, this may have implications for monitoring individuals post cholecystectomy.

Key Summary Points

1. Glucose homeostasis with the interplay of various hormones is imperative to maintain blood glucose levels in a narrow "normal" range.
2. The five phases of glucose homeostasis reflect the different fed and fasting states, and the consequent change in the metabolic pathways helps the human body to adapt to these states.
3. The main carbohydrate pathways for glucose homeostasis are as follows:
   (a) Carbohydrate digestion (in the intestine)
   (b) Fructose metabolism (in the liver)
   (c) Galactose metabolism (in the liver)
   (d) Glucose oxidation via glycolysis (in the cytoplasm), oxidative decarboxylation reaction (in the mitochondria), citric acid cycle (in the mitochondria) and the electron transport chain (ETC) (in the mitochondrial intermembrane space)
   (e) Glycogenesis (in the liver and skeletal muscle)
   (f) Glycogenolysis (in the liver, skeletal muscle and kidney)
   (g) Pentose phosphate pathway (in the liver, adipose tissue, adrenal cortex, testis, milk glands, phagocyte cells and red blood cells (RBCs))
   (h) Gluconeogenesis (in the liver, kidney, brain, testes and erythrocytes)
4. The transport of glucose across cell membranes is carried out by a family of structurally related proteins known as glucose transporters. Glucose transporters broadly have been classified into three types: GLUTs, SGLTs and the recently discovered, SWEET transporters.
5. Several organ systems play an important role in glucose metabolism. These include the pancreas, liver, kidney, brain, hypothalamus and gastrointestinal tract. Gall bladder is newly added to this list. The understanding of these physiological processes improves the clinician's understanding in diseased states as well as helps to explore novel therapeutic targets to manage disorders of glucose homeostasis.

Multiple-Choice Questions

1. With reference to the regulation of the internal environment, the term "homeostasis" was coined by
   (a) **Walter B. Cannon**
   (b) Claude Bernard
   (c) Linus Pauling
   (d) Joseph Barcroft
2. The molecule at the centre of various metabolic pathways of glucose homeostasis is
   (a) Glucose
   (b) Fructose-6-phosphate
   (c) **Glucose-6-phosphate**
   (d) Ribose-5-phosphate
3. In which phase of glucose homeostasis, the ketone bodies may become the major fuel for the brain?
   (a) Phase 7
   (b) **Phase 5**
   (c) Phase 3
   (d) Phase 1
4. Which of the following is a key metabolic process in the "fed state"?
   (a) Glycogenolysis
   (b) Lipolysis
   (c) **Glycolysis**
   (d) Gluconeogenesis
5. Deficiency of the enzyme glucose-6-phosphate dehydrogenase results in X-linked hemolytic anemia. These patients with G6PD deficiency may show which of the following abnormalities affecting homeostasis?
   (a) **Decreased insulin secretion**
   (b) Decreased ketone body formation
   (c) Decreased lipolysis
   (d) Decreased protein catabolism
6. All of the following Glucose transporters help in the transfer of glucose, except
   (a) GLUT 11
   (b) GLUT 12
   (c) **GLUT 13**
   (d) GLUT 14
7. All are true about SWEET proteins, except
   (a) **SWEET1 is not expressed in humans**.
   (b) It is a glucose uniporter.
   (c) It is expressed in the oviduct, epididymis and intestine.
   (d) Aids in glucose efflux

8. All of the following hormones are secreted by the pancreas, except
   (a) Amylin
   (b) Pancreatic polypeptide

Abbreviations

Anti-GAD	Antibodies against glutamic acid decarboxylase
Anti-IA2	Anti-tyrosine
CRTAM	Class I restricted T cell-associated molecule
CTLA-4	Cytotoxic T-lymphocyte antigen
CTSL	Cathepsin-L lysosomal protease
IA2	Insulinoma antigen 2
ICOS	Inducible gene costimulatory molecule
IFIH1	Induced interferon with dominion 1 helicase C
IFN-δ	Interferon gamma
IL2RA	Interleukin 2 receptor alpha chain
ISGs	Interferon-stimulated genes
MHC	Major histocompatibility complex
NKT	Natural killer lymphocyte-type
NOD	Nonobese diabetic mouse models
PTPN22	Protein tyrosine phosphatase, non-receptor type 22
T1D	Type 1 diabetes
TCR	Receptor for T lymphocyte antigen
WHO	World Health Organization
ZnT8	Zinc cation transporter

Introduction

Type 1 diabetes (T1D) is a chronic disease measured by immunity with a silent period that lasts for a varied time before clinically manifesting, characterized by selective loss of insulin-producing cells in the pancreatic islets of genetically susceptible individuals. It is known that the pathogenesis of this disease occurs in stages, with variations among individuals who have different genetic susceptibilities. The environmental factors may come into play as early as during gestation and would continue through early childhood. Immune dysregulation leads to beta cell destruction long before classical autoantibodies are detected. The C-peptide response is diminished at least 2 years before disease diagnosis [1]. In the last 10 years, new knowledge has been added to both the pathogenesis and treatment of this disease. The search is ongoing for new tools that can identify the earliest stages of autoimmune activation in type 1 diabetes. A better understanding of the physiopathology of this disease can change the approach to treatment and prevention.

Etiopathogenesis of Type 1 Diabetes

There is evidence that type 1 diabetes is considered an organ-specific autoimmune disease in which genetic factors (such as a strong association with HLA haplotypes and genetic linkage with immune system genes), immunological factors (such as specificity for beta cells and the presence of antigen-specific T cells), environmental factors (such as age at onset), and gut microbiota participate. It is also known that type 1 diabetes onset is triggered by an inappropriate activation of both the innate and adaptive immune systems, which causes a cascade that results in pancreatic islet destruction. Invariant natural killer T (NKT) cells interact with both systems and serve as a junction between them. Since they function through the production of cytokines, it has been suggested that they would be intrinsically involved in the disease. Figure 8.1 shows the pathogenesis of type 1 diabetes. The upper portion shows the various stages, as described by Eisenbarth [1]. Stage 1 involves genetic susceptibility. In stage II, an environmental factor triggers the immune process. During stage III, beta cell antibodies and active self-autoimmunity are present. In stage IV, metabolic abnormalities appear, leading to the symptoms manifested in stage V. Finally, in stage VI, insulin dependency results. The lower portion of the figure shows the participation of $CD4^+$, $CD8^+$, and NKT cells in the onset of T1D.

The role of NKT cells in the physiopathology of type 1 diabetes will be discussed below.

Genetic Factors

The family histories observed in epidemiological studies have sustained the search for genetic causes of T1D. The major histocompatibility complex (MHC) holds a unique position as the link that unites clinical, immunological, and genetic medicine; many diseases, including T1D, have been associated with genes located in the MHC. The most important genes are coded for the group of leukocyte antigens (HLA), a family of surface proteins essential for immunological function. HLA genes present a great variety that has given rise to diversity in immune response and susceptibility to various diseases. Overexpression of HLA molecules is considered a principal characteristic of type 1 diabetes pathogenesis and earmarks a chronic inflammatory state.

The HLA molecules associated with T1D are class II and are coded in the short arm of chromosome 6p21 (IDDM1) [2, 3]; they are responsible for the selection in the thymus of the repertory of T cells and participate directly in the presentation of antigens in the T CD4+ cells. The genetic region of class II HLA contains alleles DP, DQ, and DR, which in turn are divided into subregions.

The genes of the HLA system are the most important in conferring protection or susceptibility for type 1 diabetes, and it is believed they contribute to between 30% and 50% of the risk in the development of the disease. There are two combinations of HLA genes (or haplotypes): HLADR3-DQ2/DR4-DQ8 have a 20 times greater risk of developing type 1 diabetes compared with the general population and are present in 90% of the children with type 1 diabetes. A third protector haplotype, DR15-DQ6, is found in less than 1% of children with T1D and 20% of the general population. The genotype that combines the two susceptibility haplotypes (DR4-DQ8/DR3-DQ2) increases the risk of contracting the disease and is most frequent in children that present at an

early age [4]. It has been suggested that, in the presence of these haplotypes, the first signs of beta-cell autoimmunity might appear as early as during the first year of life [5]. Likewise, protection alleles have been reported in the Caucasian population as being DRB1-DQB1 DRB1*1602-DQB1*0602, DRB1*07-DQB1*0303, DRB1*13-DQB1*0603, and DRB1*14-DQB1*0503 [6]. First-degree relatives with positive antibodies but protector alleles delay or nullify their debut, which might indicate that the protector effect exerted by these genes occurs after the immunological process has begun.

On the other hand, the DIAMOND Project of the World Health Organization (WHO) tested the hypothesis that the variation in the expression of some risk genes for type 1 diabetes influenced the incidence of the disease according to the participating country (mainly alleles DQA1 and DQB1 with sequence codes for arginine in position 52 of the alpha chain for DQ and another amino acid apart from aspartic acid in position 57 in the beta chain of DQ, respectively). Mexico was included among the countries reporting a low incidence at the time of the study, being that DQA1*0301 was the only allele consistently associated with type 1 diabetes [7].

In the Mexican-American population, DRB1*0302 is a risk allele, while the protector is DRB1*1402. In contrast, in Mexican Mestizos, the protection haplotype is DR5/DQ6 (DRB1*0501, DQA1*0102, DQB1*0602), and for risk, it is DR4/DQ8 (DRB1*0405, DQA1*0301, DQB1*0302) [8–10]. However, the fact that 38% of the population has DR3 or DR4 indicates that there must be other factors. Effectively, it has been observed that 95% of the DR4 that have allele DQB1*0302 have diabetes, while the DR4/DQB1*0301 do not. These data suggest that HLA DQ molecules are more important in susceptibility to diabetes, and the association with DR is due to the linkage disequilibrium (association between alleles) that exists between HLA DR and HLA DQ genes [11, 12].

In addition, evidence of the participation of class II HLA in physiopathology has been observed in the murine model, since these molecules participate in the tri-molecular complex that involves a peptide and the T cell receptor of autoreactive cells that escape from the thymus. One of the peptides recognized is the I-Ag-7 molecule (part of the insulin B chain) [13]. This molecule may be involved in epigenetic alterations in Tregs of CD4+ T cells in humans [14].

Nevertheless, even when the association of HLA alleles and haplotypes is strong, these loci represent less than 50% of the genetic contribution to susceptibility to the disease; this is due to the fact that the alleles are not totally penetrating, implying that not all who have inherited them develop the disease. This has pushed T1D research to new immunological and genetic horizons, such as nonclassical HLA proteins including HLA-E, HLA-F, and HLA-G [15].

The other 50% of susceptibility to developing type 1 diabetes is given by non-HLA genes. Genomic association studies have identified around 40 non-HLA polymorphisms and other candidate loci in population studies. One of the most important is a polymorphism in the region of the insulin promotor gene, in chromosome 11p15.5 (locus IDDM2, polymorphism that consists in the number of tandem repetitions: VNTR) [16–19]. The insulin gene is transcribed and translated into the thymus and regulates glucose metabolism through insulin tolerance.

Many other susceptibility loci have been proposed after genome scanning (IDDM3-15). Another of the non-HLA genes that has been associated with T1D is the gene located in chromosome 1p13: protein tyrosine phosphatase, non-receptor type 22 (PTPN22). PTPN22 codes a specific lymphocyte phosphatase that inhibits T cell activity; the variant that changes arginine for tryptophan in position 620 alters the B and T cell response, which is accompanied by a reduction in T cell inhibition, promoting multi-organic autoimmunity, but the specific genes responsible have not yet been identified [20–22].

The genetic evidence for the participation of peripheral B cell compartments and production of cytokines (IL-10) was measured by flow cytometry by Thompson et al., who did not find evidence of changes in IL-10 production through in vitro stimulation with IL-21, suggesting that the pathogenetic role of the B cells is limited to the early stages of the disease in the isles of Langerhans and in the draining pancreatic lymph nodes [23].

IDDM12, located on chromosome 2q33, is one of the confirmed susceptibility loci for T1D [24]. This 300-kilobase region contains at least 3 genes: CD28, cytotoxic T-lymphocyte antigen (CTLA-4: cytotoxic T-lymphocyte associated protein A), and the inducible gene costimulatory molecule (ICOS). CTLA-4 codifies a molecule that is expressed on the surface of activated T cells, so polymorphism A49G has been associated with a reduction in the activation and proliferation of T cells. Genetic mapping has suggested that CTLA-4 or a closely related gene may be implicated in susceptibility to type 1 diabetes [25]. Other non-HLA risk genes include the interleukin 2 receptor alpha chain (IL2RA) as well as induced interferon with dominion 1 helicase C (IFIH1) [26, 27]. However, it was recently found that there was a significant association between the non-HLA risk genes and positivity for autoimmune antibodies. For example, PTPN22 associates with anti-GAD autoantibody, while ERBB3 associates with anti-IA-2 antibody ($p = 0.042$). By the same token, IL2RA and INS-VNTR associate with anti-insulin antibodies [28].

Other non-HLA genes not yet linked with specific antibody positivity include TFPR3, which mediates the release of intracellular calcium; BACH2, which coordinates the activation and repression of MAFK; and UBASH3A, which

promotes the accumulation of target receptors, including T cell receptors [29].

Taking all of this into account, it has been proposed that a combination of HLA and non-HLA genetic risk scores could prove to be a predictor of T1D risk [30]. This concept is further supported by a recent study which found an area under the curve for a non-HLA genetic risk score of 0.56, and for HLA, the area under the curve was 0.78 [31].

Immunological Factors

Very little has been definitively proven concerning the immunological factors involved in T1D. But as noted by Mannering et al., "an absence of evidence should not be confused with evidence of absence" [32]. To date, the known participation of the autoimmune component comes from various kinds of evidence. Insulitis is defined as an inflammation of the islets of Langerhans that results in the destruction of insulin-producing beta cells. Primary damage is due to an immune response mediated by cells, where Th1 cells (CD4+) collaborate during activation of specific in situ Tc cells (CD8+, associated with Th2) and are directed against the beta cell.

Thus, a chronic autoimmune response is manifested clinically with the destruction of 60–80% of pancreatic β insulin-producing cells [33]. The insulitis observed in the islets, as well as their surroundings, is constituted mainly of macrophages, B and T lymphocytes [34], and dendritic cells. Various studies have shown that inflammation appears in stages prior to the manifestation of tissue damage, and the destruction of beta cells activates the dendritic cells, which trigger the T cells in the pancreas [35].

Insulitis is diagnosed with the presence of at least 15 CD45+ cells per islet, in at least 3 islets. Long considered the pathologic characteristic of type 1 diabetes, it is usually, but not always, detected together with insulin-positive beta cells [36].

Although normally associated with younger patients, it has been suggested that this association is overestimated. Nevertheless, the presence of insulitis has been found in a majority of recent-onset type 1 diabetes patients [37]. However, the presence of insulitis has been shown to have an inverse correlation with time with diabetes, but not with age at onset [36]. Insulitis is probably the main cause of the destruction of T γδ lymphocytes even after 1 year of insulin treatment, which might explain part of the evolution of the disease [38].

It was recently found that islet-invading T cells differ from allogeneic T cells. There are even differences between type 1 diabetes patients and patients with allograft rejection. Those with diabetes show very low levels of cytokines and chemokines [37].

Interferon-stimulated genes (ISGs) are up-regulated by interferon to put cells into an anti-viral state. These include GBP1, TLR3, OAS1, EIF2AK2, HLA-E, IFI6, and STAT1. In type 1 diabetes and/or insulitis, the levels of these genes are increased. The presence of insulitis in the peri-islet area has been found to increase the levels of ISGs up to fivefold. However, the actual role of this overexpression in the progression of type 1 diabetes remains to be clarified [39].

Nevertheless, there are differences in youth and adult onset of T1D. In youth, there is a rapid loss of beta cells (75–85%), offset by a high potential for beta cell regeneration. The autoantibodies presented are mainly anti-insulin. In contrast, in adult-onset T1D, the loss of beta cells is more gradual (60–75%), but with a lower possibility for regeneration. There are more anti-GAD antibodies. The loss of C-peptide production varies greatly, and the reasons are not yet understood [40].

There is a direct correlation with the presence of T lymphocytes producing interferon gamma (IFN-δ) in the infiltrates located in the islets [41–45]. In fact, Gomez-Tourino et al. indicate that CD4 T cells can be considered to be characterized by the secretion of either IFN-δ or IL-17, as opposed to the secretion of IL-10 in healthy subjects. They support the important role that T1 (IFN-δ) and T17 (IL-17) play in the development of type 1 diabetes [46]. On the other hand, Mannering et al. not only showed that $CD4^+$ T cells are associated with HLA risk genotypes for T1D but also noted that clones of these T cells could recognize epitopes from the proinsulin C-peptide [32, 47].

A secondary effect is that specific autoantibodies are produced against auto-antigens of the pancreatic islets. The quantification of antibodies against auto-antigens has been useful in knowing the activity of the disease, determining its degree of progression, and contributing to the classification and prediction of the clinical status of the patients. From 60 to 80% of patients recently diagnosed present antibodies against glutamic acid decarboxylase (anti-GAD); a similar percentage (60–70%) show anti-tyrosine (anti-IA2) of zinc cation transporter (ZnT8), and only 30–50% have anti-insulin antibodies [48–50]. Nevertheless, the sensitivity and specificity of these autoantibodies vary with ethnicity and with follow-up time. However, as shown by Velluzzi et al., while positivity for 1 of these antibodies has a hazard ratio of 55.3, this drops to 14.5 with 2 positive antibodies and 3.0 for 3 [51].

In this regard, $CD8^+$ T cells have been suggested as the final cause of beta cell death. This has been supported by the presence of antigen-specific (GAD65) and HLA-restricted forms. $CD8^+$ T cells can be specific for various epitopes,

including insulin, insulinoma antigen 2 (IA 2), and GAD-65, and are pathogenic to beta cells [47]. Another study has suggested that $CD8^+$ T cells are autoreactive against such autoantigens as GAD65, ZnT8, and IA-2 [32, 38].

Environmental Factors

The rapid increase in the prevalence of type 1 diabetes, both in our country and worldwide, cannot be explained solely by the genetic component (in subjects with risk HLA haplotypes). Epigenetics is considered a nongenetic factor that possibly involves cells of both innate and adaptive immune responses, causing alterations in DNA methylation [52]. Epigenetic modifications are those that may be key regarding environmental risk factors and are probably in line with the hygiene hypothesis, which proposes that environmental exposure to microbes and other pathogens and their subproducts early in life induces immunological tolerance and a reduction in atopy and autoimmune diseases.

Recently Singh et al. noted the epigenetic changes in T1D, such as the interaction between DNA methylation and the modification of histones and variants in the helicase C domain 1 (IFIH1) gene [53].

Said changes between the genetic and environmental factors may lie in IFIH1, also known as MDA5, or the gene associated with differentiation of melanoma 5, detection of intracellular RNA of the picornavirus, a virus family that includes enterovirus. Detection of intracellular RNA leads to the activation of IFIH1 and the interferon route. It has been hypothesized that enteroviruses lead to the activation of IFIH1 in the β cells of the pancreas, elevated interferon levels, an increase in MHC class I expression, activating CD8 T cells, and the death of pancreatic β cells. The variants that result from less function of IFIH1 are protectors from type 1 diabetes [32].

Some other viruses [54] (*Coxsackie B*, *parotitis* [55], and rubella [56]) have been implicated as possible initiators, accelerators, or precipitators of the disease. The virus with the most demonstrated role is congenital rubella syndrome (children that acquire the infection in utero), where there is a 30% risk of presenting type 1 diabetes between 5 and 30 years later; however, this only explains a small proportion of the cases.

Many of the viruses use different mechanisms to ultimately lead to beta cell death. In the case of the rubella virus, it causes two-way reactions between the antigens and GAD, stimulating T lymphocyte activity and leading to beta cell infection. Cytomegalovirus also causes infection of beta cells but uses clonal activation of T cells to induce the recruitment of macrophages to the pancreas. However, in the case of mumps, there is increased expression of class I and II HLA in the beta cells, while rotavirus uses molecular imitation to infect the cells. In contrast, parvovirus does not infect beta cells, but rather uses macrophages to activate a ThI immune response while at the same time increasing Th2 responses [57].

It has been suggested that the inability to quickly cure viral infections could be part of the reason that beta cells, but not alpha cells, suffer apoptosis during the development and progression of type 1 diabetes [58]. The "bystander hypothesis" infers that the infection of pancreatic cells leads to the release of pro-inflammatory cytokines, which may explain the aforementioned cell death [59, 60]. However, the "molecular mimicry" mechanism attributed to rotavirus, among others, remains controversial, due to conflicting experimental results [59, 61].

In fact, infection may delay or avoid the development of type 1 diabetes through various mechanisms. Over time, there is a mutual adaptation. Infections which trigger immunoregulatory cytokines, such as IL-10, help control inflammation and also reinforce regulatory T cell activity while sparking NKT cell activity. On the other hand, activated macrophages and "tolerogenic" dendritic cells inhibit Th1 responses through a variety of mechanisms, such as rerouting the response to Th2, prompting T cells, and producing amino acid catabolizing enzymes. This activity limits tissue pathology [62].

Nevertheless, the enterovirus genus has been given special attention in regard to type 1 diabetes, thanks to advances in techniques to identify it. Enteroviruses are the most common viruses causing disease in humans, including foot-and-mouth disease and poliomyelitis. Most are extremely resistant to antibiotics, as well as to the chlorine usually added to treated water, meaning they can be transmitted by water, food, or soil. This genus includes the *Coxsackie* family, most notoriously *Coxsackie B*. One study found enteroviral genomes in the islets in pancreatic biopsies of patients with type 1 diabetes [63]. In the Diabetes Virus Detection Study (DiViD), enterovirus was found in all of the insulin-containing islets of pancreas samples of patients with recent-onset (<10 weeks) type 1 diabetes [64]. This supports the idea that viral infection precedes the appearance of diabetes. Several other studies in children have reached the same conclusions, such as VirDiab [65] and the study conducted by Laitinen et al. [66], both of which were carried out in children with type 1 diabetes against apparently healthy controls. With the growing body of evidence, it has been suggested that the enterovirus infection, and possibly other viral infections as well, may be the last straw and push an already unbalanced metabolism into a critical loss of beta cells [67]. Nevertheless, for the virus to have an effect, it has

been suggested that a second factor should also be present, such as a genetic or epigenetic predisposition [68].

On the other hand, among the environmental risk factors studied is diet, especially during the lactation period, which can modulate intestinal microbiota and is among the mechanisms that influence type 1 diabetes. Various studies have considered early exposure to cow's milk and highly hydrolyzed casein formula as the trigger for autoimmunity in some genetically susceptible individuals [69–72]. However, studies of the association between vitamin D, another suspected factor, and the development of type 1 diabetes remain controversial [73, 74]. Nevertheless, a recent study has found a significant inverse relationship between vitamin D and C-reactive protein, as well as with various cytokines, including IFN-γ, TNF-α, IL-6, IL-1β, IL-4, and IL-10 [75].

Microbiota

The development of intestinal microbiota is influenced by many factors, including diet, lifestyle, use of antibiotics, type of birth (natural or cesarian), and breastfeeding. It is known that a balance in the intestinal microbiota is fundamental for a wide variety of physiological mechanisms, including the function of the immune system. It has been suggested that an imbalance in the intestinal microbiome, called dysbiosis, is related to the pathogenesis of type 1 diabetes.

In genetically susceptible subjects, the intestinal microbiota plays a decisive role in the maturity of the immune system. Intestinal dysbiosis can interrupt the integrity of the intestinal barrier, allowing the unregulated passage of antigens that escape from antigen-presenting cells (APC), bringing deregulation of the immune response, including the innate and adaptive immune systems, resulting in the destruction of beta cells and the appearance of T1D [76]; therefore, immune maturity mediated by intestinal microbiomes during the first 3 years of life is fundamental to prevent the development of disease [77]. It was recently reported that high levels of *Firmicutes* confer 7.3 (CI: 2.2–23.5) times more risk of type 1 diabetes, while a higher number of *Bifidobacterium* in the intestine was a protector factor (1.03, CI: 1.01–1.05) [78].

In light of these facts, several recent studies have examined the microbiome profiles of healthy individuals compared with those with T1D. One such study, conducted in Spain, found significant differences between *Bifidobacterium, Lactobacillus*, and *Clostridium.* Patients had higher levels of *Clostridium* and lower levels of *Bifidobacterium* than controls, suggesting a relationship with glycemic levels. In addition, they found that the quality of the bacteria was lower in T1D children than in healthy controls [79]. This agreed with a later study, also in Spain, which found higher *Clostridium*, *Bacteroides*, and *Vellionella* and lower *Bifidobacterium* and *Lactobacillus* in T1D patients [80]. This contrasts with a study in the Netherlands, which found higher levels of *Bacteroidetes* and lower levels of *Clostridium* (IV and XIVa) in T1D, which was found to be age-specific (2.9 years) [81]. Another study in Mexican children in Sonora found that newly diagnosed cases of T1D showed high levels of *Bacteroides*, while healthy children had high levels of *Prevotella*. However, after 2 years of treatment, the levels of both bacteria had returned to those of the healthy children, suggesting not only the involvement of dietary changes but also the possibility of using therapies with microbiota to reduce the possibility of developing diabetes [82].

The development of gut microbiota is influenced by changes in diet, which may explain the influence of breastfeeding and the introduction of solid food [83].

Nevertheless, whereas children with T1D have high levels of *Bacteroidetes*, children with obesity have reduced levels but increased *Lactobacillus*, which indicates an important difference in the two conditions [82, 84]. However, this difference may depend on other factors, such as genetic risk, in addition to the gut microbiota profile. In a portion of the TEDDY study, which included American and European children, it was found that probiotic supplementation was associated with a decreased probability of islet autoimmunity, but only in those with the high-risk genotype (DR3/4). The absence of any benefit in other genotypes may indicate a therapeutic strategy for high-risk individuals [85]. However, more research will be needed before implementing this kind of treatment, including genetics, the effect of infections, and the influence of the many other factors that affect microbiota profiles.

COVID-19 Infection

Probable mechanisms for the adverse outcomes in patients with uncontrolled type 1 diabetes secondary to COVID-19 include alteration of the innate and adaptive immune response (due to elevation in TH1, Th2, and Th17 and reduced Tregs), chronic inflammation (insulin resistance and elevated cytokines), endothelial dysfunction (activation of pro-inflammatory cytokines and the cascade of coagulation due to the release of pro-coagulant molecules), oxidative stress (overproduction of superoxide), and the deregulation of the expression of angiotensin II converter enzyme on β cells [86]. In addition to its participation in viral transmission, it has been suggested that the angiotensin II converter enzyme receptor may also contribute to the outcome of new-onset type 1 diabetes with secondary ketoacidosis [87]. It has been noted that COVID-19 reduces ACE2, leading to hypokalemia, as well as lung damage. The reduction in ACE2 also leads to increased angiotensin II levels, which in turn may alter glucose metabolism [88]. However, as noted by

Francisco Rubin, while type 1 diabetes poses a risk of developing COVID-19, the latter is also a trigger for new-onset T1D [89].

The Role of NKT Cells in the Physiopathology of Type 1 Diabetes

Finally, the participation of the autoimmune response in type 1 diabetes is due to an alteration in the regulatory mechanisms of acquired autoimmunity, which corresponds to the expansion and/or function of populations of regulatory T lymphocytes.

The interaction of the innate and adaptive immune systems is definitive in the genesis of the disease. Immune system responses are complex and have evolved to protect multicellular organisms from aggressors; evolutionary pressure has specialized the effecting functions that may also damage the organism's tissue. The immune system specialized in two arms: the innate, capable of mounting nonspecific responses quickly, and the adaptive, capable of promoting longer-lasting, specific responses. Evolution has given rise to specialized cells to carry out these functions. There are some cells that have mixed abilities, that is, both innate and adaptive. This cellular group may be key to understanding the physiopathology of various autoimmune diseases, including T1D. They have recently been linked to type 2 diabetes as well [90]. They share functions and cellular surface markers in both arms. In addition, their evolutionary permanence among species makes them an important link in the homeostatic regulation of the immune system.

To date, the regulatory cell population has not been accurately identified, but there are various candidates, including T lymphocytes CD4+CD25+ and natural killer lymphocyte-type (NKT) cells. NKT cells were identified in 1987 in mice [91], and later their counterpart was described in humans [92]. They are a population of lymphocytes that express the receptor for T lymphocyte antigen (TCR), as well as the common marker of NK cells (NK 1.1 for mice and CD161 in humans). Said heterogeneous population can be $CD4^{+}$, or $CD4^{-}CD8^{-}$ (double negatives), or even $CD8^{+}$; these express a repertoire of conserved TCR [93], in humans made up of variable regions Vα24 and Vβ11. Unlike most T cells, NKT cells recognize lipids in the presence of CD1d molecules. They respond to antigens presented in the context of CD1d molecules, and their important regulatory function is mediated by the secretion of cytokines: INF-δ or IL-4 [94]. NKT cells are found in significant numbers at the site of inflammation and may be a marker of diabetes risk. The frequency of NKT cells is associated with the relative frequency of specific tolerogenic dendritic cell subsets. It appears that NKT cells regulate diabetes, then, by influencing the frequency and possibly the function of dendritic cell subsets, as suggested by Naumov et al. in their work with nonobese diabetic (NOD) mouse models [95]. In addition to playing a key role against bacteria, viruses, and parasites, they are involved in the body's defense against tumors, as well as immune regulation.

In terms of autoimmunity and inflammation, the main results come from the prevention of diabetes in NOD mice [96]. Various studies show a defect in the number and function of NKT cells in these mice, so the disease may be reduced through the adoptive transfer of populations rich in NKT cells [97–100].

The numerical and functional deficiency of NKT cells (detected in the thymus and spleen of NOD mice at 3 weeks of age) mediates the pathogenesis of type 1 diabetes, but the phase of development of T cells in which this deficiency occurs is still unknown. Wagner et al. propose that conventional T cells and doubly negative NKT have a common lineage and that this lineage in the development of the thymus of NOD mice is defective [101]. Some evidence suggests that a deficiency in NKT cells may be coded by risk genes IDD9 and IDD6 (locus Idd9.1, Idd6, Nkt1, and NKt2) for the disease [102–104].

In the last 10 years, studies in humans have documented a decrease in the number and production capability of IL-4 [105] of NKT cells in patients with T1D, while others have described an increase in the frequency of these cells [106–108].

On the other hand, both the frequency of NKT and the production of IL-4 are maintained during the course of type 1 diabetes. Recently, in Colombian patients, upon comparing a healthy control group with type 1 and type 2 diabetes and autoimmune thyroid alterations, no differences were found between the group with type 1 diabetes and healthy controls, but the levels of NKT cells were found to be elevated in type 2 diabetes [109].

The discrepancy in the data seems to come from the type of population selected for the study, as well as the status of the patient in relation to the natural history of the disease, or the subpopulation of NKT cells quantified in those studies since it has recently been suggested that the subset of CD4+ NKT cells may be activated in the prevention of autoimmunity while the subset of double negative NKT (CD4− CD8−) may be pathogenic; to prove this hypothesis, a new monoclonal antibody (6B11) was used to identify the subpopulations of NKT and thus evaluate the individuals at risk and with type 1 diabetes. The results showed an increase and expansion of double negative NKT cells ($CD4^{-}CD8^{-}$) in patients at risk [110].

In Mexico, the incidence of T1D has been on the rise [111]. It is imperative to search for mechanisms that explain the pathophysiology of this disease. To this end, our work group began working with children with type 1 diabetes and their first-degree relatives, where we found a reduction in

NKT cells, in addition to identifying in these cells two populations, a majority one that expressed an elevated quantity of invariant TCR (Vα24/Vβ11) and another minority population that expressed a low density of invariant TCR [112–114]. In this subpopulation, we found that they expressed the activation marker CRTAM (class I restricted T cell-associated molecule) [112]. CRTAM is also expressed on $CD4^+$ and $CD8^+$ T cells and is associated with the inflammatory process. Both CRTAM and CD69 are expressed in NKT cells with low invariant TCR, suggesting a state of activation [113]. In addition, a clear association has been observed between the expression of CRTAM and the production of IFN-γ in NKT cells in both healthy individuals and those with type 1 diabetes, which suggests that CRTAM can be used as a marker to identify the NKT cells [115].

On the other hand, in Class II MHC molecules, cathepsin-L lysosomal protease (CTSL) exercises broad influence on the immune system and has an important role in the expression of antigen-presenting cells. In CTSL nkt/nkt mice, it has been shown that the activity of the CTSL gene impacts the positive selection of CD4+ thymocytes and regulates the level of expression of various components of the extracellular matrix in lymphoid organs, influencing the number and composition of central and peripheral T lymphoids [116]. However, to date, the role of NKT cells and CTSL gene expression has not been clearly established in humans as a biomarker in the physiopathology of type 1 diabetes. In the belief that CTSL is involved in the promotion of the survival of cytotoxic T lymphocytes, it was recently shown that the percentage and absolute numbers of NKT cells correlate with low levels of expression of the CTSL gene in T1D in humans [117].

To date, the complete pathogenesis of type 1 diabetes remains unknown. It is known that the process of developing this disease involves a myriad of factors.

Genetically, 50% of susceptibility to T1D can be associated with HLA genes, and the other 50% with non-HLA genes, such as PTPN22, CTLA-4, and IFIH1. Research continues to identify new candidates for the latter. The alleles that indicate risk or protection from the development of T1D vary with country and ethnicity. In addition, the presence of two or more autoantigen antibodies is an important indicator of risk.

It is possible that the drastic increase in the prevalence of T1D is largely due to the implicated environmental factors. Technological advances have helped identify genetic overexpression in reaction insulitis. Dysbiosis is involved in alterations in the immune system and has been linked to the pathogenesis of T1D. Current studies are focusing on this important aspect of the epigenetics of the disease.

Finally, NKT cells are found in significant numbers at the site of inflammation and may be a marker of diabetes risk. Their participation in both innate and adaptive autoimmunity has made them a target of interest. The clinical value of this tool remains under investigation.

Multiple-Choice Questions

1. Type 1 diabetes
   (a) Is diagnosed only in children
   (b) Has a silent period before manifestation and diagnosis
   (c) Is diagnosed during pregnancy
   (d) Is often confused with type 2 diabetes
   (b) It has a silent period before manifestation and diagnosis
2. Which of the following is **not** a factor in the development of T1D?
   (a) Microbiota
   (b) Environmental factors
   (c) Immunological factors
   (d) Alterations in insulin secretion
   (d) Alterations in insulin secretion are a factor for type 2 diabetes
3. The genotype that combines the two susceptibility haplotypes (DR4-DQ8/DR3-DQ2)
   (a) increases the risk of T1D
   (b) has no effect on the disease
   (c) never appears in relatives
   (d) always appears in relatives
   (a) The genotype that combines the two susceptibility haplotypes (DR4-DQ8/DR3-DQ2) increases the risk of contracting the disease.
4. HLA genes
   (a) Are responsible for all of T1D genetic susceptibility
   (b) Are not responsible for T1D genetic susceptibility
   (c) Are partially responsible for T1D genetic susceptibility
   (d) Have no connection with T1D susceptibility
   (c) T1D is a multifactorial disease, where HLA genes have around 50% of the genetic responsibility for T1D susceptibility. The other 50% comes from non-HLA genes.
5. Which of the following non-HLA genes is associated with T1D?
   (a) PTPN22
   (b) TCF7L2
   (c) SCL16A11
   (d) DRB1-DQB1
   (a) PTPN22 associates with T1D.
6. Insulitis has been associated with
   (a) Age at disease onset
   (b) Elderly patients
   (c) Time with diabetes
   (d) Patient siblings

(c) Insulitis has an inverse correlation with time with diabetes.

7. All of the following have been associated with T1D except
   (a) rubella
   (b) Coxsackie B
   (c) enterovirus
   (d) parvovirus

   (d) Parvovirus has not been shown to have an association with human T1D.
8. In children with type 1 diabetes, NKT cell populations usually
   (a) Are increased
   (b) Are not present
   (c) Are reduced
   (d) Are hyperactive

   (c) NKT cells are usually reduced in frequency in children with T1D.
9. Which mechanisms are not associated with adverse outcomes of COVID-19 in patients with type 1 diabetes?
   (a) Elevation of TH1, TH2, and TH17
   (b) Chronic inflammation
   (c) Oxidative stress
   (d) Age at onset of T1D

   (d) To date, no clear association has been observed between the age at the onset of type 1 diabetes in children or adults.
10. The quantification of antibodies against autoantigens in T1D helps us know all of the following **except**
    (a) The activity of the disease
    (b) Time since the onset of the disease
    (c) The degree of progression of the disease
    (d) Prediction of the clinical status of disease

    (b) The quantification of antibodies against autoantigens has been useful in knowing the activity of the disease, determining its degree of progression, and contributing to the classification and prediction of the clinical status of the patients.

Glucose Homeostasis

In healthy individuals, normal glucose homeostasis in the basal or post-absorptive state is maintained, despite wide fluctuations in supply and demand, by means of a highly regulated and dynamic interaction between tissue sensitivity to insulin and insulin secretion. While maintenance of plasma and tissue glucose levels is required for vital functions of the brain, elevated glucose levels are deleterious or toxic to the vascular endothelium and a myriad of other vital tissues. Normally, in the postabsorptive state, most of the glucose utilization occurs in insulin-independent tissues like brain (50%) and splanchnic areas (25%) while the rest occurs in insulin-dependent tissues like muscles and adipose tissue. The insulin secretion during the next 2 h depends on the glucose disposal rate and the degree of suppression of hepatic glucose production (HGP). Additionally, insulin stimulates lipoprotein lipase in the vascular endothelium and promotes lipolysis and the removal of chylomicrons and VLDL from circulation. A derangement in the appropriate β-cell insulin secretion or insulin action at the level of muscle, liver, and adipose tissue foregoes the hyperglycemic states of prediabetic and diabetic states [1, 2].

Pathophysiology of Type 2 Diabetes

Individuals at risk of T2D are thought to inherit a genetic predisposition to insulin resistance [3, 4]. Chronic fuel excess is the chief pathogenic event that triggers T2D development in these genetically and/or epigenetically susceptible individuals [5]. In states of normal insulin sensitivity, HGP is suppressed by insulin. However, in the event of hepatic IR, gluconeogenesis continues during the basal state even when the fasting insulin level is high and leads to hyperglycemia [6]. During the fed state, suppression of HGP in response to insulin is impaired as well [7]. With peripheral tissue IR, post-meal glucose uptake ensues, and postprandial hyperglycemia sets in [7]. The current epidemic of obesity and physical inactivity [8] are IR states [9] that unmask the pancreatic β-cell defect when they fail to augment insulin secretion to offset the effects of IR [3, 10]. As long as the β-cells are able to enhance their insulin secretion to compensate for the impact of IR, glucose tolerance/euglycemia is maintained [11]. However, with time, β-cells become unable to compensate for the IR, and initially, the postprandial plasma glucose (PPG) levels and later the fasting plasma glucose (FPG) levels begin to rise, leading to overt diabetes. Individuals in the upper tertile of impaired glucose tolerance (IGT) are highly insulin-resistant and would have lost 80% of their β-cell function [10, 12].

In 1987, DeFronzo put forward the concept that T2D resulted from deficits in the pancreatic β-cell, muscle, and the liver, which were collectively referred to as the "Triumvirate" (see Fig. 9.1) [12, 13].

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_9

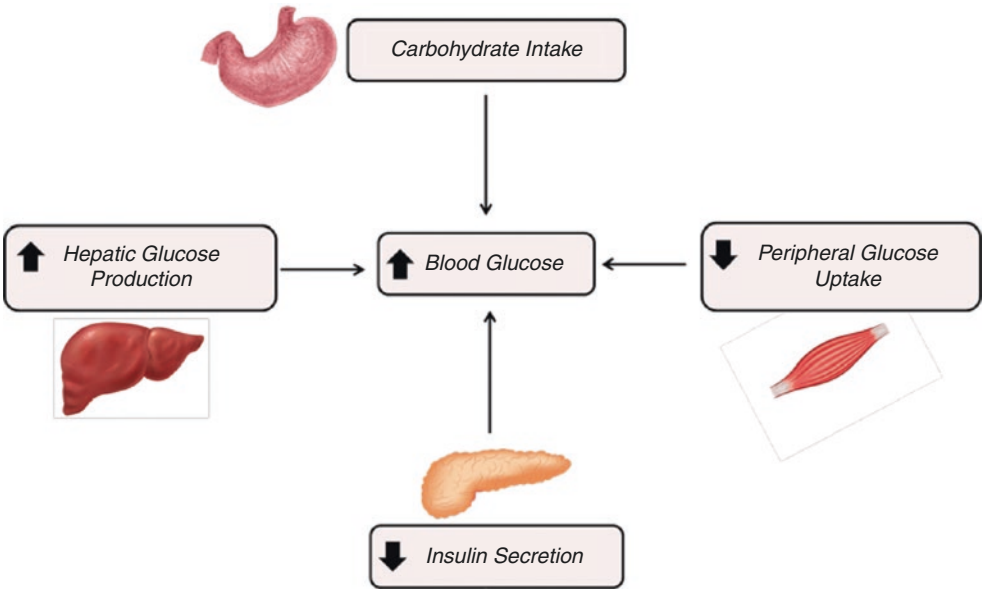

Fig. 9.1 The Triumvirate: The core physiological defects that were earlier proposed to be involved in type 2 diabetes pathogenesis [10]. (*Adapted from Chawla R. Manual of Diabetes Care: Jaypee Brothers, Medical Publishers Pvt. Limited; 2014*)

In addition to the triumvirate, numerous other factors have been demonstrated to contribute to T2D pathophysiology. In his Banting Lecture, Defronzo revealed some of the other players, viz., adipocytes (accelerated lipolysis), incretin defect, α-cells (hyperglucagonemia), kidney (increased glucose reabsorption), and brain (neurotransmitter dysfunction and central appetite dysregulation), that play important roles in the development of glucose intolerance in T2D individuals [10]. Collectively, these eight players were named the "ominous octet" [12].

The cast list in T2D pathophysiology is still being unraveled. In 2013, Kalra et al. suggested that another four factors responsible for T2D be added to the list of ominous octets, viz., dopamine, vitamin D, testosterone, and the renin-angiotensin system (RAS), and labeled all 12 factors as the "dirty dozen" [14]. In 2016, Somasundaram and Wijesinghe proposed a 13th mechanism—the role of gut and gut microbiota in T2D [15]. Other factors such as iron overload and gut-derived serotonin have also been proposed to have a role in T2D development [16].

The Ominous Octet

β-Cell Dysfunction

β-cell dysfunction plays a major role in T2D development, across the spectrum of hyperglycemia, from prediabetes to overt diabetes. These cells are in a constant state of dynamic change, with continued regeneration of islets and simultaneous apoptosis. This delicate balance can be disrupted by multiple abnormalities. As the β-cell failure progresses, insulin secretion becomes inadequate to avert the rising blood glucose levels [1]. Although the plasma insulin response to IR is usually increased during the natural history of T2D, this does not imply that the β-cell is functioning normally. In fact, the onset of β-cell failure is found to occur much earlier, and the contribution to hyperglycemia is, in fact, more severe than previously appreciated [10]. For as long as the β-cells are able to augment insulin secretion sufficiently to overcome IR, glucose tolerance remains within limits. β-cell responds to an increment in glucose (ΔG) with an increment in insulin (ΔI) and $\Delta I/\Delta G$ was initially considered the measure of β-cell function. The β-cell also takes into account the severity of IR and accordingly adjusts insulin secretion. Thus the gold standard to measure β-cell function is the insulin secretion/IR, i.e., $\Delta I/\Delta G \div$ IR, known as the glucose disposition, index [17]. In individuals susceptible to T2D, there is a limitation to this hypersecretion of insulin. The insulin secretion/IR index seen in normal glucose-tolerant (NGT), IGT, and T2D individuals as a function of the 2 h PPG during an oral glucose tolerance test (OGTT) is shown in Fig. 9.2. The onset of T2D is not associated with a further deterioration in insulin sensitivity, but rather insulin secretion that wanes and fails to compensate for the prevailing IR [18]. Individuals in the upper tertile of "normal" glucose tolerance (2-h PG = 120–139 mg/dL, i.e., 6.7–7.7 mmol/L) would have lost two-thirds of their β-cell function (see first arrow in Fig. 9.2), while subjects in the upper tertile of IGT (2-h PG = 180–199 mg/dL, i.e., 10.0–11.1 mmol/L) would have lost 80–85% of their β-cell function (see second arrow in Fig. 9.2) [10, 19–21]. Concisely, although IR in liver/muscle is well established early in the natural history of T2D, overt diabetes will not develop in the absence of progressive β-cell failure [12]. Also, with the acquisition of recent knowledge, it appears that β-cells may become dedifferentiated in people with T2DM and that these dedifferentiated cells may convert to other cell types such as glucagon-secreting α-cells [22].

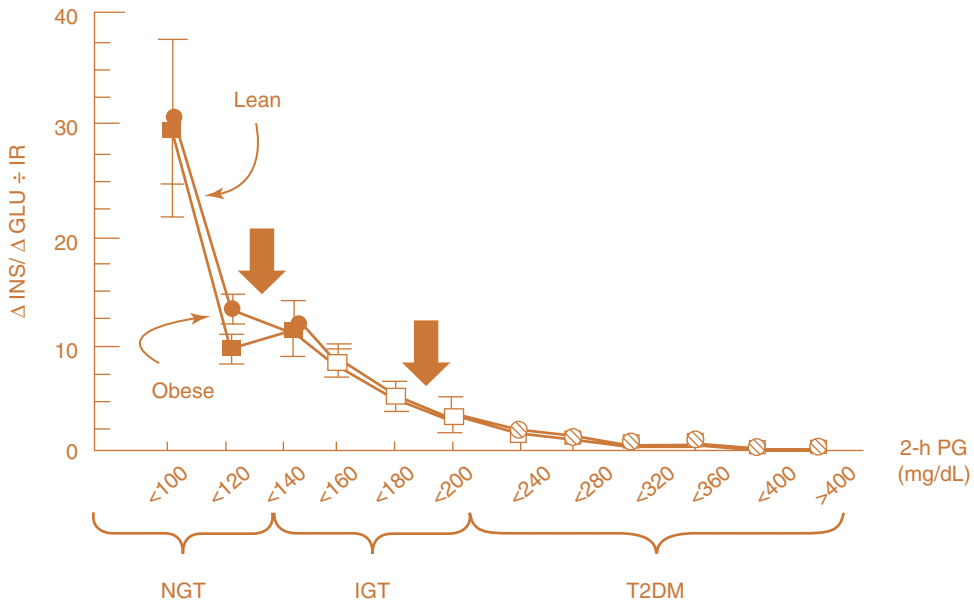

Fig. 9.2 Insulin secretion/insulin resistance (disposition) index in subjects with normal glucose tolerance (NGT), impaired glucose tolerance (IGT), and type 2 diabetes (T2D) as a function of 2 h PPG in lean (closed circle) and obese (open circle) individuals [10]. *(Adapted from DeFronzo RA. From the triumvirate to the ominous octet: a new paradigm for the treatment of type 2 diabetes mellitus. Diabetes. 2009;58(4):773-95)*

Age and genes are two well-known non-modifiable factors which influence the state of β-cell health. A progressive age-related decline occurs in β-cell function [23], and the incidence of diabetes is found to increase with advancing age. β-cell failure clusters in families, and a number of genes have been associated with T2D in people from multiple ethnic backgrounds. Most common are the transcription factors associated with β-cell dysfunction (e.g., the T-allele of single nucleotide polymorphism rs7903146 of the TCF7L2 gene) [4, 24, 25]. However, the modifiable contributors to insulin secretion and IR, e.g., lipotoxicity, glucotoxicity, and incretin defects, can improve β-cell function and should be sought [10, 26]. Hypersecretion of islet amyloid polypeptide (co-secreted with insulin) gives way to subsequent amyloid deposition within the pancreas, and it is speculated to be involved with disease progression rather than initiation [27, 28] (see Fig. 9.3).

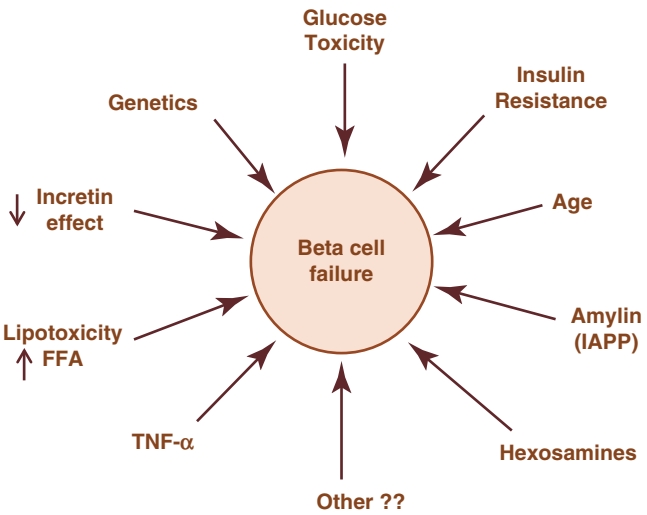

Fig. 9.3 Pathogenic factors implicated in progressive β-cell failure [26]. *(Adapted from DeFronzo RA, Ferrannini E, Alberti KGMM, Zimmet P, Alberti G. International Textbook of Diabetes Mellitus, 2 Volume Set: Wiley; 2015)*

Insulin Resistance

Insulin resistance is the diminished ability of insulin to exert its biological action across a broad range of concentrations [29]. Relatively high insulin levels observed during fasting and in response to insulin secretagogues are indicative of IR. Insulin resistance is a consistent finding in T2D, and it may appear many years before the disease's onset. It is also a well-known associate of obesity, and many obese individuals develop T2D. Interestingly, some patients, despite being obese, never develop T2D, highlighting the significant contribution of the β-cell deficit in individuals who develop T2D. Important to note, physical activity has a significant positive effect on insulin sensitivity, even when correcting for confounding factors such as being overweight. What's more, during the latter half of pregnancy, even in women with normal glucose homeostasis, IR increases due to the production of placentally derived hormones like human placental lactogen. Gestational diabetes mellitus (GDM) ensues if the maternal β-cells are unable to produce sufficient insulin to overcome the IR. Insulin resistance is mediated at three organ levels—liver, muscle, and adipose tissue. Much more than the mere IR, the triad of factors contributes to the biochemical potpourri of diabetes [1, 16].

Hepatic Insulin Resistance

Insulin resistance in the liver is manifested by glucose overproduction during the basal state despite fasting hyperinsu-

linemia [6] and impaired suppression of HGP by insulin [30], following a meal [7]. Due to its obligate need for glucose, the brain uses up more than half of the glucose produced. This glucose demand is met primarily by the liver and, to a lesser extent, by the kidneys [31]. Normally, the liver produces 2 mg/kg per min of glucose, whereas in diabetes-affected individuals, this basal rate of HGP is increased to 2.5 mg/kg per min. This increased HGP occurs even when the fasting plasma insulin levels are increased 2.5- to 3-fold, indicating severe resistance to the suppressive effect of insulin on HGP.

In the early stages of T2D, postprandial hyperglycemia is attributed to, reduced glucose uptake by the muscles, and during the postabsorptive period, the fasting levels are maintained by HGP. Both sources of HGP, glycogenolysis, and gluconeogenesis, are under insulin control. But in the IR state, the latter accounts for nearly the entire increase in hepatic glucose output. Around one-fourth of the glucose derived from a meal is extracted by the liver during the recycling of portal and systemic blood, and insulin is suggested to facilitate the storage of this glucose as glycogen. Gluconeogenesis accounts for even greater amounts of glycogen. Moreover, during active gluconeogenesis, glycogenolysis is inhibited and results in excess hepatic glycogen [32] in uncontrolled diabetes. The accelerated gluconeogenesis in T2D can be due to elevated circulating levels of precursor molecules like lactate and alanine from the muscles and glycerol from the adipose tissue. A simultaneous upsurge in free fatty acids (FFA) and concomitant hyperglucagonemia facilitate gluconeogenesis. Insulin resistance also stimulates VLDL and apo-B synthesis in the liver, while HDL is lowered due to a greater exchange of cholesterol ester transport proteins. An increase in small dense low-density lipoprotein particles is also noted during the process [13].

Muscle Insulin Resistance

In the muscle, IR is manifested by impaired glucose uptake after carbohydrate ingestion, resulting in postprandial hyperglycemia [30, 33, 34]. In the insulin-stimulated post-prandial state, skeletal muscle accounts for more than 75% of the excess glucose uptake [35], and in diabetes patients, it accounts for the largest part of the impairment of glucose disposal. Adipose tissue mass being smaller in size accounts for the rest, whereas there may not be any change in the case of brain and splanchnic tissues [1]. In T2D, the muscle IR accounts for more than 85–90% of the impairment in total body glucose disposal [3, 13, 33, 34].

Adipose Tissue Insulin Resistance

Though deranged adipocyte metabolism was initially not considered to play a significant role in T2D pathogenesis, later on, evidences supported the adipose tissue being considered the "fourth musketeer" along with the triumvirate [10, 36, 37]. In healthy individuals, insulin exerts an anti-lipolytic effect on fat cells, whereas in T2D individuals, IR prevents insulin from exerting its anti-lipolytic effect. The result is sustained lipolysis with a day-long elevation in plasma free fatty acid (FFA) levels. This, in turn, stimulates gluconeogenesis, induces hepatic and muscle IR, and impairs β-cell function (lipotoxicity). FFAs also enhance the activity of glucose-6-phosphatase, which ultimately controls the release of glucose by the liver [38]. Dysfunctional adipocytes produce pro-inflammatory adipocytokines in excess (IL-6, TNF-α, leptin, visfatin, etc.), which induce IR and atherosclerosis. This also induces a feed-forward process in which activation of transcription factors leads to further pro-inflammatory cytokine production [39, 40]. Deranged adipocytes also tend to secrete subnormal amounts of insulin-sensitizing adipocytokines (e.g., adiponectin). Enlarged fat cells are insulin-resistant and have a lesser capacity to store fat. When the storage capacity of adipocytes is exceeded, lipid "overflows" into muscle, liver, β-cells, and arterial vascular smooth muscle cells, leading to muscle and hepatic IR, impaired insulin secretion, and acceleration of atherosclerosis [41].

Meanwhile, the discovery of functional brown adipose tissue raised the possibility of its involvement in human energy homeostasis and in preventing T2D. The detectability of this tissue lessens with age, high BMI, and high FPG [5, 42]. A healthy obese state has been entertained, and the theory is based on the existence of differences in IR between adipose deposition sites. In other words, adipose site-specific IR with intra-abdominal adipose tissue is seemingly more insulin-resistant and harmful than subcutaneous adipose tissue (SAP). The former has particularities related to higher lipolysis, higher release of adipokines, etc., which are longitudinally associated with an increased risk of incident metabolic syndrome (MetS) [43]. In individuals who remain resistant to T2D, excess calories are safely partitioned to SAP rather than to the muscle, liver, heart, and β-cells, thus avoiding damage to the key organs. Major mechanisms for such protective effects include β-cell compensation, maintenance of near-normal blood nutrient levels, development of minimal IR, increased expansion of SAT relative to visceral adipose tissue, and limited increase in liver fat [5].

Alpha Cells (Increased Glucagon Secretion)

In as early as the 1970s, it was established that T2D individuals have elevated plasma glucagon levels [44–46]. While a reduction in β-cell mass is seen in diabetes patients as compared to normal individuals, there occurs no reduction in the α-cell mass. It is also proposed that β-cells dedifferentiate in T2D individuals and get converted to other cell types like glucagon-secreting α-cells [22]. Substantiating these, even when insulin levels progressively decline over

the course of T2D, basal glucagon levels tend to remain elevated [47, 48]. The role of hyperglucagonemia in the maintenance of increased rates of HGP in T2D was demonstrated by Baron et al. [49]. In T2D, fasting glucagon levels are elevated and the postprandial glucagon levels are not suppressed, but paradoxically elevated. These raised blood glucagon levels increase the HGP, leading to an elevation in FPG and PPG levels, resulting in a worsening of diabetes [48, 50].

Upon somatostatin infusion, there were declines in plasma glucagon levels by 44% and in basal HGP by 58%. When somatostatin was administered to alloxan-diabetic dogs [51] or to insulin-deprived T2D subjects [52], hyperglucagonemia was suppressed and hyperglycemia was reduced, even though insulin had been reduced or discontinued. Many other studies also support the prime role played by glucagon in T2D pathogenesis [44, 53, 54]. The drugs capable of inhibiting glucagon secretion or blocking the glucagon receptor have now proven effective in treating T2D [55–57].

Incretin Defect

Glucose ingestion can elicit a higher insulin response than an intravenous infusion, which is explained by the incretin effect. The incretin hormones, glucagon-like peptide-1 (GLP-1) secreted by the L-cells of the distal small intestine and glucose-dependent insulinotropic peptide (GIP) by the K-cells of the more proximal small intestine, collectively act on the pancreatic islet [10, 39, 58, 59]. Of these, GLP-1 acts on the β-cells to increase insulin and on the α-cells to suppress glucagon secretion [58]. GLP-1 thus imparts an indirect benefit on β-cell workload, since a reduction in glucagon levels leads to a reduced postprandial HGP. Gut hormones, including GLP-1, also have roles in the central nervous system's (CNS) regulation of energy balance and appetite [5, 60]. GLP-1 delays the rate of gastric emptying, results in a feeling of fullness and satiety, and is therefore associated with the control of weight gain [10, 61, 62]. In T2D, the incretin effect is substantially impaired possibly due to impaired GLP-1 production and reduced sensitivity of β-cells to GIP [5, 63, 64]. Dysfunction in glucagon secretion due to impaired incretin action is also suggested [65]. In subjects with NGT, IGT, or T2D, plasma GLP-1 levels do not seem to differ much [65], which suggests that the β-cell response to GLP-1 following meal ingestion is deficient, as seen during intravenous administration of GLP-1 under controlled conditions [66]. Elevations in GLP-1 levels are reported after bariatric surgery, which might partially explain the multiple beneficial effects of this intervention, especially among T2D individuals [39]. Numerous pharmacologic approaches are available nowadays that effectively harness the potential of incretins to treat diabetes, which include GLP-1 agonists and DPP4 inhibitors [67].

Kidneys (Increased Glucose Reabsorption)

The kidney's adaptive response to conserve glucose, which enables it to meet the energy demands of the body, especially the brain and other neural issues, which have an obligate need for glucose, becomes maladaptive in diabetes. Rather than draining out the glucose into urine to correct the hyperglycemia, the kidney retains the glucose. Normally, the kidney filters around 162 g of glucose daily, and the high-capacity SGLT2 transporter in the convoluted segment of the proximal tubule reabsorbs almost 90% of the filtered glucose, while the remaining 10% is reabsorbed by the SGLT1 transporter in the straight segment of the descending proximal tubule [68]. In both T1D and T2D, the maximum renal tubular reabsorptive capacity (Tm) for glucose is higher [69–72]. Therefore, in normal individuals, no glucose appears in the urine until the plasma glucose level is >180 mg/dL [73], whereas in T2D, this threshold is much higher [71]. Medications to inhibit renal proximal tubular glucose reabsorption were thus thought out to treat T2D [68]. SGLT2 inhibitors confer multiple benefits like better glycemic control by improving β-cell function and insulin sensitivity, reductions in body weight and blood pressure, etc. [74]. Currently, therapies aimed at inhibiting the SGLT1 receptors in the gut and downstream from the SGLT2 receptors in the kidney are also underway [75–77].

Brain (Neurotransmitter Dysfunction and Central Appetite Dysregulation)

The nervous system also plays a key role in T2D pathogenesis. Sympathetic and parasympathetic nervous systems control glucose metabolism directly through neuronal input and indirectly via circulation to regulate insulin and glucagon release and HGP [39, 78]. Severing the vagus nerve impaired insulin secretion, revealing its important role in regulating the islet [79]. Ablation of the hypothalamus leads to β-cell dysregulation and subsequent hyperinsulinemia [80]. Insulin has a powerful appetite-suppressing effect [81]. However, in obese individuals with or without diabetes, even though IR results in compensatory hyperinsulinemia, food intake seems to be higher, indicating that the appetite centers are also IR. In a functional magnetic resonance imaging study where the cerebral response to ingested glucose was examined [82], consistent inhibition was noted in the lower posterior (which contains the ventromedial nuclei) and upper posterior (which contains the paraventricular nuclei) hypothalamus upon glucose ingestion. Both of these areas are key appetite regulation centers, and the extent of inhibitory response upon glucose ingestion was decreased in these areas in obese, insulin-resistant subjects even when euglycemic. A delay was also observed in the time taken to reach the maximum inhibitory response in these individuals even in the presence of a high plasma insulin response. Further studies have also indicated that cerebral IR leads to increased HGP and

reduced muscle glucose uptake [83, 84]. High-fat diet-fed rodents are prone to inflammation-induced neuronal injury, and in humans, structural changes in the hypothalamus have been observed in keeping with gliosis in obese compared to lean individuals [85]. Reduced dopamine levels in the hypothalamus and increased catecholamine levels in the CNS also contribute to appetite dysregulation and are suggested to directly cause IR in liver and peripheral tissues [84, 86]. The neuroendocrine hormone amylin is also deficient in T1D and T2D [15], and its effect on appetite dysregulation is suggested to be chiefly mediated via central pathways that include high-affinity binding sites in the area postrema in the hindbrain [87]. It also has direct gut effects through a decrease in the rate of gastric emptying [88]. Clock genes located in the brain which are major determinants of circadian rhythmicity, together with sleep, are now being investigated due to their role in metabolic processes [89, 90].

The "Dirty Dozen," the "Unlucky Thirteen," and Much More

Dopamine

Dopamine, the most abundant catecholamine in the brain, has been nicknamed the "forgotten felon" of diabetes [16], and along with the other catecholamines of the autonomic nervous system, this neurotransmitter modulates glycemia. It was Kalra et al. who proposed the specific addition of the dopaminergic system as a ninth contributor to T2D development [91]. Mammalian species have an inherent capacity to alter their metabolism from the insulin-sensitive/glucose-tolerant state to the insulin-resistant/glucose-intolerant state at exactly the right time of the year to meet the varying energy demands. Such seasonal metabolic changes are governed by the changes in monoaminergic concentrations/activity in the suprachiasmatic nuclei (SCN) of the hypothalamus—the mammalian circadian pacemaker—and in the ventromedial hypothalamus (VMH). Development of an IR state during such seasonal changes exactly mimics the T2D state: muscle and hepatic IR, increased HGP/gluconeogenesis, hyperglycemia, adipocyte IR and enhanced lipolysis, increased plasma FFA and triglyceride levels, and obesity. Evidences implicate endogenous dopaminergic and serotonergic rhythms in SCN and VMH in the transition from the insulin-sensitive to insulin-resistant state. In animals that undergo seasonal changes in metabolism, within the VMH, during the insulin-resistant state, both serotonin and noradrenergic levels and activity are enhanced and decrease to normal levels upon returning to the insulin-sensitive state. On the contrary, dopamine levels decrease during the IR state and increase to normal following the return of the insulin-sensitive state. A selective destruction of dopaminergic neurons in the SCN of the hypothalamus resulted in severe IR [86, 92, 93].

Both systemic [94, 95] and intracerebral [96] bromocriptine (a sympatholytic D2-dopamine agonist) administration to insulin-resistant animals decreased the elevated VMH noradrenergic and serotonergic levels with a resultant decline in HGP, reduced adipose tissue lipolysis, and improved insulin sensitivity. In T2D and obese nondiabetic individuals, systemic bromocriptine administration improved glycemic control and dyslipidemia without changes in body weight [97]. It was postulated that in T2D patients, hypothalamic dopamine reduces in the early morning, leading to elevated HGP and lipolysis, resulting in glucose intolerance, IR, and dyslipidemia. Timed bromocriptine (quick-release formulation) administration within 2 h of awakening augmented low hypothalamic dopamine levels and decreased the sympathetic tone within the CNS, leading to an increase in insulin sensitivity, suppression of HGP, and thereby a reduction in PPG levels [86].

Vitamin D

Vitamin D subserves a range of biological functions like cell differentiation, inhibition of cell growth, and immunomodulation. Both direct and indirect effects of vitamin D on various mechanisms related to the T1D and T2D pathophysiologies have been postulated, including pancreatic β-cell dysfunction, impaired insulin action, systemic inflammation, and apoptosis. Over the past decade, vitamin D has emerged as a potential risk determinant for type 2 diabetes. Vitamin D receptors occur in all tissues and organs that are involved in these diseases, and the machinery for producing vitamin D locally is also present in islets, immune cells, and other tissues involved [14, 98–100]. Owing to the broad tissue distribution of the vitamin D receptor (VDR) and extrarenal activation of 25(OH)D to $1,25(OH)_2D$, vitamin D imparts extraskeletal effects. Consequently, a low level of 25(OH)D has been found to be associated with the risk of developing type 2 diabetes [101]. Various factors such as body weight and fatness, assessed by the body mass index (BMI), influence the blood 25(OH)D level. Specifically, a higher BMI is associated with a lower blood 25(OH)D level and hence with an increased risk of diabetes [102]. Children receiving the recommended dose of vitamin D during the first year of life had an 80% reduced T1D risk [103]. Lower vitamin D levels might result in impaired β-cell function with lowered insulin secretion and sensitivity and higher IR [104], and might also pose a risk for developing macrovascular and microvascular complications [105]. Among Caucasian children and adolescents, low vitamin D levels were associated with total adiposity, MetS, and hypertension [106]. Vitamin D supplementation in T2D and nondiabetic subjects imparts beneficial effects on glucose homeostasis and other markers

of MetS like improving β-cell function and insulin secretion and reducing IR [107, 108]. Solutions to clinically relevant queries are rarely dichotomous ("positive" or "negative"), and a recommendation of whether "to D or not to D" should be made based on the available data from both observational studies and clinical trials. However, results from the trials are congruent with mounting evidence from observational studies highlighting the role of vitamin D in regulating diabetes risk.

Renin-Angiotensin System

Evidences suggest a role for the RAS in the development of IR and T2D [109, 110]. Detrimental effects that RAS has on insulin secretion are mediated by a decrease in pancreatic blood flow and induction of islet fibrosis, oxidative stress, and inflammation, whereas both impaired skeletal muscle function (disturbances in skeletal muscle blood flow, insulin signaling, and mitochondrial function) and adipose tissue (AT) dysfunction (adipocyte hypertrophy, inflammation, and impairments in AT blood flow and lipid metabolism) may contribute to RAS-induced IR [110]. Frequent association of T2D with hypertension, retinopathy, nephropathy, and cardiovascular disease (CVD) has also implicated RAS in the initiation and progression of these disorders.

RAS blockade significantly improves insulin sensitivity [111–113] and significantly reduces the incidence of vascular complications in T2D [114–116]. Such improvements are postulated to be due to the improvement of blood flow and microcirculation in skeletal muscles, decrease in adipocyte size, protective actions on pancreatic islets, etc., thereby facilitating insulin signaling at the cellular level and improvement of insulin secretion by pancreatic β-cells [15, 117–120]. Among high-risk populations, RAS blockade using either angiotensin II receptor blockers (ARB) or angiotensin-converting enzyme inhibitors (ACEI) led to a 22% reduction in the incidence of new-onset T2D [121]. The DREAM study in individuals without CVD but with impaired fasting glucose levels or IGT showed that the ACEI ramipril did not significantly reduce the diabetes incidence or death but significantly increased the regression to normoglycemia [122]. The NAVIGATOR study among individuals with IGT and CVD or risk factors showed that ARB valsartan use, along with lifestyle modification, caused a relative 14% reduction in diabetes incidence but did not reduce the rate of CVD events [123]. Despite the lack of consistency in the findings between many of these trials, subanalyses of some of them have shown that RAS inhibitors improve glucose levels and reduce the risk for diabetes in higher-risk populations [109, 124, 125].

Testosterone

An association between low testosterone and T2DM risk in men is well-proven [126–128]. Morbid obesity imposes negative effects on the hypothalamic-pituitary-gonadal axis in men [129]. A bidirectional relationship between visceral fat and testosterone is suggested, which sets up a self-perpetuating cycle promoting IR and diabetes. High visceral fat increases the secretion of proinflammatory cytokines, estradiol, insulin, and leptin, all of which may inhibit the hypothalamopituitary gonadal axis activity at multiple levels [130, 131]. Decreased testosterone levels also build up IR via mechanisms involving muscle [132], liver [133], and bone [134]. Testosterone decreases IR by regulating mature adipocytes and myocytes. Testosterone also increased catecholamine-induced lipolysis in vitro [135] and decreased lipoprotein lipase activity and triglyceride uptake in abdominal adipose tissue in humans [136]. A positive correlation exists between testosterone levels and insulin sensitivity, and the individuals with hypogonadal testosterone levels had a higher BMI and a higher prevalence of the MetS than their eugonadal counterparts [132]. Other studies including landmark studies like the Massachusetts Male Aging Study (MMAS) and the Multiple Risk Factor Intervention Trial (MRFIT) have all demonstrated an inverse association between low testosterone levels and risk for MetS and diabetes [128, 137–139]. Further, low sex hormone binding globulin (SHBG) may lead to IR and lower total testosterone [140]. Among prostate cancer patients subjected to androgen deprivation therapy (ADT), lower testosterone levels were associated with increased IR [141, 142] and an increased diabetes risk [143]. Testosterone substitution in hypogonadal men improved insulin sensitivity and glycemic control [144, 145]. In men with newly diagnosed diabetes, the addition of testosterone to a regimen of diet and exercise significantly improved the outcomes on glycemic control and reversal of the MetS [145, 146].

Interestingly, the effect of testosterone on IR and T2D is opposite in males and females. Its low concentrations in males but high concentrations in females favor IR and T2D [147–149]. In a systematic review and meta-analysis by Ding et al., endogenous levels of testosterone and SHBG were found to exhibit sex-dependent relations with the risk of T2D. Elevated testosterone levels were linked to greater T2D risk in females but a lower risk in males. Meanwhile, SHBG was more protective in females than in males [149]. Polycystic ovary syndrome (PCOS), characterized by chronic anovulation and hyperandrogenism, was also suggested to have partly contributed to this observed positive testosterone association in females. Insulin resistance with compensatory hyperinsulinemia is the key pathogenic factor in PCOS and can lead to the onset of hyperandrogenism by stimulating ovarian androgen production and by decreasing SHBG levels. Females of reproductive age with PCOS are thus prone to metabolic disorders and T2D [149, 150].

Gut and Gut Microbiota

Gut

Centuries ago, the ancient Greek physician Hippocrates said, "All Disease Begins in the Gut." Mounting evidence strongly supports the above-quoted hypothesis, and in 2016, Somasundaram et al. proposed the role played by the gut as the 13th mechanism in diabetes pathogenesis [15]. Even though the contribution of gastrointestinal (GI) carbohydrate absorption towards T2D pathogenesis had long been known, its contribution was rather underutilized as a target for therapy. Alpha-glucosidase inhibitor (AGI) is the only class of drug that effectively utilizes this mechanism for the treatment of diabetes and has clear beneficial effects on glycemic control and post-load insulin levels [151]. SGLT1 plays a distinct and complementing role to SGLT2 in glucose homeostasis. Within the GI tract, SGLT1 is responsible for glucose absorption and is also involved in 10% of renal glucose reabsorption. Inhibition of SGLT1 and combined inhibition of SGLT1/SGLT2 is thus a new anti-hyperglycemic concept [75–77], which further implies the contribution of GI carbohydrate absorption in T2D pathogenesis.

Bile acids also play a significant role in modulating glucose homeostasis, and bile acid homeostasis is altered in T2D. Bile acids act as signaling molecules through receptor-dependent and receptor-independent pathways [152]. They act as endogenous ligands of the farnesoid X receptor (FXR), and their activation of FXR leads to the release of fibroblast growth factor (FGF) [153]. Through FXR, bile acids suppress the in vitro expression of fructose-1, 6-biphosphatase-1, gluconeogenic phosphoenolpyruvate carboxykinase, and glucose-6-phosphatase [154]. G-protein-coupled receptors TGR5 (also termed GPR131) located on intestinal L-cells are activated by bile acids, resulting in GLP-1 secretion [155]. Intraduodenal bile acid infusion dose-dependently enhanced plasma FGF19 concentrations, with smaller effects on GLP-1 and CCK [156, 157]. FGF19 possesses insulin-like effects, inducing glycogen and protein synthesis while suppressing glucose production [39]. A second-generation bile acid sequestrant colesevelam modestly reduces glucose in T2DM when used as an adjunct to other agents. Suggested mechanisms include its effect on bile acid receptors in the intestine as well as in the liver to reduce endogenous glucose production [15, 158].

Gut Microbiota

Besides the gut, the gut microbiome is also involved in T2D pathogenesis [15, 39, 159, 160]. Gut dysbiosis, intestinal barrier dysfunction, and subsequent metabolic endotoxemia are all closely related to inflammation, IR, and finally CVD events in T2D [161, 162]. Individuals with prediabetes or T2D have a moderate degree of gut microbial dysbiosis in terms of a reduction in the abundance of certain universal butyrate-producing bacteria (*Faecalibacterium prausnitzii*, *Roseburia intestinalis*, etc.) and an increase in various opportunistic pathogens (like *Lactobacillus* sp.) [162, 163]. In individuals with MetS, vancomycin treatment decreased the abundance of butyrate-producing gram-positive bacteria, which correlated well with impaired insulin sensitivity [164]. Decreased levels of butyrate-producing gut microbes in T2D individuals were thus suggested to lead to disease pathogenesis. Among the short-chain fatty acids, butyrate acts as a prominent energy source for intestinal epithelial cells and influences a variety of colonic mucosal functions, reinforcing the colonic defense barrier and attenuating oxidative stress [165]. Butyrate also enhances the intestinal barrier by modulating the assembly of tight junctions (TJs) via AMP-activated protein kinase (AMPK) activation [166]. Feces of T2D subjects were relatively enriched with endotoxin-producing gram-negative bacteria (phyla Bacteroidetes and Proteobacteria), which suggested the role played by these phyla in T2D pathogenesis through an endotoxin-induced inflammatory response pathway [163]. In the liver, cholic acid and chenodeoxycholic acid constitute primary bile acids produced from cholesterol, and the gut microbiota transforms these primary bile acids into secondary bile acids [167]. In line with these facts, 6 weeks after the infusion of intestinal microbiota from lean subjects, an improvement in insulin sensitivity was noted in subjects with MetS [168]. Studies on the association between body composition and gut microbiota (Firmicutes, Bacteroidetes, Clostridium *leptum*, *Bacteroides, Bifidobacterium, Akkermansia muciniphila, Escherichia coli, and Faecalibacterium prausnitzii)* in type 2 diabetes using body composition of lean tissue index (LTI) and fat tissue index revealed that T2D with higher abundance of phylum Firmicutes and a higher ratio of phyla Firmicutes to Bacteroidetes (phyla *F*/*B* ratio) had higher LTI. This significant correlation between phyla *F*/*B* ratio and LTI was evident in type 2 DM with high body mass index and was independent of glycemic control or dipeptidyl peptidase-4 inhibitor usage, thus demonstrating the positive association of LTI with the abundance of phylum Firmicutes and the phyla *F*/*B* ratio in type 2 DM [169].

Iron Overload

There is no active mechanism for iron excretion in humans, and the amount of iron absorbed into the body is balanced by the iron lost by means of sloughing of intestinal mucosa and skin, as well as lesser amounts that are excreted in the urine and bile [170]. Iron overload is thus a risk factor for T2D [171], whereas its depletion has a protective effect against T2D.

The foremost evidences for this were obtained from studies related to pathologic iron overload disease conditions like hereditary hemochromatosis (HH) [172] and transfusional iron overload [173]. Both insulin deficiency and IR can con-

tribute to the T2D pathophysiology associated with HH [174, 175]. Individuals with HH have an inherent insulin secretory defect, making them highly prone to develop diabetes, especially when IR from an independent mechanism such as obesity intervenes [176]. HH individuals have extremely high ferritin levels (1000–10,000 ng/mL), and around 25–60% of them develop "secondary" T2D [177, 178]. Transfusional iron overload is usually seen in transfusion-dependent chronic hemolytic anemia such as β-thalassemia. Due to the numerous transfusions that are required to maintain adequate erythrocyte levels and the resultant increased iron absorption, these patients become iron-overloaded [179]. Individuals with β-thalassemia mostly develop IGT during the second decade of life, and a diabetes prevalence is reported among 6–14% of the patients [180, 181]. T2D is also prevalent among survivors of pediatric bone marrow transplantation [182] and allogeneic hematopoietic cell transplantation [183]. Some rare inherited diseases that cause diabetes such as Friedreich ataxia are associated with iron imbalance and mutations in the proteins involved in iron metabolism [184].

Positive associations between elevated body iron stores (measured as circulating ferritin) and the risk of T2D and of other IR states such as MetS, GDM, PCOS, and possibly CVD have been demonstrated [177, 185, 186]. Moderate increases in iron stores (lower than the levels found in HH subjects) were associated with increases in blood glucose and insulin levels. Furthermore, moderately increased body iron stores at baseline were associated with an elevated risk of developing T2D in future [178]. In a National Health and Nutrition Education Survey (NHANES), the odds ratios for newly diagnosed diabetes in individuals with higher serum ferritin levels were 4.94 for males and 3.61 for females [187]. A link has also been established between increased dietary iron intake (particularly heme iron) and the risk for T2D and GDM [188–191]. No significant association between dietary intakes of total iron, nonheme iron, and supplemental iron intake was found with the risk of T2DM, whereas heme iron intake showed a positive association after adjustment for potential confounders. Individuals who consume meat (a major source of heme iron) are thus reported to have more IR compared to vegetarians [177, 178].

Iron overload is also implicated in the pathogenesis of many diabetes-associated vascular complications including diabetic nephropathy (DNP) and CVD [188]. In individuals with DNP, an increased proximal tubular lysosomal iron concentration has been observed. In iron-loaded subjects with thalassemia, an early development and accelerated course of DNP is reported. Similarly, mutations for HH appeared to predict the development of DNP [192]. Iron has an adverse effect on the endothelium and accelerates the development of atherosclerosis. Elevations have been observed in ferritin gene expression during the course of atherosclerotic plaque formation [192, 193].

Multiple mechanisms have been proposed towards the association between iron and abnormal glucose metabolism, like β-cell dysfunction and IR, possibly mediated through oxidative stress [188, 194]. Being a redox-active transitional metal, excess iron is potentially hazardous. It catalyzes several cellular reactions that lead to the production of reactive oxygen species and thereby to an elevated oxidative stress, which is proposed to contribute to an increased risk of T2D. Pancreatic β-cells, due to their weak antioxidant defense system, are highly susceptible to oxidative damage, and thus iron deposition in these cells can result in impaired insulin secretion. In the muscle, iron overload may diminish glucose utilization, thereby leading to a shift from glucose to fatty acid oxidation, resulting in an increased IR. Increased substrate recycling to the liver may contribute to an elevated HGP. Iron may also impair the action of insulin and interfere with glucose uptake in adipocytes. Elevations in systemic inflammation may also modify iron metabolism. Inflammatory cytokines are found to induce the synthesis of ferritin [177, 178]. As iron influences the action of insulin, insulin also is in turn known to influence iron metabolism. Insulin plays a role in redistributing transferrin receptor (TfR) to the cell surface and thereby increasing the cellular uptake of iron in adipose tissue and the liver. Thus, in the IR states, inherent hyperinsulinemia leads to elevations in levels of the circulating soluble form of TfR (sTfR), a marker of iron status [177].

The potential benefit of iron depletion on insulin sensitivity and/or T2D has been evaluated by many. Phlebotomy enhanced insulin sensitivity and glycemia in normal as well as T2D subjects with elevated ferritin levels [177, 195]. In HH patients, phlebotomy and/or iron chelation therapy (to decrease body iron stores) improved their glycemic control, and 30–40% of them achieved either the elimination of oral diabetes therapy or a substantial decrease in dosage [196]. Blood donations reduce circulating ferritin levels, and frequent blood donors seem to have better insulin sensitivity than non-donors. An increased number of lifetime blood donations was found to be associated with a decreased prevalence of T2D [197]. Among T2D individuals who were negative for common HH but had increased serum ferritin concentration, bloodletting improved their insulin sensitivity and reduced their C-peptide levels [192].

Covid-19 and Type 2 diabetes

The importance of testing and treating diabetes has been overemphasized during the Covid pandemic.

The severity of Covid-19 is found to be increased in patients with uncontrolled diabetes mellitus and also in patients with new-onset hyperglycemia. There are multiple factors that can contribute to hyperglycemia in a Covid-

affected individual. Blood glucose is currently recognized as the fifth vital sign in all patients, irrespective of the previous history of diabetes [198]. The interaction of hyperglycemia with other risk factors might modulate immune and inflammatory responses, thus predisposing patients to severe Covid-19 and possible lethal outcomes. Angiotensin-converting enzyme 2 (ACE2), which is part of the renin–angiotensin–aldosterone system (RAAS), is the prime entry receptor for the SARS-CoV-2 virus, even though dipeptidyl peptidase 4 (DPP4) might also act as a binding target [199]. Potential pathogenic links between Covid-19 and diabetes include effects on glucose homeostasis, inflammation, altered immune status, and activation of the renin–angiotensin–aldosterone system (RAAS) [200]. Also, a known history of diabetes and a fasting plasma glucose ≥7.0 mmol/L (126 mg/dL) before steroid treatment were recognized as independent predictors of mortality.

Conclusion

The alarming rise in the prevalence of type 2 diabetes due to obesity, reduced physical inactivity, and an aging population demands rigorous efforts to improve our understanding of the devastating disease and its prevention. Extensive research on the causality and pathophysiology of T2D has contributed to a better understanding of the overwhelming effects of T2D. From modest steps, with the identification of only two factors, defective insulin secretion and IR, we are now able to appreciate the complexity and heterogeneity of the role-players in the pathogenesis of T2D (see Fig. 9.4). It is likely that many more factors are yet to be unveiled. The complexity of T2D demands a multifaceted therapeutic approach, which combines pharmacological and non-pharmacological interventions in an individualized way. While investing efforts to address the underlying complications and the mod-

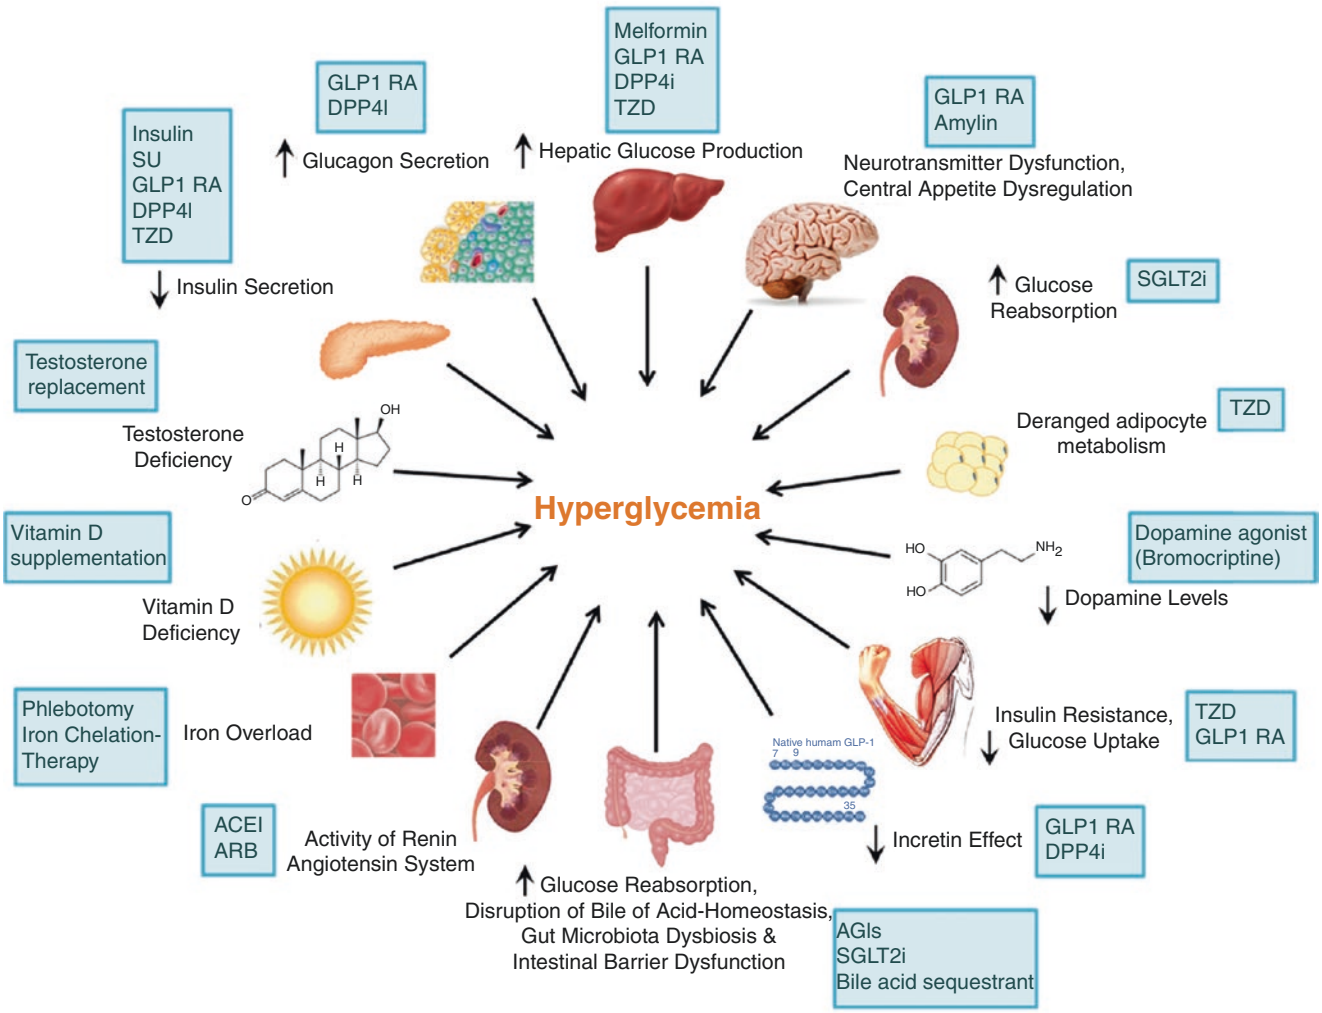

Fig. 9.4 Players in the pathophysiology of T2D

ifiable risk factors to prevent T2D, this knowledge will strengthen our views on the effective use of the existing therapies and allow us to explore and develop innovative solutions to tackle chronicity.

Multiple-Choice Questions

1. In the postabsorptive state, most of the glucose utilization occurs:
   (a) **In the muscle**
   (b) In the brain
   (c) In adipose tissue
   (d) In beta cells
   (e) In red cells
2. Regarding lipoprotein metabolism:
   (a) Insulin has not demonstrated effects
   (b) Insulin increases circulating VLDL levels
   (c) Insulin stimulates lipoprotein lipase in adipocytes, promotes lipolysis and removal of chylomicrons
   (d) **Insulin stimulates lipoprotein lipase in the vascular endothelium, reduces lipolysis and removal of chylomicrons**
   (e) Insulin increases triglyceride levels
3. In the event of hepatic insulin resistance:
   (a) Hepatic glucose production is suppressed by low fasting insulin levels
   (b) Hepatic glucose production initially continues but is suppressed as insulin levels increase
   (c) Hepatic glucose production is stable
   (d) **Hepatic glucose production continues even when fasting insulin levels are high**
   (e) Hepatic glucose production is suppressed
4. Postprandial hyperglycemia results:
   (a) From hepatic insulin resistance
   (b) **From peripheral tissue insulin resistance**
   (c) From beta-cell insulin resistance
   (d) From increased hepatic glucose production
   (e) From decreased transport of glucose in the central nervous system
5. The core physiological defects proposed in the triumvirate concept include the following, except:
   (a) **The central nervous system**
   (b) Pancreatic alpha-cells
   (c) Pancreatic beta-cells
   (d) The liver
   (e) Skeletal muscle
6. Individuals in the upper tertile of "normal" glucose tolerance:
   (a) Maintain 100% of beta-cell function
   (b) Have lost 20% of beta-cell function
   (c) **Have lost 50% of beta-cell function**
   (d) Have lost 70% of beta-cell function
   (e) Have lost 100% of beta-cell function
7. Amyloid deposits within the pancreas:
   (a) Have a protective effect on beta-cell function
   (b) Are crucial to initiating type 2 diabetes
   (c) **Are involved with disease progression**
   (d) Are associated with disease remission
   (e) Indicate glucose-toxicity
8. Insulin resistance
   (a) **Appears years before the onset of type 2 diabetes**
   (b) Is an unusual manifestation of type 2 diabetes
   (c) Is a late manifestation of type 2 diabetes
   (d) Occurs at the same time as beta-cell failure
   (e) Always evolve to type 2 diabetes
9. Hepatic gluconeogenesis is facilitated by:
   (a) The incretin effect
   (b) By overactivity of the beta-cells
   (c) By basal insulin secretion
   (d) By high levels of VLDL lipoproteins
   (e) **By high levels of free fatty acids**
10. In persons with type 2 diabetes, the largest impairment of glucose disposal occurs:
    (a) In the central nervous system
    (b) In adipose tissue
    (c) In the kidney
    (d) **In skeletal muscle**
    (e) In erythrocytes

Genetic Determinants of Type 2 Diabetes

10

Miguel Cruz, Adán Valladares Salgado, Eugenia Flores Alfaro, José de Jesús Peralta Romero, and Joel Rodriguez-Saldana

Definition of Genetic Polymorphisms

The genetic information of modern man, or *Homo sapiens*, is kept along 23 pairs of chromosomes located in the nucleus of every diploid cell. Diploid is understood as the cells that have in their nucleus a double number of chromosomes, that is, two complete copies of the genomes inherited from the parents, which correspond to maternal and paternal alleles.

Sequencing studies have described that the human haploid genome is made up of approximately 3300 million pairs of bases (3300 Mb), of which approximately 25,000 genes have a coding function and, of these, only 8% (8000) have a known function and/or action mechanism [1].

Genes are considered the unit of genetic information that codes a functional product and as a unit of inheritance, which is distributed throughout the chromatids of the chromosomes in a specific position of DNA known as the locus. During the process of transcription, a copy of the DNA is made, which is known as the heterogeneous nuclear RNA, which proceeds to form mRNA, which codes for structural and functional proteins.

Approximately 99.9% of the DNA sequence is identical in humans; the remaining 0.01% represents genetic or allelic variations, also called SNPs. The presence of SNPs varies in different populations, which can explain evolution theories, migrations and even the ethnic origins of different populations. In addition, it offers information about the phenotypical diversity within the same species, which describes a proportion of relative susceptibility to certain diseases among individuals.

The Importance of Studying Genetic-Environmental Variant Interaction and Its Perspective in Clinical Application

There are various kinds of polymorphisms which are characterized by their presence or absence, their shape or size, the largest being insertions and deletions. In addition, there are other genetic variants known as repetitions of the copy number (CNV, copy number variation) and SNPs. Unlike mutations, SNPs are changes with a frequency greater than 1% of the population. If SNPs are characterized by a simple exchange of nucleotides of adenine, cytosine, thymine or guanine in the alleles, they are extremely important due to the fact that they are responsible for almost 90% of human phenotypical diversity. In 2008, for the first time, the "1000 Genomes Project" initiative was proposed to analyze the genetic material of 1000 people around the world and to study genetic variability. Finally, in 2015, the number of subjects analyzed reached 2500; the data suggested that in every healthy individual, there are around 150 variants that cause premature protein termination and another 30 implicated in the appearance of rare diseases. In addition, to the presence of more than 84 million SNPs in the human genome, they located between 100 and 300 pairs of bases throughout the genome [2, 3], generated by genetic recombination or missense (http://www.internationalgenome.org/data#download).

It has been reported that approximately 88% of the SNPs associated with disease are located in intronic and intergenic non-coding regions, which are found in areas not related to sequences that contain essential information for the expression of a gene [4]. The remaining 12% of the SNPs are called "coding", integrated into exonic areas, giving way, in the majority of

cases, to proteins that can differ in their composition and biological functions. Also, exonic SNPs may be synonymous and not produce a change in amino acid or nonsynonymous and change the sequence of amino acids, which would alter the structure, conformation and shape of the protein. Due to the fact that SNPs are genetically stable, they are maintained for various generations and can act as true biological signals. Currently SNPs are considered ancestral risk or protector markers for diseases, from a clinical point of view. Nevertheless, their analysis is complex due to the fact that clinical phenotypes are the result of the interaction between the genotype and the exome that involves personal pathological backgrounds and unhealthy lifestyles, which contribute to the metabolic alteration present in T2D. Therefore the evaluation of the gene-environment correlation in cohorts will allow a better understanding and interpretation of the physiopathology of the genic behavior of complex metabolic diseases, which hold first place in global morbi-mortality. In addition, they will create useful tools for early detection, prevention and more effective treatment in order to reach adequate therapeutic goals [5].

Genome-Wide Association Studies (GWAS)

Identifying the genetic determinants associated with T2D has been a complex task due to the role that is also played by the environment in the development of the disease. Nevertheless, currently, there are various genetic markers distributed throughout the genome. Analysis of previously reported candidate genes has allowed confirmation of the association of the genes with the disease in various populations; however, replication is not always successful due to phenotypical variation and ancestry. GWAS is a method that bases its analysis on statistical and biological associations among various SNPs and phenotypes of diseases.

The rapid development of genotyping techniques and the reduction in costs have allowed for a greater number of GWAS. These studies use microarrays with more than 1,000,000 SNPs and have transformed research into the genetics of complex diseases, with diabetes being outstanding. GWAS are characterized by the possession of a greater power to discover variants with a modest effect, whose association is not previously known. The first studies confirmed the associations between T2D and various genetic variants located on *PPARG* genes, adding six new loci (*CDKAL1*, *HHEX*, *SLC30A8*, *IGF2BP2*, *CDKNA2A* and *FTO*). Typically, each copy of these susceptibility alleles increases the risk of suffering diabetes by 10–15% [6].

Initially, GWAS was performed on the European population and later on other populations from the African and American continents with different ethnic groups, which has contributed to the identification of a greater number of genes associated with T2D. Table 10.1 shows the association of

Table 10.1 Association of SNPs with susceptibility to developing T2D in a trans-ethnic meta-analysis that included thousands of cases and controls with the ancestry groups European, East Asian, South Asian, Mexican and Mexican American

Taken from [7]

various SNPs with susceptibility to developing T2D in a trans-ethnic meta-analysis that included thousands of cases and controls with the ancestry groups European, East Asian, South Asian, Mexican and Mexican American [7]. To date, there are more than 80 SNPs, among which are variants in genes *WFS1, HNF1A, HNF1B, IRS1* and *MTNR1B*. The importance of the genetic component of T2D is clear when a concordance of 70–90% of the disease is observed between identical twins.

GWAS has allowed us to understand with greater precision the physiopathology of T2D in order to establish better opportunities for treatment, diagnosis and patient monitoring. From a genetic viewpoint, T2D is a multifactorial disease where the phenotype of a group of genes is modulated by environmental factors. The action mechanisms involved in the majority of signs associated with T2D offered by the GWAS are involved in a reduction in the secretion of insulin (be it due to dysfunction of the pancreatic beta cells or through reduction of cellular mass) or insulin resistance (associated with obesity). In conclusion, GWAS has offered important knowledge of the genetic variants most associated with T2D in the world [8]. Another focus for complex diseases is whole-exome sequencing. This has been successful in the study of low-frequency variants.

The Importance of Ancestry in Association Studies

It is known that in populations native to the American continent, there was a process of miscegenation that took place when the Amerindians and Europeans met in the New World five centuries ago. The latest studies show that the genetic composition is different in each country, and within the same country there are regional differences. For example, in Mexico, it has been shown that Mexico City has the following percentages: 65% Native Americans, 30% Europeans and 5% Africans, while in Monterrey City, N.L., the percentage was 56% Native Americans, 38% Europeans and 6% Africans [9, 10]. Even in Mexico City, there are variations in the proportions of ancestry when we compare the IMSS vs. INMEGEN studies [11]. Recently, a high prevalence of Amerindian ancestry was reported in the Montaña region of the State of Guerrero, reaching 80% Amerindian [12].

In Mexico, there is a very high degree of stratification, where the differences in allele frequencies between groups and controls can lead to false associations [9]. The Admixture Mapping method avoids these false associations and requires markers that may be informative concerning ancestry, that is, those for which allele frequencies differ between mixed populations. With this method, data is combined from all the markers to obtain information about the ancestral alleles of each marker locus and then the association of the disease with ancestral background. We can combine the information from multiple markers in a multivariate analysis to obtain information about the ancestral alleles of each locus of each individual in the admixture.

The importance of this chapter is to describe the most important genetic variants associated with T2D (Table 10.1). For more information about frequencies, haplotypes, etc., consult http://www.internationalgenome.org/, and variants associated with diseases like T2D are listed in the link to the ENCODE Project at https://www.genome.gov/10005107/.

Genes Associated to T2D

TCF7L2 Variants Gene

The *TCF7L2* gene has clinical relevance because it is implicated in a wide variety of signals, insulin resistance and T2D, specifically the variant rs7903146 in European populations, later also in Latin peoples. In 2006, the first gene implicated in susceptibility to T2D was identified through microsatellite markers, being identified without previous biological knowledge and with an important power of association, and which was named *transcription factor 7-like 2 gene* (*TCF7L2*; *TCF4*). It is known that *TCF7L2* is a transcription factor that influences the transcription of various

genes, thus exercising a great variety of functions within the cell. This transcription factor is a member of the signaling pathways of Wingless Int (WNT), located on chromosome 10q25. Stimulation of the WNT pathway goes along with the association of β-catenin with BCL9 and its translocation to the nucleus associated with *TCF7L2,* which results in the activation of WNT target genes, specifically in the repression of the synthesis of proglucagon in enteroendocrine cells. The non-coding area contains cis-regulatory elements that lead to the expression of *TCF7L2* in various tissues involved in the homeostasis of glucose, which suggests that the variants are probably regulating the expression of this gene. The T risk allele of *rs7903146* presents greater expression in the pancreas than the C protector allele [13]. Markers located on intron 3, *DG10S478*, and SNPs *rs12255372* (allele G > T) and *rs7903146* (allele C > T) were the first markers associated with T2D in individuals in Iceland [14]. Later, this association was replicated in various populations around the world, so this gene susceptible to T2D has become the most important worldwide. In the European population, each copy of the susceptibility allele increases the risk of developing T2D 1.4–1.5 times. In the Mexican population, the risk is 1.78 for each copy of the T allele for rs12255372, after adjusting for ancestral markers [15].

Lyssenko et al. showed that the risk given by the T allele of *rs7903146* is associated with a lack of insulin secretion, the effect of incretin and increase in the production of hepatic glucose. In addition, a cohort in Bosnia and another in Malmö showed how diabetes-free survival is greater in individuals with genotype CC than in individuals with CT/TT del *rs7903146* [12].

Variants of Genes *ABCC8* and *KCNJ11*

Genes of the family *ABCC8* (union cassette ATP, subfamily C, member 8; SUR1) and *KCNJ11* (inwardly rectifying potassium channel, subfamily J, member 11; KIR 6.2) are located on chromosome 11p15.1; it has been observed that both are expressed in beta cells, and it has been reported that various polymorphism versions on these genes associate with insulin secretion disorders [16].

It has been noted that carriers of the variant *p.Arg1420His* of gene *ABCC8* have twice the risk of developing T2D, mainly among Pima Indians, although this also applies to subjects with mostly Native American ancestry [17].

In Europeans, the association has been reported with variant *KCNJ11 E23K* (OR 1.23), but not with *ABCC8* [15]. Nevertheless, between these two genes, there is a high degree of linkage disequilibrium (LD), which makes it harder to identify the variant causing the risk of the disease [18].

Variants of Gene *CAPN10*

Calpain is a cysteine protease which participates in various functions such as apoptosis, exocytosis, mitochondrial metabolism and remodeling of the cytoskeleton and insulin secretion. Its expression is very high in metabolically important organs such as the heart, liver, pancreas islets and muscle. Known as the common gene in diabetes, it is located on chromosome 2q37.3, formed by 15 exons and showing 8 isoforms [19]. The most recent meta-analysis showed that the C allele of *rs2975760* of *CAPN10* was the best associated with increased risk of T2D [20]. However, an analysis by haplotypes showed that individuals with haplotype 1121/1121 for SNPs -44, -43, -19, or -63 presented twice the risk of T2D than only SNP-*43* [21]. This haplotype is not associated with other populations, which means that the genetic structure of each population is important and should be considered, as in other SNPs.

Variants of *PPARγ* Gene (Peroxisome Proliferator-Activated Receptor Gamma)

PPAR is a protein member of a superfamily of nuclear receptors which has a weight of approximately 56 kDa. PPAR affects mechanisms present in the control of steroid hormones, glucocorticoids, or thyroxine, retinoic acid and vitamin D, but mainly acts in the regulation of the expression of specific genes through a mechanism that is common to members of the nuclear receptor superfamily. It has been reported that the PPAR family is comprised of various subtypes known as PPARα, PPARβ/δ and PPARγ. This latter is coded by three different genes: *PPARγ1, PPARγ2* and *PPARγ3*. The main function is the regulation of genes that participate in lipid and glucose metabolism. Variants of *PPARγ2* in 3p25 are only expressed in adipose tissue and regulate the differentiation, storage of lipids and control of the transcription of various genes implicated in metabolism, and they also participate in insulin sensitivity [22]. Various studies have shown that PPAR antagonists improve hyperlipidemia and glucose levels.

Pro12Ala (*rs1801282*) has been associated with T2D in different populations. *Pro12Ala* has a prevalence of 12% in the Caucasian population, 10% in Native Americans and 1% in Chinese. This change in amino acid near the extreme amino terminal (NH2-terminus) modulates the transcriptional activity. Alanine favors the formation of alpha-helix, which does not occur with proline, which forms alanine isoforms, and stimulates deficiency in the target genes of the gene, carrying to the individual carriers a lesser accumulation of adipose tissue. In the latest meta-analysis, an OR of 0.86 was calculated, but unfortunately, the majority of the

population at the global level carries the allele Pro12, which generates a high risk of T2D [22].

On the other hand, it has been noted that *PPARγ* has been highly studied due to the fact that its ligands interact with thiazolidinediones, drugs used in the treatment of T2D. The effects of ligands of *PPARγ* are diverse, but the total effect is improvement in insulin sensitivity, in addition to regulation of other genes that have functions in glucose homeostasis and adipocyte differentiation.

Variants of the *CDKN2A/B* Gene

CDKN2A/B gene is located in region 9p21 and codifies for a protein p16, which has the function of inhibiting cyclin-dependent kinases p16 (INK4A) and p15 (INK4B), coded by the gene *CDKN2A* and a long non-coding RNA known as *ANRIL* (*CDKN2B-AS*) [23]. It participates in the cellular cycle and helps maintain pancreatic beta cell mass, but the mechanism by which *CDKN2A/B* influences diabetes risk is not yet clear. The risk allele of marker *rs10811661* has been associated with reduced insulin secretion in the European population [24], while genes *MTNR1B, TCF7L2* and *KCNJ11* are associated with the dysfunction of β cells; both pathways are related to the reduction of insulin secretion [16].

Variants of the *FTO* Gene

Association of the fat mass and obesity-associated (*FTO)* gene with obesity was first reported in a European GWAS study performed in individuals with T2D [25]. The power of association of the variant of the *FTO* gene with T2D was lost when correcting for body mass index (BMI), which suggested that susceptibility was being measured through obesity. Other studies have reported that the association between the variant and the risk of T2D is maintained after adjusting for BMI. It appears that the main cause of the variability of results is related to the time when BMI was measured. The association has been demonstrated before the development of T2D when BMI is more elevated and is reduced or lost with the greater time of evolution of the disease.

Studies confirm the association between the variant *rs9939609 (T/A)* of *FTO* and obesity as the main risk factor for developing T2D. In other populations, such as the Mexican, the association is not as evident, particularly in children [26]. European homozygote populations for the risk allele (AA) of *rs9939609* have 1.7 times the risk of developing obesity and on average have 3 kg more weight than the average population. Some studies have tried to identify the mechanism by which this association exists. In a metabolomic focus, metabolites have been identified, such as valine amino acid, a hexose, and other metabolites relevant to the phosphatidylcholine pathway. The alteration of valine metabolism leads to the accumulation of branched-chain amino acids in relation to the risk allele of *FTO*. The branched-chain amino acids and their derivatives seem to be an early manifestation of insulin resistance, probably via *mTOR/S6K1* kinase, which results in the phosphorylation of various residues of serine in the substrate of the insulin receptor (IRS-1). Metabolites of phosphatidylcholine are associated with apolipoprotein B, and it has been demonstrated that the risk allele of *FTO* is associated with the particles that form part apolipoprotein B.

Variants of the IRS-1 Gene

The molecules of IRS are important mediators in the signaling of insulin, in addition to playing an important role in the metabolism, growth and survival of the cell. The IRS family is formed by four members, IRS-1 to IRS-4, each presenting a different tissue distribution and therefore a different expression. IRS-1 and IRS-2 are key for insulin action and glucose homeostasis. IRS-1 is coded on chromosome 2q36.3. Polymorphism *Gly972Arg* of *IRS-1* has been most associated with the development of T2D. The union of insulin to its active phosphorylated receptor *IRS-1* phosphorylates tyrosine residues, serine and threonine (Ser/Thr), which join and activate PI3K, which contains the subunit p85, and p110 phosphorylates PI, which allows it to join with akt and PDK1. The phosphorylation of tyrosine residues accompanies the mobilization of glucose transporters (GLUT 4) that mediate the internalization of glucose. However, when the serines or threonines are phosphorylated, it leads to an accelerated degradation of the IRS protein, which generates an alteration in insulin signaling, insulin resistance and a decrease in the translocation of GLUT4.

As mentioned earlier, the polymorphism *Gly972Arg* has been the most reported in studies of association with T2D, in combination with environmental factors such as diet, age and physical activity. Like other genes and depending on the population, important associations have also been reported (such as in Europeans), weak ones as with the Japanese, or absence of, as with the Pimas [27]. In the Mexican population, variant *Arg* has been observed in 2.6% of controls and 7.9% of cases [28].

Variant of the Gene Hepatocyte Nuclear Factor 1-Alpha (*HNF1A)*

HNF1A is coded on chromosome 12q24.31. The protein joins the inverted palindrome 5′-GTTAATNATTAAC-3′ for the activation and regulation of gene expression, mainly in

the cells of the pancreatic islets and the liver. Some variants of the gene have been found to be associated with maturity-onset diabetes of the young 3 (MODY3). Through the study of exome sequencing, the variant pE508K has been identified and associated with T2D. This variant generates a reduction in the function of the protein, unlike MODY3 diabetes, where the function is almost lost. The mechanism related to the affinity of the protein for joining DNA sequences does not appear to be altered. It seems the reduction in activity occurs mainly through a reduction in expression, and the protein shows altered localization in the nucleus.

The effect of the variant on European populations is very high, with results similar to those of two studies on the Latin population. Carriers of the variant have up to a fivefold increased prevalence of T2D. Interesting from a clinical viewpoint, carriers of the variant respond better to treatment with sulfonylureas than with metformin, the drug of choice in the treatment of T2D [29].

Variant of the Gene *Solute Carrier Family 30 Member 8 (SLC30A8)*

This transporter, coded on chromosome 8q24.11 and expressed importantly in the Isles of Langerhans in the pancreas, participates in the packaging of proinsulin in secretory granules and liberation. These processes require the presence of the ions Zn^{2+} and Ca^{2+}, which form complexes with proinsulin. The ions of Zn^{2+} are transported by transporter 8, which is found in abundance in the pancreas beta cells and also located in alpha cells and participates in the liberation of glucagon. GWAS have associated the gene with susceptibility to developing T2D. A recent study showed that the marker associated with the greatest frequency in the European, Asian and African populations is rs13266634 [30]. However, other authors have not found this gene to be associated with T2D [31].

Other Variants Associated to Insulin Resistance and Dyslipidemias

Variant *R230C* of gene *ABCA1* of the HDL receptor participates in the reverse transport of cholesterol, which is associated with early-onset diabetes and obesity, particularly in the Mexican population, with values of $p = 10^{-6}$ [11]. Also, in the Japanese population, the presence of a haplotype with an OR of 2.59 has been reported to be associated with T2D [32].

In a meta-analysis of Mexican and Mexican-American samples to characterize genes associated with T2D in Hispanics, the following genes were identified, with values of $<10^{-5}$: gene *ATP2B2*, located on chromosome 3; *UNC5C* on chromosome 4 and *PIWIL4* on chromosome 11, in addition to three independent intergenic regions located on chromosome 10 and an expressed sequence tag (*EST*) sequence located near the area of gene *RXRA* on chromosome 9. Upon adjusting for BMI, two additional groups of markers were observed, one in the intergenic area of chromosome 20 and the other within genes *C22orf30/DEPDC5*, located on chromosome 22. This meta-analysis showed SNPs with a high level of significance in ten genomic areas. In addition, two additional regions were identified when BMI was incorporated, in particular an intronic variant of the *ANK2* gene and two intronic variants of the *MCPH* gene [33, 34]. Other population studies have identified genes such as *HNF1A*, *KCNQ1* and *PTPRD*. Also, two other genes identified, *CSMD1* and *ANK2*, were relevant due to their functionality in metabolic regulation. Other regions associated with T2D showed statistical significance, including the *CDKN2A/CDKN2B* and *IGF2BP2* genes.

Biological Validation Studies

After the identification of the genes associated with a disease, what is sought is to know their biological function, so that the genes mentioned above have been studied for their expression in adipose tissue, skeletal muscle, and lymphoblast cell lines. One of the most significant signals of SNP *rs202983*, located within the *CIT* gene (chromosome 12), showed an important effect on the regulation of gene *WFS1*. It has been documented that mutations in the *WFS1* gene cause monogenic diabetes and common variants of this gene have been associated with T2D. Lineal regression analysis of these genetic markers with five parameters (BMI, total cholesterol, HDL-C, LDL-C and triglycerides) showed values of the association at the genomic level in polymorphisms near the *APOA5* gene, which is located on chromosome 11. The variant *rs964184* showed the lowest value at $p = 2.3 \times 10^{-9}$. Other variants of interest are those of the *SYNE1* gene, which is found on chromosome 6, for triglycerides (*rs998147*, $p = 5.3 \times 10^{-7}$) and an area near the *MAD2L1* gene on chromosome 4 for HDL-C (*rs4568220*, $p = 7.1 \times 10^{-7}$) [33, 34].

Conclusions

T2D is a complex disease that presents differences in prevalence between populations. Epidemiological data indicate that the risk of suffering the disease is higher in Amerindian populations than those of European origin. There is evidence of the influence of genetic factors in populations; to date, over 80 loci associated with T2D have been identified, which do not always replicate among populations. Analysis by admixture mapping has been specifically designed to identify genes involved in complex diseases that show differences

in prevalence among populations. Given the history of miscegenation in the Mexican population, admixture mapping is an ideal method for identifying the genetic factors that increase the risk of suffering from T2D. The first GWAS performed in patients with T2D in Mexico showed that less than 10% of the 46 candidate genes reported in 2011 in the European population were found to be associated with our population. These populations are characterized mainly by low levels of HDL-C, high levels of LDL-C and elevated triglycerides. The genetic factors most associated with these alterations have been variants of *ZNF259/APOA5* genes, such as rs964184, associated with triglycerides, rs2367970 of the same gene, and rs2472386 of *ABCA1* gene, associated with HDL.

It is a priority to establish the genetic history of the Mexican in order to have risk markers for developing T2D, markers associated with complications and metabolic disorders, conditions very evident in our population thanks to current lifestyles.

Multiple-Choice Questions

1. A gene is considered to be:
   (a) A sequence of nitrogenated bases
   (b) **The unit of genetic and inherited information**
   (c) The chromatid unit that forms chromosomes
   (d) A sequence of nucleosides
   (e) Triplets of bases
2. What percentage of the DNA sequence is identical among humans?
   (a) **99.9**
   (b) 98.0
   (c) 95.0
   (d) 98.5
   (e) 99.0
3. The main difference between a mutation and an SNP is:
   (a) A mutation is lethal and an SNP is not
   (b) In mutation, there is a change in various bases
   (c) SNPs occur only in introns
   (d) **The frequency of an SNP is greater than 1%**
   (e) An SNP is presented at any stage of life
4. All are characteristics of SNPs except:
   (a) They are generally bi-allelic
   (b) They are presented throughout the structure of the gene
   (c) **They are only present in exons and introns**
   (d) They are inherited
   (e) They allow the identification of an individual
5. The gene most frequently associated with T2D worldwide is:
   (a) *IRS-1*
   (b) *CAPN10*
   (c) ***TCF7L2***
   (d) *PPARg*
   (e) *FTO*
6. Which is the action mechanism of variant rs1801282 of the gene *PPARγ*?
   (a) **Transcriptional modulation of the change of alanine**
   (b) Oxidation of free fatty acids
   (c) Transcriptional modulation of the signaling pathways of TZD
   (d) All of the above
   (e) None of the above
7. What is the main problem with the low replication of the association of obesity with T2D of the various genetic variants of the gene *FTO* upon analyzing it in different populations?
   (a) The loss of statistical power in meta-analysis
   (b) The ancestry of various populations
   (c) The time of evolution of the disease and the difficulty in performing metabolomics studies
   (d) **All of the above**
   (e) None of the above
8. Why is it important to determine the genetic component of metabolic diseases?
   (a) To identify risk or protector markers associated with the disease
   (b) To perform studies in metabolomics
   (c) **All of the above**
   (d) None of the above
9. What is the function of the gene *CAPN10*?
   (a) Participate in apoptosis, exocytosis, mitochondrial metabolism and remodeling of the cytoskeleton
   (b) The gene codes for calpain-10, an atypical cysteine protease that participates in the mechanism of insulin secretion
   (c) Participate in the oxidative use of glucose for skeletal muscle
   (d) **All of the above**
   (e) None of the above
10. Characteristics of gene *SLC30A8* include:
    (a) The transporter is coded on chromosome 8q24.11. It is expressed at a high level in the pancreas, particularly in the islets of Langerhans
    (b) It participates mainly in the packaging of proinsulin in secretory granules, the hepatic liberation and the elimination of insulin
    (c) It processes require the presence of ions Zn2+ and Ca2+, which form complexes with proinsulin
    (d) **All of the above**
    (e) None of the above

Glossary[1]

Ancestry The term may refer to the geographical origin of populations, for example, "individuals of European ancestry", or the line of heritage or descent of a group.

Diabetes Diabetes is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. The chronic hyperglycemia of diabetes is associated with long-term damage, dysfunction, and failure of different organs, especially the eyes, kidneys, nerves, heart, and blood vessels (American Diabetes Association).

Genetic marker A gene or (a fragment of) DNA sequence having a known location on a chromosome has an easily identifiable phenotype and an inheritance pattern that can be followed. Genetic markers act as chromosomal landmarks. They are used to trace or identify a specific region of a gene (especially one that is associated with an inherited disease) on a chromosome. They are also used to determine a linkage group or a recombination event.

Genome-Wide Association Study (GWAS) GWAS is a relatively new way to identify genes involved in human disease. This method searches the genome for small variations, called single nucleotide polymorphisms, or SNPs (pronounced "snips"), that occur more frequently in people with a particular disease than in people without the disease. Each study can look at hundreds or thousands of SNPs at the same time. Researchers use data from this type of study to pinpoint genes that may contribute to a person's risk of developing a certain disease.

Microarrays A microarray is a hybridization of a nucleic acid sample (target) with a very large set of oligonucleotide probes, which are attached to a solid support, to determine sequence or to detect variations in a gene sequence or expression or for gene mapping.

Single nucleotide polymorphisms (SNPs) SNPs are the most common type of genetic variation among people. Each SNP represents a difference in a single DNA building block, called a nucleotide. For example, an SNP may replace the nucleotide cytosine (C) with the nucleotide thymine (T) in a certain stretch of DNA.

Gene Expression Modifications in Type 2 Diabetes

11

Fernando Suárez-Sánchez and Jaime Gómez-Zamudio

Objectives

- Understand changes in gene expression that underlie the phenotype of T2D.
- Review the deregulation of inflammation, oxidative phosphorylation, carbohydrate, and lipid metabolism and mitochondrial function in four key organs involved in the development of T2D.
- Discuss the emerging role of microRNAs as local and distant regulatory molecules in T2D.

Introduction

The pathogenesis of type 2 diabetes (T2D) is not completely understood. It has been shown that environmental factors such as obesity, physical inactivity, unhealthy diet, and aging, in addition to genetic factors, play important roles in the genesis of T2D. The evolution of the technology in genomic analysis has made possible to find T2D susceptibility genes using genome-wide association study (GWAS) approaches. To date, more than 250 genomic regions have been identified related to T2D susceptibility or T2D-related glycemic traits [1]. Many of these loci have been associated with impaired β-cell function and insulin secretion. However, T2D is a complex metabolic disorder and is clear that several genes play important roles in this polygenic disease. It is not completely understood how those genomic variants (SNPs) are associated with T2D, if they are involved in the pathogenesis of the disease or act simply like risk markers. Only about 10% of the total variance of T2D is explained by the common variants identified by GWAS, and interestingly, most of the identified variants (>85%) fall in noncoding regions of the genome. This finding highlights their potential role in gene regulation.

Adipose Tissue

The participation of adipose tissue in the development of insulin resistance and T2D is tightly linked to two distinct groups of cells: adipocytes and immune cells. Adipose tissue has been recognized as an organ whose function is not limited to the sole storage of fat but has endocrine functions as well. The complex and still not-well-understood communication between cells during obesity triggers changes that end up with alterations in glucose homeostasis. These modifications are accompanied by the release of several signaling molecules such as adipokines and cytokines that can travel through the blood stream allowing them to reach local and distant organs where they exert their effects. Among an ample range of effects, these molecules may be able to modulate cell signaling and regulate expression of single or most often groups of genes in response to certain stimuli.

One of the most recognized molecules expressed differentially between lean and obese people is adiponectin. The concentration of this protein in circulation is inversely proportional to the body mass index (BMI). Furthermore, it has been reported that adiponectin gene expression is downregulated in obesity due to DNA hypermethylation of a region in its promoter [2]. This regulation is mediated by the DNA methyltransferase 1 (DNMT1) whose expression is elevated in adipocytes of obese individuals. Other studies have indicated that the leptin gene (its product has been classified as an adipokine which increases in concentration in obesity) may be regulated by DNA methylation [3]. In addition, protein-DNA affinity studies have identified the transcription factor *FOSL2* as an important regulator of *LEP* [4]. Leptin is a hormone that inhibits food intake and stimulates energy expenditure in lean individuals, but its function is lost or

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_11

decreased in obesity where an increase in concentration tries to compensate for the development of leptin resistance. However, this increase in leptin levels generally does not improve obesity. The same pattern of expression has been observed with resistin which is a hormone that can cause insulin resistance and decrease adipocyte differentiation. The transcriptional regulation of this gene is related to the transcription factor FOXO1. The non-phosphorylated, active form of FOXO1 can activate the resistin promoter by binding to two regions upstream of the transcription start site (−1539 to −1366 bp and −1016 to −835 bp) [5].

There are a number of other genes whose expression is modified in obesity. For example, Hoggard et al. [6] performed a study in which they compared the gene expression between visceral adipose tissue (VAT) and subcutaneous adipose tissue (SAT) which was obtained from obese individual. They found 22 genes that showed gene expression differences equal or greater than 5× in omental adipose tissue compared with SAT. Three of them codify secreted proteins (*GREM1*, *PTN*, and *SLPI*), but their function in adipose tissue has not been completely elucidated. However, recent data indicates that *GREM1* blocks *BMP4* which in turn decreases the expression of *PPARγ* and *C/EBPα*. These two transcription factors are key regulators in adipocyte differentiation. Thus, impairment of adipocyte differentiation in subject with fat-rich diets promotes the storage of excess of energy in enlarged adipocytes. Hypertrohy of adipose tissue is generally viewed as more negative than hyperplasia [7]. Indeed, it has been observed that adipose tissue hypertrophy is more frequent in diabetic subjects compared to nondiabetic subjects [8]. Regarding the *PTN* gene, one association study has found that the SNP rs161339 near this gene is associated with BMI [9]. PTN is able to induce the production of inflammatory cytokines; thus, it may be involved in the inflammatory response classically observed in obesity [6]. Recently, it has been reported that PTN and ADAMS1 inhibit the initiation of adipocyte differentiation which may further contribute to adipose tissue impairment [10]. The third differentially expressed gene, *SLPI*, codifies a protein with anti-inflammatory properties which may be produced to counteract the obesity-associated adipose tissue inflammation. This is supported by reports showing a positive association between circulating levels of SLPI and progression of metabolic dysfunction [11].

Other studies have shown that the genes *CIDEC/FSP27* (whose gene expression correlated with insulin sensitivity) and *PLIN1* (its dephosphorylated form inhibits lipolysis) are mainly expressed in the SAT and their levels in the VAT are negatively regulated by BMI, fat in depots, homeostatic model assessment (HOMA), and fasting glucose and are positively associated with genes that play a role in adipogenesis such as *PPARγ*, *GLUT4*, *FASN*, and *ACACA* and mitochondria biogenesis such as *PPARGC1A*, *PPARGC1B*, *TFAM*, and *MT-CO3* [12]. It has been demonstrated that TNF-α, a proinflammatory molecule usually found in obesity, decreases the expression of *CIDEC* by modifying the activation of the transcription factor PPARγ [13].

A study in subcutaneous adipose tissue from postmenopausal woman following a weight loss regime for 6 months indicates that a greater weight loss is associated with a decrease in 17b-hydroxysteroid dehydrogenase-1 (*HSD17B1*) and leptin (*LEP*) expression and marginally significant increased expression of estrogen receptor-1 (*ESR1*) and insulin-like growth factor-binding protein-3 (*IGFBP3*) [14]. HSD17B1 is an important component of the estrogen metabolism pathway because it catalyzes the conversion of less active estrone to estradiol [14]. Other pathways that were regulated during weight loss in postmenopausal woman were the mTOR and IGF-1 signaling pathway [14].

Changes in the expression of transcription factors during obesity and T2D excerpt broad effects in the cells since a single transcription factor is able to regulate several genes. However, due to its broad effect, it is sometimes challenging to fully understand its functions. For example, in adipogenesis, the expression of the transcription factor MAFB is upregulated. It increases with BMI in WAT and correlated with adverse metabolic features such as proinflammatory gene expression in adipocytes and macrophages of the adipose tissue. Weight loss decreases its expression [15]. However, these results do not agree with observations in mice where deficiency of this transcription factor lead to increased body fat due to larger adipocyte size and serum cholesterol levels. Possibly, this association is mediated by a reduction in AIM (apoptosis inhibitor of macrophages), which is an inhibitor of lipogenesis in adipocytes [16]. Another transcription factor which is regulated by hypoxic conditions in obesity is the HIF1. Previous reports showed that HIF1 inactivation in the adipose tissue reduced obesity and insulin resistance. These results point to this transcription factor as a potential therapeutic target to treat T2D and obesity. Other transcription factors that are regulated in obesity are PPARγ and C/EBPα; both are important regulators of adipocyte differentiation and inflammation.

It is well established that low-grade chronic inflammation is a hallmark of obesity and T2D. However, the signals that trigger the inflammation in the adipose tissue are not well understood, but one molecule that has shown a great capacity to elevate expression levels of chemokines and cytokines in subcutaneous adipose tissue is the nutrient-induced intestinal hormone glucose-dependent insulinotropic peptide (GIP). Reports indicate that GIP may be involved in the crosstalk of adipocytes and macrophages by the stimulation of the GIP receptor in monocytes and the increase of *MCP-1* mRNA expression [17]. Other genes whose expression was elevated were *MCP-2*, *IL-6*, *IL-6R*, and *TNF-α* [17, 18]. This observa-

tion was confirmed in co-cultures of 3T3L1-adipocytes and RAW 264.7 macrophages but not in isolated cell lines which further supports the hypothesis of a crosstalk between macrophages and adipocytes [17]. Expression of IL-6 and its receptor in subcutaneous adipose tissue (SAT) is positively modulated by obesity and correlates with the expression of *CD11b* (subunit of a complex involved in leukocyte adhesion and migration), *CD163* (marker of the monocyte/macrophage lineage), *TNF-a*, *MCP-1*, and *IP-10* (or *CXCL10*) (it as a role in chemoattraction of immune cells in response to IFN-γ) [18]. Adipose tissue accounts for the expression of approximately 30% of systemic IL-6 [19]. Higher concentration is associated with insulin resistance and T2D development [19].

Another molecule that has been demonstrated that is able to positively regulate the expression of inflammatory genes such as *TNF*, *IL6*, *STAMP2*, *LBP*, *MCP1*, and *NF-κB* in adipose tissue is *DBC1* [20]. Particularly, regulation of *NF-κB* is mediated through the interaction of DBC1 with sirtuin 1 and inhibition of its deacetylase activity [21]. Decrease in sirtuin 1 action is also associated with macrophage recruitment in adipose tissue [21]. In humans, expression of *DBC1* is associated with adipose tissue senescence in morbid obese subjects [20]. Other inflammation-related genes expressed in adipocytes of obese patients are part of the NOD-like receptor pathway which has been identified as one group of genes associated with inflammation in adipose tissue. NOD-like receptors are intracellular sensors of pathogen-associated molecular patterns (PAMPs) or damage-associated molecular patterns (DAMPs) which regulate caspase-1-mediated IL-1β secretion. Particularly, it has been reported that the expression of *NLRP3* and *PYCARD* (two important proteins required for the NLRP3 inflammasome activity) and the class II major histocompatibility complex (MHCII) correlate with adiposity phenotypes [22]. Activation of the NLRP3 inflammasome in hypertrophic adipocytes may be partially responsible of the adipocyte death by pyrosis which is an inflammation-programmed cell death which is observed in adipose tissue of obese individuals. The important role of NLRP3 in the development of T2D becomes clear in experiments where attenuation of the NLRP3 inflammasome was performed. The results showed a delay in the progression of diabetes, improved hyperglycemia, insulin signaling, and attenuated IL-1b secretion [23, 24]. When NLRP3 is not present, a reduction in the expression of other proinflammatory genes and the chemokine *CCL2*, *MCP-1*, and its receptor *CCR2*, which play an important role in macrophage chemotaxis, was observed [25]. On the other hand, recent findings point to an important role of MHCII in the CD4(+) T-cell activation and induction of IFNγ-dependent adipocyte IL-1β secretion which results in a diet-induced early insulin resistance in adipose tissue [26–28]. Interestingly, expression of MHCII is higher in hypertrophic adipocytes which are commonly found in metabolically abnormal obese when compared to metabolically healthy obese patients [28].

Whole gene expression studies by van Greevenbroek et al. [29] performed in SAT obtained from subjects with familial dyslipidemia showed higher expression of genes of the complement system and genes that regulate such system. The activation of the complement system by local cues in adipose tissue could facilitate the recruitment of immune cells and induce inflammation and insulin resistance in the adipose tissue. Involvement of the complement system in immune cells recruitment is supported by studies with C3a-receptor knockout mice which are protected from high-fat diet insulin resistance and decreased macrophage infiltration.

Studies performed in adipose tissue from subject with insulin resistance have identified the increase in the expression of *SELS*. This correlated with expression levels of cytokines in the adipose cells. It has been suggested that this protein is a serum amyloid-A protein receptor (which is bound to high-density lipoprotein, HDL) which can trigger the onset of insulin resistance. However, the exact functional relationship of this protein with insulin resistance is still under debate [30, 31]. Another protein regulated during insulin resistance and T2D is GSTA4 which plays a role in the elimination of lipid peroxidation products. Levels of GSTA4 decrease at the onset of insulin resistance and T2D since the primary enzymatic method for lipid aldehyde detoxification is via GSTA4-dependent glutathionylation. In part, it may explain the increase in protein carboxylation, reactive oxygen species (ROS) production, and mitochondrial dysfunction observed in such metabolic diseases [32].

Intake of *n*-3 polyunsaturated fatty acid (PUFA) by mice also downregulates the expression of proinflammatory genes such as caspase 1, *Nlrp3*, and *Il1b*, and it is thought that something similar occurs in humans [33].

Other studies have also reported increase in gene expression of oxidative phosphorylation, ribosome genes, and decrease expression of genes coding proteins participating in the WNT and MAPK signaling pathways in adipose tissue in response to exercise, which is recommended to persons with the risk of developing metabolic alterations and obesity [34].

Another study in patients that underwent two-step bariatric surgery (BS) separated by 12 months indicated an increased expression of cell death-inducing DFFA-like effector A (CIDEA) and LPIN1. Both genes are involved in the formation of lipid droplets in fat depots in response to significant weight loss as well as after treatment with the PPARγ agonist rosiglitazone [35]. Adequate triacylglyceride (TG) deposition in adipose tissue is necessary to prevent fatty acid overload in the skeletal muscle and liver [36]. Another gene associated with TG metabolism whose expression is augmented in adipose tissue of patients that underwent weight loss due to laparoscopic gastric banding surgery is the gene

PNPLA3. This gene negatively correlated with BMI, fasting glucose, and fasting insulin and encodes a triacylglycerol lipase that mediates triacylglycerol hydrolysis in adipocytes and has been associated with nonalcoholic fatty liver disease (NAFLD) [37]. It has been demonstrated that Lpin-1 expression levels in adipose tissue correlate with a favorable metabolic profile and expression of fatty acid oxidation genes [38]. Those two genes correlate positively with whole-body insulin sensitivity [35]. The same study observed that the expression of the genes associated with metabolic reactions involved in NAD+ (NMNAT2) and glutathione (NNT) is significantly increased in adipose tissue depots after surgery-induced weight loss. This can explain the better response toward ROS which is observed after BS [35]. Another distinctive observation was the modulation of expression of genes associated with branched chain amino acid metabolism (*BCAT1* and *BCAT2*). Both genes participate in the catabolism of chain branch amino acids (BCAA) whose levels increase in plasma from obese patients.

In animal models with rats which underwent Roux-en-Y gastric bypass (RYGB), the improvement of metabolic parameters was accompanied by a decrease in the expression of *NLRP3* and other inflammation-related genes (*IL-6*, *MCP-1*, *IL-18*, caspase-1 and apoptosis-associated speck-like protein) in omental fat [39]. This observation straightens the role of inflammation in the downregulation of glucose homeostasis. This coincides with the observations of diabetes remission accompanied with an improvement of inflammation, insulin resistance (IR), and other relevant parameters reported in diabetic patients that underwent the same surgery [40].

Similarities between the gene expression profile of adipose tissue of diabetic patients and obese individuals were found. Decrease in the expression of genes related to oxidative phosphorylation (carbohydrate, amino acid, and lipid metabolism) and an increase in expression of genes involved in inflammation and glycan degradation were found [41]. Among the differentially expressed genes, *ELOVL6*, *GYS2*, *FADS1*, *C12orf39*, *SAA1*, *STOX1*, *CASQ2*, *AGPAT9*, *FADS2*, and *B4GALT6* show a lower expression in diabetic patients, while *SPP1* (*OPN*), *TM4SF19*, *MMP9*, *CCL18*, *PRG4*, *IL1RN*, *PLA2G7*, *MSR1*, *VSIG4*, and *LGI2* show a higher expression in diabetic compared with nondiabetic patients [41]. This same study reported that the most regulated pathways in diabetic patients participate in the amino acid metabolism, carbohydrate metabolism, lipid metabolism, and energy metabolism. Some basal transcription factors are downregulated, while genes in the glycan biosynthesis, immune system, and signaling molecules pathways were upregulated [41]. These results in regulated gene expression are very similar to the regulation described with diet, BMI, IR, exercise, and bariatric surgery. This shows the strong relationship between T2D, bad dietary, and exercise habits.

Pancreas

The pancreas is an endocrine gland which has important roles in glucose homeostasis. It has the capacity to produce hormones such as insulin, glucagon, somatostatin, and pancreatic polypeptide but also secrete other enzymes involved in digestion. This gland contains specialized cells such as β-cells, α-cells and γ-cells, PP-cells, and epsilon cells; each can secrete certain hormones. Failure in the functions of this gland leads to the development of type 1 and 2 diabetes. T1D is characterized by a complete ablation of insulin secretion, while T2D is characterized by partial impairment of insulin secretion and insulin resistance that worsens with time. In this chapter, we will discuss gene expression changes that occur in the human pancreas when T2D develops.

Although the pancreas is a highly specialized organ, one study indicates that only 0.7% of all the genes coded in the genome are enriched in the pancreas. This represents approximately 146 genes, but its expression accounts for up to 68% of all the mRNA found in the pancreas. Significant quantities of these expressed genes are secreted proteins involved in the digestive metabolism. Forty-three additional genes mainly associated with neuroendocrine functions were enriched specifically in Langerhans islets [42]. Some of the genes that have the most elevated mRNA expression are shown in the Table 11.1.

The same study found that gene expression in β-cells is responsive to inflammatory cytokines. When exposed to pro-inflammatory molecules, 20% of the transcripts showed modification in their expression levels [42]. Many of these regulated transcripts were related to apoptosis and inflammation. This is highly relevant since diabetes is characterized by the development of low-grade chronic inflammation which promotes a pro-inflammatory environment in several tissues. Inflammation is accompanied by a decrease in the production of insulin which may precede β-cell death. This is in agreement with observations that T2D patients have a reduced β-cell mass, partially due to an increased apoptosis rate which is the results of factors such as gluco- and lipotoxicity and the increase in inflammatory cytokines. It has been reported that during the evolution of T2D, the pancreatic stone protein/regenerating protein (PSP/reg) is upregulated in β-cells and its levels correlated with the duration of diabetes. This protein is related to islet cell regeneration and diabetogenesis [43]. Another gene whose product participates in the regulation of β-cell apoptosis is *MST1* which under diabetologic conditions is transcribed and translated. Its activation leads to the ubiquitination of the important transcription factor PDX1 and induce the mitochondrial-dependent pathway of apoptosis. Downregulation of *PDX1* has an impact in the expression of insulin and *GLUT2* [44]. The potential of the transcription factor Pdx1 to induce the differentiation of acinar cells into β-cells was tested by creating transgenic

Table 11.1 Genes whose expression is elevated in islets of Langerhans (adapted from [42])

Gene	Description	Function
INS	Insulin	Lowering blood glucose
GCG	Glucagon	Elevating blood glucose
SST	Somatostatin	Regulation of endocrine system
PPY	Pancreatic polypeptide	Regulation of pancreatic and gastrointestinal functions
NKX6-1	NK6 homeobox 1	Transcription regulation in β-cells
PAX6	Paired box 6	Development and differentiation of α-cells
NPTX2	Neuronal pentraxin II	Excitatory synapse formation
SCG5	Secretogranin V (7B2 protein)	Regulation of secretory pathways
SCGN	Secretagogin, EF-hand calcium binding protein	Calcium influx and cell proliferation
GAD2	Glutamate decarboxylase 2 (pancreatic islets and brain, 65 kDa)	Autoantigen in diabetes
PTPRN	Protein tyrosine phosphatase, receptor type, N	Autoantigen in diabetes
IAPP	Islet amyloid polypeptide	Inhibition of insulin-stimulated glucose utilization and glycogen deposition
CFC1	Cripto, FRL-1, cryptic family 1	Embryonic development
FAM159B	Family with sequence similarity 159, member B	Unknown
RBPJL	Recombination signal binding protein for immunoglobulin kappa J region-like	Putative transcription factor
RGS9	Regulator of G-protein signaling 9	Regulation of dopamine/opioid signaling

mouse where *Pdx1* expression was inducible. The result was the generation of endocrine precursor cells which migrate into the pancreatic islets and differentiate into insulin-, somatostatin-, and PP (pancreatic polypeptide)-producing endocrine cells [45]. Thus, deregulation of this transcription factor results in hyperglycemia worsening [46].

In the β-cell fractions from diabetic patients, the expression of *UCHL1* (an important component of the deubiquitin system) is lower than in cells from nondiabetic individuals. This results in endoplasmic reticulum stress duo to an additional reduction in proteasomal activity. Higher expression of the endoplasmic reticulum stress proteins *BIP*, *CHOP*, and *GADD34* was found in β-cell fractions from T2D patients. It is in agreement with the observed reduction in β-cell function and survival described in diabetic patients [47]. Inflammatory cytokines produced during the development of T2D are other source of damage to the pancreas. It has been demonstrated that treatment of nondiabetic human islets with palmitate (saturated fatty acid associated with cardiovascular risk) results in the development of an inflammatory response characteristic of T2D patients. This comprise the induction of chemokines and cytokines such as IL-1β, TNF-α, IL-6, IL-8, chemokine (C-X-C motif) ligand 1 (CXCL1), and chemokine (C-C motif) ligand 2 (CCL2). It is proposed that the palmitate-induced NF-kB activation and the signaling through IL-1β is key to the inflammatory process [48]. In addition, some data indicate that during fatty acid-induced β-cell apoptosis, NF-kB activation is responsible for the downregulation of *PGC-1α* expression which acts as a transcriptional coactivator in the regulation of energy metabolism genes [49].

One feature of T2D is an abnormal lipid profile. Particularly, lipotoxicity due to exposure to saturated fatty acids is a predictor of the development of insulin resistance and T2D. Chronic exposure to palmitate, the most common saturated fatty acid impairs β-cell function in part by inhibition of the expression of the insulin gene [50]. However, this is not the only gene whose expression is altered due to continuous exposure. Pathway analysis showed upregulation of genes belonging to functions such as cell death, cellular movement (mainly chemokines), cellular development, gene expression, and lipid metabolism, while downregulated genes correspond to categories of cellular movement, cell morphology, lipid metabolism, molecular transport, and small molecule biochemistry. Palmitate inhibited expression of important transcription factors in β-cells such as *PDX1*, *PAX4*, *PAX6*, *FOXA2*, *MAFA*, *MAFB*, and *NEUROD1* [51]. PDX1 and PAX4 have important roles in developing and maintaining pancreatic islet function [44, 52], and SNPs in these genes have been associated with maturity onset diabetes of the young (MODY) [53]. Mutations in *PAX6* cause abnormal glucose metabolism by deregulating the proinsulin processing via modulation of *PC1/3* production which is a protein-cleaving enzyme [54]. *FOXA2* and *FOXA1* are major regulators of glucose homeostasis, the first by controlling the expression of glucagon, *MAFB*, and the ATP-sensitive channel KIR6.2 which controls insulin secretion in β-cells [55]. Other observations indicate that alleviation of hyperglycemia in mouse models is beneficial for the expression of the transcription factors *Pdx1* and *Mafa* and their targets insulin 1, glucose transported (*Slc2a2*), and Glp-1 receptor (*Glp1r*) in islets [56].

Palmitate inhibited the expression of other genes associated with T2D (*ASB9*, *GLRA1*, *MIA2*, *PRSS35*, *RAB15*, *RASGRP1*, *SEMA6D*, *TBC1D4*, *TSPAN4*, *TSPAN8*, *KCNK16*, *ADCY5*, *ADRA2A*, *TP53INP1*, *CDC123*, *PRC1*, *TCF7L2*, *GLIS3*, *HNF1B*, and *SLC30A8*). On the contrary, palmitate upregulated the expression of *LOC388022*, *C2CD4A*, *ADAMTS9*, and *SPRY2* [51, 57–59]. Islets exposed to palmitate also showed a reduction of proteasome activity,

lower stimulated insulin secretion, and higher caspase activity [47, 58]. To counteract the negative impact of lipotoxicity in β-cell survival, the cells have evolved a mechanism in which the enzyme prohormone convertase 1/3 (*PC1/3*) is upregulated. This enzyme is key in the processing of proglucagon into GLP-1 peptides in α-cells which is able to enhance cell survival through its interaction with its receptor GLP-1R [60, 61].

Hall and Volkov [58] found that a short exposure of islets to palmitate have an impact in the expression of genes in the glycolysis/gluconeogenesis, pyruvate metabolism, and biosynthesis of unsaturated fatty acid pathways. Downregulation of several genes that are part of the respiratory chain was described too. This may have a negative impact in ATP production and insulin secretion [58]. Palmitate also has an impact on the overall methylation of DNA which has been demonstrated to have a strong correlation with gene expression [58]. In fact, studies comparing DNA methylation between diabetic and nondiabetic T2D donors have identified candidate genes that influence insulin secretion which is a hallmark of T2D. Hypermethylation of CpG sites was found in 853 genes. Some of those demonstrated T2D susceptibility genes such as *TCF7L2*, *FTO*, and *KCNQ1*. From the differentially methylated genes, *CDKN1A*, *PDE7B*, *SEPT9*, and *EXOC3L2* also showed differential expression in islets from T2D and nondiabetic donors. Overall, the study found that many of the hypermethylated regions that showed difference between T2D and nondiabetic donors are located in the intergenic regions, around the transcription start site (TSS) and the 3′UTR region. It is worth to notice that several of the SNPs associated with T2D that have been found in GWAS are located in intergenic regions where silencers or enhancers are regularly placed. This may be an indication of a link between these variants, methylation of DNA, and gene expression [62].

Alterations in epigenetic regulation influence insulin secretion as well. Previous studies have shown that epigenetic regulation in islets from T2D patients lead to a lower expression of *PPARGC1A* which results in decreased insulin secretion [63]. Other genes that have been associated with a decrease in insulin secretion are *CHL1*, *LRFN2*, *RASGRP1*, *PPM1K*, *TSPAN33*, *NT5E*, *TMED6*, and *PAK7* [64].

T2D is characterized by an increase in glycosylated hemoglobin (HbA1c) which is an indicator of historic glucose levels in the patients. Thus, HbA1c values are a good indicator of noncontrolled T2D and indirectly could be related to pancreatic function. To date, variants associated with HbA1c explain only a small portion of the increase in HbA1c, but gene expression analysis comparing islets from diabetic and nondiabetic patients has identified ten genes which can explain 24% of the variance in HbA1c. These genes are *JAZF1*, *CHL1*, *LRNF2*, *RASGRP1*, *ABCC8*, *RASGRF1*, *KLHDC5*, *ELAVL4*, *KCNJ11*, and *SLC2A2* [51]. This is highly significant since a detailed study of the function of these few genes may render clues on the pathophysiology of T2D.

No protein-coding genes have been implicated in pancreatic damage as well. Multiple studies have demonstrated that long noncoding RNAs (lncRNAs) have a role in gene regulation, mainly by controlling the transcription of protein-coding genes in *cis*. These transcripts are synthetized by the cell, but they do not contain any protein coding sequence. When ill-regulated, they are associated with pathogenic roles. Particularly, it has been shown that expression of the lncRNA *KCNQ1OT1* is increased, while *HI-LNC45* is decreased in T2D islets. *HI-LNC45* regulates the expression of the transcription factor *GLIS3* which contains variants in the gene body that are associated with T2D. *GLIS3* is mutated in a form of monogenic diabetes as well [65]. *GLIS3* can regulate the expression of *MAFA*, *INS2*, and *GLUT2* and inhibit glucose oxidation and insulin secretion and is involved in the development of β-cells and modulates pancreatic β-cell apoptosis [66]. On the other hand, *KCNQ1OT1* is involved in the silencing of the *KCNQ1* gene which has variants associated with T2D, gestational diabetes, and glucose levels [67–69]. The conserved long noncoding RNA *βlinc1* is able to regulate hormones such as insulin and somatostatin as well as a number of nearby islet-specific transcription factors needed for the proper development and function of Langerhans islets [70]. Although lncRNAs are regulators of other genes, it has been demonstrated that some lncRNA genes are subjected to epigenetic modifications and transcriptional regulation as well [71]. microRNAs (miRNAs) have also been associated with transcriptional regulation of several genes in the pancreas. This double layer of gene regulation may reflect the importance of such genes in functions and processes such as insulin production and secretion, differentiation and proliferation, apoptosis, and survival.

Skeletal Muscle

The skeletal muscle is considered the major site of glucose uptake in the organism, approximately 75% of glucose uptake after a meal occurs, and is metabolized in the skeletal muscle where insulin plays a key role. In normal conditions, insulin binds to the insulin receptor (IR) which is self-phosphorylated and activates the signaling pathway which results in the translocation of the glucose transporter 4 (GLUT4) to the membrane. The presence of GLUT4 in the membrane is required to transport glucose into the cells of the organs with sensitivity to insulin such as the skeletal muscle and the adipose tissue. However, T2D is characterized by a insulin resistance which is characterized by the loss of the insulin capacity to trigger the glucose uptake into the cells, despite of normal or high serum insulin concentrations.

Multiple pathways have been described to contribute to the pathogenesis of insulin resistance: alterations in the insulin signaling, mitochondrial oxidative metabolism and ATP production, fatty acid oxidation, proinflammatory signaling, and modifications in β-cell development and metabolism.

It is known that T2D is a multigenic disease and involves changes in the expression of several genes in different biological pathways. For this reason, the transcriptomic analysis has been useful to identify gene expression profiles on specific tissues that are related to the pathogenesis of this disease and predict possible complications or provide new therapeutic targets for the treatment of T2D. However, due to the large list of genes that reportedly change their expression in T2D and that the gene expression can vary depending of several factors such as diabetes model, ethnicity, age, gender, pharmacological treatment, stage of diabetes, etc., it is difficult to interpret the results obtained by transcriptomic studies. In Table 11.2, we summarized the most commonly expressed genes in skeletal muscle, arranged by metabolic pathway, from studies with diabetic patients or murine models of diabetes [72–77].

Carbohydrate Metabolism

Most of the studies in gene expression of skeletal muscle have found an impaired expression of important genes involved in the transport of glucose, insulin pathway, and metabolism of glucose, for example, insulin receptor substrate-1 (*IRS1*), glycogen synthase (*GYS1*), uncoupling protein 3 (*UCP-3*), GLUT4 (*SLC2A4*), hexokinase II (*HK2*), phosphatidylinositol 3-kinase (*PI3K*), mitogen-activated protein kinase (*MAPK*), and serine-threonine kinase (*AKT*). Although several of these genes have showed changes in their expression in T2D in previous studies, none of them has emerged as a leading candidate responsible for diabetes. Several authors have proposed that the study of the coordinated pattern of gene expression could be more useful to identify the mechanisms involved in the pathogenesis of the disease and to propose potential new targets for the therapy of diabetes.

Lipid Metabolism

The metabolism in skeletal muscle in T2D involves an increased demand of fatty acid oxidation for its energy needs when glucose is not available. This alteration in lipid metabolism has been related to the accumulation of lipids in the skeletal muscle, a key mechanism involved in insulin resistance development. The expression profiles observed in different studies on skeletal muscle samples from human or murine models of diabetes were controversial; some of them agree with a significant increase in the mRNA for proteins involved in the fatty acid oxidation pathways, whereas some others described a significant decrease on the same genes. Similar discrepancies were found on the expression of β-oxidation pathway genes.

An altered lipid metabolism is also present in obesity, which has been considerate one of the main factor related to insulin resistance and T2D development. In this regard, the fat mass and obesity-associated gen (*FTO*) (a well-characterized gen associated with the increase in obesity risk) is expressed in tissues related to metabolic diseases, including skeletal muscle and adipose tissue. However, there are many inconsistences when the *FTO* expression in adipose tissue is related to obesity. On the other hand, some gene polymorphisms in the *FTO* gen have been associated with T2D in several populations, and their expression was related to defects in glucose and lipid metabolism in skeletal muscle and adipose tissue. In a study where the *FTO* expression in skeletal muscle from obese nondiabetic subjects was compared with type 1 and T2D patients, it was found that in T2D patients, *FTO* increases their expression at mRNA and protein levels, whereas the expression in obese nondiabetic subjects and T1D patients was unchanged. To probe the specific actions of *FTO* expression, it was overexpressed in myotubes, resulting in decrease expression of oxidative phosphorylation and antioxidant genes, increased lipid accumulation, and increased oxidative stress, similar to what was observed in the diabetic skeletal muscle, suggesting that FTO may contribute to the muscle alterations observed in T2D. Interestingly, *PGC-1α* gene was downregulated in diabetic patients, as was reported previously, but *FTO* overexpression did not modify the expression of *PGC-1α* in human myotubes [78].

Mitochondrial Function

It is important to note that despite the differences in experimental methods and ethnicity in the analyzed subjects from several studies, they agree that there is a significant decrease in the expression of genes involved in mitochondrial function. These studies in muscle biopsies from diabetic patients have reported a decrease of multiple components of the mitochondrial respiratory chain, and mainly, the oxidative phosphorylation (OXPHOS) pathway. Mitochondrial OXPHOS is an important source of reactive oxygen species (ROS), such as superoxide anions, hydrogen peroxide, and hydroxyl radicals that are formed by products of cellular metabolism. The ROS have been implicated in the development of insulin resistance. Interestingly, patients without T2D but with a family history of diabetes have a decrease expression in genes of OXPHOS pathway, suggesting that alterations in gene expression of this pathway could be related to the initial steps for T2D development [77].

Table 11.2 Summary of genes with altered expression in skeletal muscle samples from diabetic patients or animal models of diabetes

Gene	Description	Function	Expression
Carbohydrate metabolism			
SLC2A4	Solute carrier family 2 member 4 (GLUT4)	Glucose transport into the cells	↓
INSR	Insulin receptor	Insulin pathway	↓
AKT1	Serine/threonine kinase	Insulin pathway	↓
IRS-1/2	Insulin receptor substrate 1/2	Insulin pathway	↓
PIK3	Phosphatidylinositol 3-kinase	Insulin pathway	↓
GYS1	Muscle glycogen synthase	Glucose storage	↓
PTPN11	Protein tyrosine phosphatase, non-R type 11	Insulin pathway	↓
MAPK 4, *8*, *12*	Mitogen activated protein kinases	Insulin pathway	↓
PKC-ζ	Protein kinase C (PKC)-ζ	GLUT4 translocation	↓
HK2	Hexokinase II	Phosphorylates the glucose after uptake by the cell	↓
FBP2	Fructose-1,6 biphosphatase 2	Glucose metabolism	↑↓
Lipid metabolism			
FABP1	Fatty acid transporter type 1	Regulates the uptake of long chain fatty acids to muscle cells	↑
LIPE	Hormone-sensitive lipase	Contributes to increase the pool of nonsterified fatty acids in the cytosol	↑↓
LPL	Lipoprotein lipase	Hydrolyses triglycerides	↑↓
MGLL	Monoglyceride lipase	A key enzyme in triglyceride hydrolysis	↑↓
ACADM	Acetyl-CoA dehydrogenase	It is a rate-limiting enzyme catalyzing the first dehydrogenation of fatty acids	↑
ETFB	Electron transfer flavoprotein-β	It is an electron acceptor protein for many dehydrogenases in the mitochondria	↑
ECI	Δ^3, Δ^2-enoyl-CoA isomerase	Required for β-oxidation of unsaturated fatty acids	↑↓
SCD	Steroyl-CoA desaturase	A rate-limiting enzyme in unsaturated fatty acid synthesis	↓
LOC51706	Cytochrome b_5 dehydrogenase	A rate-limiting enzyme in unsaturated fatty acid synthesis	↓
OXCT1	Succinyl-CoA: 3-oxoacid-CoA transferase	A rate-limiting first step in extra hepatic metabolism of ketone bodies	↓
PPARα	Peroxisome proliferator-activated receptor α	Lipid metabolism	↓
Mitochondrial function			
PKM	Pyruvate kinase	Protein involved in glycolysis	↓
PDHA	Pyruvate dehydrogenase	Catalyzes conversion of pyruvate to acetyl-CoA and CO_2	↓
ATP5B	ATP synthase, H+ transporting, mitochondrial F1 complex, beta polypeptide	Synthesis of ATP	↓
SLC25A4	Solute carrier family 25 member 4	Involved in ADP/ATP flux between cytosol and mitochondria	↓
PGC1α	PPARγ coactivator 1α	Transcriptional coactivator that regulates genes involved in energy metabolism	↓
PGC1β	PPARγ coactivator 1β	Transcriptional coactivator that regulates genes involved in energy metabolism	↑↓
UCP3	Uncoupled protein 3	Mitochondrial protein expressed mainly in the skeletal muscle, participate in the fatty acid metabolism	↓
SOD2	Superoxide dismutase 2	Mitochondrial protein with antioxidant properties	↓
NDUFB2	NADH dehydrogenase-ubiquinone 1 beta subcomplex, 2	Electron transport chain	↓
NDUFB5	NADH dehydrogenase-ubiquinone 1 beta subcomplex, 5	Electron transport chain	↓
NDUFC2	NADH dehydrogenase-ubiquinone 1, subcomplex, 2	Electron transport chain	↓
SDHB.	Succinate dehydrogenase cytochrome b subunit	Electron transport chain	↓
NNT	Nicotinamide nucleotide transhydrogenase	NADPH production and involved in the antioxidant system	↓
UQCRC2	Ubiquinol cytochrome c reductase core protein II	Electron transport chain	↓
HSP70	Heat shock protein 70	Involved in protein folding process	↑↓
NRF-1	Nuclear respiratory factor 1	Transcription factor	↓

The arrows represent up (↑) or down (↓) regulated genes [72–77]

Most of the genes involved in OXPHOS pathway are encoded in the nuclear genome, and their expression is regulated by transcription factors. Particularly, the expression of the nuclear respiratory factor-1 (NRF-1) has demonstrated a key role in diabetes. In the skeletal muscle from diabetic patients, the expression of the nuclear respiratory factor-1 (NRF-1) was decreased as well as genes regulated by the NRF transcription factor family. The promoter region from several OXPHOS genes has been reported to contain binding sites for NRF-1, suggesting that this gene contributes to the diabetes-related expression pattern in diabetes. In this regard, NRF-1 has been proposed as an important gene that modulates mitochondrial biogenesis, respiratory capacity, and the glucose transporter protein GLUT4 [77].

In addition, the peroxisome proliferator-activated receptor (PPAR) gamma coactivator-1 (*PGC-1α*) gene has been proposed as a master regulator of mitochondrial gene expression that mediates the oxidative phosphorylation expression phenotype in prediabetic and diabetic patients. The PGC-1α is a transcriptional regulator that does not bind directly to the DNA but influence transcription by interacting with other transcription factors, modifying the chromatin or altering protein-protein interactions within the transcriptional complex. In diabetes, PGC-1 not only activates NRF but also PPARα, PPARγ, hepatocyte nuclear factor 4, and other transcriptions factors critical for the metabolic function [77, 79]. Interesting, members of the PGC-1 family, PGC-1α and PGC-1β, had a significant reduction on their expression that correlates with a decrease in OXPHOS gene expression in patients with T2D [80]. On the contrary, when the PGC-1α was overexpressed in a muscle cell line, an upregulation of OXPHOS genes was observed in a time-dependent manner [79].

The Role of Insulin in Gene Expression

The changes in glucose metabolism observed in T2D are related to insulin resistance, which has been proposed as one of the initial steps related to T2D development. Insulin is a hormone released by the pancreas, specifically by β-cells, which has an extensive capability to regulate gene expression. Some published investigations indicate that the insulin action in skeletal muscle may modify the expression of around 800 genes related to signal transduction, vesicular traffic, and cytoskeletal function and fuel metabolic pathways [81, 82]. These effects have been related with changes on at least 70 transcription factors involved in the insulin response. Some of them that stand out are *RRAD*, *IGFBP5*, *INSIG1*, and NGF1-B (*NR4A1*), which were upregulated in L6 skeletal muscle cells [82].

As was mention before, the action of insulin on gene expression is very important to regulate genes on specific metabolic pathways. To determine the direct contribution of insulin on the altered expression in T2D, the group of Yechoor et al. analyzed the gene expression profiles on a muscle insulin receptor knockout mice (MIRKO) and compared it to controls (Lox-controls) under three different conditions: (1) at basal state, (2) after streptozotocin (STZ)-induced diabetes, and (3) after STZ-induced diabetes rendered euglycemic with insulin treatment. The results obtained demonstrated that insulin action has a role in maintaining basal expression levels in 1% of the genes in comparison to 4% of genes that are altered in diabetes. Although insulin is not associated with these changes at basal state, it was observed that insulin receptor is required to reverse the effects induced by diabetes. Suggesting that the presence of an intact insulin-signaling system is needed to return its expression toward normal [76]. This phenomenon was also observed in humans where at early stages of T2D, high serum insulin levels are commonly observed and were related to an increase in the expression of insulin pathway genes, possibly as a mechanism to compensate elevated serum levels of glucose. However, this compensatory effect is lost in people with T2D where the expression of insulin signaling molecules is reduced [73].

Liver

The liver is an important organ that participates in the homeostasis and metabolism of glucose. Hepatic glucose metabolism includes glucose transport, glycolysis, gluconeogenesis, glycogen synthesis, and glycogenolysis. In fed state, the liver synthesizes and stores glycogen in response to insulin stimulation, whereas in fasting state, the liver activates the gluconeogenesis and releases glucose in response to glucagon stimulation. An imbalance in the metabolism of hepatic glucose has been related to the T2D development, where hyperglycemia correlates with hepatic insulin resistance.

The hepatic glucose homeostasis is maintained by many enzymes involved in hepatic glucose metabolism that have been proposed as potential targets in diabetes, for example, glucokinase (*GCK*) the key enzyme of glycolysis; fructose-1,6-biphosphatase (*FBP1*); phosphoenolpyruvate carboxykinase (*PCK1* and *PKC2*); and glucose 6-phosphatase (*G6PC*) control key points in the gluconeogenesis pathway. Glycogen phosphorylase (*PYGL*) is a rate-limiting enzyme of glycogenolysis [83]. G6PC and GCK act in opposition to regulate the intracellular levels of free glucose. An increased ratio of G6PC/GCK promotes a glucose efflux to the bloodstream, whereas a decreased ratio causes glucose influx. The GCK activity has been reported to decrease in patients with T2D. A decrease of 60% in *GCK* expression has been observed in diabetic subjects with HbA1c >7.0 that also correlates nega-

tively with Hb1Ac and fasting glucose, suggesting an important dysregulation of hepatic *GCK* expression in diabetes [84]. On the other hand, in fasting conditions, normoglycemia is maintained by hepatic gluconeogenesis, controlled by rate-limiting enzymes such as *FBP1*, *PCK1*, and *G6PC* that are regulated by insulin. An alteration in gluconeogenesis is observed in T2D. It has been related to an increased expression of *FBP1*, *PCK1*, and *G6PC* due to the incapacity of insulin to suppress their expression due to hepatic insulin resistance.

It has been described that transcriptional activation of *PCK* requires the coactivation of the glucocorticoid receptors and the liver-enriched transcription factor hepatic nuclear factor-4α (*HNF4A*) by *PGC-1α* [85]. The *PGC-1α*, as mentioned before, is a key regulator of the OXPHOS-related genes in other tissues such as skeletal muscle, producing a downregulation of the OXPHOS pathway in DT2. On the contrary, several genes in the OXPHOS pathway appear to be upregulated in the liver from diabetic patients (Table 11.3). However, no correlation was observed between the expression of *PGC-1α* and the upregulation of genes involved in OXPHOS in the liver of patients with T2D [86].

Like OXPHOS pathway, other metabolic pathways have been shown to differ in their expression pattern when compared with other insulin-sensitive tissues. For example, several genes co-expressed in the liver, skeletal muscle, and adipose tissue, related to glycolysis/gluconeogenesis, fatty acid beta oxidation, tricarboxylic acid cycle, and electron transport chain pathways, are downregulated in skeletal muscle and in adipose tissue but are upregulated in the liver from diabetic patients [75].

The lipid metabolism is well known to be altered in the diabetic liver. Interestingly, none of the expression enzymes related to fatty acid metabolism, including fatty acid oxidation, fatty acid synthesis, and fatty acid storage were downregulated in the liver of diabetic mice. On the contrary, enzyme genes involved in fatty acid oxidation (*CPT1a*, *CPT2*, *EHHADH*, ACOT2, *ACOT3*, *ACOT4*, *ACOT5*, *ACOT6*, and *PPARα*) and fatty acid storage (*ELOVL6*, *SCD1*, *GPAT*, *DGAT1*, and *DGAT2*) were significantly upregulated, whereas the genes involved in fatty acid synthesis (*ACLY* and *FASN*) showed no significant changes. In addition, genes related to fatty acid transport (*CD36* and *SLC27a2*) were also upregulated in the liver of diabetic mice, showing that enhanced fatty acid transport is consistent with the increased expression of enzyme genes related to fatty acid storage. These data suggest that diabetes enhances liver fatty acid oxidation, which has been reported to stimulate gluconeogenesis and suppress glycolysis. In this sense, it was reported that key enzymes in glycolysis such as pyruvate kinase, phosphofructokinase, and glucokinase enzyme activity and mRNA expression are decreased in diabetes. However, in the liver of diabetic mice, no changes in pyruvate kinase or phosphofructokinase expression were observed. On the contrary, the *PKLR* gene that encodes the rate-limiting enzymes pyruvate kinase was significantly upregulated, suggesting an increased glycolysis activity in the liver. But this enhanced glucose consumption is not sufficient to decrease the hepatic glucose levels because gluconeogenesis and glycogenolysis were also enhanced to produce more glucose [83].

On the other hand, the inflammation is one important factor that leads to diabetes. Surprisingly the downregulated genes found in diabetic mice liver were mainly enriched in immune-related process, such as adaptive immune response and lymphocyte mediate immunity. However, the results showed that besides inflammatory signaling, another hepatic immune-related pathway is also correlated to T2D. For example, the downregulated genes in diabetic mouse liver were also enriched in pathways related to cancer, hepatitis, adenovirus infection, and liver tumor. These data are consistent with previously reported data that reported an increase in the frequency of hepatitis B and C virus infection in diabetic patients. That is in line with the association of hepatitis with T2D. Furthermore, epidemiological studies have reported that liver cancer is increased in diabetic patients; however the biological mechanism is still unknown [83].

Table 11.3 OXPHOS genes upregulated in patients with T2D [86]

Gene	Description	Function
NDUFA6	NADH: ubiquinone oxidoreductase subunit A6	Electron transport chain
SDHC	Succinate dehydrogenase complex subunit C	Electron transport chain
UQCRB	Ubiquinol-cytochrome c reductase-binding protein	Electron transport chain
COX4i1	Cytochrome c oxidase subunit 4i1	Electron transport chain
ATP5B	ATP synthase, H+ transporting, mitochondrial F1 complex, beta polypeptide	ATP synthesis

Whole-Blood Gene Expression in DT2

Studies of gene expression in peripheral blood mononuclear cells (PBMCs) have identified changes in more than 1000 genes which are differentially expressed in diabetic patients. Those genes were grouped according to their function, and changes in profile expression of several signaling pathways were observed when compared with subjects without diabetes.

The most important pathways altered in T2D patients were OXPHOS, MAPK, electron transport chain pathways, fatty acid metabolism, inflammatory response, and DNA repair [85, 87]. However, some of the altered genes were involved in two or more biological process, such as *RELA*, *UCP3*, *STAT5B*, *PLD2*, *PSEN2*, *IL17A*, and *CRCP* (upregulated

Table 11.4 Genes expressed in the WBC, adipose tissue, liver, and skeletal muscle related to the progress of T2D

Gene	Description	Function
FABP5	Fatty acid binding protein 5	Protein involved in the fatty acid uptake, transport, and metabolism has been associated with the development of insulin resistance and T2D in obesity
CFD	Complement factor D	Serine peptidase protein secreted by adipocytes that has been implicated with insulin secretion in mice
PC-1	Ectonucleotide pyrophosphatase/phosphodiesterase 1	Transmembrane protein that acts as an inhibitor of the insulin pathway and has been related to insulin resistance
UCP3	Uncoupling protein 3	Mitochondrial protein expressed mainly in skeletal muscle, it participates in the fatty acid metabolism and has been observed a decrease in their expression in patients with T2D

genes involved in inflammation, response to hypoxia and oxidative stress, and fatty acid response), as well as *ARNT*, *CAT*, and *MDH2* (downregulated genes implicated in response to oxidative stress, DNA repair, and response to hypoxia) [87]. Interestingly, the pathways involved in stress response, such as MAPK, TNF signaling, apoptosis, and mTOR signaling, were significantly altered after glycemic control [85].

The ceramide and adipocytokine signaling pathways were significantly upregulated in T2D patients, probably as a result of the presence of obesity in the patients. In the case of ceramides, they are lipids related to structural components of the cell membrane. However, an increase of ceramide production has been associated with different stress stimuli such as inflammatory mediators, heat, UV radiation, hypoxia, chemotherapeutics, and oxidative stress. High levels of ceramides are involved in the inhibition of AKT/PKB, resulting in insulin resistance. It suggests an important link between obesity and diabetes. In addition, the adipose tissue releases several factors including FFA and proteins called adipocytokines (TNF-α, IL-6, and resistin) that control various metabolic functions. Those adipocytokines and the proinflammatory cytokines secreted by the macrophages residing in adipose tissue have been related to insulin resistance development. This phenomenon occurs by the activation of JNK and NF-κB pathways that impair the insulin action by interfering with the insulin binding to its receptor [87]. In this sense, genes related to the JNK pathway were coordinately upregulated in diabetes; however, after glycemic control, a downregulation in this pathway was observed. The gene expression of JNK genes was also significantly correlated to fasting glucose levels and HbA1c. It suggests that the upregulation of the JNK genes in the PBMCs may be associated with hyperglycemia. In this regard, diabetes and hyperglycemia have been related to oxidative stress which causes activation of the JNK pathway by endoplasmic reticulum stress in pancreatic β-cells and hepatocytes. Besides, JNK activation suppresses insulin biosynthesis and impairs insulin action.

On the other hand, the OXPHOS pathway was significantly downregulated in diabetes. However, it was not altered by glycemic control. The altered expression in OXPHOS pathway was correlated with neither fasting glucose nor HbA1c. It suggests that OXPHOS may predict the existence of diabetes, because it was coordinately downregulated in PBMCs of patients with T2D but was not altered by glycemic control. These data are in agreement with the profile expression observed in the skeletal muscle and adipose tissue, where the OXPHOS is one of the main pathways that suffer alteration in gene expression in diabetes [85].

To compare if the gene expression observed in WBC was related to the gene expression in insulin-sensitive tissues such as the liver, adipose tissue, and skeletal muscle, a microarray analysis was performed in OLETF rats. The results showed that more than 300 genes were differentially expressed in blood cells, and only 4 genes were related to the insulin-signaling pathway: *Pc-1*, *Sihps-1*, and *Grb2* were upregulated, and *Pten* was downregulated. In addition, 57 genes were concurrently expressed in the analyzed tissues with the adipose tissue showing the best correlation with WBC, sharing 41 genes. It was followed by the liver with 25 genes and 14 genes with the skeletal muscle. From these 57 genes, only 4 genes have been well related to the progress of T2D (Table 11.4) [88].

Whole-Blood Gene Expression as a Possible Tool for Early Detection of T2D

The diagnosis of T2D is generally obtained by measuring fasting glucose levels, oral glucose tolerance test (OGTT), or percent of HbA1c. However, these methods do not determine the risk to develop T2D at early stages. The expression profile has been proposed as a very good tool to evaluate the risk to develop T2D. However, lack of samples from specific tissues makes difficult to perform this kind of studies. It is not ethically correct to obtain tissue samples from organs involved in the pathogenesis of the disease from healthy humans only for an early diagnosis. For this reason, recent studies have been focused to determine the expression profile on whole blood cells (WBC), which are very accessible. This is a tissue that may show the oxidative stress caused by high levels of glucose, insulin, free fatty acids, and tissue-derived circulating bioactive mediators.

The studies on WBC have demonstrated that gene expression profile in diabetes is different from other pathologies such as metabolic syndrome or coronary artery disease. Suggesting that gene expression profiles in WBC can be useful to identify the altered pathways involved in the patho-

physiology of T2D and pre-clinical symptoms of T2D. This technology can also be used as a new diagnosis method that could predict the progression of the disease.

miRNAs in Blood Samples

Today it is widely recognized that not all the RNAs are traduced to proteins; there are noncoding RNAs named microRNAs (miRNAs). They are involved in gene regulation of specific target genes. The miRNAs are a class of 19–24 nucleotides of RNA, which mediate post-transcriptional gene silencing by binding to the 3′-UTR or open reading frame (ORF) region of target mRNAs. The involvement of miRNAs has been reported in several biological activities including cell proliferation, cell differentiation, cell migration disease initiation, and disease progression [89]. Increased levels of specific miRNAs have been associated with a variety of diseases including cancer, obesity, diabetes, and cardiovascular disease. In the case of diabetes, several studies have reported that miRNAs play a critical role in glucose homeostasis and T2D pathogenesis, because a vast number of miRNAs are implicated in pancreatic development (miR-124a, miR-15a/b, miR-192, miR-375), insulin secretion (miR-9, miR-124a, miR-375), glucose transport (miR-29a/b), and β-cell dysfunction (miR-124a). In addition to the hyperglycemia, miRNAs also participate in the inflammatory response, vascular endothelial damage, and fibrosis processes that are involved in DT2 complications. There is evidence that demonstrates that T2D complications are associated with miRNAs dysregulation in various target tissues, especially the brain, eyes, nerves, and kidneys. For example, the miR-133 highly expressed in diabetic hearts has been associated with long QT syndrome and cardiac hypertrophy, whereas upregulation of miR-192 has been implicated in diabetic nephropathy [90].

In addition to the expression of miRNAs in tissues, they are expressed in many biological fluids such as saliva, urine, breast milk, and blood where its expression is stable. They are found packed into exosomes or microvesicles and as extracellular miRNAs that are loaded into high-density lipoprotein (HDL) or bound to an argonaute protein (AGO2) outside of the vesicles. These conformations protect the miRNAs from degradation and confers them stability in those fluids. The work published by Wang et al. [91] investigates whether there were differences in the serum miRNA expression profiles between T2D patients with or without diabetic microvascular complications, in comparison with nondiabetic patients. The results showed that serum miRNA expression profiles varied among diabetic patients and the healthy group. From the 754 miRNAs evaluated in the array, 25 miRNAs were upregulated, and 118 were downregulated in the two T2D patient groups compared with the nondiabetic controls. The validation analysis showed that five miRNAs (showed in Table 11.5) were significantly increased in both T2D patients with and without complications relative to healthy controls. Furthermore, those five miRNAs were higher in T2D patients with complications than in those who were free of complications [91].

Table 11.5 Significantly upregulated miRNAs found in T2D patient groups in comparison with nondiabetic group [91]

miRNAs	Diabetic complication
miR-661	Regulation of insulin biogenesis and the SNAIL-triggered epithelial to mesenchymal transition that has been related to microvascular complications
miR-571	Chronic liver disease by their participation in fibrogenic and inflammatory process in the liver
	Contribute to kidney fibrosis that is related to diabetic nephropathy
miR-770-5p	Retinopathy and neurological diseases
miR-892-b	Retinopathy and neurological diseases
miR-1303	Tumor/cell cycle-related miRNAs

Recently, a study in adipose tissue of Dicer KO mice (AdicerKO) demonstrated that miRNAs released to the circulation can regulate gene expression in other tissues. For example, the miR99b produced and released to the circulation by the adipose tissue was responsible in modulating the expression of the fibroblast growth factor 21 (FGF21) gen in adipose tissue, as well as in the liver, muscle, and pancreas. Suggesting that miRNAs secreted by the adipose tissue may act at paracrine and endocrine levels [92]. Interestingly, the Dicer KO mice used in this study showed an alteration in glucose levels and insulin resistance. Thus, the miRNAs released by the adipose tissue may affect the glucose metabolism possibly by their influence in insulin-sensitive tissues.

As a summary, the publications reviewed propose that miRNAs detected in the circulation can be used as potential noninvasive biomarkers for various diseases, including T2D and its complications. However, more studies are necessary to validate this hypothesis.

Concluding Remarks

- Changes in the expression of several genes arising before phenotype changes are observed.
- Insulin resistance and insulin secretion are linked to the modification of gene expression in the pancreas, liver, adipose tissue, muscle, and blood.
- Inflammation, oxidative phosphorylation, carbohydrate and lipid metabolism, and mitochondrial function are distinctive pathways that are deregulated during T2D progression.
- Gene regulation in distant organs can be achieved by secreted hormones and microRNAs

Multiple-Choice Questions

1. Mention two transcription factors that participate in the regulation of adipocyte differentiation.
   (a) **PPARγ and C/EBPα (both molecules coordinately regulate the expression of many hundreds of genes responsible for the establishment of the mature adipocyte phenotype)**
   (b) FOXO1 and HIF1
   (c) PDX1 and PGC-1α
   (d) FOXO1 and PDX1
   (e) HIF1 and PDX1
2. Mention one role the NOD-like receptors have in adipocytes of obese individuals.
   (a) Decrease the expression of inflammation-related genes.
   (b) **Induce adipocyte death by pyrosis. (Activation of caspase-1 leading to membrane breakdown and proinflammatory cytokine processing)**
   (c) Increase lipid uptake.
   (d) Increase adipogenesis.
   (e) Sense blood glucose.
3. How is the expression of inflammation-related genes in obese vs. lean individuals?
   (a) Inflammation-related genes expression is lower in obese than in lean individuals.
   (b) Inflammation-related genes expression is the same in obese than in lean individuals.
   (c) **Inflammation-related genes expression is higher in obese than in lean individuals. (This enhanced expression of inflammatory genes is linked to the development of insulin resistance.)**
   (d) Inflammation-related genes expression is not related to obesity.
   (e) Inflammation-related genes expression is not relevant.
4. What effects does saturated fat consumption exert in the pancreas?
   (a) Increases the expression of transcription factors such as PDX1 and PAX4.
   (b) Positively regulates ATP production in the pancreas.
   (c) **It decreases the expression of insulin and induces apoptosis of β-cells. (Inflammation and saturated fat consumption inhibit the expression of important transcription factors in β-cells)**
   (d) Induce macrophage recruitment
   (e) Trigger mechanism to protect from inflammation-induced damage
5. What are the most distinctive pathways that are deregulated in T2D?
   (a) Inflammation, urea cycle, carbohydrate, lipid metabolism, and mitochondrial function
   (b) Inflammation, oxidative phosphorylation, carbohydrate metabolism, nucleotide metabolism, and mitochondrial function
   (c) Xenobiotics degradation, oxidative phosphorylation, nucleotide metabolism, lipid metabolism, and mitochondrial function
   (d) **Inflammation, oxidative phosphorylation, carbohydrate, lipid metabolism, and mitochondrial function (deregulation of genes in these pathways has been observed in the main tissues associated with T2D)**
   (e) Inflammation, oxidative phosphorylation, urea cycle, lipid metabolism, and polar amino acids
6. Which genes are considerate as two key regulators of the expression of OXPHOS pathway related genes?
   (a) *GLUT4* and *FTO*
   (b) *PGC1α* and *SOD2*
   (c) ***NRF-1* and *PGC-1α* (downregulation of OXPHOS genes in diabetes are associated with low expression of NRF-1 and PGC1α genes)**
   (d) *PGC-1β and IRS*
   (e) *PPARα* and *FASN*
7. How PGC-1α can influence the gene transcription?
   (a) Binding directly to DNA and activate the transcription in target genes
   (b) **Interacting whit other transcription factors such as *PPARα*, *PPARγ,* and *HNF4*. (The *PGC-1α* is a transcriptional regulator that does not bind directly to DNA but influence transcription by interacting with other transcription factors including *NRF-1*, *PPARα*, *PPARγ,* and *HNF4*)**
   (c) Activating directly specific sites of the RNA polymerase II increasing their affinity to DNA
   (d) Inhibiting the union site of the transcription factors in the DNA
   (e) Stabilizing the mRNA and inhibiting its degradation
8. Besides the expression pattern in OXPHOS pathway, what other pathways are downregulated in skeletal muscle and adipose tissue but upregulated in liver in diabetic patients?
   (a) **Fatty acid beta oxidation, tricarboxylic acid cycle, glycolysis/gluconeogenesis, and electron transport**
   (b) Inflammation, urea cycle, carbohydrate, lipid metabolism, and mitochondrial function
   (c) Inflammation, carbohydrate metabolism, nucleotide metabolism, and mitochondrial function
   (d) Xenobiotics degradation, oxidative phosphorylation, nucleotide metabolism, lipid metabolism, and mitochondrial function
   (e) Fatty acid transport, urea cycle, glycogenolysis, insulin transport, and glucose uptake

9. What is the tissue that had the best expression pattern correlation with whole blood cells in diabetes?
   (a) Skeletal muscle
   (b) Pancreas
   (c) Liver
   (d) Brain
   (e) **Adipose tissue (the adipose tissue and WBC share the expression of 41 genes, followed by liver with 25, and the skeletal muscle with 14)**
10. Why miRNAs detection in blood stream would be a potential risk marker in diabetes?
   (a) Because they are small noncoding RNAs that can be detected in blood samples
   (b) Because miRNAs are very stable to degradation in blood samples
   (c) Because miRNAs expression is increased in blood samples from DT2 patients
   (d) **Because some miRNAs detected in the circulation are related to gene regulation in altered pathways in diabetes and diabetes complications**
   (e) Because adipose tissue can release miRNAs to blood stream

- This paper described the importance of the transcriptome to identify genes related to diabetes development.

Hayashi Y, Kajimoto K, Iida S, Sato Y, Mizufune S, Kaji N, et al. DNA microarray analysis of whole blood cells and insulin-sensitive tissues reveals the usefulness of blood RNA profiling as a source of markers for predicting type 2 diabetes. Biol Pharm Bull. 2010;33(6):1033–42.
- In this paper compare the expression pattern of different insulin sensitive tissues with RNA expression in blood samples from diabetic patients.

Wang C, Wan S, Yang T, Niu D, Zhang A, Yang C, et al. Increased serum microRNAs are closely associated with the presence of microvascular complications in type 2 diabetes mellitus. Sci Rep. 2016;6:20032.
- This paper focuses on the importance to study the miRNAs expression in blood circulation related to diabetes and vascular complications.

Glossary

3′-UTR region Untranslated regions (UTRs) at the 3′end of mRNA contain important sequences that are related to the regulation of gene translation. The 3′UTR plays a critical role in the stability of mRNA and in post-transcriptional regulation.

Apoptosis Is a process of programmed cell death that is considerate to be important in several processes including normal cell turnover, development and function of immune system, hormone-dependent atrophy, embryonic development, and chemical-induced cell death. Human conditions such as neurodegenerative diseases, ischemic damage, autoimmune disorders, and may types of cancer are related to inappropriate apoptosis.

Bariatric surgery Is a surgical process employed to reduce weight in obese patients, by restricting the amount of food the stomach can hold, causing malabsorption of nutrients. The most common bariatric surgery procedures are gastric bypass, sleeve gastrectomy, adjustable gastric band, and biliopancreatic diversion with duodenal switch.

Damage-associated molecular patterns (DAMPs) Are cell-derived molecules that can initiate and perpetuate immunity in response to trauma, ischemia, and other setting of tissue damage in the absence of overt pathogenic infection. DAMPs can be found in the nucleus and cytoplasm (HMGB1), cytoplasm alone (S100 proteins), exosomes (HSP), extracellular matrix (hyaluronic acid), and in plasma such as complement (C3a, C4a, and C5a). Examples of nonprotein DAMPs include ATP, uric acid, heparin sulfate, RNA, and DNA. Increased levels of DAMPs are associated with inflammatory diseases such as sepsis, arthritis, atherosclerosis, systemic lupus erythematosus, Crohn's disease, and cancer.

Deacetylation Histones acetylation has been linked to transcriptional activation. The enzymes regulating the histone acetylation are the histone acetyltransferases (HATs). On the contrary, the deacetylation by histone deacetylases (HDACs) is related to transcriptional repression.

DNA hypermethylation DNA methylation is a heritable epigenetic mark that involves the covalent transfer of a methyl group to a cytosine ring of DNA. The methylation reaction is catalyzed by a family of DNA methyltransferases (DNMTs). DNA methylation is associated with decreased transcriptional activity.

Enhancer Is a DNA sequence that activators or transcriptional factors bind and increase gene transcription. Its location is variable in the gene; it can be present in the 5′-UTR, in the 3′-UTR, or into the codify region of the gene.

Epigenetics Epigenetics is the study of biological mechanisms that switch genes on and off. There are three major levels of epigenetic changes: (1) chemical modification at nucleotide level (DNA methylation and RNA interference), (2) modifications at histone level, and (3) nucleosome remodeling.

Genome-wide association studies (GWAS) Are studies that identify DNA markers (SNPs) in the whole genome that are common to the human genome and to determine how these SNPs are distributed across different populations. GWAS are used to determine genetic risk markers associated with a disorder, for example, diabetes, obesity, hypertension, or cancer.

Glycosylated hemoglobin (HbA1c) Is also known as glycated hemoglobin. The glycation of hemoglobin consists in a nonenzymatic interaction between glucose and the amino groups of the valine and lysine residues in hemoglobin. This interaction is irreversible and is a test that indicates the exposition of the proteins to glucose for the last 3 months.

Knock-out mice Is a model used is the laboratory in which a mouse has inactivated, or "knocked out" an existing gene by replacing it or disrupting it with an artificial piece of DNA.

Maturity-onset diabetes of the young (MODY) Is a rare form of diabetes different from both type 1 and type 2 diabetes and runs strongly in families. Is caused by a mutation in a single gene.

OLEFT rats The Otsuka Long-Evans Tokushima fatty (OLETF) rat is an animal model of spontaneous T2D. This rat model of T2D is characterized by mild obesity with visceral fat accumulation and late-onset insulin resistance. It resembles human obese patients with T2D.

Pathogen-associated molecular patterns (PAMPs) Are derived from microorganisms and recognized by pattern recognition receptor (PPR)-bearing cells of the innate immune system as well many epithelial cells. Major PAMPs are microbial nucleic acids, including DNA, double-stranded RNA (dsRNA), single-stranded RNA (ssRNA), and 5′-triphosphate RNA and lipoproteins, surface glycoproteins, membrane components (peptidoglycans, lipoteichoic acid, lipopolysaccharide, and glycosylphosphatidylinositol).

Promoter The promoters are sequences in the DNA that define the start point in the transcription of a gene.

Reactive oxygen species (ROS) Are radical and non-radical oxygen species formed by the partial reduction of oxygen, for example, superoxide anion (O_2-), hydrogen peroxide (H_2O_2), and hydroxyl radical (HO•). They are generated endogenously by the oxidative phosphorylation process in the mitochondria or are produced from interactions with exogenous sources such as xenobiotic compounds.

Roux-en-Y gastric bypass (RYGB) Is often called gastric bypass and is considerate the "gold standard" of weight loss surgery. This surgery consists to create a new stomach pouch, using a small portion of the stomach. The smallest stomach is connected directly to the middle portion of the small intestine (jejunum), bypassing the rest of the stomach and the upper portion of the small intestine (duodenum).

Single nucleotide polymorphisms (SNPs) Is a variation in a single position in a DNA sequence among individuals.

This variation have to be present in almost 1% of a population to be considered as an SNP.

Streptozotocin (STZ)-induced diabetes Streptozotocin is a glucosamine-nitrosourea compound derived from *Streptomyces achromogenes*. STZ is employed to induce cellular damage specifically in **β**-cells, resulting in hypoinsulinemia and hyperglycemia.

Transcriptomic The transcriptome is the complete set of expression products transcribed from the genome in a specified tissue or populations of cells. Transcriptomic has emerged as a powerful technic that analyses thousands of genes in one sample using RNA microarrays. This technic has allowed the study of gene expression patterns on several tissues involved in the pathogenesis of the T2D and to identify genetic markers for the early diagnosis of T2D.

The Immune System and Inflammation in Type 2 Diabetes

12

Rebeca García-Macedo and María de los Ángeles Fortis

Objectives

- Obesity-associated inflammation as a major contributor toward the progression to IR and T2D.
- Relevance of adipocytes and some classes of immune cells in obese adipose tissue as mediators of inflammatory state.
- Several proinflammatory markers expressed by immune cells have been considered as potential risk factors for developing T2D.
- Anti-inflammatory therapeutic approaches to alleviate IR and T2D.

Introduction

This chapter focuses on immune cells' participation during type 2 diabetes (T2D) development. Obesity is a major driver of T2D. However, obesity per se does not necessarily lead to T2D, but rather to individual differences regarding body composition, fat distribution, and adipose tissue (AT) function.

Most findings demonstrating the correlation between AT dysfunction and T2D have been observed on mouse models or obese subjects and/or those with impaired insulin sensitivity. It is also known that increasing overweight and obesity incidence have been linked to increasing amounts of T2D cases. It is a well-recognized fact that chronic low-grade inflammation is correlated to obesity-associated comorbidities. Furthermore, adipose tissue (AT) is an important immunologically active organ that contributes during inflammation processes.

The development of T2D results from a combination of insulin resistance (IR) and pancreatic beta-cell failure, thus resulting in hyperglycemia. A chronic activation of the innate immune system is associated with T2D, and there is evidence suggesting that both IR and beta-cell failure are regulated by this inflammatory status in humans [1, 2].

Some intervention studies have shown that therapies for obesity-induced T2D relying on immune markers include those approaches intended to increase insulin sensitivity by blocking the activity of inflammatory mediators, e.g., interleukin (IL)-1α, IL-1β, IL-6, tumor necrosis factor (TNF-α), and macrophage chemoattractant protein 1 (MCP-1) [3, 4].

Increased adipocyte size is associated with a decreased population of precursor cells able to differentiate into adipocytes. Large adipocytes are more frequently found in subjects with impaired glucose tolerance and T2D in comparison to those with a similar degree of adiposity but with normal glucose tolerance. Impaired adipocyte differentiation appears to be one of the most important factors for T2D progression [5]. The presence of proinflammatory cytokines in blood hampers the capacity of the insulin receptor to convey signals within insulin-sensitive tissues.

Insulin has several functions in its target tissues including nutrient transport as well as the regulation of gene expression and energy homeostasis. It acts on a several target tissues and through many different intracellular signaling cascades. Elevated levels of intracellular free fatty acids (FFAs) may blunt the response toward insulin and its subsequent metabolic effects. The insulin receptor substrate (IRS)-1 is a key molecule in this signaling pathway, and failure to activate it leads to systemic IR [6–8]. Inflammatory cytokines such as TNF-α and IL-6 may induce an inhibitory phosphorylation of IRS-1. A similar response is achieved by activating the receptors of the innate immune system, such as the toll-like receptors (TLR) or by the presence of intracellular molecules, e.g., lipids and reactive oxygen species

(ROS). By interacting with their respective receptors, TNF-α and IL-6 activate the nuclear transcription factor κB (NF-κB) and the Janus kinase (JNK); both of them are important inflammation activators. JNK is also activated by FFAs and endoplasmic reticulum stress. Interestingly, these factors are associated with obesity [9, 10]. The regulator of cytokine function known as the suppressor of cytokine signaling (SOCS) inhibits insulin effects on IRS-1, either by interfering with tyrosine phosphorylation or by targeting IRS-1 for proteasomal degradation [11, 12].

Ectopic lipid accumulation in the pancreas, concomitantly with a decreased activation of the insulin receptor in adipocytes, minimizes insulin production and impairs insulin-stimulated glucose transport, and its anti-lipolytic effect as well as lipoprotein lipase production and activity, whereas it increases the release of FFA and hampers preadipocyte differentiation. All these effects will lead to IR, T2D development, including cardiovascular diseases.

Types of Adipose Tissue

Systemic inflammation induced by obesity is predominantly originated at the AT. Mammalian body contains several types of fat reservoirs, classified as white and brown fat [13]. White adipose tissue (WAT) is in turn classified as subcutaneous (Sc) and visceral adipose tissue (VAT). The former stores the calorie surplus, and it may be further classified as upper and lower body obesity. On the other hand, VAT (omental and mesenteric) supplies energy to all organs. Sc predominates over VAT by a 3–4 factor [14, 15].

WAT stores nutrients within a single large fat droplet. This tissue is one of the main endocrine organs in the organism. VAT is located in the abdominal cavity, it is the main source of chronic systemic inflammation, and it is of outmost importance for T2D establishment [15]. In different mice strains (Kunming, C57BL/6, BALB/c, and ICR) with high-fat diet (HFD), it was observed an increase of body weight and largest adipose cells, and the animals showed altered response on glucose and insulin loads (OGTT and ITT, respectively) [16]. The content of specific immune cells (natural killer (NK) cells) in VAT is modified when obesity develops [17].

Brown adipose tissue (BAT) is mostly found in newborn humans, even though adults possess small amounts of this type of fat. In spite of WAT and BAT sharing many metabolic features, the former stores energy, whereas the latter dissipates energy and produces body heat [13]. In BAT, the signaling mediated by the mammalian target rapamycin complex 2 (mTORC2) stimulates cold-induced glucose uptake and glycolysis. AdRiKO mice, which have deleted mTORC2 in adipose tissue, are hypothermic and show more cold sensibility and glucose uptake and impaired glycolysis [18]. Also, in this tissue, the increase in UCP-1 expression can increase glucose uptake [19].

Ectopic Fat Accumulation

Fat is accumulated in specific regions along the body when obesity develops. Normally, the abundance of AT is low in these zones.

Ectopic fat is defined as a triglyceride deposition within non-adipose tissue cells that normally contain small amounts of fat. The liver, skeletal muscle, and pancreas contain an excessive lipid accumulation. In the skeletal muscle, this fat accumulation is correlated with IR and cardiovascular disease and T2D [20, 21].

Lipid accumulation in the liver and muscle is an early sign of T2D, whereas it has been shown to precede the suppression of glucose-mediated insulin production by the pancreas. In cardiac tissue a lipid overload has been shown to produce a metabolic deregulation, and it may induce IR, resulting in impaired glucose oxidation and, consequently, heart failure [22–24].

Epicardial Adipose Tissue

This specific tissue possesses some anatomical and metabolic features that distinguish it from other visceral fat depots, such as increased fatty acid metabolism and a transcriptome including genes associated with inflammation and endothelial functions. Some bioactive adipokines such as adiponectin, TNF-α, IL-6, and resistin, as well as FFA from epicardial AT may impact on cardiovascular function and morphology. Therefore, they may directly contribute to cardiovascular complications and IR [24, 25].

Perivascular Fat

The perivascular adipose tissue surrounding blood vessels is produced from the vascular lamina adventitia in response to circulating factors and local stimuli. This fat tissue has been considered a largely passive structural support for arteries. Nevertheless, it can play an active role to regulate vascular tone and the release of adipocyte-derived vascular-relaxing factors into the blood vessels. Perivascular adipose tissue contributes to the modulation of vascular tone in vivo [26].

Obesity and Acute and Chronic Inflammation

Inflammation is a series of cellular and molecular responses in order to protect the body from infections or other insults. The inflammation process is continuous over a time period. Acute and chronic are terms used to describe different inflammation stages. This event is triggered by a stimulus and, when it ceases, inflammation is attenuated. If it does not remain in the acute period, it becomes chronic.

When compared to acute inflammation induced by bacteria or viruses, chronic inflammation may be driven by an abnormal reaction toward the presence of endogenous factors, including metabolic factors such as advanced glycation end products (AGES), modified lipoproteins, type 2 T helper cells (Th2), cytokines, hyperglycemia, and others [27–29].

Monocytes, one of the key cell types on the innate immune system, recognize the presence of these factors in the bloodstream, they migrate to the respective tissues, and they may recruit macrophages with pathological functions. Obesity-associated inflammation is characterized by an increased amount of macrophages and proinflammatory cytokines in the AT.

It was been shown that one type of monocytes (CD16+) was increased in patients with metabolic disorders, and it positively correlates with body mass index, insulin resistance, diabetes, and intima media-thickness. Likewise, the percentage of nonclassical monocytes was increased in individuals with obesity compared to lean subjects and showed an imbalance among CD16+ monocyte subsets. After high-intensive training, the percentage of nonclassical monocytes was reduced, and the balance among CD16+ monocytes was restored. In another study it was reported that higher account of intermediate monocytes subset (CD14++CD16+) was associated with CVD risk [30, 31].

Inflammation is the response of the living tissue toward injury. It involves a well-organized cascade of humoral and cellular changes within living tissues. Blood is the primary delivery system for inflammatory components such as adipokines TNF-α, IL-6, leptin, resistin, and adiponectin.

Obesity and its associated metabolic pathologies, such as IR, T2D, and atherosclerosis, are chronic and concomitant associated with inflammatory responses such as increased acute-phase reactants as the C-reactive protein (CRP), activation of inflammatory signaling pathways, high levels of circulating inflammation biomarkers as interleukin (TNF-α, IL-6, IL-1β, plasminogen activator inhibitor-1 (PAI-1)), and low adiponectin levels (an anti-inflammatory adipokine). The latter may predict the future establishment of T2D. The inflammatory response is mainly located in adipose tissue, and it is triggered therein, although other tissues may be involved when T2D is developing [32, 33].

In the AT, immune cells participate on tissue remodeling and homeostasis, and these roles are controlled by inflammation. AT is considered a complex endocrine tissue containing multiple cell types, including its precursors, vascular, immune, and neuronal cells. All of them contribute to the inflammatory response occurring in obesity. A nutrient excess promotes adipocyte expansion, resulting in its dysfunction. Cytokines, chemokines, and adipokines secreted by adipocytes induce immune cell accumulation in the AT and trigger local and systemic inflammation, being one of the causes contributing to IR [34].

Type 2 Diabetes and Immune Cells

The immune response has been classified as innate and adaptive. The former represents a rapid response toward some stimuli, and it is characterized by physical, chemical and biological barriers, specialized cells, and soluble molecules. They occur in all individuals, regardless of their previous contact with harmful agents or immunogens, and they do not qualitatively or quantitatively change after contact [35].

The human leukocyte antigen (HLA) constitutes a system also known as the major histocompatibility complex MHC. This is a protein set derived from highly polymorphic genes linking innate and adaptive responses. The human genes are allocated in classes I, II, and III. Only those of classes I and II participate to present antigen proteins to T cells. All MHC molecules found on the cell's surface contain an associated peptide.

Those from class I possess one α-chain coded by the HLA-A, B, or C genes and a small non-variable chain: the β2-microglobulin. HLA class II possess two chains: α and β. HLA discriminates between intrinsic and foreign elements, and they ensure a suitable immune response in order to protect against external agents capable to generate an infection.

Adaptive or acquired immune response depends on the activation of specialized cells and the soluble molecules produced by them. The main features of the acquired response are memory, specificity and diversity of recognition, self-restraint, specialized response, and tolerance to the components of the organism itself. The cells that are mainly

involved on the acquired immune response are lymphocytes. Antigen-presenting cells (APCs) play a key role during lymphocyte activation by presenting them with antigens bound to the major histocompatibility complex (MHC) molecules [36, 37]. Type-T lymphocytes recognize antigenic fragments derived from pathogens that previously entered the cells but only when associated with the major histocompatibility complex proteins. In humans, the latter is termed the human leukocyte antigen (HLA). Concomitantly with the innate immune system signs, it triggers the T-cell-mediated immune response [38].

Macrophages, neutrophils, dendritic cells, and natural killer (NK) cells are the main effectors of innate immunity. The central mechanisms of innate immunity comprise phagocytosis, the release of inflammatory mediators, activation of the complement system proteins, and the synthesis of acute-phase proteins, cytokines, and chemokines. These are activated by specific stimuli, such as the lipopolysaccharides commonly found on the outer membrane of microorganisms [35].

AT is comprised by mature adipocytes (≈50%) and other cells (≈50%) from the stromal vascular fraction (SVF) that contains pre-adipocytes, fibroblasts, endothelial cells, and immune cells, e.g., macrophages [39].

After analyzing several adipose reservoirs, it was observed that immune cells represent approximately two thirds of the SVF, containing approximately 2–5 million cells/g of tissue. In morbidly obese subjects, AT represents up to 50% of total body mass, and it is the main compartment of the immune system having an effect on systemic inflammation [40].

Cell populations within the AT display a plasticity that is regulated by both acute and chronic stimuli including body weight status, diet, feeding, and fasting. Mice fed with a HFD recruit immune cells (such as T and B cells, M1 phenotype macrophages) to AT [41, 42].

Obesity and insulin resistance are concomitant with macrophages infiltrating the AT [42]. In addition to these, other immune cell populations change in obese AT, and they affect insulin sensitivity. Some of them have an impact on inflammation by altering AT-macrophage recruitment or activation. Lean AT also contains regulatory cells such as eosinophils and invariant natural killer (iNK) cells. These preserve tissue homeostasis by excreting two types of cytokines, such as IL-4, IL-5, and IL-13, whereas they keep AT-macrophages in an anti-inflammatory status (M2). When diet-induced obesity develops, AT homeostasis is disrupted and a type 1 inflammatory response in VAT is engaged. This is characterized by the presence of interferon gamma (IFN-α), a shift toward a proinflammatory profile (M1) by most of the recruited macrophages and the loss of regulatory T cells (Treg) [43]. Further sections show the interrelation of major immune cells and obesity-related T2D.

Macrophages

In vertebrates, innate immunity greatly depends on myeloid cells as they engulf and destroy pathogens. Mononuclear phagocytes, macrophages derived from blood monocytes, and polymorphonuclear phagocytes are comprised within myeloid cells. Macrophages are distributed throughout the body, and in some cases they are located within the parenchyma of some major organs (e.g., heart, brain, lungs, and liver), adopting diverse morphologies such as spindle-shaped tissue histiocytes, Küpffer cells of hepatic sinusoids, and stellate microglial cells of the central nervous system. Macrophages are within the periphery of invasive organism or at the site where a chemical or biological insult occurs. As such, they are also involved on IR, T2D, and atherosclerosis development [44].

> Histiocytes are derived from the bone marrow; they circulate throughout the body to subsequently infiltrate some organs where they undergo differentiation into histocytes (e.g., macrophage or dendritic cells).

In lean mice, approximately 10–15% of all cells express the macrophage marker F4/80+, whereas they constitute about 45–60% of cells in adipose tissues of obese animals. This indicates that obesity significantly modifies the macrophage/adipocyte ratio. Macrophages are normally located in lean AT in which they participate in normal remodeling, they are the primary source of TNF-α significant amounts of inducible nitric oxide synthase and IL-6. Nutrient overlap triggers AT remodeling and inflammation in this tissue. Macrophage-specific gene expression is markedly upregulated in WAT from obese mice. When diet-induced obesity occurs, this phenomenon precedes to an increase of circulating insulin levels [45, 46].

The macrophage proportion on the SVF is estimated to increase from ≈10% in lean conditions to ≈40–50% in obese AT. Furthermore, obesity induces a macrophage phenotype switch from M2 (producing anti-inflammatory cytokines as IL-10) to the M1 type (producing proinflammatory cytokines as IL-12, inducible nitric oxide synthase, and major histocompatibility complex class II). The latter is associated with IR in both mice and humans. Endoplasmic reticulum stress or hypoxia may contribute to the M2-M1 transition of macrophages. In addition to increase inflammatory responses, the factors released by macrophages also modulate adipokine production, and they inhibit adipogenesis [1, 47–55].

Infiltration of proinflammatory macrophages in association with obesity do not only occur in WAT but also on the skeletal muscle, bone (osteoclasts), liver (Küpffer cells), and pancreas. In the latter, they contribute to IR and to β-pancreatic cells dysfunction by activating inflammatory

processes [56–59]. During T2D development, macrophage recruitment seems to occur in several tissues, implying a general inflammation status rather than a WAT-specific inflammation.

Mast Cells

Mast cells contribute to antimicrobial defense by secreting granules rich in histamine, serine proteases, and cytokines, mainly TNF-α and IL-1β. These cells have a role in anaphylaxis and allergy. In obesity models fed with a HFD, mast cells are recruited to AT, and they contribute to inflammation, whereas they participate in IR by secreting inflammatory cytokines [60]. Mast cell deficiency in diet-induced obese mice protects from weight gain and IR, possibly due to a decrease of inflammatory cytokines, MCP-1, and matrix metalloprotease-9 in both VAT and serum [61]. Additionally, human mast cells cultured in vitro in the presence of high glucose levels are activated and highly express proinflammatory cytokines, including TNF-α, IL-1β, and IL-6 [62]. Nevertheless, a recent work has presented contradictory conclusions regarding mast cell involvement in IR, as phenotypes may be more dependent on the Kit mutation used in those mouse models rather than a mast cell deficiency per se [63]. WAT obtained from morbidly obese patients displays a mast cell increase regardless of IR. Furthermore, mast cells do not contribute neither to inflammation caused by obesity, glucose intolerance, or IR, as these were observed on mast-cell-deficient mice with diet-induced obesity [64].

Eosinophils

The stromal vascular fraction (SVF) of lean AT contains eosinophils, although they rapidly decline during obesity onset, as shown in a DIO model. In the lean state, eosinophils repress AT inflammation by producing IL-4, a key driver of alternative M2 macrophage polarization in order to preserve a "lean phenotype." When fed with a HFD, eosinophil-deficient mice exhibit a significant weight gain, impaired glucose tolerance, and IR. Conversely, transgenic mice engineered to contain high eosinophil levels were protected against obesity and IR when a HFD was supplemented. This highlights the importance of eosinophils in order to prevent IR [46, 65].

Lymphocytes

A lymphocyte is a white blood cell that triggers an immune response when activated by a foreign molecule (antigen). The different T lymphocyte types are distinguished by a differential expression of their transmembrane proteins or co-receptors known as CD. T lymphocytes are generated in the thymus, and they are responsible for cell-mediated immunity. They comprise innate (γδ T, NK) and adaptive immune (CD4+, CD8+ T lymphocytes, and B lymphocyte) cell subpopulations. CD4+ T lymphocytes are further sub-classified as T helper (Th) type 1 (Th1) (they secrete IFN-γ and IL-2), Th2 (they secrete IL-4, IL-5, and IL-13), Th17 (a subset of Th CD4 cells that mainly express IL-17, IL-21, and IL-22), and T regulatory cells (Treg). Th cells display the CD28 co-receptor on its surface. Additionally, activated Th cells express a CD40 ligand on its surface, but not in their nonactivated form [66, 67].

In adult animals, T and B lymphocytes in secondary lymphoid organs are comprised by a mixture of cells in at least three maturation stages. They are designated as virgin (or naïve cells), memory cells, and activated cells. When virgin cells are exposed to an antigen for the first time, some of them are stimulated in order to multiply and mature to become activated cells. These are defined as those cells engaged in a response (activated T cells carry out cell-mediated responses or they secrete mediators, whereas activated B cells secrete antibodies) [68, 69].

During the inflammatory events occurring in obesity, IR, and T2D, some lymphocyte subpopulations display abnormalities. In patients undergoing T2D onset, IL-22(+) CD4(+) T cell populations were higher when compared to healthy individuals, and they may contribute to the early stages of the disease. Proinflammatory γδ T, Th1, and CD8+ T cells were increased in response to a HFD [39, 70]. Ketogenic diet feeding in mice causes obesity, impairs metabolic responses, and depletes the adipose-resident γδ T cells; these cells are mediators of protective immunometabolic responses that link fatty acid-driven fuel use to reduced adipose tissue inflammation [71]. Th1 and Th17 cells expressed the IFN-γ and IL-17 proinflammatory cytokines, previously associated with IR [72–74]. NK cells were positively associated with glucose levels, glycated hemoglobin (HbA1c), and in women with morbid obesity and varying levels of IR [75]. Differentiation of Treg and Th17 cell are events that often counteract each other, whereas Treg cell abundance is decreased in obesity [74].

The amount of CD4+ and CD8+ T cells increased in VAT in response to diet-induced obesity (DIO) [73]. In diet-induced obesity (DIO), adiponectin, an anti-inflammatory adipokine, inhibits IFN-γ and IL-17 production from CD4+ T cells. CD8+ T cells promote macrophage recruitment mediated by MCP-1 production, and its deletion significantly decreases systemic inflammation and IR in mice submitted to DIO [73, 76, 77].

Immune cells may increase glucose utilization during diabetes progression. Possibly they control their own activation and polarization in order to acquire proinflammatory pheno-

types. For instance, T helper 17 (Th17) cells are dependent on glycolysis, and its inhibition shifts T-cell differentiation from proinflammatory Th17 cells to anti-inflammatory Treg cells. Similarly, glucose metabolism is required by mouse macrophages in order to secrete IL-1β [78, 79].

In mice receiving HFD, the CD8+ effector T cells and proinflammatory macrophages infiltrating adipose tissues were increased, and Treg was reduced in both AT and the liver. These mice under weight loss improve their metabolic profile and increase CD4+ T, but they showed an active CD8+ T cell inflammation mediated by macrophages in AT and the liver, and Treg remained low [73, 80].

In T2D patients the Treg/Th1 and Treg/Th17 ratios significantly decreased when compared to healthy controls. T2D patients with coronary heart disease (CHD) showed a significant decrease of Treg/Th1 regarding T2D patients without a CHD diagnosis [81]. Subsequently, AT in obesity conditions exhibit some typical symptoms of chronic inflammation, thus leading to systemic IR, T2D, and cardiovascular diseases.

Mice under HFD treated with pioglitazone, a PPAR-γ agonist, showed an increase of the number of Treg cells in AT along with decreased inflammation. In obesity conditions Treg may be critical regulators of immune cell components in VAT. The evidence reveals that their modulation may represent a potential novel strategy to treat obesity-related metabolic disorders, such as IR and T2D [82, 83].

B Cells

In mammals, B cells or B lymphocytes are produced in the bone marrow, and they secrete circulating antibodies. B cells are responsive to bacterial products such as lipopolysaccharide (LPS), and thus they are considered one of the first lines of defense against bacterial pathogens. Similar to T cells, B cells are comprised by different subsets with distinct surface phenotypes, functions, and cytokine secretion profiles. B cells may be classified in two broad types: B-1 or B-2 cells based on their development, phenotypes, functions, and cytokine secretion profiles [84].

B-1 cells have been found in fatty tissues such as omentum, the fat pads near the peritoneal cavity, and in mucosal tissues. B-1a cells are major producers of natural IgM antibody, and they are responsible for adaptive humoral immune responses toward T cell-independent antigens. In the steady state, there is constant B-1 cell trafficking between the peritoneal cavity and the abdominal VAT, such as the omentum [85–87].

B-cell populations infiltrate inflamed tissues such as VAT in mice fed with a HFD, and they subsequently undergo functional and phenotypic changes. B-cell infiltration is thought to precede that of T cells into VAT. Once in there, they may regulate systemic and local inflammation, concomitant with antibodies and cytokines secretion. Similar to macrophages, B cells express the major histocompatibility complex II (MHCII), and they possess the ability to present antigens to T cells [88–90].

B-2 cells produce several cytokines, and some populations are able to produce proinflammatory cytokines such as IFN-γ, IL-12, and TNF-α, whereas other populations produce IL-2, IL-4, and IL-13. More recently, the presence of regulatory B cells ("Breg" cells) that possess the ability to suppress inflammatory responses has been described. One subset of these includes a type of B cells termed "B10" that produce a high amount of IL-10 [91, 92].

B cells may modulate T cell and macrophage polarization and cytokine production at multiple levels; thus, they represent a potential attractive target for immune therapy to treat insulin resistance. During the early stages of the disease, the depletion of B-cell co-receptor caused by a CD20 antibody induce a therapeutic and beneficial effect on glucose metabolism. Additionally, T-cell activation was hampered, and both IFN-γ and TNF-α levels were decreased in VAT. Conversely, detrimental effects on metabolic disease are mediated by B cells by producing pathogenic IgG [93–95].

Natural Killer T Cells

Natural killer (NK) T cells are a subtype of innate T lymphocytes, they exhibit both innate and adaptive features, and they mediate the consequent immune responses. NK cells are the body's sentinels searching for signs of cellular stress, activating the immune system in response to viral infection or oncogenic transformation. They recognize peptides presented by the MHC molecules. NK cells also recognize lipids presented by CD1d molecules. The latter is a non-polymorphic MHC class I-like molecule that is mainly expressed by dendritic cells (DCs) and other cell types. NK lymphocytes are classified in three groups: invariant (iNK), type II, and NK-like lymphocytes, based on their antigen specificity and the expression of their T-cell receptor (TCR). NK cells are located within the AT. It has been recently shown that NK cells are associated with obesity and diabetes. In several obesity models and in obese patients, NK cells are increased, and they drive proinflammatory M1 macrophage polarization mediated by IFN-γ production, and subsequently they promote IR [96–98].

When activated, NK cells promote the death of a target cell by releasing cytolytic granules [86]. NK cell activity is controlled by the balance of signals received from receptors on the cell's surface that convey either activating or inhibitory signals [99]. Under normal physiological conditions, NK cell activation is inhibited by ligands expressed by healthy cells that engage the inhibitory NK receptors. In

stressed cells the expression of these ligands is decreased, leading to NK cell activation. Furthermore, diet-induced IR may be delayed by preventing NK cell activation using a soluble NK cell-activating receptor (NCR1). Mice fed with a HFD exhibit an increased number of NK cells concomitantly with an enhanced production of proinflammatory cytokines, particularly TNF-α in epididymal but not in subcutaneous fat depots. Additionally, NK cells are an important source of IFN-γ in VAT [100].

Invariant Natural Killer T

iNKT cells are a specialized subset of innate T cells highly abundant in the liver, and they are readily activated by lipid antigens. These cells are potent transactivators of other immune cells, and they serve as a bridge between innate and adaptive immunities. They are highly conserved in mammals, they are part of human and murine AT, and they display a unique phenotype characterized by a surface marker. iNKT recognize glycolipids presented by CD1d, and they participate to preserve AT homeostasis through both immune and metabolic pathways. These cells have an anti-inflammatory role in VAT as they produce IL-4 and IL-2. In obese patients iNKT cells are decreased when compared to lean controls. This effect has been also observed in DIO and genetic obesity models. The activation of iNKT (iNKT10) cells mediated by the lipid agonist α-galactosylceramide (αGC) led to macrophage polarization to a M2 phenotype, and it improved glucose sensitivity through anti-inflammatory cytokine signaling. Furthermore, the number of iNK cells is recovered after weight loss, whereas proinflammatory macrophage infiltration is decreased [101–103].

The decreased amount of iNKT cells in the liver of obese mice contribute to hepatic IR. Conversely, their increase in obese liver results in improved hepatic steatosis and glucose tolerance [104].

iNKT cells are linked to obesity-induced IR [102]. However, the role of iNKT cells during HFD-induced inflammation and IR is still controversial, because in vitro studies showed that iNKT cells display considerable plasticity with respect to their cytokine output, which can be skewed toward a more proinflammatory profile [105, 106].

iNKT cells are decreased in obesity, although their activation leads to improved glucose control, insulin sensitivity, and even weight loss, and they represent a therapeutic possibility to restore homeostasis in obese adipose tissue [107].

Dendritic Cells

There are three subpopulations of dendritic cells (DC): myeloid, CD4+, and CD8+. DCs play an important role for the transition between innate and adaptive immunity by presenting antigens to the T-cell receptors (TRs) of CD4 Th cells via MHC II. In AT of obese animals, macrophages and dendritic cells (MDC) increased and display the classically activated M1-like phenotype in obese adipose tissue (AT) and may contribute to AT inflammation and insulin resistance. Murine adipose tissue contains a novel CD11c+ dendritic cell subset that is distinguished by an immature phenotype. AT from mice fed with an HFD contained an increased number of CD11c+ DCs and CD4+IL-17+ T cells regarding lean controls. A link between CD11c+ DCs and AT inflammation caused by Th17 cells may exist in obesity conditions [108–110]. In obese patients, the frequencies of DCs, Th1, and Th17 cells increased, and Treg and Th2 cells decreased compared with normal controls. The frequency of DCs and Th1 cells consistently declined after laparoscopic sleeve gastrectomy surgery, while Th17 cells declined at 6 months after surgery compared with baseline in the same obese patients [111].

Markers of Inflammation

T2D as an inflammatory process is concomitant with increased levels of circulating proinflammatory immune mediators that lead to impaired insulin signaling and the selective destruction of insulin producing β-cells, a process in which cytokines play an important role. Generally, some of the inflammatory markers playing a pathogenic role in T2D are expressed in both adipocytes and immune cells. Among these are proinflammatory molecules as TNF-α, IL-1β, 4, 6, 18, resistin, and leptin. Anti-inflammatory molecules are also involved such as the IL-1 inhibitor or IL-1 receptor antagonist A (IL-1RA), transforming growth factor-β1 (TGF-β1), IL-10, and adiponectin [112, 113].

Regarding the activation status of WAT macrophages, mice with DIO display a M2 to M1 shift, as previously indicated. The former is characterized by the expression of anti-inflammatory cytokines (e.g., IL-10, IL-1Ra), whereas the latter are distinguished by an elevated production of proinflammatory cytokines (e.g., TNF-α and IL-6) [114].

Some of the proinflammatory and anti-inflammatory proteins have been implicated in obesity, IR, and T2D, and their respective functions are described below.

The cytokines expressed by adipocytes and immune cells, such as TMF-α, IL-1β, and IL-6, either impair insulin signaling or induce β-cell apoptosis [115, 116]. TNF-α and IL-18 are considered potential risk factors for T2D development and its associated metabolic complications [117, 118].

TNF-α

TNF-α is a classical proinflammatory cytokine that actively participates during the development of obesity-related diseases. It is secreted by mature adipocytes, although it is also expressed by macrophages. It has been implicated in obesity and T2D development. The expression of TNF-α mRNA increases in AT reservoirs, and it correlates with IR, body mass index, percentage of body fat, and hyperinsulinemia. A short-term treatment with a TNF-α inhibitor decreased systemic inflammatory markers without improving insulin sensitivity in obese patients. The serum levels of this cytokine diminishes after weight loss in obese subjects. Moreover, anti-TNF-α antibody reduces IR in rats with sepsis-induced stress hyperglycemia. Besides, a novel inhibitor JTP-96193 was reported that acts on the TNF-α converting enzyme/a disintegrin and metalloproteinase domain-containing protein 17 (TACE/ADAM17), which is a key sheddase that releases TNF-α from its inactive precursor and is a new drug to inhibit TNF-α production. This inhibitor will become a new treatment option of T2D [119–122].

In vivo studies with mouse models clearly show that inhibition of TNF-α function improves obesity-induced inflammation. High TNF-α levels were also found in the AT from obesity experimental models: rat (fa/fa), mouse (ob/ob), and mice fed with HFD. In obese fa/fa rats, the impairment of TNF-α expression increased insulin effect on glucose uptake. Similar results were observed in two murine obesity models: significantly improved insulin sensitivity was detected in animals lacking TNF-α or its receptors when compared to their obese wild-type counterparts. The mechanisms underlying insulin resistance mediated by TNF-α may involve the phosphorylation of insulin receptor substrate (IRS)-1 on its serine residues, as they inhibit normal phosphorylation of IRS-1 on tyrosine residues, thereby blocking insulin signaling. TNF-α downregulation, in HepG2 cells, improves IRS-1 phosphorylation after insulin stimulation [123–125].

TNF-α contributes to the development of peripheral insulin resistance on AT and the liver by stimulating lipolysis mediated by cyclic adenosine monophosphate (cAMP) and by stimulating the activity of the hormone-sensitive lipase. In WAT, TNF-α induces a decrease of lipoprotein lipase as well as GLUT-4 expression and activity. In the liver, TNF-α stimulates the expression of genes involved in cholesterol and FA de novo synthesis, whereas it inhibits those genes involved in glucose uptake and metabolism as well as FA oxidation. The effects promoted by this cytokine on lipid metabolism result in high FFA plasma levels, fatty acid deposition in non-adipose fat reservoirs, including muscle. Therefore, they might contribute to IR observed in obesity [126, 127]. TNF-α increases acyl-CoA synthesis by induction of acyl-CoA synthetases in human macrovascular endothelial cells. TNF-α-mediated processes may be involved in complications associated with T2D such as cardiovascular disease [128].

IL-1β

IL-1 family is a group of cytokines that play a central role to regulate immune and inflammatory responses. Additionally, other circulating inflammatory markers and high IL-1β levels have been reported on humans with IR [129, 130].

IL-1β may drive sterile inflammation, and it is considered a metabolic disease initiator in T2D patients and in animal models with T2D. Studies conducted on humans and animals have found that IL-1β or inflammasome (a complex required for the IL-1β secretion) is increased in metabolic diseases. Moreover, treatment with IL-1β antagonists can improve glycemia. Pancreatic β-cells in mice (db/db) and rat beta cell line (INS-1) are able to produce the proinflammatory cytokine (IL-1β) when cultured in the presence of high glucose levels, thus impairing β-cell function and inducing apoptosis. In a clinical trial, it was observed that the administration of anakinra, a recombinant human IL-1-receptor antagonist (IL-1Ra) improved glycemia on rheumatoid arthritis with comorbid T2D patients [131, 132].

IL-1β interferes with insulin signaling in both adipocytes and hepatocytes, it suppresses insulin-induced glucose uptake, and it inhibits lipogenesis and decreases adiponectin release [131, 133]. Some contradictory results have been observed on pancreatic β-cells, low IL-1β doses improve insulin secretion, enhance β-cell replication, and decrease β-cell apoptosis. Conversely, high IL-1β levels induced by high glucose and/or FFA levels have the opposite effects on islets [134, 135]. These effects must be taken into account, as possible diabetes treatments using IL-1β blocking as a strategy may cause a severe abrogation of its signaling pathway that will have severe consequences and they may compromise insulin secretion even further in patients with severely damaged or destroyed beta cells.

The pancreas from T2D and obese patients, but not from control subjects, expresses IL-1β [58]. IL-1β promotes β-cell dedifferentiation in cultured human and mouse islets, and in vivo, anti-IL-1β treatment improved insulin secretion of isolated islets [136]. In T2D patients, NLRP1 inflammasome expression was upregulated in islet cells, suggesting that IL-1β causes β-cell toxicity in part by NLRP1-mediated caspase-1-activation [137].

IL-6

IL-6 is a single polypeptide chain comprised by 185 amino acids; its molecular weight ranges from 21 to 28 kDa depending on its phosphorylation and glycosylation status. It is a pleiotropic cytokine secreted by a wide variety of cells: endothelial cells, β-pancreatic cells, keratinocytes, osteoblasts, myocytes, adipocytes, fibroblasts, activated leukocytes, monocytes, macrophages, and other cells, including a few tumor cells [138]. IL-6, expressed by type 2 T helper cell (Th2), specifically regulates the Th1/Th2 balance [139].

The main progression step toward T2D is insulin resistance, and it has been linked to increased circulating cytokine levels. One of them is IL-6, an inflammatory marker induced by TNF-α in cultured subcutaneous adipose cells. High IL-6 levels have been correlated with IR [140, 141]. Additionally, IL-6 serum levels increase in T2D, in mice with DIO and in obese individuals [139, 142]. IL-6 is an important inflammation mediator, and it has an essential role during the acute phase of the inflammatory response by stimulating CRP synthesis in the liver [143].

The basal circulating IL-6 levels are released from the subcutaneous AT in healthy humans, mainly from macrophages [144, 145]. Human subcutaneous AT expresses both TNF-α and IL-6, but only IL-6 is released from this tissue. IL-6 increases with adiposity and is greater in obese compared with lean subjects. These facts contribute to a chronic low-grade inflammation status in obesity [146, 147].

IL-6 in obesity is generally considered to be a proinflammatory mediator, and it antagonizes insulin action by inhibiting insulin-stimulated glucose transport [147, 148]. Mice deficient in IL-6 develop obesity that is associated with altered carbohydrate and lipid metabolism; IL-6$^{-/-}$ mice showed similar metabolic phenotypes as wild-type mice on a HFD, since these mice had similar expression profiles of lipid-related genes in adipose tissue and the liver [149]. Nevertheless, deletion of IL-6 from adipocytes did not have any effect on glucose tolerance or fasting hyperinsulinemia; adipocyte-specific IL-6 does not contribute to whole-body glucose intolerance in obese mice [150].

IL-6 functions are a consequence of its interaction with its receptor, comprised by the gp130 and IL-6R subunits. IL-6 may directly bind to this receptor complex, or it can bind to a soluble form of gp130 in order to be presented to cells expressing only IL-6R. In this regard, macrophages express high levels of this receptor. IL-6 bound to gp130 has an important participation for macrophage accumulation in AT [131, 151, 152]. Conversely, IL-6-deficient mice develop late-onset glucose tolerance. IL-6 also stimulates the expression of the IL-4 receptor (IL-4R) on macrophages, thereby promoting M2 polarization. Thus, IL-6 appears to function as anti-inflammatory mediator by preventing M1 macrophage formation in homeostasis. Therefore, IL-6 effects for T2D development seems to be time- and concentration-dependent [153].

The presence of IL-6 has been shown to correlate with a higher risk of vascular complications or mortality in T2DM, probably because of its involvement regulating lipid metabolism and CRP production, both of them recognized risk factors for cardiovascular disease (CVD) [154]. IL-6 is also linked to risks of cardiovascular events only in T2D patients with renal dysfunction. In addition, IL-6 levels showed a significant correlation with macrovascular complications in T2D patients [155].

IL-6 mediates several steps during the activation of inflammatory responses by regulating proinflammatory cytokine synthesis. However, it also promotes anti-inflammatory cytokines such as IL-1Ra and IL-10. Obese mice, after acute administration of IL-6, showed improved glucose tolerance, decreased hepatic gluconeogenic gene expression, and increased hepatic phosphorylation of AKT [156]. An acute transient IL-6 increment along with other inflammatory markers also occurs during physical activity, concomitantly with their release [136]. High-intensity interval exercise caused a significant increase in IL-6 and was greater than what was shown under low-intensity exercise of the same duration [157, 158]. Mice submitted to an intensive treadmill running protocol showed high levels of inflammatory cytokines such as IL-1β, IL-6, and TNF-α in serum and skeletal muscle samples [159]. Plasma IL-6 concentrations increased approximately 100-fold during exercise, and the extent of such increase depends on its duration and intensity [160]. IL-6 is required for exercise to reduce visceral adipose tissue mass [161]. In this case, the transient IL-6 increase does not have negative effects on tissues, and the endogenous upregulation of this cytokine in response to exercise improves insulin sensitivity. Therefore, IL-6 exhibits dual properties.

IL-18

IL-18 is a member of the IL-1 cytokine family. It is produced by several hematopoietic and non-hematopoietic cells. IL-18 was identified in human atheroma tissues, and it is an important regulator of innate and acquired immune responses. It induces the expression of several inflammatory molecules in vascular smooth muscle, endothelial cells, and macrophages. The regulation of IL-18 synthesis, its effect on cytokine release, and its mechanisms are still unknown [162].

IL-18-deficient mice develop obesity as a consequence of increased food intake. They also developed insulin resistance in the liver, muscle, and adipose tissue because of an enhanced glucose production. Replacement of IL-18 in brain reduced food intake and reversed hyperglycemia [163]. In American lifestyle-induced obesity syndrome (ALiOS) mouse model, IL-18-deficient mice were protected from early liver damage, possibly due to silencing of the proinflammatory gene expression pattern by NLRP3 activation and IL-18R-dependent signaling [164].

In addition to its role during the inflammatory response toward microorganisms, IL-18 is an important factor in human autoimmune and metabolic diseases. IL-18, IL-4, and IL-12 were significantly higher in diabetic patients regarding healthy subjects. High serum IL-18 levels were correlated with poor glycemic control (assessed as posprandial glucose), prolonged diabetes, and atherogenic index. Furthermore, IL-18 may be used as a predictor for pre-clinical atherosclerosis and poor glycemic control in T2D [165, 166].

IL-18 is considered a potential risk factor for T2D and its associated metabolic complications. In T2D patients serum

levels of IL-18 and its receptor IL-18R are significantly higher than the controls [167]. In obese individuals, the adipose tissue IL-18R/IL-18 expression is enhanced and is associated with proinflammatory gene signature and insulin resistance [168, 169]. IL-18 has been directly implicated in renal injury induction on diabetic nephropathy [170]. IL-18 was also independently correlated with MetS, a known risk factor for CVD, after considering body mass index, lipids, and fasting blood sugar [171]. A prospective study showed that IL-18 was correlated with coronary events in males, regardless of age, body mass index, inflammatory biomarkers, and classic lipid predictors [172, 173]. Mice with an activating mutation in NLRP1, and hence increased IL-18, show decreased adiposity, and they are resistant to diet-induced metabolic dysfunction [174].

TGF-β1

Initially, TGF-β is produced as an intracellular inactive protein complex that is modified before its secretion. One of the most relevant modifications is the C-terminal pro-region cleavage from the N-terminal. The pro-region is known as the latency-associated peptide (LAP), whereas the N-terminal region is the mature or active TGF-β. The latter belongs to a molecule family displaying a variety of roles in several cell types. More than 40 protein members of this family are known, they have a dimeric structure, and they are clustered in several subfamilies. The TGF-β subfamily includes six isoforms; three of them are expressed in mammals [175, 176]. Among these, TGF-β1 is involved in embryogenesis, and it has a prominent role in the immune system by controlling several aspects of inflammatory responses and T-cell differentiation, switching between B-cell isotypes.

TGF-β and retinoic acid are produced by CD103+ DCs located at the small intestine, and they are inducers of Treg cells. TGF-β also induces naive T-cell differentiation into pathogenic TH17 cells while inhibiting the generation of Th1 and Th2 cells in response to immune challenges. Animal models of pancreas-specific overexpression of TGF-β have shown that this factor inhibits diabetes development [177, 178].

TGF-β1 is synthesized as a precursor protein. As it has been associated with the pathogenesis of numerous diseases, the multiple mechanisms of latent (L)-TGF-β activation represent an opportunity to control TGF-β activity within an organ involved in a specific disease process. It is difficult to retrieve reliable epidemiological data on TGF-β1 as it circulates in the bloodstream mainly as its latent form that needs to be proteolytically modified to its active form [179].

In the MONICA/KORA study, high serum TGF-β1 levels were correlated with a high risk of T2D, after adjustment for age, sex, BMI, lifestyle factors, hypertension, lipids, and parental diabetes history [180].

Human islets undergoing β-cell apoptosis is associated with increased levels of TGF-β1; genetic or pharmacologic inhibition of TGF-β/Smad3 signals protects from β-cell apoptosis in mice [181]. Moreover, TGF-β1/Smad3 signaling pathway promotes hepatic gluconeogenesis, both upon prolonged fasting and during T2D. In contrast, genetic and pharmacological inhibition of TGF-β1/Smad3 signaling suppressed endogenous glucose production [182].

Resistin

Resistin was discovered in 2001; it is a small peptide (12.5 kDa) comprised by 108 amino acids containing several cysteine residues. It is a member of a small family of secreted proteins characterized by a unique spacing of 10–11 cysteine residues on their structure. They are known as Resistin-like molecules (RELMs) or as found in inflammatory zone (FIZZ) proteins. Resistin is a cytokine almost exclusively expressed in white adipocytes in rodents, whereas human resistin is predominantly expressed in macrophages, and it is regulated by the nutritional status. It is also expressed by the non-adipocyte stromal vascular fraction in WAT, fibrotic liver, and also on atherosclerotic lesions [183].

Resistin levels are decreased in adipose-derived mesenchymal stem cells differentiation by inducing insulin resistance, and it represents a link between obesity, insulin resistance, and T2D. The antidiabetic drugs thiazolidinediones (TZD) downregulate human resistin expression in macrophages, or they induced a decrease of resistin levels in serum [184, 185].

In obese mice models, circulating resistin levels are higher when compared to lean controls [186]. The administration of exogenous resistin or its transgenic overexpression leads to decreased insulin sensitivity. Conversely, blocking resistin activity or by genetically decreasing its levels improves insulin sensitivity and restores glucose [187, 188].

There are contradictory reports regarding the correlation between resistin and obesity or between resistin and T2D in humans [189–191]. Some reports show that resistin levels are higher in subjects with T2D, but other studies show no correlation with IR or fasting insulin levels [192]. Serum resistin does not change significantly between obese and normal children, and it is not affected by body mass index over time; pubertal girls' resistin levels are not associated with obesity [193, 194].

On the other hand, resistin levels were correlated with increased risk for T2D, even after adjusting for known diabetes risk factors in three large American case-controlled studies (Nurses' Health Study and both the Women's Health Study and the Physicians' Health Study) with follow-ups after 12, 10, and 8 years [195]. Also, higher resistin concen-

tration (above 11 ng/mL) is associated with reduced survival in T2D [196].

Resistin has important roles in CVD and atherosclerosis. Resistin promotes human macrophage proinflammatory polarization and induces further resistin production and secretion in human macrophages [197].

Additionally, resistin also stimulates endothelial cells to secrete substances such as inflammatory cytokines, monocyte chemoattractant protein-1 (MCP-1), vascular cell adhesion molecule 1 (VCAM-1), and intercellular adhesion molecule 1 (ICAM-1) [198]. In human vascular cells, resistin increased reactive oxygen species (ROS) production and impaired insulin Akt/eNOS signaling, suggesting that ROS may involve in resistin-induced endoplasmic reticulum stress [199]. In vitro analyses revealed that resistin activated protein kinase C type ε (PKCε) via TLR4 in smooth muscle cells; PKCε may represent a molecular target for resistin-associated chronic atherosclerotic inflammation [197]. Furthermore, plasma resistin levels correlate with inflammation markers and the may be predictive of coronary calcification, an indicator of atherosclerosis [200, 201].

The resistin receptor remains unidentified, although a recent report has suggested that resistin may bind to the endotoxin receptor TLR-4 [202]. In human monocytes, the inflammatory actions of resistin were mediated by its binding to adenylyl cyclase-associated protein 1 (CAP1), and in liver regulates insulin resistance-related genes [203].

Leptin

Leptin takes part in inflammation, immune cells, obesity, and T2D. This peptide is one of the most important WAT-derived hormones; it is the product of the ob gene, and structurally and functionally it may be classified as a cytokine. Leptin has a wide range of biological functions including both innate and adaptive immunity [204, 205]. In combination with cytokines and other molecules, it acts on the central nervous system, partially regulating food behavior and energy balance. It has an effect on energy metabolism in other tissues such as the liver and muscle [206].

Leptin controls food intake by interacting with anorexigenic molecules in the hypothalamus. These molecules are produced by cells secreting proopiomelanocortin (POMC) and by neurons releasing cocaine- and amphetamine-regulated transcript (CART), orexigenic molecules such as neuropeptide Y (NPY), and agouti protein (AgRP) [207, 208]. Animal models fed with an HFD show hyperleptinemia that generates a blockade of hormone functions resulting in resistance toward leptin, higher food consumption, and obesity [209].

Leptin acts by binding to a receptor (Ob-R). The latter is a class I cytokine receptor encoded by the rather ubiquitous LEP-R gene. Leptin receptors have been also detected in hypothalamic regions such as the arcuate and both paraventricular and ventromedial nuclei. These regions regulate energy balance. In studies, CRISPR-mediated deletion of LEPR in AGRP neurons causes severe obesity and diabetes, faithfully replicating the phenotype of Lepr db/db mice. The human leptin LEP-R receptors are coded by at least six homologue genes producing several mRNA variants [210–212]. It is also expressed on most immune cells, including neutrophils, macrophages, and lymphocytes. In the hypothalamus, leptin binds to its receptor on the plasma membrane, thus triggering a phosphorylation cascade [205]. One important function of leptin in the hypothalamus is to regulate body weight.

Obesity animal models lacking leptin or its receptor develop obesity due to hyperphagia caused by abnormal leptin/leptin receptor signaling, and subsequently T2D-like manifestations appear. These effects are secondary to genetic mutations that do not reflect the disease's etiology in humans, as leptin or leptin receptor deficiency is nor relevant for T2D. For more details, see review [213].

During food intake, leptin expression is stimulated in the TA. Conversely it is decreased during fasting and diabetes. Leptin synthesis is positively regulated by insulin, glucocorticoids, and estrogens, whereas catecholamines (through their β3-adrenergic receptors), androgens, and long-chain fatty acids inhibit its synthesis [214, 215]. Insulin-stimulated leptin secretion by adipocytes and the consequent stimulation of lipolysis and fatty acid release insulin and acts through the activation of the transcription factors: sterol regulatory element binding protein 1 (SREBP1), CCAAT-enhancer binding protein-α (C/EBP-α), and specificity protein 1 (Sp1) [216].

Leptin and insulin are mutually regulated. Thus, leptin inhibits insulin production in pancreatic β-cells, whereas insulin stimulates leptin production by adipocytes. Leptin stimulates the secretion of IL-1β from monocytes, and high levels of this cytokine inhibit insulin secretion and trigger proapoptotic signaling in pancreatic β-cells. When resistance toward leptin occurs, as characterized by hyperleptinemia, the homeostatic balance between these hormones is disrupted. Consequently, insulin production is not affected by leptin, and this results in hyperinsulinemia and resistance to this hormone [217, 218].

In human and mice, blood leptin levels closely correlate with AT mass [219]. In addition to its central effects, leptin may modulate the immune response. This hormone affects both the innate and adaptive branches of the immune system. Regarding innate immunity, leptin modulates the activity of NK cells, macrophages, and neutrophils by enhancing their function and promoting the production of proinflammatory cytokines [220–223]. Regarding adaptive immunity, several in vitro and in vivo experiments demonstrate that leptin positively impacts T-cell proliferation and increases Th1 cyto-

kine production while suppressing that of Th2 [218, 224, 225]. In monocytes, leptin increases the expression and release of the IL-1Ra anti-inflammatory cytokine [226], and on the contrary, IL-1Ra decreases leptin expression at both mRNA and protein levels [227, 228]. In healthy individuals it preserves the balance between inflammatory markers. However, when resistance to leptin occurs, this cytokine has a proinflammatory effect, and the balance is shifted toward the chronic inflammatory state particular of T2D and obesity [229].

Leptin-deficient mice (ob/ob) and those lacking its receptor (db/db) are obese because of their increased food intake resulting from impaired satiety. Additionally, they exhibit an important decrease of functional immune cell populations, such as NK cells, dendritic cells, and Treg cells [229, 230]. T and B cells have been shown to increase LEP-R expression when activated. Moreover, when leptin is included in the cell culture media, it increased the survival of activated lymphocytes [231].

Macrophage and NK cell populations increase during the first weeks after feeding an HFD, specifically in VAT [232]. In vitro leptin stimulation resulted in a higher production of interferon-γ in NK cells, but long-term leptin stimulation had no significant influence on numbers of proliferating NK cells [233]. Furthermore, leptin promotes NK cell survival in bone marrow; it attenuates macrophage infiltration and inflammatory gene expression in AT, in spite of weight gain and adiposity. In addition, deficiency of NK cells prevented proinflammatory macrophages in VAT and decreased insulin sensitivity. However, leptin does not affect weight gain and macrophage infiltration in this tissue. Different background strains, potential effects caused by gut microbiota, different body weight baselines, and differing fat percent in the diet may be the underlying cause of such contrasting results [17, 231, 232, 234]. These elements must be considered to further evaluate the role of leptin in macrophages.

Finally, all results support the concept that inflammation plays a role for T2D pathogenesis, and proinflammatory mediators produced by adipocytes and immune cells actively participate in this phenomenon.

IL-1Ra

The IL-1Ra cytokine is a natural IL-1β inhibitor. The expression and release of the former are induced by the latter, so this cytokine is usually controlled by its antagonist. Several cell types and tissues throughout the body express IL-1Ra; thus its high levels are probably needed in order to suppress the deleterious effects generated by the potent proinflammatory activity of IL-1β. When IL-1Ra competitively binds to the IL-1 receptor, IL-1β binding is blocked, and the conveying of proinflammatory signals from its receptor is hampered. Some evidences suggest that anti-inflammatory IL-1Ra counteracts the inflammatory effects mediated by IL-1β, and it preserves cell function in both types of diabetes [235].

High levels of circulating IL-1Ra are correlated with T2D incidence, but is decreased in islets from patients T2D. In a nested case-controlled study, those subjects who developed T2D during the 11.5-year follow-up period displayed higher IL-1Ra levels when compared to individuals who remained diabetes-free. The authors hypothesized that individuals with high risk of T2D are characterized by the presence of an early compensatory, anti-inflammatory response preceding the full development of the disease [138, 236]. The correlation between IL-1Ra levels and risk of T2D was also observed in subjects with metabolic syndrome in both cohorts. After adjustment for multiple confounders, IL-1Ra was significantly associated with metabolic syndrome (MetS) to T2D progression in males from both cohorts and in females from the FINRISK 97 cohort only. IL-1Ra displayed a significant correlation with risk of T2D in both cohorts when the data obtained from males and females was pooled [237, 238].

IL-1Ra improved β-cell function and glycemic control in patients with T2D; these effects were shown after treatment with anakinra, a recombinant of IL-1Ra. The positive effects of IL-1Ra were also observed on Goto Kakizaki (GK) rats (a spontaneous, no obese T2D model) and mice, as treatment with exogenous IL-1Ra protected them from increased proinflammatory cytokine expression in islets (IL-1β, IL-6, and TNF-α), chemokine expression, and macrophage infiltration in islets, and they also exhibited improved insulin processing. Treatment with IL-1Ra is not linked to body weight changes, either in patients or in animal models. Deletion of IL-1Ra in β-cells in mice triggered impaired insulin secretion, reduced β-cell proliferation, and decreased expression of islet proliferation genes, along with impaired glucose tolerance. Also, exenatide, a drug that increases IL-1Ra, protects, maintains, and stimulates β-cell function in humans [239–242].

Thus, when the IL-1β activity is blocked during T2D, both pancreatic β-cell function and insulin resistance are protected from the direct toxic effects caused by this cytokine and/or by antagonizing its inflammatory response [240, 241]. Therefore, IL-1Ra could be a new therapeutic agent to treat T2D.

IL-4

IL-4 is an anti-inflammatory cytokine secreted by Th2 lymphocytes, basophils, and mast cells. It has pleiotropic functions as it promotes the Th1/Th2 balance and

plays a major role in polarizing anti-inflammatory macrophage (M2), B-cell proliferation, and immune responses by regulating the proinflammatory mediators (IL-1β, TNF-α, and IL-6) produced by macrophages. IL-4 is secreted by AT and hepatocytes and then is able to modulate the local immune response and insulin sensitivity [243–245].

IL-4 may regulate insulin sensitivity, glucose tolerance, and lipid metabolism, and it could be involved in diabetic susceptibility and its complications. Leptin-deficient and leptin-resistant mice under high-fat diet (HFD) showed lower levels of circulating IL-4. The administration of IL-4 (8 weeks) improved metabolic dysfunctions. Also, the browning of white adipocytes by IL-4 was found in epididymal white adipose tissues and 3T3-L1 preadipocytes [246].

On the other hand, Fas-mutant mice exhibit leaner phenotype compared to wild type; under HFD they increased IL-4 and IL-10 levels, the promotion of thermogenic protein activity, and browning in their adipose tissues; then these mice are resistant to HFD-induced obesity [247].

Insulin sensitivity and glucose tolerance were improved in mice overexpressing IL-4; triglyceride accumulation in fat tissues was also inhibited, leading to decreased weight gain and fat mass [248]. Furthermore, 3T3-L1 adipocytes under culture conditions to induce insulin resistance were further cultured with IL-4, and they showed improved insulin sensitivity, but neither upregulated the expression of key adipogenesis markers (GLUT4 and PPARγ) and non-lipid accumulation [249]. Contrary, adipocytes isolated from rats and after incubation with IL-4 showed stimulated lipogenesis and inhibited both lipolysis and the expression of proinflammatory adipokines and also decreased adiponectin expression. Additionally, there is a correlation between IL-4/IL-4 receptor (R) genotypes and T2D and also between IL-4 genotypes and high-density lipoprotein-cholesterol (HDL-C) [250, 251]. This data reveals the previously overlooked roles of IL-4 in metabolism.

IL-10

IL-10 possesses multiple anti-inflammatory properties, including macrophage and T-cell inactivation, and it has a protective effect against atherogenesis. Adiponectin displays anti-atherogenic effects, partially by inducing IL-10 expression in human macrophages [252, 253].

Initially IL-10 was described as a product from Th2 cells that inhibits Th1 cell function. Currently, it has been identified that IL-10 is produced by most lymphocyte populations and the cells of the innate immune system, such as the antigen-presenting cells (DCs and macrophages), B cells, monocytes, and granulocytes affecting most hematopoietic cell types [252, 254–256].

In lean adipose tissue, iNKT cells and Tregs are abundant and they produce IL-10. During the adipose expansion occurring in obesity, iNKT cells and Treg populations are depleted, thus resulting in less IL-10 and a more inflammatory environment. This correlates with a proinflammatory macrophage accumulation. The decrease of iNKT and Tregs cells in obese AT contributes to local and systemic inflammation and eventually to T2D [257, 258].

IL-10 may protect against diabetes. In this regard, it was demonstrated that IL-10 overexpression in mice skeletal muscle prevented macrophage infiltration into the AT caused by a HFD. Subsequently, IL-10 restricted the expression of proinflammatory cytokines, and it promoted insulin sensitivity regarding control mice [259, 260]. The data obtained from humans attempting to correlate IL-10 and T2D are limited to a few cross-sectional studies. In a study conducted on 85-year-old subjects, it was observed that an elevated capacity of IL-10 production in whole blood was correlated with lower HbA1c levels and lower T2D prevalence [261]. Additionally, serum IL-10 inversely correlated with BMI and body fat, whereas a positive correlation was observed with insulin sensitivity when a euglycemic-hyperinsulinemic clamp was performed on subjects with impaired glucose tolerance or T2D, and also in mice, it was observed that IL-10 ameliorated hyperglycemia and insulin resistance [262, 263].

In a cohort of the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER), baseline blood IL-10 levels were positively correlated with the CRP and IL-6 proinflammatory mediators. During the follow-up period, IL-10 levels were increased, and they were associated with higher risk of cardiovascular events (death from coronary heart disease, myocardial infarction, and stroke) [264].

T2D patients showed increased numbers of circulating IL-10- and IL-17-producing CD3+ T cells when compared to controls, although there was no difference regarding the frequency of lymphocyte subsets. The authors suggest that these cytokines are involved on the immune pathology of this disease [265]. IL-10 is an interesting cytokine because of its potent anti-inflammatory effects. However, the reported data are contradictory, and currently it is not clear whether elevated circulating IL-10 levels are effective to negatively regulate proinflammatory reactivity and to confer protection against T2D or whether increased IL-10 levels are merely indicative of proinflammatory processes without providing a metabolic benefit.

Adiponectin

Adiponectin is highly expressed by adipocytes displaying potent anti-inflammatory properties. The ADIPOQ gene codes for adiponectin. This protein possesses a collagen-like domain N-terminal and a complement factor C1q-like globular domain C-terminal. It is highly expressed during adipocyte differentiation, and it is one of the main products secreted by adipocytes. In the bloodstream, it seems to occur as several isoforms: as a low-molecular-weight (LMW) trimer, as a medium-molecular-weight (MMW) hexamer (trimer-dimer), and as a high-molecular-weight multimeric (HMW) isoform [266].

Many studies have revealed that plasma adiponectin levels are significantly decreased in obesity, IR, and T2D, being a key component for the interplay between adiposity, IR, and inflammation. Adiponectin improves whole body insulin sensitivity, and its decreased levels occurring in obese rodents and humans are caused by the presence of proinflammatory factors such as TNF-α, IL-6, ROS, and hypoxia, as they suppress adiponectin expression in adipocytes [267–269]. Conversely, PPAR-γ antagonists stimulate this expression [270]. Independently, a meta-analysis study showed that increased risk of T2D was strongly associated with low adiponectin levels and high of inflammatory cytokine levels (TNF-α, IL-1β, IL-6, IL-18, CRP) [271].

Several studies described a significant negative correlation between adiponectin and obesity parameters. Serum adiponectin levels decrease when MetS components increase [272–274]. Additionally, urinary excretion of HMW-adiponectin is an independent predictor of kidney disease progression in T2D patients affected by early kidney disease, and serum adiponectin level can be a good predictor of diabetic nephropathy in patients with T2D [275–277].

Adiponectin beneficial effects on lipid and glucose homeostasis are caused by multiple mechanisms, mainly by ceramidase activity and adenosine monophosphate-dependent kinase (AMPK)/sirtuin 1 (SIRT1)-dependent activation of the PPAR cofactor 1α (PGC-1α) [278, 279]. In obesity models, fatty acid oxidation and glucose uptake in skeletal muscle and AT are stimulated by adiponectin, and it was shown that they are dependent on AMPK signaling. Adiponectin is also involved in hepatic glucose outsuppression mediated by AMPK activation [280, 281].

Obesity is correlated with increased cardiovascular risk, especially when it is concomitant with T2D. Patients with coronary artery disease (CAD) significantly showed reduced adiponectin levels when compared to controls with matching ages and body mass indexes [282–284]. It was also correlated with a low risk of myocardial infarction [285].

In addition to its antidiabetic functions, adiponectin also suppresses atherosclerosis, fatty liver diseases, and liver fibrosis [286, 287]. Adiponectin administration blocked the effect of proinflammatory agents, e.g., TNF-α and IL-6, and it directly improved endothelial dysfunction by increasing the production of nitric oxide [288].

Adiponectin acts as an immunomodulator; it promotes the differentiation of anti-inflammatory M2 macrophages [289, 290]. This adipokine also modulates T-cell activation and the inflammatory function of NK cells. Adiponectin receptors are upregulated on the surface of human T cells after an antigen-mediated stimulation, and they mediate apoptosis of antigen-specific T cells, subsequently suppressing T-cell expansion [291]. Furthermore, adiponectin suppresses TLR-mediated IFN-γ production in NK cells without affecting cytotoxicity [292]. Adiponectin inhibits LPS-induced TNF-α production in macrophages by inhibiting NF-κB activation and by stimulating anti-inflammatory IL-10 secretion [293, 294]. Therefore, adiponectin may contribute to this role by reducing inflammation within AT.

Two adiponectin receptors have been identified: AdipoR1 and AdipoR2. They possess seven transmembrane domains, although they differ structurally and functionally. The liver expresses AdipoR2, whereas the skeletal muscle contains AdipoR1 and AdipoR2. The biological effects caused by these receptors depend not only on adiponectin blood levels but also on tissue specificity. By interacting with its receptors, ADIPO R1/2, adiponectin activates AMPK to enhance fatty acid oxidation and glucose uptake in muscle and to suppress gluconeogenesis in the liver [295]. Moreover, adiponectin regulates energy expenditure by activating AMPK in the hypothalamus, where AdipoR1 and AdipoR2 co-localize with the leptin receptor, ObR [296]. It has been previously demonstrated that adiponectin stimulates appetite and decreased energy expenditure. These effects were eliminated following the ablation of AdipoR1 small interfering RNA (siRNA) or AMPK signaling (AMPK dominant negative) [297, 298].

Dysregulation of immune cells and released molecules from them may participate in the development of inflammation associated with metabolic diseases (Fig. 12.1). In an effort to revert these deleterious effects, the loss of weight, among several strategies, can help to avoid inflammation, pancreatic β-cell dysfunctions, insulin resistance, and then final steps to drive to T2D and other metabolic alterations (Fig. 12.2).

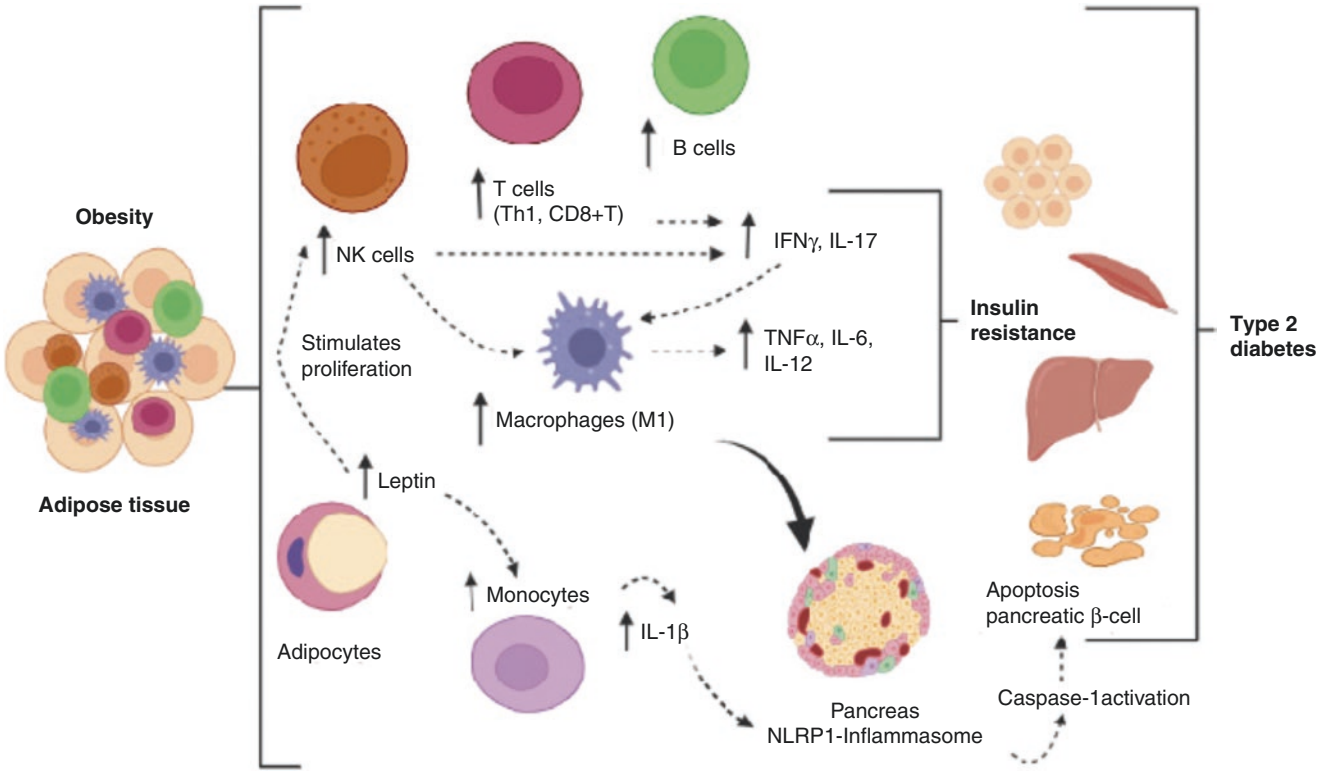

Fig. 12.1 Cells and molecules of the immune system may mediate insulin resistance associated with obesity and T2D. NK, T, B cells, monocytes, and other cells produce different cytokines (such as INF-γ, IL-17), which promote macrophage polarization to M1 phenotype, generating IL-6, IL-12, and TNF-α; these cytokines support an inflammatory milieu and insulin resistance. Furthermore, leptin, an adipokine increased in obesity, stimulates cells proliferation, such as NK cells, and also increases IL-1β secretion (from monocytes); this cytokine together with macrophages infiltration mediates β-cell dysfunction. All of these alterations contribute to T2D development. (The drawing was designed by Dr. A. Fortis)

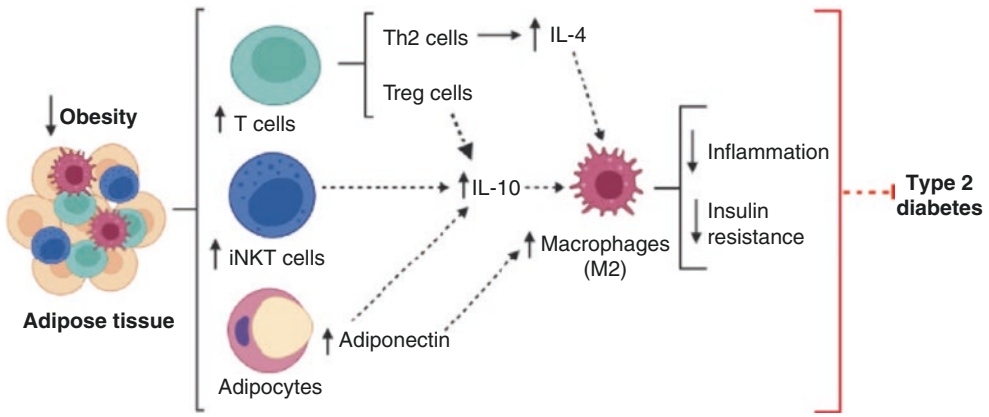

Fig. 12.2 The effect of reduction of obesity on immune cell functions. After weight loss, among other alternatives, the accounts of T cells (Th2 and Treg) and iNK cells increase, and IL-10 and IL-4, the cytokines generated by these cells, also increase. An increase in adiponectin levels (excreted by adipocytes) and macrophages polarization to M2 (anti-inflammatory phenotype) reduces inflammation, restorings insulin sensitivity and prevents T2D progression. (The drawing was designed by Dr. A. Fortis)

Perspectives onT2D Immunotherapy

The use of several anti-inflammatory methods has been implemented on obese subjects with IR. Based on this, salsalate (a salicylate analogue) has been shown to improve insulin sensitivity [299, 300]. The thiazolidinediones antidiabetics (e.g., rosiglitazone, pioglitazone, and lobeglitazone) induced a decrease of adipose tissue macrophage populations [301], and rosiglitazone increased adiponectin, ameliorates hepatic and systemic insulin resistance, hepatic inflammation, and fatty liver in rats [302]. Pioglitazone

reduced liver fibrosis and increased insulin sensitivity in patients with T2D [303]. Rosiglitazone in polymeric particles provide an efficient and selective delivery of the drug on specific place; it is a new strategy for therapeutic effects of TZDs reducing their secondary effects [304].

In patients with T2D, after a 12-week treatment with trelagliptin (an oral dipeptidyl peptidase (DPP)-4 inhibitor), serum adiponectin levels significantly increased [305]. Anti-TNF antibodies were proved to decrease blood glucose in obese subjects [3, 306]. Anti-IL-1β monoclonal antibody therapy improved glycemic condition and β-cell insulin secretion [307, 308].

Inflammation, improved insulin sensitivity, and normalized glucose tolerance were observed on obese mice fed with a HFD supplemented with *ω*-3 fatty acids [309]. Dietary supplementation with monounsaturated and *n*-3 polyunsaturated fatty acids showed a significant improvement in several functions such as chemotaxis, phagocytosis, digestion capacity, natural killer activity, and lymphoproliferation in response to mitogens [310]. In human studies, a supplementation with fish oil yielded mixed results regarding metabolic end points. A limitation of some of these studies has been the lack of discrimination between fatty and lean fish [311, 312].

IL-1β, the main macrophage-derived cytokine, increases in T2D obese subjects, and it enhances IL-17 and IL-22 release by AT CD4+ T cells. IL-22 stimulated pro-IL-1β transcription leading to enhanced IL-1β production by human VAT macrophages. Early clinical data describe promising effects caused by blocking IL-17 in several autoimmune diseases. An immunotherapy has been proposed by using an anti-IL-1β and anti-IL-22 antibody mixture in order to improve inflammation in human obesity-linked T2D [313].

Concluding Remarks

- Obesity, through adipose tissue expansion may contribute to the development of insulin resistance and type 2 diabetes.
- Adipose tissue is considered an important immunologically active organ and is constituted by adipocytes and immunological cells as macrophages, eosinophils, lymphocytes, etc.
- Immune cells participate on inflammatory processes, and they are the most represented cell types within adipose tissue.
- IL-1β, TNF-α, IL-6, and other cytokines expressed in immune cells and in adipocytes are promoters of inflammation.
- Insulin signaling is altered by proinflammatory cytokines and adipokines and they are important key targets to control or delay the T2D advance.

Multiple-Choice Questions

1. Inflammation associated with type 2 diabetes and obesity is mainly generated in this tissue or organ
   (a) Hearth
   (b) Kidney
   (c) **Adipose**
   (d) Muscle
   (e) Brain

   Answer: Inflammatory molecules are derived mainly on adipocytes and immune cells that constitute the adipose tissue.
2. Immune cells involved in diabetes
   (a) Myocytes
   (b) Cardiomyocytes
   (c) Astrocytes
   (d) **Lymphocytes**
   (e) Hepatocytes

   Answer: In obesity-associated diabetes, the number of lymphocytes increases.
3. Proinflammatory markers occurring in inflamed tissue
   (a) Glucose and sucrose
   (b) **Gamma interferon and interleukins**
   (c) Phospholipids and HDL
   (d) Leucine and proline
   (e) Insulin and glucagon

   Answer: Here, only interferon and interleukins are markers associated with inflammation.
4. Change that TNF-α undergoes between the lean and obese status
   (a) Inhibition
   (b) **Activation**
   (c) Inflammation
   (d) Polarization
   (e) Suppression

   Answer: TNF-α is activated during obesity and participates on insulin resistance development.
5. Effect caused by adiponectin on the arteries
   (a) **Antiatherogenic**
   (b) Pro-inflammatory
   (c) Insulin receptor-serine phosphorylation
   (d) Adipocyte dysfunction
   (e) Insulin deficiency

   Answer: Adiponectin is considered antiatherogenic due its effects on endothelial function by inhibition of ROS production and on monocyte adhesion.
6. Functions of mast cells
   (a) Secrete anti-inflammatory cytokines
   (b) Protect tissues from inflammation
   (c) **Secrete granules rich in histamine and serine proteases**
   (d) Express adiponectin mRNA
   (e) Protect from weight gain

Answer: Mast cells secrete granules rich in in histamine, serine proteases, and cytokines as a defense mechanism.

7. This effect has been demonstrated during development of type 2 diabetes.
   (a) Inhibition of adipocytes accumulation
   (b) **Macrophage recruitment in adipose tissue**
   (c) Decreased adiponectin expression in adipocytes
   (d) Increased serum IL-R1a
   (e) Inhibition of TNF-α activity

   Answer: There is a significant increase in the number of macrophages on adipose tissue from subjects with type 2 diabetes, which contributes to inflammatory process.
8. Invariant NKT (iNKT) cells
   (a) **Innate immune cells activated by lipids**
   (b) Cells that express INF gamma
   (c) The level of these cells increase in obesity
   (d) These cells produce high amount of IL-10
   (e) These cells are suppressed during obesity outset

   Answer: iNKT cells are innate lipid sensors, and their activation, using their prototypic ligand α-galactosylceramide.
9. It is a mouse macrophage marker.
   (a) CD28
   (b) CD40
   (c) **F4/80+**
   (d) CD4+
   (e) Th2

   Answer: F4/80+ are molecules found only on macrophage surface.
10. Regulation of this subtype of T cell is considered a novel target for treat type 2 diabetes
    (a) B cells
    (b) Th1
    (c) Th2
    (d) **Treg**
    (e) Th17
    (f) Mast cells

    Answer: Regulatory T cells (Tregs) are essential negative regulators of inflammation.

Glossary

Adipokine A cytokine or hormone that is secreted by adipose tissue

Chemokines Are signaling proteins secreted by cells, whose main function is to act as a chemoattractant to guide the migration of near cells. They are implicated in various diseases, such as cancer, autoimmune disorders, and diabetes

Cytokine Small proteins secreted and released by cells, they have a specific effect on the interactions and communications between cells

Diet-induced obesity (DIO) Obesity mouse model induced by high-fat diet

FA A carboxylic acid with aliphatic chains of 4–28 carbons, which can be esterified with glycerol to form triacylglycerols, the main stored form of lipids

HFD High-fat diet

IgG, IgM Are members of immunoglobulin (Ig) superfamily, they are ubiquitously present in several cells and tissues of vertebrates and share structural homology with cell adhesion molecules and some cytokines

Innate immune cells Are white blood cells that mediate innate immunity and include basophils, dendritic cells, eosinophils, mast cells, monocytes, macrophages, neutrophils, and natural killer cells

Mitogen-Activated Protein Kinase (MAPK) A mammalian Ser/Thr protein kinase

NF-κB Nuclear factor-κB is a ubiquitous transcription factor involved in the control of processes, such as immune and inflammatory responses, developmental, cellular growth, and apoptosis. The NF-κB pathway has been considered as proinflammatory signaling pathway, based on the role of NF-κB in the expression of proinflammatory genes including cytokines, chemokines, and adhesion molecules

Omental adipose tissue The fat depot found within the peritoneum, in close association with stomach and other internal organs

PPAR-γ Peroxisome proliferator-activated receptor gamma is an essential transcription regulator of the adipocyte differentiation and is required for mature adipocyte function

Salicylates A group of derivatives of salicylic acid, including aspirin and acetylsalicylic acid, which are widely used as analgesics, and anti-inflammatory medicaments

Thiazolinediones Antidiabetic drugs used therapeutically, which are known to be high-affinity ligand activators of PPARs

White adipose tissue (WAT) The predominant fat storage tissue in animals, consisting mostly of adipocytes but also other cell types as mast cells and macrophages

Abbreviations

AGE	Advanced glycation end products
AIF	Apoptosis inducing factor
Apaf-1	Apoptotic protease-activating factor 1
ATF6	Activating transcription factor 6
ATM	ATM serine/threonine kinase protein
Bak	Bcl-2 homologous antagonist killer
Bax	Bcl-2-associated X protein
Bcl-2	B-cell lymphoma 2
Bcl-xl	B-cell lymphoma-extra large
BH (1–4)	Bcl-2 homology domains
Bok	Bcl-2 related ovarian killer
Caspasa	Cysteine-aspartic proteases, cysteine aspartases
CHOP	C/EBP homologous protein
ChREBP	Carbohydrate response element-binding protein
Drp1	Dynamin-related protein 1
ΔΨm	Mitochondrial membrane potential
eif2α	Eukaryotic translation initiation factor 2α
ER	Reticulum stress
ERE	Endoplasmic reticulum stress
EZH2	Enhancer of Zeste Homologue 2
FADD	FAS-associating death domain-containing protein
Fas	Death receptor
FFA	Free fatty acids
Fis1	Mitochondrial fission 1 protein
FOX A1/2	Forkhead box
G3P	Glyceraldehyde 3-phosphate
GADD34	Downstream growth arrest and DNA damage-inducible protein
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
GATA4/6	GATA-binding protein
GLUT	Glucose transporter
GSIS	Glucose-stimulated insulin secretion
H3K27me3	Histone H3 trimethyl K27
HNF1β	Hepatocyte nuclear factor
IAPP	Islet amyloid polypeptide
IFNγ	Interferon gamma
IGF1	Insulin-like growth factor 1
IL-1β	Interleukin 1 beta
iNOS	Nitric oxide synthases inducible
Ins	Insulin gene
INS1	Insulin secreting beta-cell-derived line
IRE1α	Inositol-requiring enzyme
IRS-2	Insulin receptor substrate
Isl	Islet
MafA	Musculo aponeurotic fibrosarcoma protein A
Mdm2	Murine double minute 2
Mff	Mitochondrial fission factor
Mfn	Mitofusin
Mouse *db/db*	Model of obesity, diabetes, and dyslipidemia with a mutation in leptin receptor
mTOR	Mammalian target of rapamycin
NAD^+	Nicotinamide adenine dinucleotide
NADH	Nicotinamide adenine dinucleotide reduced
NADPH oxi	Nicotinamide adenine dinucleotide phosphate-oxidase
NeuroD1	Neurogenic differentiation 1
NF-κB	Nuclear factor kappa B
Nkx	Homeobox protein
NLRP3	NACHT, LRR, and PYD domain-containing protein 3
NLRs	Nucleotide oligomerization domain (NOD)-like receptors
NO	Nitric oxide
NOD	Nucleotide oligomerization domain

Notch	Transcription factor
•OH	Hydroxyl radical
8-OHdG	8-hydroxy-2′-deoxyguanosine
O–2	Superoxide anion
O-GlcNAc	O-linked β-N-acetylglucosamine
Opa1	Protein of mitocondrial internal membrane
P/CAF	P300/CBP-associated factor
p16	Cyclin-dependent kinase inhibitor 2A, multiple tumor suppressor 1
p21	Cyclin-dependent kinase inhibitor 1 or CDK-interacting protein 1
p27	Cyclin-dependent kinase inhibitor 1B
p300/CBP	E1A binding protein p300/CREB-binding protein
p38 MAPK	P38 mitogen-activated protein kinases
p53	Tumor protein p53
PARP	Poly ADP ribose polymerase
Pax4	Transcription factors paired box gene 4
Pdx1	Pancreatic and duodenal homeobox 1
PERK	Protein kinase-like ER kinase
PI3k	Phosphatidylinositol-3-kinases
PKC	Protein kinase C
PP-1	Protein phosphatase 1
Ptf1α	Pancreas transcription factor 1α
RAMP1	Receptor activity-modifying protein 1
Rfx 6	Regulatory factor x
RING-finger	Really interesting new gene
RINm5F	Rat insulinoma cells
ROS	Reactive oxygen species
Sox9 SRY	Sex-determining region Y-box 9
SPT	Serine C-palmitoyltransferase
T2D	Type 2 diabetes
TLRs	Toll-like receptors
TNFRI	Tumor necrosis factor receptor type I
TNFα	Tumor necrosis factor alpha
TXNIP	Thioredoxin-interacting protein
UCP2	Uncoupling protein 2
UDP-GlcNAc	Uridine diphosphate N-acetylglucosamine
UPR	Unfolded protein response

Objectives

- To briefly describe the embryonic development of pancreatic β
- To analyze the universal literature on the mechanisms that underlie the loss of pancreatic β-cell mass
- To provide information on the regulation of p53 by hyperglycemia and its participation in the induction of pancreatic β-cell apoptosis

Introduction

Insulin produced and secreted by β-cells is responsible for blood glucose level regulation. The major stimulus for insulin secretion is glucose itself. When the latter is taken by β-cells in a process mediated by the glucose transporter 2 (GLUT 2), it enters the glycolytic pathway, the Krebs cycle, and oxidative phosphorylation, and it promotes the increase of the ATP/ADP ratio. Subsequently, this leads to the closure of the ATP-dependent potassium channels, to membrane depolarization and to Ca^{2+} influx through the voltage-dependent Ca^{2+} channels. An increase of cytosolic Ca^{2+} is the signal that triggers glucose-stimulated insulin secretion (GSIS). Alterations of insulin secretion and glycemia increases lead to the settlement of type 2 diabetes (T2D). Additionally, this disease depends on external factors such as diet, body weight, and genetic background that may delay or enhance all clinical sings of the disease. It is known that, in modern society, an increased carbohydrate intake and the lack of exercising lead to the development of obesity. This condition increases insulin demand in order to maintain normal glycemia; thus the ability of β-cells in order to fulfill the insulin requirements is critical to preserve glucose homeostasis. The initial response toward an increased insulin demand is adaptive **hyperplasia** and an increased synthesis of the hormone [1]. However, if **resistance to insulin** persists during extended time periods, β-cells become exhausted, and their mass decreases due to an increase of the apoptotic rate and consequently hyperglycemia appears [2]. This latter condition activates several metabolic pathways impairing β-cells, such as glucolipotoxicity, mitochondrial alterations, oxygen reactive species (ROS), oxidative and endoplasmic reticulum stresses (ERE), proinflammatory cytokines, deposition of amyloid polypeptide, and p53 translocation to mitochondria (Fig. 13.1). Recently, it has been proposed that p53 protein is a major apoptosis trigger in β-cells during hyperglycemia conditions [3, 4]. These events impair β-cells by hampering their proliferative ability

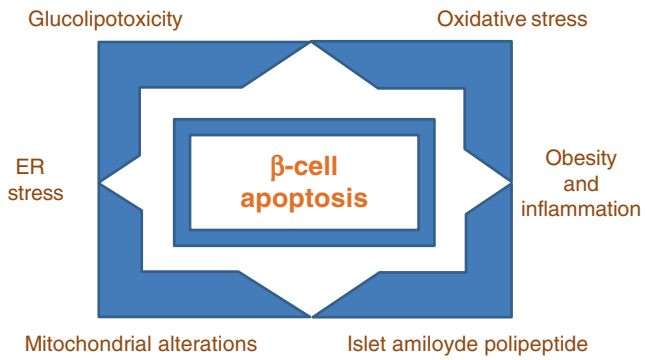

Fig. 13.1 Metabolic pathways by hyperglycemia induced β-cells death. *ER* endoplasmic reticulum

and also by decreasing insulin expression and secretion and promoting their death. Several of these alterations, either separate or combined, may be observed in T2D models; thus it is likely that β-cell loss in humans is linked to the activation of the aforementioned mechanisms and not to just one of them [5]. The contribution from each one of such mechanisms to the decrease of pancreatic β-cell amounts will be reviewed in this chapter.

The Origin of β-Cells

Embryonic Development and Differentiation

During embryonic development or even during the first postnatal days, β-cell may be generated by stem or progenitor cells within the pancreatic ducts, bone marrow, or even pancreatic islets. Islet genesis initiates on the week 12 of gestation in humans. In weeks 13–16, the early endocrine precursor cells on the duct's wall form cell aggregates and generate an early islet. In weeks 17–20, the connection between islets and duct is lost, and the islets are properly formed. At this stage, they contain only pancreatic polypeptide, somatostatin, and glucagon derived from immature precursor cells. In weeks 21–26, β-cells are located at the islet center [6].

Studies conducted on rodents have allowed the identification of the molecular mechanisms regulating pancreatic β-cell establishment and differentiation. In mouse, it begins on the E8.5 day of development, and it depends on several factors secreted by neighboring early gut cells and mainly from vessels. During pancreas development several transcription factors intervene, such as the pancreatic transcription factor (Ptf1a) and the pancreatic duodenal homeobox (Pdx1). Other factors such as SRY (sex-determining region Y)-box 9 (SOX9), forkhead box (FOX) A1/2, hepatocyte nuclear factor (HNF) 1β, and GATA4/6 have a critical participation during the establishment of the pancreatic progenitor cell pool. The development of endocrine progenitors requires Notch activation, whereas the formation of β-cells depend on Nkx 6.1, NeuroD1, the regulatory factor x (Rfx) 6, islet 1(Isl), Nkx2.2, and Pax4. The first hormone-producing cells are detected on E9.5, and their numbers increase by E13.5. At that time, the expression of β-cell-specific genes may be observed, such as GLUT 2 [7, 8].

Postnatal Development of the Pancreas

After birth, when feeding initiates, pancreatic mass increases due to the rapid expansion of the exocrine tissue. During the first 2 years of life, β-cell population keeps a 3–4% replication rate, and the pancreas reaches its maximum volume by 5–10 years old due to a decreased replication rate (0.05–0.1%) [9]. By the third decade of life, pancreatic mass is stabilized and constant until approximately 60 years of age. From that moment on, pancreas size begins to decrease [10] because an increase of cell proliferation inhibitors such as p16, p26, p27, and cyclin D3, whereas Pdx1 decreases. The latter is needed for β-cell differentiation [6]. In rodents, the β-cell population is established during the first 4 weeks of life. In rats, between postnatal days 3 and 24, a proliferation rate of 3% occurs, and during this period apoptosis also contributes to β-cell population curtailing. However, this stage is highly influenced by the prevailing nutrigenic environment [11].

In adults, during physiological conditions such as pregnancy or during adaptation toward weight increase, it is possible to observe an increase of β-cell replication rates [12]. It has been demonstrated that β-cell replication may be induced in rodents by providing a high-fat diet or a chronic glucose infusion [13]. Hyperglycemia also stimulates cell proliferation by activating glycolysis and by shortening the quiescence period of the cell cycle and also by promoting the G1-S transition through the activation of the ChREBP (carbohydrate response element-binding protein) transcription factor [5]. This confirms β-cell adaptive ability when facing a metabolic demand.

β-Cell Dysfunction and the Loss of Pancreatic B-Cell Mass

Chronic exposition of β-cells to high glucose levels impairs their functions, and it may induce dedifferentiation and even death and a decreased pancreatic β-cell mass (β-cell failure). The onset of β-cell progressive deterioration and loss of function occurs at an earlier stage, before TD2 symptoms even appear, which are evident due to decreased insulin synthesis and secretion [14]. Postmortem studies on human pancreas from patients with a clinical history of fasting glucose alterations demonstrated approximately a 50% decrease of β-cell mass caused by apoptosis [15]. Similarly, an increased glucose-induced insulin secretion was observed due to the remaining 50% [16]. However, the decreased β-cell mass is not only induced by an enhanced apoptosis as alterations of cell proliferation rates have also been documented. Additionally, during hyperglycemia conditions, other studies have reported that β-cell undergoes dedifferentiation or regression processes characterized by a decreased expression of the specific genes for these cells [17].

β-Cell Apoptosis

Apoptosis is a physiological mechanism for cell suppression that enables the elimination of some cells without affecting neighboring cells and without releasing the cell contents, unlike **necrosis** that is concomitant with an inflammatory reaction (Table 13.1). Apoptosis may be triggered through the activation of two major pathways: intrinsic or extrinsic. The latter is activated by death ligands that bind to cell surface receptors, thus transmitting death signals. Fas and TNFRI are the best described death receptors. They possess a cysteine-rich extracellular domain and a cytoplasmic death-domain. Fas ligand (FasL) binds to one of three Fas molecules, and it promotes receptor oligomerization and FADD (Fas-associated protein with death domain or Mort-1) interaction with the receptor's death domain. Subsequently, FADD binds to procaspase-8 leading to its activation. In turn, **caspase** 8 leads to the activation of other caspases, such as caspase-9. These are located within cytoplasm as inactive **proenzymes**, and they may be activated by other caspases, death receptors, or by **cytochrome c** [18] through its interaction with the apoptosis protease-activating factor-1 (Apaf-1) and procaspase 9, thus leading to **apoptosome** formation and the triggering of the caspase-activating cascade.

The extrinsic pathway initiates with the release of several proapoptotic factors, such as cytochrome c, from the mitochondrial intermembrane space toward cytosol. As mentioned above, this event lead caspase activation through the formation of the apoptosome, the activation of caspase 9, and the subsequent activation of executing caspases 3, 6, and 7 and with these the apoptosis proteolytic cascade. Mitochondria also release the apoptosis-induced factor (AIF), a **flavoprotein** that translocates to the nucleus where it triggers chromatin condensation and DNA fragmentation. Mitochondrial membrane potential ($\Delta\Psi_m$) alterations are also observed as well as respiratory chain uncoupling, all of them identified as early dysfunctions leading to cell death. Ceramides, oxidative agents, and pathologic increases of cytosolic Ca^{2+} may also induce the disruption of mitochondrial external membrane. Other proteins involved in permeating the mitochondrial membrane are those belonging to the Bcl-2 family. All of its members possess one to four preserved residues, known as the Bcl-2 homology domains (BHI to BH4). The apoptosis-inhibitor Bcl-2 and BcI-xl possess BH1 and BH2, whereas apoptosis-inducers such as Bax, Bak, and Bok display BH1, BH2, and BH3. There are some other proteins that only possess BH3 also known as death proteins. The Bcl-2 family members either promote or inhibit apoptosis in response to different stimuli such as lack of growth factors, Apaf-1 sequestration, and oxidative stress, among others [19].

Table 13.1 Apoptosis vs. necrosis

Apoptosis	Necrosis
Single cells	Cells group
Cell shrinkage	Cell swelling
Lysosomal enzymes are not involved	Involvement of lysosomal enzymes
Oligonucleosomal nucleus fragmentation	Complete nucleus dissolution
Apoptotic bodies	Cell disintegration
Phagocytosis by adjacent cells	Intracellular content release

At physiologic level, apoptosis is crucial for pancreas remodeling in newborns [20]. In adults, β-cell mass may increase and subsequently return to their normal size during some physiologic situations such as pregnancy and depending on the organism requirements. In other conditions as obesity and resistance to insulin, it has been proposed that β-cell hyperplasia may be reverted by body weight decreases and the increase of the apoptosis rate [21].

Whereas glucose-mediated stimulation is essential for physiologic maintenance of β-cells, chronic hyperglycemia induces severe damage to these cells, and it creates a vicious cycle contributing to the progressive loss of functional β-cell mass. Chronic hyperglycemia decreases β-cell sensibility toward glucose and induces exhaustion and toxicity. Desensitizing is a reversible protective mechanism facing a steady demand for insulin. When glycemia levels are restored and stimulation ceases, β-cells may regain their sensibility toward glucose [22]. Conversely, if hyperglycemia persists, β-cells become exhausted, thus implicating the loss of insulin granules and that of two transcription factors regulating insulin expression: the musculoaponeurotic fibrosarcoma protein A (MafA) and PDX-1. It is important to mention that these effects may also be restored when glycemia decreases [23, 24]. However, if resistance to insulin is persistent and glycemia increases, an overstimulation of β-cells occurs, thereby altering their functions and mainly the mechanisms for insulin synthesis and secretion [3, 21, 25–27]. If hyperglycemia is not adequately controlled, persistent stimulation of β-cells may eventually lead to degranulation, exhaustion, and apoptosis. In vitro studies have shown that culturing insulin-producing cells (RINm5F) in the presence of high glucose levels, an increased ROS production is observed and it triggers apoptosis [3]. In these conditions, Bax oligomerization also increases along with cytochrome c release and caspase-3 activation [21], but the precise mechanisms involved in β-cell apoptosis have not been completely elucidated.

Glucolipotoxicity

Although, free fatty acids (FFA) in physiologic levels contribute to preserve glucose-induced insulin secretion (GSIS). Exposition toward high FFA levels for prolonged periods,

along with hyperglycemia, affects the expression of the *Ins* gene and induces resistance to insulin and also pancreatic β-cell dysfunction. FFA contribute to apoptosis triggering in β-cells through activation of protein kinase C (PKC, apoptosis mediator), increases in ceramide synthesis and Bcl-2 inhibition [28], and increased levels of the type 2 uncoupling protein (UCP2) [29], thus decreasing ATP production [30] and glucose-induced insulin secretion, besides contributing to both oxidative and endoplasmic reticulum stresses [31, 32]. It has been observed that unsaturated fatty acids (e.g., palmitic acid) are more toxic when compared to their monounsaturated counterparts (e.g., palmitoleic acid), as the latter may even exhibit a protective effect because they are rapidly esterified in order to form **triacylglycerols** [33]. However, it is currently accepted that FFA-induced damage depends on concentration, exposure time, and blood glucose levels [32, 34]. When these factors converge, fatty acids and glucose compete for metabolism through the glycolytic pathway. During hyperglycemia, oxidative phosphorylation becomes saturated with glycolytic products, thus promoting the formation of manoyl-CoA that inhibits the β-oxidation of fatty acids. This effect forces β-cells to divert fatty acids to other metabolic pathways in order to metabolize them; thereby it increases the production of esterified fatty acids such as **ceramides** [35]. Accumulation of the latter occurs from sphingomyelin cleavage and/or de novo ceramide synthesis by condensing serine and non-oxidized palmitoyl-CoA through the activity of serine-palmitoyl transferase (SPT) located in the mitochondria and endoplasmic reticulum. Ceramides affect mitochondrial membrane potential and permeability, and they represent a ROS production mechanism. They also enable the release of apoptosis induction factors such as cytochrome c and procaspases, thus leading to β-cell death [36]. Some experiments have demonstrated apoptosis induction mediated by ceramides after inhibiting their synthesis. In such conditions fatty acid-induced apoptosis also decreases [35]. Additionally, ceramides induce the activation of the NF-κB transcription factor that increases both inducible and non-inducible nitric oxide (NO) production. The interaction between NO and O^{-2} produces peroxynitrite, thus inducing DNA damage and the activation of poly (ADP-ribose) polymerase (PARP), a NAD^+-dependent enzyme [36]. Therefore, its over-activation decreases both, the NAD^+ pool and glycolytic rate, electron transport, and ATP synthesis. Besides negatively affecting insulin secretion, this situation may lead to pancreatic β-cell death [37].

Oxidative Stress

Whereas low ROS levels exert a beneficial effect on β-cells [11], their overproduction causes oxidative damage to proteins, lipids, and nucleic acids, and it induces oxidative stress. In hyperglycemia conditions, ROS are mainly generated by glucose auto-oxidation and also through an increased electron flow in mitochondrial respiratory chain [38]. Although, in recent years, it has been demonstrated an important participation of the NADH oxidase complex [3], as their components have been identified in rat pancreatic β-cells [39]. An increased mitochondrial pathway initially accelerates NADH production. The latter participates in the mitochondrial respiratory chain, and it represents the first step for superoxide anion ($O^{-}_{2}\cdot$) production that also generate other radicals such as hydrogen peroxide (H_2O_2) and the hydroxyl radical ($^{\circ}OH$), one of the most potent biomolecule oxidants. An increased $O^{-}_{2}\cdot$ inhibits glyceraldehyde 3-phosphate dehydrogenase (GAPDH) inducing accumulation of glyceraldehyde 3-phosphate (G3P) within the glycolytic pathway. This leads to the activation of ROS-producing pathways and to oxidative stress [40, 41] in the form of advanced glycation end-products (AGE), as their precursor (methylglyoxal) is generated from G3P. It also leads to PKC activation as glycerol (its activator) is also produced from G3P (Fig. 13.2) [42].

Alterations induced by oxidative stress range from synthesis modifications and insulin secretion, endoplasmic reticulum stress, and activation of the apoptotic intrinsic pathway [9]. ROS lead to activation mechanisms that reinforce β-cell death and their decreased cell mass. They also induce mitochondrial membrane potential alterations, thus modifying permeability and the release of proapoptotic proteins (cytochrome c, apoptosis-inducing factor, among others) and activating the apoptotic proteolytic cascade [3]. β-cell susceptibility toward the damage induced by free radicals and their low abundance of **antioxidant** mechanisms have been previously demonstrated [41]. Therefore, it is considered that oxidative stress is greatly responsible for pancreatic β-cell death after being exposed to hyperglycemia. The ROS-induced damage on β-cells have been quantified by the presence of 8-hydroxy-2-deoxiguanosine (8-OHdG) on subjects affected by T2D, in animal models [32] and in vitro on insulin-secreting cells [3, 43]. It has been demonstrated that H_2O_2 addition to rat and mouse β-cell cultures alters mitochondrial membrane potential; it decreases ATP levels as well as glucose-induced insulin secretion (GSIS) [44]. This effect is abolished when the expression of antioxidant enzymes is increased. GSIS decrease induced by ROS has been linked to GAPDH and glycolysis, and, as previously mentioned, it consequently decreases ATP levels.

In addition to direct damage induced on biomolecules, oxidative stress favors the activation of other pathways such as O-glycosylation, poly ADP-ribosylation, and *N*-acetylglucosamination. All of them may modify or inhibit the function of proteins. Approximately 2–3% of glucose entering β-cells is diverted to the hexosamine biosynthesis pathway in order to synthesize uridine diphosphate

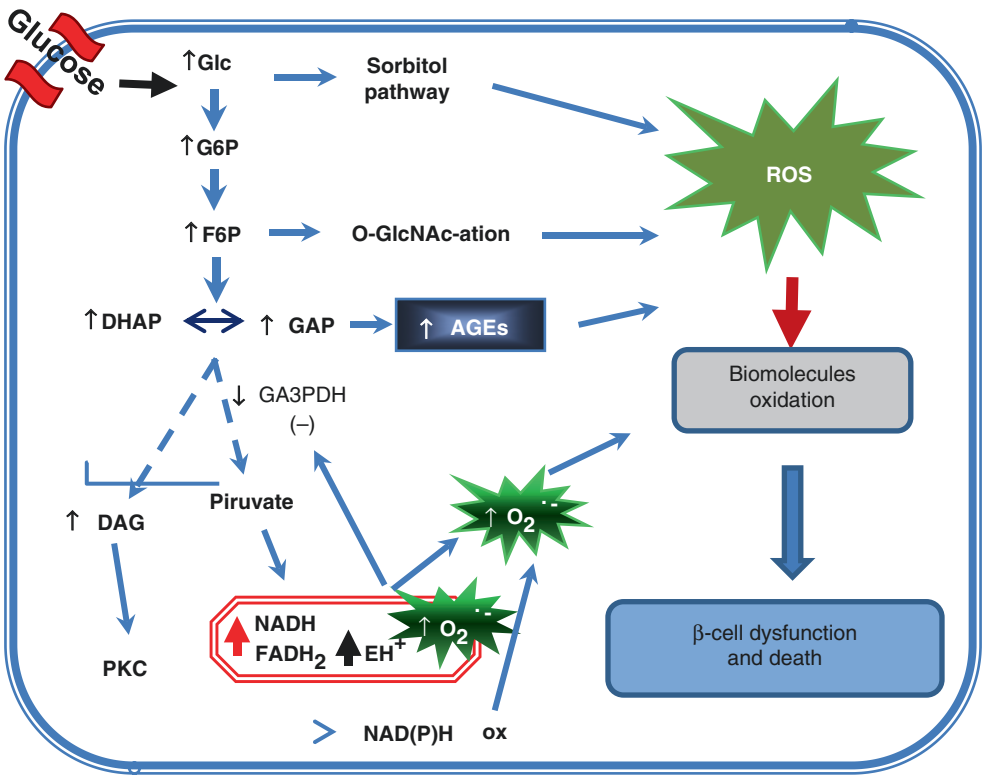

Fig. 13.2 Hyperglycemia induces ROS production and oxidative stress by increasing glycolysis and phosphorylation pathways. This situation induces biomolecule oxidation and β-cell exhaustion and death. *ROS* reactive oxygen species, *O-GlcNAc-ation* glucosaminylation, *AGES* advanced glycation end-products

N-acetylglucosamine (UDP-GlcNAc); thus O-GlcNAcylation regulates protein function depending on glucose availability. Among the proteins prone to modification by OGT are Pdx1, FoxO1, NeuroD1, IRS2, Akt, and p53; thus it regulates glucotoxicity and β-cell apoptosis [11].

Mitochondrial Alterations

Mitochondrial physiology plays a very important role on the regulation of the insulin secretion mechanism. When exposed to hyperglycemia, β-cell mitochondria exhibit important functional and morphological changes that affect the ATP/ADP ration required for insulin release. ROS increased due to hyperglycemia modifies mitochondrial permeability and induce apoptosis. ROS oxidizes **cardiolipin**, a phospholipid responsible to preserve mitochondrial architecture and membrane potential maintenance, and it also provides support for proteins involved in mitochondrial bioenergetics. Through hydrophobic and electrostatic interactions, cardiolipin keeps cytochrome c attached to the inner membrane. During early apoptosis, ROS oxidize cardiolipin, and they disrupt its interaction with cytochrome c that become detached from inner membrane, and it is released to cytoplasm [45], where it participates for apoptosome formation in order to activate proapoptotic caspases (intrinsic pathway). Cardiolipin is also the target of the proapoptotic protein tBid that is activated by caspase-8 (extrinsic pathway). tBid promotes pore formation on the external membrane mediated by Bax and Bak [46]. Thus, cardiolipin is a central regulator to achieve the activation of both apoptotic pathways.

Mitochondrial integrity and abundance are also regulated by **fission** and fusion mechanisms. These processes, although opposite, are coordinated in order to preserve mitochondrial morphology, size, and abundance. Mitochondrial fusion is regulated by **mitofusins** 1 and 2 (Mfn1 and Mfn 2) as well as by the mitochondrial inner membrane protein (Opa1). Mitochondrial fusion allows the exchange and merging of the organelle's content, including membranes, genetic material, and other metabolites. It also contributes for mitochondrial function preservation in metabolic stress conditions and during glucolipotoxicity [47]. Conversely, mitochondrial fission is mediated by several proteins such as the transmembrane fission protein (Fis1), the membrane fission factor (Mff) on the external membrane, and the GTPase dynamin-related protein 1 (Drp1). Fission is essential in order to segregate damaged or dysfunctional mitochondria [48]. Alterations of mitochondrial dynamics balance mediated by the loss or gain of proteins regulating fusion or fission events impact on mitochondria structure (fragmentation) and their function as well as glucose-dependent insulin secretion [47].

In response to glucose, cell energy and mitochondrial membrane function are also regulated by **uncoupling proteins** (UCPs) located at their external membrane. UCPs are mitochondrial transporters on the inner membrane that regulate the coupling status of the respiratory chain as well as

ATP synthesis. Thus, they keep the necessary ATP/ADP needed for glucose-stimulated insulin secretion. They also contribute to the mitochondrial antioxidant defense by inducing physiologic uncoupling that accelerates metabolism and decreases ROS and oxidative stress [29]. Five uncoupling proteins have been identified in humans as important regulators of corporal weight gain, the energy balance, and T2D. The most important are UCP-2 and UCP-3 because of their participation for mitochondrial membrane potential maintenance and ATP production. UCP-2 protects β-cells against oxidative stress. INS-1 cells cultured in the presence of H_2O_2 increase UCP-2 expression as well as survival rate; they also decrease ROS and caspase activation—however, hyperglycemia and **hyperlipidemia** increase UCP2 activation; consequently they reduce ATP synthesis and insulin secretion. UCP-2 also promotes mitochondrial membrane potential alterations along with the consequent release of proapoptotic factors and β-cell dysfunction that may lead to apoptosis [49].

Endoplasmic Reticulum Stress

Oxidative and endoplasmic reticulum stress (ERS) are interlinked regarding β-cell dysfunction because of their direct effects on insulin biosynthesis and secretion [50]. The endoplasmic reticulum (ER) ensures the appropriate folding and processing of proteins that will be secreted, among them insulin, as well as the degradation of **misfolded proteins** or those exhibiting alterations. Thus, the organelle's overload leads to misfolded protein accumulation and ERS. The latter triggers the unfolded protein response (UPR) in order to restore ER homeostasis and to decrease protein synthesis. It also increases the expression of genes involved in protein folding and ER-linked protein degradation. UPR is mediated by proteins bound to the ER membrane: PERK (protein kinase-like ER kinase), IRE1α (inositol-requiring enzyme), and ATF6 (activating transcription factor 6) [51]. When stress occurs, PERK autophosphorylation induces eif2α (eukaryotic translation initiation factor 2α) phosphorylation, a factor that inhibits protein synthesis, whereas it promotes ATF-4 transcription. The latter positively regulates the expression of ERS target genes such as the C/EBP homologous protein (CHOP) and the downstream growth arrest and DNA damage-inducible protein (GADD34). These two proteins activate protein phosphatase-1 (PP-1) that in turn dephosphorylates eif2α, thereby restoring transcription. Acute exposition of β-cells to high glucose levels induces an intermediate UPR signaling characterized by IRE1α phosphorylation and activation as well as glucose-stimulated insulin secretion. However, excessive UPR stimulation induces β-cell death and diabetes. In patients displaying insulin resistance and in islets isolated from *ob/ob* mice, it has been demonstrated that a constant and steady demand for insulin represents ER constant stimulation, and it eventually leads to stress [51]. Additionally, the increase of FFA also induces ER stress as it affects protein processing and trafficking, Ca^{2+} regulation, and oxidative stress in mouse insulin-producing cells (INS1) and in human cell lines [52]. Palmitate activates the UPR response through phosphorylation of IRE1 and PERK as well as β-cell apoptosis mediated by caspase-12 and caspase-3 activation [53].

Obesity and Inflammation

Currently, obesity stands out as a risk factor to develop T2D. Nevertheless, if obesity actually causes diabetes, most obese individuals sooner or later would develop hyperglycemia and T2D. In spite of this, approximately 20% of all obese individuals are diabetic [54]. This suggests that obesity and resistance toward insulin are factors that increase the risk to develop diabetes, but they are not inductors. Thus, it has been proposed that, in obese individuals, hyperglycemia may be more related to β-cell-impaired function and decreased mass [55] and/or their inability to adapt themselves toward the new metabolic demand [56]. Even though some of these studies have demonstrated a decreased β-cell mass in obese humans affected by T2D (postmortem donors) and in those who displayed alterations of fasting glucose levels by 65 and 40%, respectively [12], in obese individuals not affected by T2D, β-cell mass and insulin secretion are increased by 50% in order to cope with resistance to insulin [57]. In obese rodents a physiologic-adaptive expansion of β-cells is observed due to increased generation, decreased death, and β-cell hypertrophy [58]. Through this adaptation, β-cells preserve normal glycemia until they become exhausted and eventually die, thus leading to T2D development. Cell expansion is a complex process involving the activation of several pathways that converge to regulate proliferation, survival, cell size, and insulin secretion. Apparently, proliferation and hypertrophy are most important during the β-cell expansion phase, whereas apoptosis may participate in the final phases, during β-cell failure caused by hyperglycemia. Some evidence shows that, in animals displaying resistance toward insulin, the IGF1/PI3k/Akt/mTOR pathway participates during β-cell adaptation induced by a high-fat diet. mTOR (mammalian target of rapamycin) mediates protein synthesis in response to nutrients and growth factors, and it stimulates the phosphorylation of some components of the protein synthesis machinery such as p70S6K (ribosomal S6 kinase protein) and 4E-BP (IF4E-binding protein). Akt also participates in cell cycle regulation by inducing phosphorylation and degradation of the cyclin-dependent kinase inhibitors such as p21 and p27. Apparently, the increased β-cell mass in obese individuals

may be a reversible event, similarly to pregnancy. Some studies have reported that insulin secretion decreases concomitantly with weight loss or caloric restriction, whereas sensibility toward insulin is regained as well as β-cell function. Furthermore, caloric restriction enhances mitochondrial biogenesis and respiratory efficiency; it decreases ROS production and promotes metabolic homeostasis [59].

Additionally, because of the FFA increase, obesity predetermines a chronic inflammation state in adipose tissue that is characterized by increased proinflammatory **adipokines** and cytokines. These attract B-cells, T-cells, and macrophages toward the pancreas and adipose tissue where they secrete even more proinflammatory cytokines and chemokines, thereby contributing to inflammatory reaction and to autoimmune elimination of β-cells. The presence of reactive T-cells in islets is observed in patients affected by T2D exhibiting severe β-cell lesions and low insulin secretion [60]. Obesity implies an increased amount of adipocytes and also of their fat content, a vascularization decrease, hypoxia, and cell necrosis. Signal molecules derived from cell elimination may bind to Toll-like receptors (TLRs) and to nucleotide-binding oligomerization domains (NOD) in order to induce a local or generalized immune response. The latter consists on the assembly of cytosolic protein complexes comprised by bound nucleotides, leucine-rich repeats sequences (NLRs), and caspase-1. Once active, they initiate IL-1β production [61]. Hyperglycemia increases the production of the NLRP3 **inflammasome**, whereas FFA activate TLR2 and TLR4, thus promoting macrophage recruitment and β-cell stress [60].

Plenty of evidence exists on the importance of proinflammatory cytokines (IL-1β, TNF-α, and interferon-γ (IFN-γ) to activate signaling cascades in β-cells, such as NF-κB, the mitogen-activated protein kinase (MAPK), and the Janus kinase/signal transducer and activator of transcription (JAK/STAT). β-cell elimination by the proinflammatory cytokines IL-1β, TNFα, and IFNγ begins by their binding to specific receptor in β-cells and to the endoplasmic reticulum [61]. The consequences of increased ROS were previously mentioned. Conversely, in the presence of cytokines, the 12/15-lipoxygenase (12/15-LO) induces the cleavage of arachidonic acid to produce highly reactive metabolic such as 12-hydroxyeicosatetraenoic that may induce oxidative stress and mitochondrial dysfunction [32]. It has been also demonstrated that thioredoxin-interacting protein (TXNIP) interacts with NLRP3 and contributes to IL-1β production induced by hyperglycemia [62]. The latter contributes to β-cell dysfunction and apoptosis in T2D. TNFα negatively regulates the insulin receptor substrate 2 (IRS-2) in β-cells by inducing its phosphorylation and modifying insulin signaling. In obesity leptin secretion by adipose tissue also predominates. Leptin inhibits glucose-induced insulin secretion in β-cell lines and normal mice [63], and it also contributes to intolerance toward glucose in diabetes.

B-Islet Amyloid Polypeptide (IAPP)

Amylin is synthesized by pancreatic islets, and it is secreted along with insulin. Amylin is comprised by 37 amino acids, although it may produce polypeptides and be accumulated in islets in response to stress. IAPP effects initiate after binding to its receptors. Only three of them are known. They contain the calcitonin receptor in their inner structure and one of the following three receptor activity-modifying proteins: RAMP1, RAMP2, or RAMP3. The accumulation of intracellular amylin has been linked to both oxidative and endoplasmic reticulum stresses. β-amyloid plates are a common feature in patients affected by T2D. During hyperglycemia/hyperlipidemia, IAPP synthesis also increases in β-cells along with proinsulin, and they reach enough levels in order to allow for oligomer formation [20]. They also stimulate IL-1β, islet inflammation, and β-cell apoptosis. IAPP-soluble peptides have been detected. They represent early intermediates for fibril formation, and they are also responsible for cell death. In peripheral tissues, IAPP modifies glucose metabolism [64]; it suppresses glucose uptake induced by insulin in muscle cells [65] and digestive secretion (gastric acid, pancreatic enzymes), and it delays gastric emptying. IAP administration to rats decreases food intake [66], but when an IAPP antagonist is provided, food intake increases as well as body weight [67].

β-Cell Apoptosis and p53

β-cell apoptotic death after being exposed to high glucose levels has been associated with p53 protein translocation toward mitochondria [3]. Furthermore, β-cell population recovery and the rescue form the diabetic phenotype was demonstrated in p53-knockout mice, thus highlighting the importance of this protein for diabetes establishment [4].

The p53 protein is a transcription factor engaged in DNA damage monitoring. Depending on the severity of the damage, p53 triggers apoptosis or arrests the cell cycle until the DNA-repairing mechanisms are activated. p53 activation occurs in response to several types of stress, mainly those damaging DNA, and this leads to its stabilization and accumulation in cells submitted to stress conditions. p53 is also involved in apoptosis triggering by interacting and forming

complexes with Bcl-2 and Bcl-XL through its DNA-binding domain, thus allowing Bax-Bax oligomerization and the release of cytochrome c [68].

Apoptosis onset induced by p53 at mitochondria level is associated with oxidative stress. In insulin-producing cells (RINm5F) cultured on glucose 30 mM, p53 translocation to mitochondria, cytochrome c release, and apoptosis were induced because of oxidative stress [3]. Taking this into account, it was proposed that glucose increase modifies intracellular p53 distribution, and it promotes its mitochondrial localization besides inducing p53 phosphorylation, impairing its degradation, and increasing its biologic activity [69]. The presence of p53 in mitochondria is correlated with a decreased Bcl-2/Bax ratio and a decreased mitochondrial membrane potential [3], p53 activation, and increases of p21, Bax, and apoptosis [70]. This emphasizes p53 participation during the decrease of β-cell mass induced by hyperglycemia.

Hyperglycemia regulates p53 stability and function by inducing posttranslational modifications such as phosphorylation, poly(ADP-ribosylation, and N-acetylglucosamination [71].

p53 Phosphorylation

Hyperglycemia promotes p53 mitochondrial localization and its phosphorylation at serine 392 (homologous to Ser289 in mouse). This correlates with a Bcl-2 decrease, Bax increase, and β-cell apoptosis. The inhibition of the p38 MAPK hampered p53 phosphorylation, and it curtailed β-cell apoptosis induced by hyperglycemia, thereby suggesting its participation during the decrease of pancreatic β-cell mass. As in mitochondria p53 is engaged in complex formation with other antiapoptotic and/or proapoptotic proteins, and as it triggers the mitochondrial permeation process, it is likely that its phosphorylation is a requirement that may enable its interaction with such proteins and to induce cell death. Additionally this process stimulates the interaction between p53 and the p300/CBP and P/CAF coactivators that promote its acetylation, thereby inhibiting its ubiquitination and degradation [72]. These results indicate the importance of p53 phosphorylation as one of the factors contributing to β-cell elimination as a consequence of hyperglycemia through mitochondria (Fig. 13.3). Hyperglycemia also leads to ATM activation in cytosol, which in turn phosphorylates p53 at serine15, thus avoiding its recognition by Mdm2, its ubiqui-

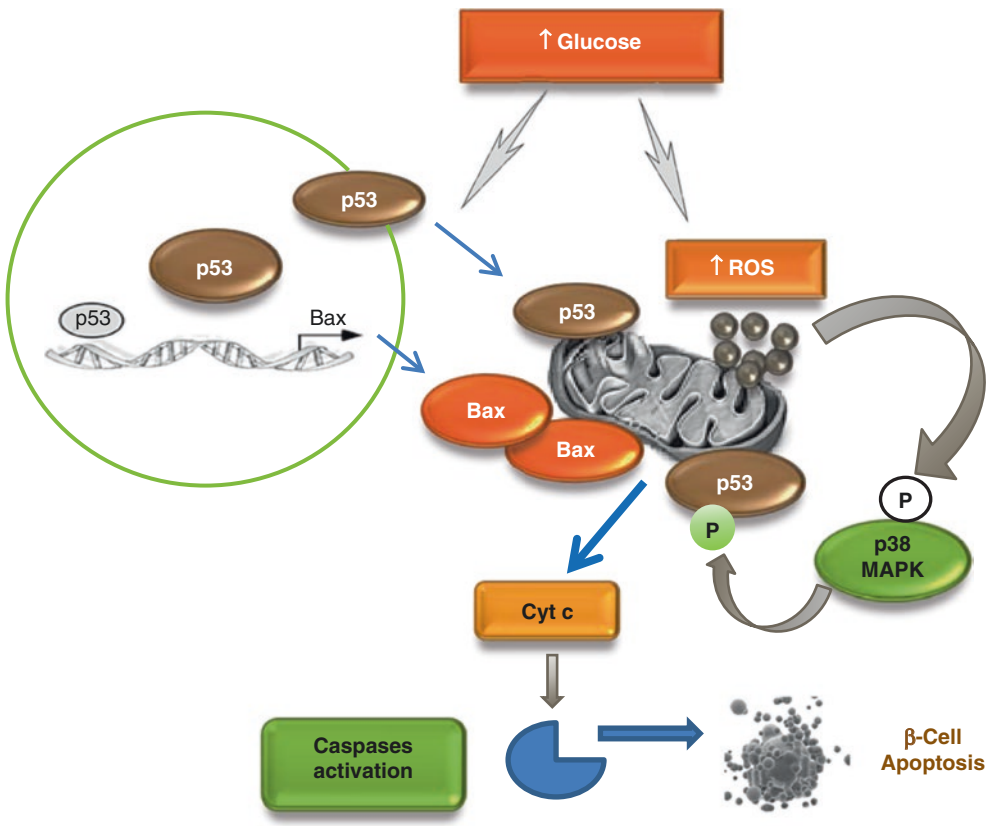

Fig. 13.3 Hyperglycemia promotes p53 translocation to mitochondria and its phosphorylation. p53 contributes to mitochondrial permeability, cytochrome c release, and β-cell apoptosis. *P* phosphorylation, *ROS* reactive oxygen species, *Cyt c* cytochrome c

tination, and nuclear degradation and also contributing to apoptosis triggering in response to hyperglycemia in β-cells [73].

p53 O-N-Acetylglucosamination

Hyperglycemia promotes N-acetylglucosamination (O-GlcNAc) of several proteins, including p53. This consists on the addition of a *N*-acetyl-glucosamine moiety in serine or threonine residues. O-GlcNAc is analogue to phosphorylation, and it regulates the stability, activity, or subcellular localization of target proteins. This modification depends on glucose availability, and it represents a cellular regulation mechanism according to nutritional environment. In a glucose-rich environment, the O-N-acetylglucosamination of p53 has been observed, and it is liked to its stability, and it prevents its degradation. O-GlcNAc in p53 at Ser149 enhances its stability by interfering with phosphorylation at Thr155, by overcoming its interaction with Mdm2 and its ubiquitination and its subsequent proteolysis. All of this results in higher p53 stability [74]. Thus, it has been proposed that O-GlcNAc stabilizes p53 and it may represent a signal for its translocation to mitochondria [73], where it may contribute to the release of proapoptotic factors [75].

p53 Poly(ADP-Ribosylation)

Another protein that becomes active when DNA suffers damage is poly(ADP-ribose) polymerase (PARP). This enzyme catalyzes the transfer of ADP-ribose units from NAD^+, an essential cofactor for ATP synthesis and redox potential balance, to the carboxylic residues glutamic and aspartic acids of several nuclear proteins. Poly(ADP-ribosylation) is important for DNA replication and repair, transcription, inflammatory response, and cell death mainly caused by genotoxic agents, infection, and stress. PARP fragmentation is concomitant with β-cell apoptosis triggering induced by hyperglycemia. These results are in agreement with previous reports showing that hyperglycemia triggers apoptosis in β-cells and pancreatic cell lines such as RINm5F. Poly(ADP-ribosylation) of p53 in the presence of high glucose levels is an early response that may contribute for protein stabilization and probably to its translocation to mitochondria as well as to the increased apoptotic rate of RINm5F cells caused by high glucose levels [75].

p53 Regulation by Mdm2

Cell survival depends in great extent on the balance between synthesis and degradation of p53. Among the mechanisms regulating p53, the expression and activation of Mdm2 (murine double minute 2) is of great importance. Mdm2 is an E3 ubiquitin ligase that binds p53, and it transfers **ubiquitin** to the latter residues, thereby enabling its recognition by **proteasome**s for targeted degradation. Depending on the amount of ubiquitin residues attached to p53, this protein will be degraded or exported to the cytosol. Mono- and/or poly-ubiquitination of p52 is defined by the concentration and activation status of Mdm2.

As previously mentioned, the interaction between p53 and Mdm2 depends on intracellular environment impacting on those posttranslational modifications displayed by these proteins. In the case of Mdm2, ubiquitination, **sumoylation**, and phosphorylation disrupt the formation of the p53-Mdm2 diene, and they stabilize p53 levels. It has been demonstrated that Mdm2 phosphorylation on Ser395 mediated by ATM decreases its ability to target p53 for degradation. Previously it was demonstrated that p53 phosphorylation by Akt participates in its regulation as it attenuated transactivation and increased p53 ubiquitination [76]. High glucose concentration decreases the expression of Mdm2 mRNA and its protein levels on both nucleus and cytosol [77]. Mdm2 expression is regulated by p53. Although we previously demonstrated its stabilization in presence of high glucose levels, this protein is not targeted toward the nucleus, but it translocates to other organelles such as mitochondria; thus it cannot stimulate Mdm2 expression. Additionally, DNA fragmentation induced by hyperglycemia also may affect the expression of Mdm2 mRNA [3].

The formation of the p53-Mdm2 complex increased in the presence of high glucose, although its ubiquitination was not observed. The latter demonstrates that glucose-increased levels induce Mdm2 activation in cytosol and its interaction with p53 is also promoted, whereas its ubiquitination is inhibited [73]. It is known that the E3 ubiquitin ligase activity of Mdm2 depends on other domains comprising this protein. The latter activity is located within the **RING finger domain** at the C-terminal. This region also contains the substrate lysine acceptor, and its main function is to label p53 for degradation. The central acid domain of Mdm2 binds to the RING finger domain, and it stimulates catalytic activity, thereby promoting ubiquitin release from the E3 enzyme. The interaction between the acid domain and the RING finger domain depends on its phosphorylation by ATM [78]. An increase of ATM-mediated phosphorylation has been also observed in hyperglycemia. Thus, it is not excluded that stress and the phosphorylation cascade induced by high glucose levels may phosphorylate some residues on the RING finger domain and/or on nearby regions and on the acid central domain in Mdm2 leading to the inhibition of p53 poly-ubiquitination and degradation.

Conversely, p53 ubiquitination also depends on ATP levels. In hyperglycemia conditions, ATP decreases due to increased ROS and mitochondrial uncoupling. Therefore, if ATP-decreased levels occur, ubiquitin ligases are unable to

condensate the glycine residues on their C-terminal region with the lysine residues on p53. Thus, it is necessary to analyze these factors in hyperglycemia conditions in order to know about its participation for p53 ubiquitination in RINm5F cells.

Cell Cycle Alterations

Cell Proliferation Rate

In obese subjects, β-cell failure to compensate for insulin resistance has been related to either an inappropriate cell mass expansion or the inability of preexisting cells to respond toward glucose. This may be generated from defects of insulin signaling or the absence of insulin receptors and IGF-I in these cells [64]. For instance, *knockout* mice for these receptors exhibit a decreased cell mass and develop diabetes from an early age. It has been pointed out that progression through the cell cycle is also altered. It has been observed that cyclin inhibitor p27kip1 is progressively accumulated inside β-cell nucleus in mice lacking the insulin receptor substrate-2 (IRS-2) and also in *db/db* mice. p27kip1 accumulation in oxidative stress and hyperglycemia conditions may be another pathway by which ROS decrease β-cell mass as the deletion of its gene hampers hyperglycemia effects and induce β-cell proliferation [79]. Another important regulator of β-cell replication is the cell cycle inhibitor p21, which is expressed at high levels in adult β-cells and it has been linked to proliferation decrease during senescence. It is known that β-cell replication potential is lost with age, and it is correlated with the loss of expression of genes such as EZH2 (enhancer of Zeste homologue 2), a histone methyl transferase that represses the transcription of cell cycle inhibitors when histone 3 is trimethylated in its lysine 27 residue (H3K27me3). EZH2 decreases H3K27me3 and increases p16 and p19 expression, and it inhibits β-cell proliferation [80].

β-Cell Dedifferentiation

During recent years it has been observed that pancreatic β-cells undergo a **dedifferentiation process** when metabolic demand increases and also during hyperglycemia and inflammation. In mouse, hyperglycemia modifies the expression of transcription factors and insulin secretion. For instance, the loss of FOXO1 leads to β-cell dedifferentiation, decreases insulin content, and reverts its phenotype toward progenitor-like cells, characterized by the expression of Ngn3. Although changes in transcriptional factors have been observed on humans and primates affected by diet-induced prediabetes, a dedifferentiation process has not been demonstrated. β-cell dedifferentiation induced by hyperglycemia is reverted when blood glucose values are restored. Insulin immunostaining loss correlates with an increased glucagon staining in several diabetic mouse models. In one of these, it was observed that small β-cells begin to express glucagon, although it is not known if these cells will transform into α-cells or if they represent an intermediate cell type expressing glucagon [56, 81]. The Pax4 gene also participates in β-cell dedifferentiation. The latter is an embryonic development regulator of pancreatic islets, and its presence on adult β-cells from animals confers protection against stress-induced apoptosis, and it stimulates cell proliferation. However, the sustained Pax4 expression promotes β-cell dedifferentiation and hyperglycemia. Pax4 overexpression is concomitant with Ngn3 expression. This suggests that an acute Pax4 increase protects cells but its steady or chronic expression induces β-cell dedifferentiation into progenitor cells apparently as a protective mechanism against deleterious environmental effects [82].

Adaptative β-Cell Proliferation

Adaptive β-cell proliferation has a very important role in delaying or preventing diabetes; this has been demonstrated in several models of mice whose β-cells have alterations in the replication pathway, which accelerates the development of diabetes in response to diets high in fat [83]. The adaptive expansion of the mass of β cells, in response to insulin resistance and hyperglycemia, may be due to hypertrophy, hyperplasia, and/or neogenesis [1].

The ability to adapt pancreatic β-cells to various adverse situations has been previously recognized. Studies in obese mice/OB C57BL/6J [84] and animal models of metabolic syndrome (dyslipidemia, insulin resistance, glucose intolerance, and hypertension) induced by the consumption of corticosteroids [85] or fructose [86] show an increase in the proliferation of β-cells and increase in the volume of the islet. These modifications resulted in an increase of insulin release despite marked apoptosis of β-cells [87].

In addition, it is known that the mass of pancreatic β-cells changes along the natural history of T2D. This was demonstrated at the rodent *Psammomys obesus*, which develops the disease in captivity and fed a high-fat diet. At the beginning, it has hyperinsulinemia/normoglycemia and insulin resistance; subsequently pancreatic β-cells die and hyperglycemia becomes evident [26]. These studies support the initial increase of cell proliferation rate and for a certain time in different models of metabolic syndrome, including carbohydrate consumption, as an adaptive response to stop the increase in plasma glucose by increasing insulin secretion [2, 88]. The presence of apoptosis has also been demonstrated [87], which can be increased if the stimulus persists (insulin resistance, chronic exposure to excess glucose and lipid) and then glycemia increases and diabetes is presented.

MicroRNAs in Pancreatic β-Cells Function and Dysfunction

miRNAS are small noncoding RNA molecules (21–23 nucleotides); those act as the main regulators of gene expression and control various biological and pathological processes. In humans, more than 1600 precursor miRNAs are known, which can produce up to 2237 mature miRNAs, each with the potential to control hundreds of targets. MiRNAs can be found and studied in blood and other body fluids associated with proteins, micro vesicles, and/or high- and low-density lipoproteins [89].

The miRNAs form a complex network that regulates the activities of β-cells and the compensatory response during pregnancy, obesity, and the development of T2D. Changes in the expression of miRNAs of β-cells and insulin target tissues have been observed in animal models of obesity and diabetes and even in the human pancreas from donors [90], which suggests its involvement in the early stages of diabetes.

In β-cells, miRNAs-375, miRNAs-7, and miRNAs-204 are regulators of multiple cellular functions and determinants of the balance between differentiation/maintenance of phenotype and cell growth/proliferation [91]. miRNA-375 regulates the expression of genes related to glucose-induced insulin secretion, Na+ channels, insulin exocytosis, phenotype, and β-cell expansion during insulin resistance. Circulating miR-375 represents 10% of the miRNAs present in β-cells; therefore it was proposed as a potential marker of β-cell mass in patients with IR and T1D [92, 93]. miRNA-375 also plays an important role in pancreatic organogenesis and in vitro differentiation of pancreatic β-cells. The overexpression of miRNA-375 together with let-7g, let-7a, miR-200a, and miR-127 in human embryonic stem cells derived from pancreatic progenitors promotes the exit of the cell cycle and its differentiation toward endocrine cells [94]. The miR-7 family (miR-7a-1, miR-7a-2, and miR-7b) [94] is also elevated in β-cells. miR-7a has been associated with decreased glucose-stimulated insulin secretion and loss of the β-cell phenotype in T2D models (Goto-Kakizaki rat) [95]. The expression of miR-204 is high in human pancreatic β-cells. A recent study demonstrated that the deletion of miR-204 in islets of *db/db* mice increases cell proliferation, decreases apoptosis due to ER stress, and increases insulin secretion [96].

In pancreatic β cells, some miRNAs are involved in the induction of apoptosis. Prolonged exposure to palmitate of MIN6B1 cells and islets of *db/db* diabetic mice increases the expression of miR-34a and miR-146, both related to an increase in the rate of apoptosis [97]. The increase in miR-34a is related to the activation of p53, whose participation in the apoptosis intrinsic pathway of β cells, was demonstrated in RINm5F cells [3, 69, 73]. p53 is also involved in the regulation of glucose metabolism and oxidative stress [98, 99]. Increases in miR-21, miR-34a, miR-29 and miR-146a, miR-335, miR-152, and miR-130a/b in animal models of obesity and T2D have deleterious effects on β-cells and are have been linked to insulin resistance [100]. An increase in the expression of miR-181 and miR-342 has also been reported in adult patients with glucose intolerance (IGT) and/or with loss of glucose sensitivity of β-cells. [101].

miRNAs also protect pancreatic β cells against oxidative stress. In islets of *db/db* mice and MIN cells subjected to oxidative stress, miR-24 expression increases and ER stress-induced apoptosis decreases [102]. This miRNA also promotes functional cellular dedifferentiation and decreases insulin synthesis. Therefore miR-24 can represent a central node to coordinate survival (inhibition of apoptosis) and the maintenance of a functional phenotype dedifferentiation [94]. The decrease in miR-184 protects β-cells from death by oxidative stress, in human islets cultured with palmitate or by exposure to inflammatory cytokines [103]. The genetic deletion of miR-200's family (miR-200c/miR-141 and miR-200a/miR-200b/miR-429) also protects against apoptosis in three experimental models of apoptosis [94].

Due to their multiple functions and their participation in the control of biological processes in β-cells, miRNAs are considered optimal therapeutic targets directed to multiple objectives such as the following. (a) Production of functional cells in vitro modulating the differentiation mechanisms of pluripotent stem cells (PSC), embryonic stem cells, or transdifferentiation of other types of adult cells into mature cells, to promote or to silence the expression of specific miRNAs according to the desired effect. Thus, for example, virus-mediated overexpression of miR-375 in iPSCs derived from human skin fibroblasts promoted their differentiation into insulin-producing cells and stimulated glucose-dependent insulin secretion in vitro [104]. (b) Protecting cells from glycolipotoxic and/or inflammatory stress, for example, increased miR-24 in MIN6 cells (mouse), protects against fatty acid-induced apoptosis and inflammatory stress [102]. Another possible therapeutic target is miR-184. Inhibition of miR-184 protects β-cells from apoptosis induced by glucolipotoxicity and inflammation and increases cell mass. Finally, miR-7 is a candidate to stimulate cell proliferation [103].

In general, miRNAs could be targeted to develop an effective therapeutic strategy against T1D and T2D. Therefore, various strategies have been developed to increase or decrease the expression and function of miRNA, such as transient or stable transfection or viral transduction of pri-miRNA, pre-miRNA, mature miRNA, small interference

RNA (siRNA), RNA of short hairpin, or antagomiRs [105]. However, the selective delivery of synthetic RNA molecules to a specific cell and avoiding side effects represents the main problem of RNA-based therapy.

Susceptibility of Pancreatic β-Cells to Infection by the SARS-CoV-2 Virus

The severe acute respiratory syndrome coronavirus two (SARS-CoV-2) is a respiratory virus that causes the COVID-19 disease, declared a pandemic in March 2020 by the WHO. The initial infection occurs through receptors present in the respiratory tract, where a first replication and the first manifestations of the disease take place, whose exacerbation or complication will depend on the presence of some comorbidities. Later, the virus can migrate and settle in other organs and continue its replication. The severity of COVID-19 has been attributed to the response of the immune system to restrain the infection and that it reacts disproportionately, triggering the so-called cytokine storm [106].

The SARS-CoV-2 virus has affinity for several receptors, most notably the receptor for angiotensin-converting enzyme 2 (ACE2). After binding with the receptor, the virus protein S is proteolytically activated by transmembrane serine protease 2 (TMPRSS2), among others [107]. Therefore, the expression of ACE-2 and TMPRSS2 is frequently used as a marker of susceptibility to direct infection by SARS-CoV-2 [108].

Although at the beginning of the pandemic, COVID-19 was identified as a respiratory disease; it is currently considered a systemic disease because patients infected with SARS-CoV-2 can present respiratory, cardiac, neurological, kidney, and endocrine disorders. The prevalence of metabolic disturbances such as ketoacidosis, hyperglycemia, and insulin resistance in patients with and without pre-existing diabetes, or the development of new-onset diabetes and frequent pancreatic lesions during COVID-19 disease, suggested that SARS-CoV-2 was capable of causing diabetes [109].

In the case of β-cells, the presence of the ACE2 receptor is still controversial [110]. Thus, some studies have demonstrated the presence of ACE2 and TMPRSS2 in human pancreatic β-cells [111, 112], while in other studies, it has not been proven [106, 113]. However, it has been proposed that the presence of additional factors such as neuropilin 1 and dipeptidyl peptidase-4 (among others), in human β-cells that are known to contribute to infection by the MERS-CoV virus could also help infiltration of the SARS-CoV-2 in β-cells [112].

SARS-CoV-2 infection of β-cells has been associated with decreased insulin levels and secretion, apoptosis [111], local inflammation, and necroptosis in pancreatic islets [112]. But due to inconsistent results about virus presence in β cells, it has been proposed that pancreatic damage and glycemic dysregulation may result from exacerbated systemic inflammation "cytokine storm." Pro-inflammatory cytokines (IL-1β, IL-6, IL-12, IFN-γ, and TNF-α) can drive β-cell dysfunction, damage, and death through intrinsic cell signaling pathways. What would increase the risk of developing autoimmune diabetes in individuals with genetic predisposition [108]?

The results on the expression of ACE2 in β-cells and the islet phenotype in COVID-19 show differences between individuals or under certain conditions. Therefore, it is necessary to analyze a greater number of histological samples from donors with COVID-19. Current data do not support constant large-scale β-cell injury that acutely leads to the development of diabetes. Therefore, it is essential to follow up patients recovered from COVID-19 for longer periods of time, to know the incidence of post-COVID-19 diabetes [108].

Conclusions

Obesity, resistance to insulin, and glucose intolerance affect pancreatic β-cell functional status. Particularly, the generation of new cells (**neogenesis**, replication) is decreased, whereas the apoptotic death rate increases. Among the mechanisms leading to β-cell alterations, the participation of several proteins synthesized by the cell itself, such as amyloid polypeptide and the type 2 uncoupling protein, the molecules expressed and released by adipose tissue (free fatty acids and cytokines), the presence of high glucose levels, and the reactive oxygen species produced by glucolipotoxicity has been observed. It was recently proposed that high-ROS-appearing levels during hyperglycemia promote phosphorylation, poly(ADP-ribosylation) and/or GlcNAc, and they may interfere with p53 degradation by inhibiting the Mdm2 E2 ubiquitin ligase. Therefore, p53 degradation is avoided, and its recruitment to mitochondria and the apoptotic mechanisms are promoted along with β-cell dysfunction.

The loss of β-cell mass may reach a critical point in which the deleterious effects mediated by the aforementioned molecules might not be reverted, thus decreasing insulin production and release and contributing to diabetes development. Several treatments exist in order to attenuate β-cell deterioration. Changes of dietary routine and increased physical activity are among them. The objective is to promote weight loss and specially to decrease abdominal fat and resistance to insulin. Thus, eventually β-cell mass may be regained.

Concluding Remarks

1. Activating hyperglycemia metabolic pathways induces β-cells apoptosis.
2. Free fatty acids are more toxic when hyperglycemia is present.
3. Oxidative and endoplasmic reticulum stress, mitochondrial alterations, inflammatory cytokines, and islet amyloid polypeptide, together or separate, can decrease pancreatic β-cell mass.
4. Hyperglycemia induces posttranslational changes in p53 that inhibits its degradation and promotes mitochondrial location.
5. Many factors trigger the death of pancreatic β-cells and decrease β-cell mass. However, most appear to have their origin in hyperglycemia, so the control of glucose levels is of great importance in preserving the mass and function of pancreatic β-cells.
6. miRNAs regulate the functions and survival of β cells, under different stimuli, so their use as therapeutic targets is being studied.
7. The expression of ACE2 in β-cells shows differences between individuals. Therefore, more studies are needed to determine the role of SARS-CoV-2 diabetes development.

Multiple-Choice Questions

1. At what stage of embryonic life is β-cell mass set?
   (a) Before birth
   (b) At 2 years old
   (c) While breastfeeding
   (d) **Between 5 and 10 years old**
   At this stage of development, the rate of cell replication is reduced and the pancreas reaches its full size.
   (e) At 5 years old
2. A diminution of B-cell mass was observed in persons without diabetes but with
   (a) Chronic hyperglycemia
   (b) Metabolic syndrome
   (c) **Impaired glucose tolerance**
   Postmortem studies in humans showed a decrease in pancreatic cell mass of up to 50% in people with impaired fasting glucose.
   (d) Obesity
   (e) Type 2 diabetes
3. All are apoptotic cellular death characteristics, except
   (a) DNA oligonucleosomal fragmentation
   (b) Phosphatidylserine exposition
   (c) Death cell phagocytosis
   (d) **Intracellular content release**
   An important characteristic of apoptosis is the formation of apoptotic bodies, which consists of the invagination of the plasma membrane that surrounds the subcellular remains and prevents the release of intracellular material.
   (e) Formation of apoptotic bodies
4. Increased production of reactive oxygen species in hyperglycemic conditions is due to
   (a) Microsomes
   (b) **Oxidative phosphorylation**
   Mitochondria are the main sources of endogenous ROS in hyperglycemic conditions. Of the oxygen consumed by mitochondria, ∼1–5% is converted to ROS as byproducts of the flow of electrons in the respiratory chain.
   (c) Macrophages
   (d) Endoplasmic reticulum
   (e) NADPH oxidase
5. Endoplasmic reticulum stress is characterized by
   (a) DNA oligonucleosomal fragmentation
   (b) Increased insulin demand
   (c) **Unfolded protein response**
   Constant requirements of insulin during glucose intolerance and insulin resistance leads to alterations in the processing of proteins in the RE. This situation stimulates an ER response known as unfolded protein response and ER stress.
   (d) Oxidative stress
   (e) Changes in mitochondrial permeability
6. In hyperglycemic conditions, p53-induced apoptotic β-cell pathway:
   (a) Releases intracellular content
   (b) **Changes mitochondrial permeability**
   P53 in the mitochondria releases Bax from Bcl-2, allowing Bax oligomerization and pore formation to release proapoptotic factors as cyt c.
   (c) Activates death receptors
   (d) Expresses proapoptotic proteins
   (e) Inhibits cell cycles
7. Hyperglycemia induces the activation of metabolic pathways related to β-cell death as
   (a) An increase in reactive oxygen species
   (b) Accumulation of amyloid polypeptide
   (c) Stress of the endoplasmic reticulum
   (d) A hexosamine pathway
   (e) **All of the above**
   During hyperglycemia, the activation of all these metabolic pathways was observed, which concluded with the activation of the intrinsic pathway of apoptosis.
8. What mitochondrial alterations contribute to the dysfunction of β-cells in diabetes?
   (a) **Fission and fusion events**

Hyperglycemia alters the expression of the proteins that regulate mitochondrial fusion/fission events, which modifies the $\Delta\Psi_m$ and allows the output of proapoptotic factors.

(b) Loss of glucose sensitivity
(c) Changes in ATP/ADP rate
(d) Increased proinflammatory cytokines
(e) Modification of NAD/NADH+ rate

9. Chronic hyperglycemia affects the survival of β cells by
(a) Decreasing beta-cell mass in diabetes by apoptosis
(b) Causing β-cell hyperplasia and exhaustion
(c) Causing cell dedifferentiation
(d) Creating a loss of glucose sensitivity
(e) **All of the above**

Chronic hyperglycemia decreases pancreatic β-cell mass by activating apoptosis and inhibiting the cell cycle, in addition to inducing the dedifferentiation of β-cells.

Glossary

Adipokines Cytokines (cell signaling proteins) secreted by adipose tissue.

Amylin A 37-amino acid peptide hormone, discovered in 1987, which is co-located and co-secreted with insulin by the pancreatic beta-cells in response to nutrient stimuli.

Antioxidant Molecule that inhibits the oxidation of other molecules.

Apoptosis (a-po-toe-sis) Was first used by Kerr, Wyllie, and Currie in 1972 to describe a morphologically distinct form of cell death and energy-dependent biochemical mechanisms.

Apoptosome Molecular complex of two major components—the adapter protein apoptotic protease activating factor 1 (Apaf1) and the pro caspase-9. These are assembled during apoptosis upon Apaf1 interaction with cytochrome c. Apoptosome assembly triggers effector caspase activation.

Cardiolipin Phospholipid important of the inner mitochondrial membrane, where it constitutes about 20% of the total lipid composition.

Caspase (cysteine-aspartic proteases, cysteine aspartases, or cysteine-dependent aspartate-directed proteases) Family of protease enzymes playing essential roles in apoptosis and inflammation.

Ceramides Family of waxy lipid molecules. A ceramide is composed of sphingosine and a fatty acid.

Cytochrome c Heme protein serving as electron carrier in respiration. Cytochrome c is also an intermediate of apoptosis.

Cytokines Cell signaling small proteins. Involved in autocrine signalling, paracrine signalling, and endocrine signalling as immunomodulating agents

Dedifferentiation process Processes by which cell that were specialized for a specific function lose their specialization.

Fission Division of mitochondria into new mitochondria.

Flavoprotein Proteins that contain a nucleic acid derivative of riboflavin: the flavin adenine dinucleotide (FAD) or flavin mononucleotide (FMN).

Fusion Process mediated by several large GTPases whose combined effects lead to the dynamic mitochondrial networks seen in many cell types.

Glucolipotoxicity Combined, deleterious effects of elevated glucose, and fatty acid levels on pancreatic beta-cell function and survival.

Hyperlipidemia Elevation of fats or lipids in the blood.

Hyperplasia Enlargement of an organ or tissue caused by an increase in the cell proliferation rate.

Inflammasome A multiprotein cytoplasmic complex which activates one or more caspases, leading to the processing and secretion of pro-inflammatory cytokines—e.g., IL-1 beta, IL-18, and IL-33. Assembly of inflammasomes depends on the NOD-like receptor family members, such as the NALP proteins kinase: enzyme-catalyzing phosphorylation of an acceptor molecule by ATP.

Misfolded proteins Are proteins structurally abnormal, and thereby disrupt the function of cells, tissues, and organs. Proteins that fail to fold into their normal configuration; in this misfolded state, the proteins can become noxious in some way and can lose their normal function.

Mitofusins Proteins that participate in mitochondrial fusion.

Necrosis Morphological changes in cell death caused by enzymatic degradation.

Neogenesis Generation of new cells.

Oxidative stress Pathological changes in living organisms in response to excessive levels of intracellular free radicals.

Proenzyme Precursor of an enzyme, requiring some change (hydrolysis of an inhibiting fragment that masks an active grouping) to render it active form.

Proteasome An intracellular complex enzymatic that degrades misfolded or damaged proteins (proteolysis), after damaged proteins are tagged by ubiquitin.

Resistance to insulin Pathological condition in which cells fail to respond normally to the hormone insulin.

RING finger domain Really interesting new gene-finger is a proteins domain that plays a key role in the ubiquitination process.

Stem cells Undifferentiated biological cells that can differentiate into specialized cells and can divide.

Sumoylation Small ubiquitin-like modifier (or SUMO) proteins are a family of small proteins that are covalently attached to and detached from other proteins in cells to modify their function. Post-translational modification involved in various cellular processes.

Triacylglycerol Ester of glycerol with three molecules of fatty acid.

Ubiquitin Small (8.5 kDa) regulatory protein that has been found in almost all tissues (ubiquitously) of eukaryotic organisms and regulated proteolysis.

Ubiquitin ligase Protein that recruits, recognizes a protein substrate, and catalyzes the transfer of ubiquitin from the E2 enzyme to the protein substrate.

Uncoupling proteins Proteins that uncouples phosphorylation of ADP from electron transport.

Obesity in the Pathophysiology of Diabetes

14

Juan Antonio Paniagua and Antonio Vidal-Puig

Introduction: Obesity as a Public Health Problem

Obesity and overweight states are characterized by an excessive accumulation of body fat. Depending on the amount of fat accumulated, but also on the individual's genetic and exposure to specific environmental factors, the obese patient can develop several health problems. The increase in the prevalence of obesity and associated complications is considered a major public health issue that affects all demographic groups, irrespective of age, sex, race, education, or economic level [1]. The World Health Organization (WHO) estimates that more than 1.9 billion adults (≥18 years old) were overweight, and of these over 600 million were obese, according to the worldwide data registered in 2014 [2]. In the United States, obesity rates have been rising in both adults and children in recent years [3–5]. The maintenance of a healthy weight, usually achieved between 18 and 25 years of age, requires a life-long sustained energy equilibrium between energy intake and energy expended, which is affected not only by diet but also age, stage of development, genetic makeup as well as epigenetic, level of nutritional education, and physical and psychosocial interactions [6, 7].

A useful tool to define a person as obese or underweight is the body mass index (BMI), estimated by the relationship between weight and height. The age-standardized death rate, from any reason, was generally lowest in subjects with a BMI of 22.5–24.9 kg/m^2 [8–10]. Moreover, deaths associated with high BMI are ranked fourth, behind deaths from hypertension, smoking, and unhealthy diets and ahead of deaths related to hyperglycemia, sedentary life style, high-salt intake, alcoholism, and high blood cholesterol levels [11]. Lastly, it is also of relevance that the association between nutrient intake and diseases such as cancer, diabetes and cardiovascular disease (CVD) [12, 13], obesity, body fat distribution, hypertension, insulin resistance, and hyperglycemia is well established [14–16].

Deaths from CVD, cancer, and diabetes account for approximately 65% of all deaths, and obesity, mainly abdominal adiposity, increases the risk of all these disorders. BMIs higher than 25 kg/m^2 have a direct relationship with mortality due to CVD [6, 17–21]. CVD accounts for about 38.5% of all deaths in EE.UU. Of relevance, this figure has declined since the 1940s and 1960s [8], associated with several primary prevention activities, improved treatment for acute ischemic phase, and secondary intervention [22, 23].

Deaths from all cancers accounted for about 23% of the total [8]. As high BMI increases mortality from cancer in most specific sites [10, 24, 25], compared to people with normal weight, obesity could increase cancer incidence about 14% in men and 20% in women. People with BMI ≥ 40 kg/m^2 could increase risk of death from cancer up to 52% in men and 62% in women [26]. Higher circulating glucose levels, low-grade inflammatory state, increased oxidative stress, and an altered bioavailability of hormones, mainly insulin, estrogens, and androgens, could be implicated in the rise in current cancer rates obesity-related. Finally, during the 1990s, in the United States, there was an increase of diabetes prevalence to 61%, and of this ≈90% were type 2 diabetes (T2D), in parallel with increase in the obesity rates [27]. Diabetic patients have 2–4 times higher risk of incidents of CVD [28]. Recently, global mortality directly related to dia-

betes was observed to be 2.9 million, about 5.2% of all deaths. Of this 2–3% was observed in the poorest countries, and over 8% was in the United States, Canada, and the Middle East. In people aged 35–64, this rates increased from 6 to 27% [29].

In the United States, approximately 70% of T2D patients are overweight and obese, and over a period of 10 years, the risk of diabetes rose to 27% in people who gained 5 kg or more [30]. Specifically, central obesity is strongly related with metabolic disorders associated with insulin resistance and diabetes [31, 32]. The current advice to prevent and treat T2D includes maintaining an ideal body weight (BMI < 27–30 kg/m^2), physical activity, limiting the intake of sugar and saturated fat, and increasing the consumption of mono and PUFA, as well as whole grains and fiber [33–35].

Obesity: Measurements and Assessment

Measuring body weight provides a sense of the degree of obesity; however, a more accurate and comparable measure of obesity is obtained by relating body weight to height [36]. The BMI is calculated as the ratio between weight/height squared ratio, and expressed as kg/m^2. Based on the BMI measurement, it can be discriminated low, normal weight, overweight, and obese states in adults. The WHO has standardized BMI as (1) lower than 18 kg/m^2 as low weight; (2) between 18 and 25 kg/m^2 is normal weight; (3) between 25 and 29.9 kg/m^2 is overweight; (4) greater than or equal to 30 kg/m^2 is obese [37, 38]. However, the BMI does not provide information about body composition (fat-free muscle mass/fat mass) nor about the pattern of body fat distribution. Thus, a better measure of obesity that overcomes these limitations are the measurement of percentage of body fat (BF%), which relates total weight to the weight of the fat mass. Of course, this is more difficult to measure than the BMI, limiting its daily clinical use, but several accurate methods exist [39]. Body composition can be estimated from anthropometric measurements of skinfold thicknesses in several anatomical regions [40]. In research, BF% is determined by hydrostatic weighing (body weight by immersion) as the gold standard [41]. Alternatively, the bioelectrical impedance analysis technique can directly estimate the amount of the fat-free mass (FFM) and indirectly the body fat by subtracting from total body weight [42]. Individuals with normal weight or overweight but also have a high BF% exhibit a cardiovascular risk which is comparable to those with obesity estimated by BMI. Of note, it is observed that at the age of 20, a BMI equal to 30 kg/m^2 implies a 30% of BF%. However at the age of 60, the same BMI represents a 40% BF% in men and up to 40–50% BF% in older women [43].

BMI informs neither the location nor distribution of the excess body fat. Central obesity occurs when the excess of fat accumulates in the intrabdominal area, even at the expense of a decreased fat accumulation in the peripheral adipose tissue. Several parameters can be used to measure central obesity. The most widely used requires measuring the waist circumference (WC) and hip ratio (HR) to create the waist-HR (WHR) ratio. Subjects having a large WC have increased mortality [44] despite having a BMI < 30. Thus, high-risk individuals are better identified by incorporating WC and WHR measurements to BMI [45]. The WC measurement of central obesity varies with race and is currently accepted as >88 cm in women and >102 cm in men in United States [46]. Finally, the relationship of waist circumference to height (WHtR) can also be used to identify adults at high cardiometabolic risk [47–49]. All these parameters help also to predict the risk of metabolic diseases such as T2D [50].

In research-intensive settings, more complex and accurate techniques are available, such as dual energy X-ray absorptiometry (DEXA), computed tomography (CT), and magnetic resonance imaging (MRI). DEXA estimates body fat distribution by scanning the arms, legs, and trunk [51, 52]. Differentiation between abdominal subcutaneous fat and intraabdominal fat, which is composed of visceral adipose tissue (VAT), intraperitoneal and retroperitoneal fat, is better seen by MRI and CT [53, 54]. Finally, single-voxel magnetic resonance spectroscopy is the gold standard for measuring ectopic fat, outside anatomically defined fat depots. Ectopic fat can be estimated after separating water and fat signals within each voxel (using software such as jMRUI) [55, 56].

Adipocyte and Adiposity Development

Types of Adipocytes and Differentiation

When describing fat depots, it is important to differentiate two types of well-differentiated adipose tissues, which have specific distribution and function, and are referred to as white adipose tissue (WAT) and brown adipose tissue (BAT) (Fig. 14.1). The WAT's main function is the deposit of surplus energy as triacylglycerol (fat), which could be mobilized and offered to other metabolically relevant organs through hormonal signaling. The WAT is designed to be plastic and expand. In fact, WAT accounts from 5 to 50% of human body weight. However, WAT is also a main source of endocrine signalling [67]. One of the key hormones is adiponectin, typically associated to the metabolically "healthy" expansion of adipose tissue facilitating adipocyte lipid storage and consequently preventing ectopic lipid accumulation. Conversely, leptin prevents lipogenesis while facilitating lipolysis and fatty acid oxidation. These actions may be mediated centrally by the activation of sympathetic efferent

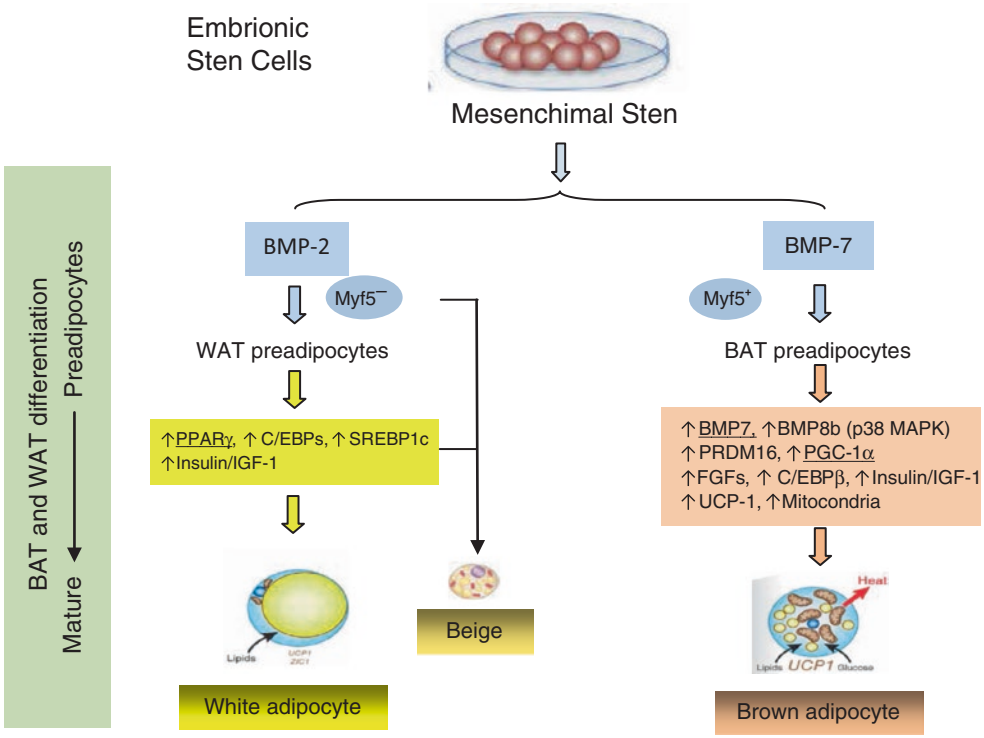

Fig. 14.1 Adipose tissue expands to store excess energy as fat and regulates fuel needs to other tissues. In WAT growth transcriptional factors such as the binding proteins CCAAT/enhancer (C/EBP) and PPAR-γ are fundamental. Sterol regulatory element-binding transcription factor 1 (SREBP1c) activates PPAR-γ expression [57] and mediates lipid biosynthesis by insulin [58]. Mature WAT is characterized by the expression of glucose transporter 4 sensitive to insulin (GLUT4) and enzymes like fatty acid synthase (FAS) and glycerol-2-phosphate dehydrogenase [59, 60]. During adipose tissue expansion, inappropriate vascular tissue development results in hypoxia and death of adipocytes, and macrophage infiltration is induced [61]. On the other hand, BAT derived from Myf5⁺ mesoderm progenitors shares a common origin with skeletal myoblasts [62]. The development of BAT requires that PRDM16 activates PPAR-γ coactivator (PGC-1α/β) or CtBPs and inhibits transcriptional factors that induce WAT [63, 64]. In addition, bone morphogenetic protein 7 (BMP-7) turn on a full program of brown adipogenesis involving induction of PRDM16 and PGC-1α and expression of UCP-1 which is a feature of brown cells [65]. Last, beige fat cells adapt functions, either like "WAT" when energy balance is exceeded, or like "BAT" in response to stimuli similar to BAT activation. Today, research in identifying the main genes that control differentiation, development, and activation of BAT is highly active. This work is licensed under a Creative Commons Attribution-NonCommercial (CC BY-NC 4.0) International License [66]

signals to both brown adipose tissue and WAT to induce lipolysis. Leptin has recently been suggested as therapy for individuals with generalized lipodystrophy, who frequently develop severe metabolic syndrome characterized by hepatic steatosis, insulin resistance, and diabetes mellitus.

The physiological expansion of WAT involves different degrees of hypertrophy and/or hyperplasia of adipocytes, and active remodeling of vascular and mesenchymal stromal cells. Also immune cells, endothelial cells, and undifferentiated or adipocyte precursor cells (APs) must also be coordinately developed [68]. Storage of excessive fat in WAT causes mechanical overload and contributes to increased risk of metabolic disorders. The repertoire of molecules secreted by adipocytes is not exhausted. Recently asprosin was described to be abundantly expressed in mature white adipocytes, accumulated in excess in the blood of humans with obesity and proportional to insulin levels, which has suggested asprosin levels may be associated with insulin resistance [69].

The role of BAT is thermogenesis contributing to energy expenditure and body weight regulation (Fig. 14.2) [70, 71]. In mammals, BAT is the primary site of thermogenesis in the absence of muscle contraction. BAT thermogenic function is mediated by the activation of a specific mitochondrial uncoupling protein 1 (UCP1) (Fig. 14.2). In humans, BAT function is particularly important for the control of body temperature after birth and in early childhood [72]. However, data from adipose tissue samples together with evidence provided by positron emission tomography coupled with computed tomography have established the existence of functionally active brown adipose tissue in adult humans [73–76]. Furthermore, some of these studies also relate the degree of activation of these sites with BAT and lower BMI, increased basal energy expenditure, and decreased onset of diabetes [77]. BAT in adult humans can be found in the cervical and supraclavicular [78] regions, depots identified as canonical BAT exhibiting similarities with the BAT in rodents. Lastly, recent studies have reported on secretory molecules from

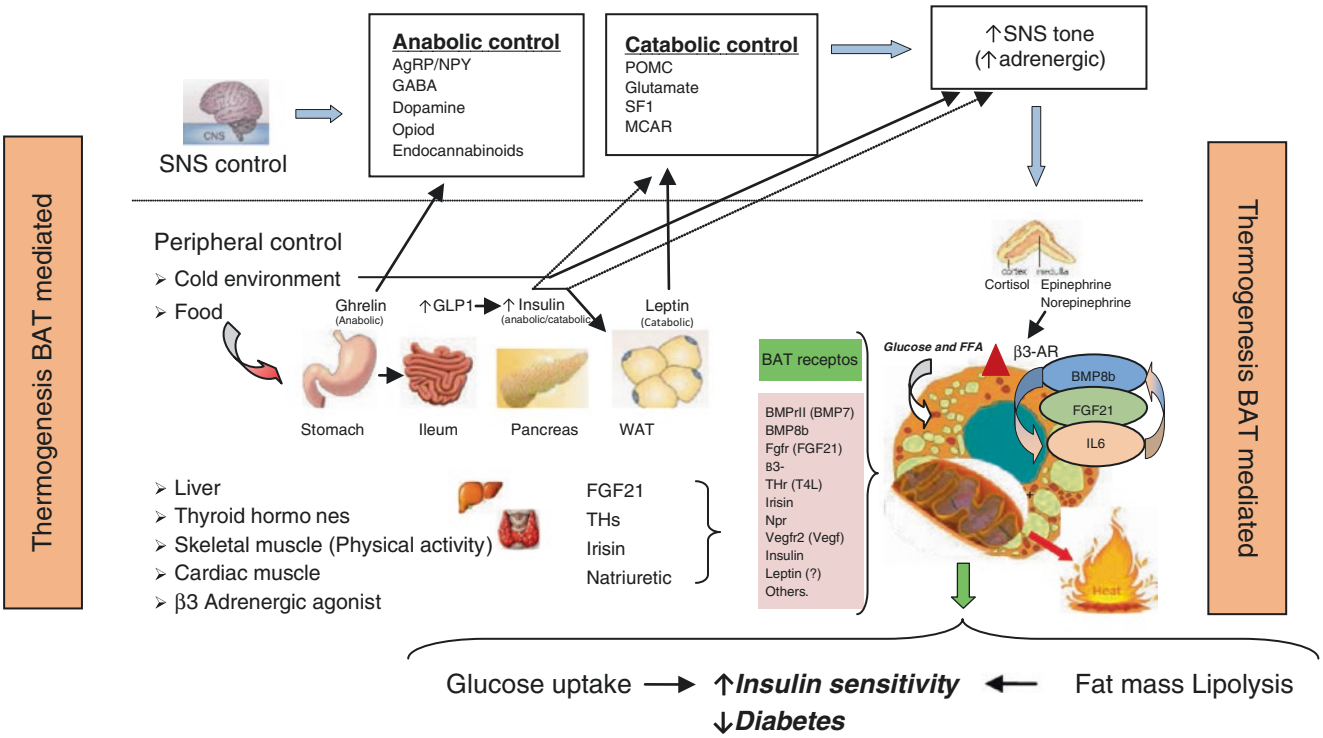

Fig. 14.2 By contrast to WAT, brown adipose tissue (BAT) was developed especially for energy expenditure (thermogenesis) mainly controlled by the SNS, which highly innervates brown fat cells. BAT is regulated in response to cold temperatures, hormones, and diet. BAT abundance and activation is highest in children and decreases with age. BAT activity decreases with BMI, body fat, and visceral obesity. Of note, BAT activity is lower in diabetics than nondiabetic subjects. Thyroid hormones play a key role in controlling BAT activation, such as the cold-induced deiodinated thyroxine (T4) to the more active T3. Norepinephrine binds to β-ARs inducing PGC1α and expression of UCP1. Whereas β1-AR mediates precursors of BAT proliferation, β3-AR plays a key role in the thermogenic function of BAT. Another signal, Irisin hormone, released from muscle to fat tissue, mediates the beneficial effects of exercise reducing diet-induced obesity and improving insulin resistance. In addition, FGF21, secreted by adipose tissue, liver and skeletal muscle, regulates lipolysis in WAT and increases substrate utilization by increasing fatty acid oxidation in the liver. This actions may be mediated increasing activity of adiponectin. *WAT* white adipose tissue, *BAT* brown adipose tissue, *PRDM16* PR domain-containing 16, *PPAR-γ* peroxisome proliferator-activated receptor-γ, *PGC-1α* peroxisome proliferator-activated receptor γ coactivator 1α, *SNS* sympathetic nervous system, *BMI* body mass index, *FGF21* fibroblast growth factor 21.

BAT, the so-called batokines, which include fibroblast growth factor 21 (FGF21), neuregulin 4 (NRG4), vascular endothelial growth factor A (VEGFA), and bone morphogenetic protein 8B (BMP8B). These studies indicate that similar to WAT, the BAT may also play a physiological role as an endocrine organ [79].

On top of white and brown adipocytes, a third fat cell named beige/brite, which shares similarities with brown adipocytes, is found infiltrating skeletal muscle as well as in diverse areas of WAT [80]. Of note, beige cells are Myf5-positive cells, a classical feature of BAT, and appear dispersed in WAT [81]. The term "beige" describes their similar morphology with white adipocytes, but the inducibility of features similar to brown adipocytes including UCP1 activity with β-adrenergic stimulation [82, 83]. There is also evidence that beige mature adipocytes can be interconvert between typical white or brown adipocytes, without the need for de novo cell differentiation from precursors cells [83]. A priori, this could mean that the rate of lipid storage or lipid oxidation could be adapted and adjusted in response to external stimuli such as a decrease or increase in temperature. Results from mice indicate that activated beige cells may contribute to improve carbohydrate metabolism and prevent/reverse fatty liver [84]. In any case, the physiological relevance of these cells in humans is far from being confirmed.

Effects of Hormones and Adipokines on Adipogenesis and Glucose Metabolism

Adipose tissue development and function are modulated by hormones and growth factors, secreted molecules by adipose tissue cells, and by nutritional factors and pharmacological drugs (Fig. 14.2).

Hormones and Growth Factors

Insulin is the key anabolic hormone that contributes to adipocyte differentiation and lipogenesis [85]. Brown preadipocyte determination is also regulated by insulin through a necdin-E2F4 interaction that represses peroxisome proliferator-activated receptor-γ (PPAR-γ) transcription [86]. When in excess hyperinsulinemia either exogenously or endogenously is a major enabler of adipose tissue expansion contributing to weight gain. Several molecules produced by cells from the adipose tissue such as tumor necrosis factor alfa (TNF-α), leptin, and resistin interact and inhibit insulin signaling on adipocytes.

Glucocorticoids and sexual hormones also affect the functionality and development of the adipose. For instance, the infusion of hydrocortisone increases levels of circulating free fatty acids (FFAs) by activating the mechanisms of lipolysis [87, 88]. Glucocorticoids promote adipogenesis by increasing the expression of both PPAR-γ transcription factors and C/EBPδ and decreasing the expression of pref-1 [89]. The adipocyte also has a complete arsenal of enzymes that regulate the metabolism of steroid sex hormones [90]. Glucocorticoids control the activity of 11-β-hydroxysteroid dehydrogenase 1 and 2 (11 βHSD1 and 2) that can change the active-form cortisol to inactive cortisone and vice versa [91]. Of note this enzyme is highly expressed in visceral adipose tissue which may contribute to the regional redistribution of fat [92, 93]. Another key aspect related to adipose tissue distribution in sex steroids. Body fat distribution is different in men and women, and adipose tissue has activity of either cytochrome P450-dependent aromatase or 17-β-hydroxysteroid dehydrogenase (17βHSD) enzymes that can modify the repertoire of steroids. Aromatase mainly regulate the rate of transformation of androgens into estrogens, while 17βHSD regulates the formation of a more active form of androgens. Of note, the ratio 17βHSD/aromatase in adipose tissue correlates directly with central obesity [90, 94].

Thyroid hormones are main contributors to global growth and development [95] by exerting an important role-controlling energy metabolism and the function of the main metabolic organs such as the adipose tissue, liver, heart, skin tissue, or muscle [96, 97].

Growth hormone and insulin-like growth factor 1: Growth hormone (GH) is critical for somatic growth but also has enormous influence of the regulation of body fat composition and distribution, through its lipolytic and anabolic effects [98].

Adipocytokines: Adipose tissue contributes to the metabolic control of energy substrates such as glucose and lipids and interacts with several hormonal systems. The molecules produced by adipose tissue (adipokines) act in many organs including the adipose, muscle, and CNS. In obese and insulin-resistant patients, there are qualitative and quantitative changes in the repertoire of adipokines. For example, some adipokines increase (e.g., leptin, resistin), while others decrease (e.g., adiponectin) (Figs. 14.2 and 14.3) [111].

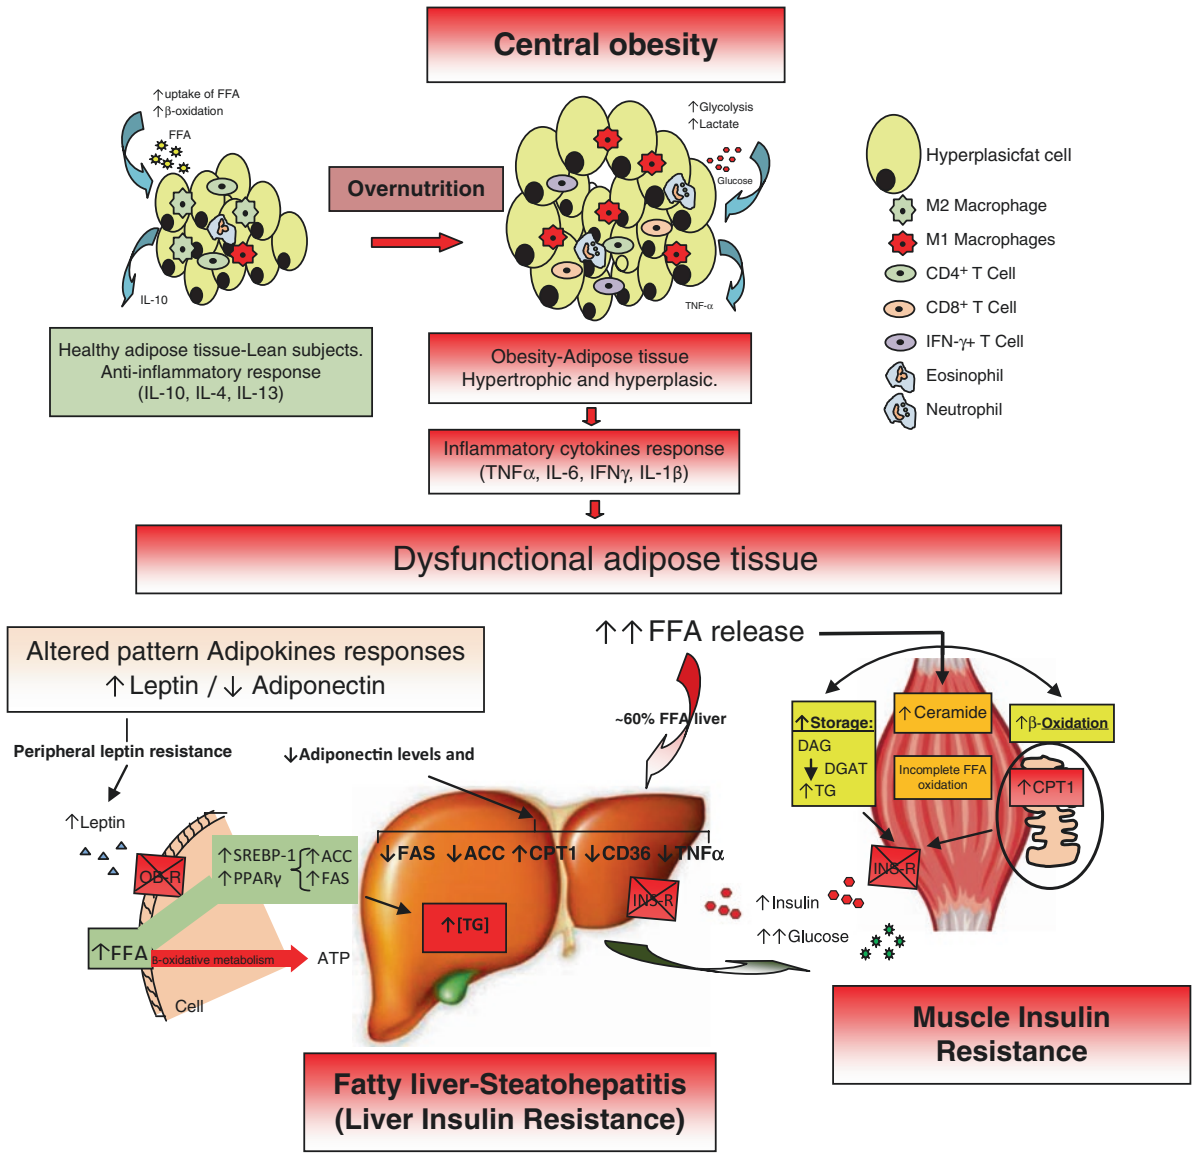

Fig. 14.3 Dysfunctional adipose tissue. When adipose tissue expands, it is slowly infiltrated by macrophages, and a low-grade chronic inflammatory state is developed [99, 100]. Several macrophage subtypes can be seen, which can be divided into pro-inflammatory M1 or alternatively activated M2 [101]. Adipocytes, macrophages, and immune T cells contribute to the production of inflammatory cytokines [99, 102–104]. The M1 macrophages are induced from precursor M0 macrophages by stimulation of type 1 T-helper (Th1) inflammatory cytokines like IFN-γ and TNF-α and lipopolysaccharide, whereas the M2 macrophages are induced by type 2 (Th2) cytokines such as IL-4 and IL-13. While adipose tissue of obese subjects show mainly M1 macrophages, lean subjects have high levels of M2 macrophages. M2 macrophages are involved in remodeling and tissue repair through the action of IL-10, IL-1 receptor antagonist, and arginase-1, which result in better insulin sensitivity. Whereas M1 macrophages use glucose for energy, M2 macrophages activate the β-oxidation of fatty acids [101, 105]. Finally, M1 macrophages are a principal source of TNF-α which, by activating Wnt signaling and suppressing expression of PPAR-γ, interferes with the development and function of adipocyte and reduces the capacity to store triglycerides [106, 107]. Peripheral adipose tissue will expand to an equilibrium point, and when exceeded (inflexibility), glucose and lipid uptake decline, while insulin levels rise in order to maintain serum glucose within the normal range [108]. In addition, inflexibility is associated with early insulin resistance which increases lipolysis in adipose tissue, generating a redistribution of fats with systemic lipotoxic effects in the muscle, liver, β-cell, etc. (lipotoxicity). Furthermore, increased TNF-α and IL-6 levels are inversely related with peripheral and hepatic insulin-mediated glucose-uptake [109]. The liver takes up excess released FFA in serum to capacity by storing with glycerol (TAG), and the slowly fatty liver could be developed (NAFLD). Peripheral FFAs contribute ~60% of total TAG stored in the liver, whereas the novo lipogenesis is ~26% and ~15% is from food [110]. On the other hand, leptin levels rise with adipose expansion, while adiponectin levels tend to decrease. The elevated leptin levels should increase β-oxidation in non-adipose tissues, decreasing excess fatty acids in these cells. However, this action may be partially blocked by the anabolic effect of hyperinsulinemia, inducing a leptin system dysfunction (peripheral leptin resistance) [111]. In addition, adiponectin action improving peripheral glucose uptake and adiponectin protective action on liver fat accumulation are decreased [112]. Finally, both leptin and adiponectin seem to regulate the deposition of fat in insulin-sensitive tissues by increasing β-oxidation. *IFN-γ* interferon-γ, *TNF-α* tumor necrosis factor-α, *IL* interleukin, *PPAR-γ* peroxisome proliferator-activated receptor-γ, *WAT* white adipose tissue, *FFA* free fatty acids, *NAFLD* nonalcoholic fatty liver disease, *CPT-1* carnitine palmitoyltransferase-1, *FAS* fatty acid synthase, *ACO* acetyl-CoA carboxylase.

Major Adipokines

Leptin: Leptin is secreted by adipocytes, establishing a negative feedback between the amount of adipose tissue and satiety centers in the brain [113, 114]. Leptin also serves as a sensor of energy availability enabling energy demands such as pregnancy and adaptation to starvation [115]. Leptin levels decrease after weight loss, enabling saving energy adaptive response involving low-thyroid activity, sympathetic tone, and decreased basal energy expenditure [116]. Thus, treating leptin deficiency with recombinant leptin not only reduces food intake and body weight [117] but also reverses infertility, prevents lipodystrophy associated metabolic complications, and reverses impaired glucose metabolism [118–121]. The leptin action appears to be facilitated by insulin, glucocorticoids, TNF-α, estrogens, and C/EBPα and is decreased by androgens, β3-adrenergic activity, GH, FFAs, and PPAR-γ agonist [122].

Leptin also plays an essential role in energy metabolism, by facilitating lipid mobilization and preventing ectopic fat accumulation (lipotoxicity syndrome) [123, 124]. Leptin facilitates lipid oxidation and by doing so can reduce excessive fatty acid accumulation in the liver, pancreas, heart, kidney, and muscle tissue (Figs. 14.2 and 14.3).

Adiponectin: Adiponectin is produced in mature adipocytes and is more abundant in peripheral subcutaneous than visceral adipose tissue [125]. Adiponectin receptors are G protein-coupled highly expressed in muscle (AdipoR1) and liver (AdipoR2) [126]. Through them adiponectin promotes lipid oxidation in the skeletal muscle and liver and reduces hepatic glucose production and postprandial hyperglycemia [112, 127] contributing to maintain metabolic homeostasis.

Adiponectin deficiency, as observed in obesity, plays a role in the development of insulin resistance and type 2 diabetes as suggested by the following: (a) Adiponectin levels have an inverse relationship with the degree of obesity, insulin resistance, and T2D [128, 129], which is reversed by adiponectin treatment which results in the improvement of IR [130]. (b) Adiponectin reduces FFA levels and is associated with improved lipid profile, glycemic control, and reduced inflammation in T2D patients [131]. (c) TNF-α plasma levels and its hepatic production are decreased by adiponectin treatment, which also improved hepatomegaly, steatosis, and ALT levels related with nonalcoholic fatty liver disease (NAFLD) (Fig. 14.3) [112]. (d) The PPAR-γ agonists (thiazolidinediones, TZDs) redistribute lipids from central to peripheral depots and also increase adiponectin levels, and improve lipid profile and insulin sensitivity, while improving diabetes and NAFLD [132]. This suggests that maintaining normal levels of adiponectin may help in the treatment of early-stage diabetes. However, the relationship between adiponectin levels and cardiovascular disease is not well established [133].

Other Adipokines

Resistin has also been related to obesity, insulin resistance, and development of T2D. Blocking the action of resistin improves insulin sensitivity [134]; however, the significance of resistin in glucose metabolism in human still is inconclusive.

Visfatin is produced predominantly by abdominal adipose tissue and has been suggested to have insulin-mimetic actions [135, 136]. However, the importance of visfatin in glucose metabolism is still unclear [137].

Omentin 1: Obesity decreases both omentin plasma levels and omentin gene expression in visceral adiposity [138]. In obese women with polycystic ovary syndrome (PCOS), glucose and insulin levels were negatively related with omentin 1 levels, whereas metformin treatment increased serum omentin levels in parallel with improvements in insulin sensitivity and glycemic control [139, 140].

Obestatin is a hormone that opposes the effects of orexigenic effect of ghrelin. Obestatin decreases in subjects with diabetes and impaired glucose tolerance [141], and its receptors are downregulated in obesity-associated T2D [142].

Retinol-binding protein 4: Retinol-binding protein 4 (RBP4) is released from adipocytes and correlates with the degree of insulin resistance in obesity, T2D, and relatives of T2D patients [143–145]. The specific role of RBP4 in insulin resistance has not been determined.

Asprosin is a 140-amino-acid polypeptide, recently described, abundantly secreted, and expressed in WAT. Levels of asprosin are increased in fasting situations in healthy humans. Asprosin acts on the liver, stimulating hepatic glucose production. Asprosin administration induces a quick increase in plasma levels of glucose and insulin. Blocking asprosin actions might be beneficial for the treatment of type 2 diabetes mellitus [69].

Inflammatory Adipokines

TNF-α is a transmembrane protein released mostly by activated macrophages and also by other cell types including endothelial cells, adipocytes, etc. (Fig. 14.3) [146–148]. Both TNF-α gene and its receptors are present in adipocytes and are expressed at higher levels in WAT [125]. TNF-α contributes to local and systemic inflammation, which limits the proliferation and differentiation of mature adipocytes. Increased release of TNF-α from adipose tissue contributes to the impairment of insulin action [102, 149, 150], and treatment with anti-TNF-α antibody led to improvement in glucose utilization in obese rats [102] at least. Similarly, obese mice genetically modified to ablate TNF-α had close to normal insulin sensitivity [150]. Moreover, weight reduction is associated with both improved insulin activity and

decreased TNF-α gene expression [151]. The mechanism how TNF-α promotes insulin resistance may involve the decrease in the expression of PPAR-γ and target genes involved in lipid and glucose uptake [152, 153]. A link between fatty acid-binding protein 4 (aP2), FFAs, and increased expression of TNF-α in obesity has been suggested [149]. Not only TNF-α but also interleukin-6 (IL-6) were both increased after nutritional fatty acid activation of Toll-like receptor 4 (TLR4) [154].

IL-6 is secreted by adipose tissue, T cells, and macrophages (Fig. 14.3). Adipocytes can produce IL-6, which is associated with C-reactive protein (CRP) levels and inflammatory states typically found in obese patients [155]. About 1/3 of the total concentration of IL-6 is produced in adipose tissue, mainly by visceral adipose tissue compared with peripheral adipose tissue [125]. It has been suggested that IL-6 levels are directly linked to obesity and insulin resistance [156] and to the inhibition of the activity of lipoprotein lipase (LPL) [157].

Chemokine molecules are potent chemo attractants of leucocytes and modulate the formation of reactive oxygen and cytokines. The chemokine molecule 5 (CXC ligand 5, CXCL5) is expressed at high levels by the macrophage of white adipose tissue [158]. Serum levels of CXCL5 are elevated in obese patients independently of their degree of insulin resistance above the levels observed in normal-weight subjects [158]. Furthermore CXCL5 serum levels are reduced after weight loss.

Fatty Acid Metabolism Effects on Adipogenesis and Glucose Metabolism

FFAs are energy-rich molecules which are fundamental regulators of metabolism. Excess calories ingested as fat, protein, and carbohydrates end up stored as triglycerides in white adipocytes. FFAs are also essential constituents of the cell membrane, influencing its fluidity and the topology of receptors, transporters, and other membrane proteins. In addition, FFAs can have hormone-like actions and serve as ligands of nuclear receptors controlling gene expression [159]. Although food is the main source of essential fatty acids, de novo endogenous biosynthesis could supply nonessential fatty acids [160].

Both linoleic acid (ω-6 series) and linolenic acid (ω-3 series) have been related to decreased insulin resistance and CVD and must be included in the diet [161]. By contrast, excess saturated fatty acids and trans fats in the diet is associated with increased insulin resistance and risk of CVD [161].

LPL activity is increased by insulin and depends on apo CII and apo CIII being released by adipocytes. LPL is essential for FFA uptake from lipoproteins and storage [162]. In addition, cytoplasmic fatty acid-binding proteins (FABPs) facilitate intracellular transport and partition of FFA to specific compartments and functions [163]. FABPs link lipid metabolism, hormone action, and systemic energy homeostasis involving glucose metabolism [149].

De novo biosynthesis of saturated chain fatty acids is carried out mainly in the liver where acetyl-CoA is formed from pyruvate. Most de novo FFA are synthesized from acetyl-CoA and malonyl-CoA through two enzymatic steps, including acetyl-CoA carboxylase (ACC) and fatty acid synthase (FAS). The ACC controls production of short fatty acids which are elongated until 16-carbon palmitic acid is formed by FAS (cytosol). Nearly all fatty acids required can be synthesized from palmitic acid by several steps of oxidation and elongation [164]. Finally, various enzymes which regulate the synthesis of triglycerides are also implicated in glucose metabolism [165]. Overexpression of diacylglycerol acyltransferase 1 (DGAT1) results in increased adipose tissue without affecting IS but increases the secretion of TNF-α [166]. A remaining question is whether de novo lipogenesis-originated fatty acids may have a specific fate or contribute to specific functions different from the pools of FAs generated from dietary nutrients.

Obesity Effects on the Pathogenesis of Type 2 Diabetes

Type 2 diabetes (T2D) mellitus is characterized by hyperglycemia, insulin resistance, and inappropriately low secretion of insulin. The prevalence of T2D has increased in parallel with the increased prevalence of obesity [167] and sedentary lifestyle [168]. The pathogenesis of common forms of T2D is complex [169], requiring the combination of different degrees of insulin resistance and insulin deficiency [170]. In addition, insulin resistance and defects in insulin secretion can be determined via genetic and/or varying environmental factors, complexity that makes difficult to isolate a single cause in diabetic patients [171]. However, it is clear that the final development of diabetes requires beta cell failure as suggested by the fact that obese subjects do not necessarily develop T2D.

The potential molecular links between obesity and increased risk of T2D include exacerbated inflammatory response with excessive cytokine secretion (TNF-α and IL-6), insulin resistance, defects in fatty acid metabolism and lipotoxicity, mitochondrial dysfunction, and endoplasmic reticulum stress. However, weight loss is a central intervention working on most forms of prediabetes, because even modest weight loss improves glycemic control and reduces diabetes risk.

The risk of T2D and cardiovascular disease rises with the amount of body fat, and more particularly when fat accumulates in the central or abdominal depots [172]. Whether subcutaneous fat deposition is less pathogenic than visceral fat is quite likely but requires further investigation. In addition, the contribution of the subtypes of adipose tissue to glucose metabolism is important. For instance, increased level of brown adipose tissue may help to control carbohydrate metabolism and prevent or reverse obesity [73, 173].

Infiltration of immune cells in adipose tissue can alter its metabolic functions. Although the adipose tissue is not the cause of obesity per se, taking advantage of the specific functions of the repertoire of fat cell types and functional characteristics of the depots including the immune cells may help to uncouple obesity from its complications.

The main proposed mechanisms linking obesity to insulin resistance and T2D include (1) increased and altered secretion of adipokines (TNF-α, adiponectin, leptin, etc.) directly to inflammation and insulin resistance; (2) ectopic fat deposition, predominantly in the liver, skeletal muscle, and β-cell, contribute to altered fat, insulin resistance, and glucose metabolism; and (3) mitochondrial dysfunction causing a bioenergetic cellular defect leading to decreased insulin sensitivity and defective pancreatic β-cell function.

Effects of Fetal Develop on Adult Glucose Metabolism

The Nurses' Health Study (NHS) of over 69,000 women found an inverse relationship between birth weight and adult diabetes [174]. A meta-analysis with an adjusted odds ratio of diabetes of 0.80, 95% CI 0.72–0.89 for each 1-kg increase in birth weight confirmed this [175]. However, a higher birth weight (>4.0 kg) is also associated with an increased risk of diabetes [176]. Lastly, a U-shaped relationship between birth weight and the development of T2D was found in a meta-analysis. Thus, high and low birth weight are associated with a similar increased risk of diabetes (ORs 1.36 and 1.47) [177] although not necessarily attributable to the same mechanisms.

The Effect of Adult Obesity on Glucose Metabolism

After absorption in the intestine and synthesis in the liver, triglycerides (TG) are transported in specialized lipoproteins (chylomicron and very-low-density lipoprotein (VLDL)) to adipose and other tissues. Intracellular toxic accumulation of diacylglycerol and the input and output flows of FFA and acyl-CoA can be ameliorated by the formation and safe storage as TG [178]. Droplets containing TG are surrounded by a monolayer of phospholipids and proteins, e.g., perilipin (ADRP), which regulates lipid droplet formation, growth, and dissolution [179].

Obesity and the Lipotoxicity Syndrome

The main function of the adipose tissue is fat storage. Adipose release of FAs and uptake into non-adipose tissues must be coupled, matching demand and supply. For instance, in fasted state or during physical exercise, the lipolysis in adipose tissue is increased, a process that requires the coordination of suppression of plasma insulin and elevation of contrainsulin hormones (glucagon, cortisol, epinephrine, etc.). However, in obesity it is quite normal to reach a prolonged overfeeding state, where fat load may exceed the functional storage capacity of the adipose tissue determining a state of metabolic inflexibility, where lipid uptake and mobilization is inefficient (inflexibility) (Fig. 14.4).

Another factor contributing to its functional defect is the adipocyte cell size. When adipocytes enlarge in an attempt to increase their capacity, they also become insulin resistant. This reduced the antilipolytic effect of insulin and increased the lipolysis of triglycerides from the adipose tissue as a whole and the bulk FFA release. This leak of FFA and accumulation in plasma subsequently promote insulin resistance in the muscle and liver [184] and also inhibits insulin secretion [185], ultimately causing β-cell apoptosis [186].

Among the most important factors controlling adipocyte capacity for storage and functional switch between storage and lipolysis, we identify the nuclear receptor PPAR-γ as a key transcription factor that controls the coupling between lipid storage and adipogenesis and lipolysis [187]. In addition, the direct role of leptin on adipose tissue functionality has been suggested. However, common forms of obesity are typically characterized by leptin resistance predominantly located at the central hypothalamic action [188]. Central and/or peripheral leptin action appears to be implicated in processes that prevent lipotoxicity in non-adipose tissues through the regulation of β-oxidation mediated in part by its effects through peroxisome proliferator-activated receptor-α (PPAR-α) activity. This prooxidative effect helps to minimize the metabolic burden of ectopic accumulation of lipids. Patients with insulin resistance syndrome have lower mRNA leptin abundance in peripheral adipocytes than IS patients (leptin resistance), even though insulin treatment acutely increases leptin levels [111, 189]. Another factor to consider is that a chronic increase of β-oxidation may contribute to oxidative stress and to generate inflammation, which may be potentially harmful [188].

Adiponectin, another adipose tissue-derived hormone, also has a major role in improving insulin sensitivity, anti-inflammatory, anti-apoptotic, and pro-angiogenic effects that enhance whole body and adipose metabolic flexibility. Adiponectin action in adipose tissue improves both the efficiency of the adipose tissue at regulating the releases of FFAs and increases the rate of FFA re-esterification during the postprandial state [190]. However, the low-serum adiponectin levels typically observed already in the early stages of insulin resistance are not sufficient to prevent the subsequent derail of adipose tissue function [111]. As part of the natural history toward the development of diabetes, there is progressive failure of the adipose tissue homeostatic mechanisms. When they are overwhelmed, lipids cannot hold efficiently in the adipose tissue and accumulate in tissues that

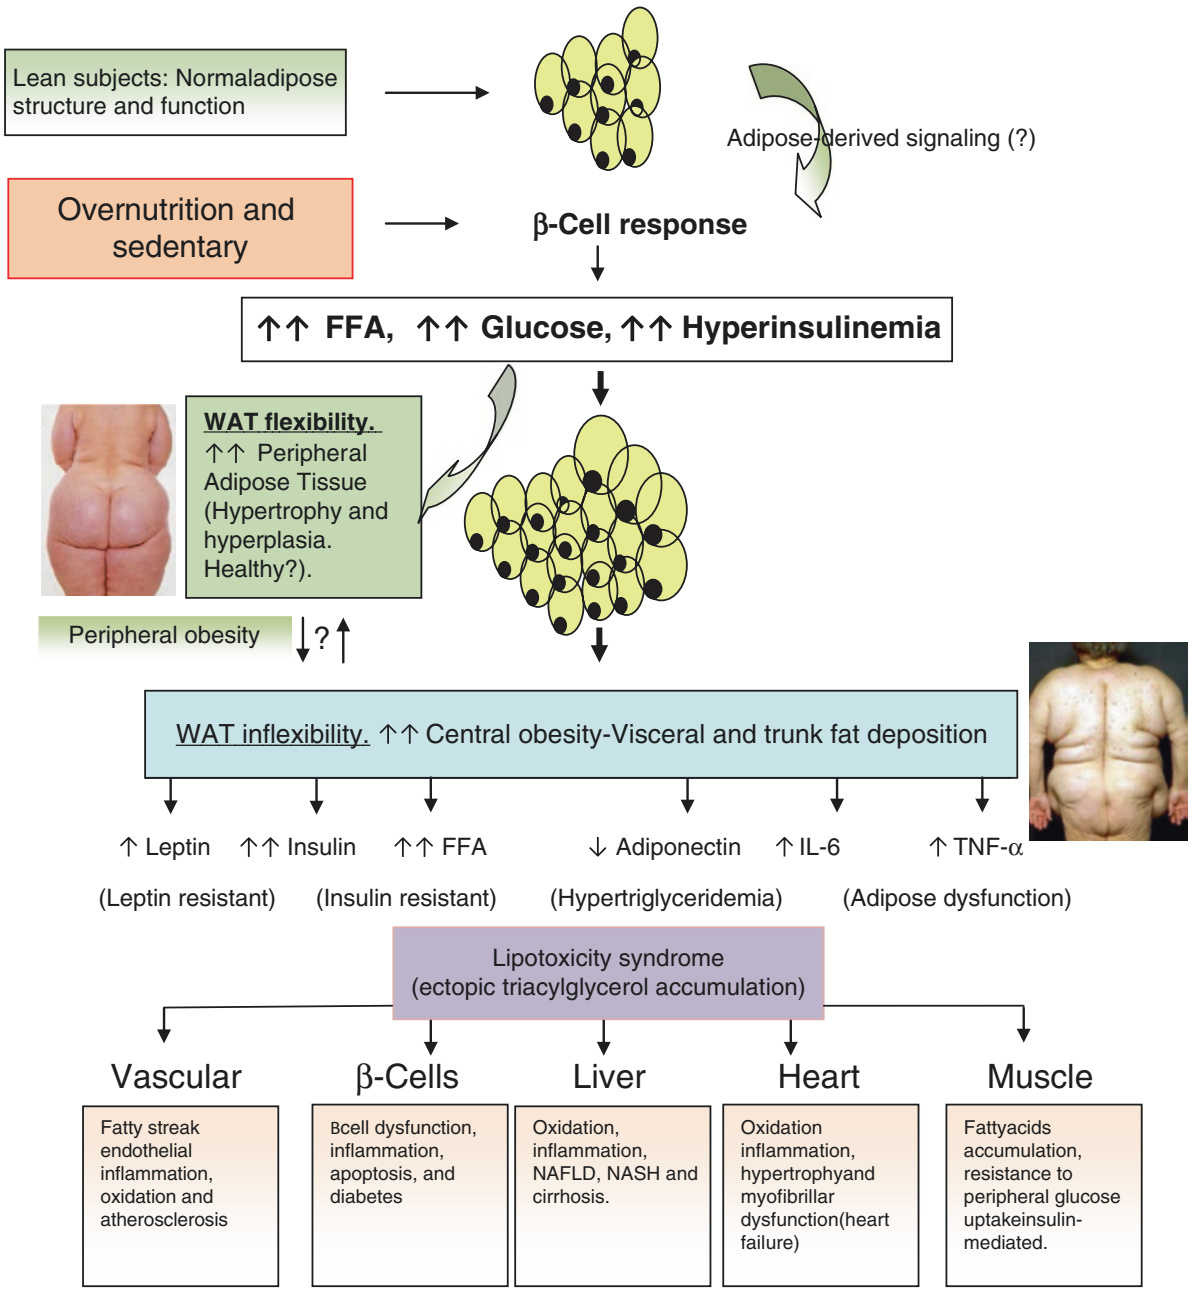

Fig. 14.4 Adipose tissue expandability and metabolic syndrome. After overeating with positive energy balance, adipose tissue increases its storage capacity, which is regulated by several factors. In individuals with a high capacity for storing fat, mainly when WAT is expanded (WAT flexibility), most, despite obesity developing, will remain normal, known as metabolically healthy obese (MHO). However, a low-grade chronic inflammatory response is frequently observed leading to dysfunctional adipose tissue [180]. Therefore, a proinflammatory milieu with elevation in IL-6 and mainly TNF-α, an altered adipokines profile with decreased adiponectin and increased leptin levels, will result in a dysfunctional adipose system. Increased release of cytokines and adipokines are related to insulin resistance, hyperglycemia, altered lipid profile, and cardiovascular diseases [111, 181, 182]. Insulin resistance is associated with the accumulation of lipids in non-adipose tissues such as the muscle (lipotoxicity), due to increased lipolysis of fatty acids from adipose tissue. On the other hand, when the maximal storage capacity of adipose tissue is achieve, dysfunctional adipose tissue results, and redistribution of fat is initiated. Limitation in fat storage capacity could be necessary and even precedes the development of metabolic factors. Ectopic lipid accumulation in non-adipocyte cells causes lipotoxicity in these organs, including inflammation and apoptosis. Thus, lipotoxicity in β-cells could decrease β-cell mass (β-cell dysfunction) and can cause diabetes. Increased fat in the liver leads to NAFLD and nonalcoholic steatohepatitis (NASH) and could cause hepatic dysfunction, myocardial dysfunction in the heart, the endothelial fatty streak could be a precursor of generalized arteriosclerosis, etc. The point at which adipose tissue begins to fail is probably influenced by genetic and epigenetic factors. However, the question is can storage capacity in WAT be enhanced to meet an increased demand [183]? One answer in humans is treatment with PPAR-γ agonists (TZDs) that transfer fat from central to peripheral deposits, improve lipid profile, insulin-sensitivity, and reduce diabetes and NAFLD [132]. *WAT* white adipose tissue, *MHO* metabolically healthy obese, *IL* interleukin, *TNF-α* tumor necrosis factor-α, *NAFLD* nonalcoholic fatty liver disease, *NASH* nonalcoholic steatohepatitis, *PPAR-γ* peroxisome proliferator-activated receptor-γ, *TZD* thiazolidinedione.

cannot store excess lipids such as the muscle, β-cells, liver, heart, and kidneys [124] without triggering metabolic toxic responses.

In addition with the leak of FAs, the dysfunctional adipose tissue also produces and releases an abnormal pattern of adipocytokine (e.g., decreased adiponectin and increased leptin, TNF-α, and IL-6). This promotes an inflammatory state that further compromises the insulin sensitivity and functionality of the adipose tissue depot. Advancing in the natural history, the development of central obesity further exacerbates hyperinsulinemia and hyperglycemia, initially in the postprandial state and finally to global hyperglycemia. This phenotype is typically associated with hypertriglyceridemia, hypoalphalipoproteinemia, hypertension, and fatty liver (dysfunctional metabolism in the liver), a cluster of pathologies commonly diagnosed as metabolic syndrome (MetS) [191].

Pathogenesis of Obese Type 2 Diabetes

Obese T2D is typically associated with four clinical and metabolic defects: obesity, insulin resistance, dysfunction of β-cells, and increased hepatic endogenous glucose production [192]. However, the mechanisms by which these defects progress, the way they affect each other and contribute to the increase of glucose levels in obese T2D, is not fully elucidated. In a landmark longitudinal study of obese subjects with high incidence of T2D (Pima Indians of Arizona), peripheral insulin effect (euglycemic clamp), acute insulin secretory response (AIR), and endogenous glucose production, in those whom glucose tolerance deteriorated from normal (NGT) to impaired (IGT) to T2D over 5.1 ± 1.4 years, were measured [192]. Patients who developed IGT typically presented increased body weight and decreased insulin sensitivity and defective acute insulin secretion. In those who developed an open T2D, a greater increase in body weight, coupled with a more severe insulin resistance and impairment of insulin secretion, and further increase of hepatic glucose production (HGP), was observed. By contrast, overweight patients who maintained normal glucose tolerance still gained weight despite decreased insulin-stimulated glucose disposal; however they maintained a robust insulin secretory response (AIR that was increased).

Another organ that is gaining relevance in metabolic failure associated with diabetes is the gut. The gastrointestinal tract should be considered as a large and specialized endocrine organ that releases two major incretin peptides. The glucagon-like 1 (GLP-1) by L-cells (distal small intestine) and glucose-dependent insulinotropic peptide (GIP) by k-cells (early small intestine). GLP-1 and GIP jointly contribute to rise by 60–70% insulin released in response to a mixed meal [193]. In the context of the obese T2D patients, their β-cells generate resistance to GLP-1 and GIP [194]. Thus, despite their levels being normal or minimally reduced, their signaling in beta-cells is dysfunctional. Moreover, GLP-1 also reduces glucagon releases by α-cells on the pancreas and reduces appetite. Finally, in these patients, the GLP-1 resistance results in hyperglucagonemia and increased HGP and contributes to weight gain by promoting an orexigenic response [195].

The kidney is another point of metabolic control [196]. The kidney generates about 15–20% of the endogenous glucose production, mainly in fasting period, and is controlled by insulin function. But the kidney in obese T2D is insulin resistant, leading to an increase in its glucose production. Furthermore, the glucose filtered is efficiently reabsorbed by sodium glucose transporter 2 (SGLT2) (80–90%) and SGLT1 (10–20%). During early stages of hyperglycemia, this capacity of reabsorption is increased and contributes to maintain elevated glucose levels but also to retain sodium and water which may contribute to increase high blood pressure.

Contributing to the phenotype, it could be argued that as insulin and amylin, which is released together with the insulin, have anorectic signaling properties acting in the hypothalamus, in obese T2D this signal of insulin is likely to be dysfunctional so that appetite is not suppressed which may contribute to overweight [197, 198].

Underlining Factors of Obesity-Induced Insulin-Resistance

Inflammation and Insulin Resistance

Long-time overfeeding and positive energy balance require adipocytes to increase their number and size. Excessive expansion of adipose is associated with adipose tissue metabolic dysfunction, changes in adipokines, increased hypoxia, immune cell infiltration, and attempts to remodel, cell death, and apoptosis. Inflammation is part of an early homeostatic response aimed to repair of damaged tissues (Figs. 14.3 and 14.4).

Enlargement of adipose tissue is associated with secretion by adipocytes of monocyte chemoattractant protein (MCP)-1, which promotes monocyte infiltration in WAT and differentiation in adipose tissue macrophages (ATM) [103]. Moreover, adipocytes also induce the expression of the adhesion molecules (ICAM-1) and platelet and endothelial cell adhesion molecule 1 (PECAM-1) on endothelial cells, which further attract monocytes [199]. The physiological role of this process is to facilitate the physiological remodeling of an expanding tissue. In obesity, failure to maintain the homeostasis of the organ results in uncontrolled inflammatory response generating a chronic low-grade inflammatory state. ATM contributes to the release of

inflammatory factors. Of relevance macrophages share many adipocyte genes such as fatty acid-binding protein 4 (FABP4) and PPARγ, whereas adipocytes can express numerous macrophage factors such as TNF-α, IL-6, and MMPs [200]. Moreover, ATMs have been artificially classified as M1 pro-inflammatory and M2 anti-inflammatory macrophages on the basis of membrane markers. In obesity typically there is an enrichment with a greater ratio of activated M1 than M2 macrophages [201, 202]. These proinflammatory M1 ATMs secrete pro-inflammatory cytokines such as TNF-α, IL-1β, and IL-6, whereas M2 ATMs secrete anti-inflammatory cytokines including IL-10 and IL-1 receptor antagonist [202]. Of relevance the preferential type of ATM and degree of infiltration are linked with the progression of insulin resistance [203]. Hence, oversecretion of TNF-α from macrophages and to a lesser extent by adipocytes are a major characteristic of obesity and contributes to insulin resistance of obese humans (Fig. 14.3) [102, 109].

Inflammation of adipose tissue in obesity also involves infiltration of different T cells. Regulatory T cells (T_{reg}) represent 5–20% of the $CD4^+$ T cells and play a major role in controlling immune actions [204]. T_{reg} release anti-inflammatory cytokines, preventing macrophage infiltration and promoting an M2 macrophage phenotype [203]. Of relevance, with weight gain, a decrease in T_{regs} is observed [204], whereas there is an infiltration and activation of $CD8^+$ T cells that contribute to attract macrophages in the early stages of obesity [205].

Another relevant type of immune cells are the eosinophils, main contributors to IL-4-secretion, and represent about 4–5% of cells in WAT. Macrophages are the main target of IL4 promoting an anti-inflammatory M2 phenotype which can improve glucose metabolism through preservation of M2 macrophages in WAT [206]. Lastly, neutrophils also seem to participate in the immune cell infiltration of the AT, contributing to obesity-induced insulin resistance [207].

Insulin sensitivity is affected by inflammation through various mechanisms. **TNF-α** inhibits insulin action by altering insulin receptor substrate 1 (IRS-1), through the activation of its p55 receptor [208]. In addition, TNF-α, FFA, ROS, and hypoxia activate IκBα kinase β (IKKβ) and c-Jun N-terminal kinase 1 (JNK1) in WAT and the liver, inhibiting insulin activity by changing phosphorylation of IRS-1 [209, 210]. Furthermore, TNF-α also inhibits PPARγ function, impairing lipid synthesis and fat store in WAT. Moreover, inflammation increases plasma FFA levels through the stimulation of lipolysis and reduction of TG synthesis, inducing insulin resistance in adipose tissue [211].

IL-1β activity requires two stress response signals. The first, necessary for production of pro-IL-1β, needs the activation of TLR4 (LPS, SFA, etc.) [212]. The second, which converts pro-IL-1β to active IL-1β, is controlled by the NOD-like receptor (NLRP)3-caspase 1 inflammasome complex [213]. The formation of NLRP3 inflammasome is induced by stressors that include FFAs, glucose, adenosine triphosphate (ATP), uric acid, ROS, etc. [214]. Thus, activation of the NLRP3 induces caspase-1 activity that converts pro-IL-1β to mature IL-1β. The major roles of NLRP3 inflammasome and caspase-1 activity in obesity-induced IR have been recently described [215].

Interleukin-6 is secreted by the WAT, skeletal muscle, and liver [99, 216]. Plasma IL-6 levels increase in overweight patients [217] in response to high levels of insulin and TNF-α. IL-6 inhibits insulin action through phosphorylation of IRS-1 [218]. In addition, raised IL-6 plasma levels are also associated with steatohepatitis and liver dysfunction [216]. However, IL-6 appears to stimulate insulin secretion by increasing the number of GLP-1 receptors in β-cells [219]. Thus, increased IL6 may contribute to the early increase of insulin secretion observed in obese patients. In addition, while elevated IL-6 secretion from WAT and the liver appears to have adverse metabolic effects, increased IL6 secretion by the skeletal muscle seems to be metabolically advantageous. In fact, physical inactivity has been shown to reduce skeletal muscle IL-6 expression and secretion [220]. The difference may be that whereas the increase in plasma IL-6 levels induced by exercise results from glycogen/MAPK activation and activation of anti-inflammatory levels of IL-1RA and IL-10 levels [221], the IL6 secretion from adipose and liver is mediated by NF-κB—thus emphasizing the pleiotropic role of IL-6.

Finally, **interleukin-10** is an anti-inflammatory cytokine produced by monocytes, M2 ATMs, DCs, T cells, and B cells. Thus it is expected to play a favorable role in obesity-induced IR. Of relevance IL10 is decreased in T2D [222], whereas weight loss increases IL-10 expression in WAT concurrent with diminished pro-inflammatory gene expression [223].

Mitochondrial Dysfunction and Obesity-Induced Insulin Resistance

Mitochondria is the main site for oxidation of fatty acids and glucose; thus its dysfunction may contribute to FFA and lipid accumulation and favor IR [224]. Mitochondrial biogenesis is activated by insulin and diminished in subjects with IR [225, 226]. In humans the existence of mitochondrial dysfunction in obese T2D who display lower NADH:O_2 oxidoreductase activity and reduced mitochondrial size than lean subjects has been observed [227]. Moreover, mitochondrial dysfunction in obese and insulin-resistant patients decreases lipid metabolism in muscle compared with lean control subjects [227–229]. Therefore, when mitochondria is exposed to excess lipids for β-oxidation, the oxidation of glucose may

be impaired, contributing to a state of insulin resistance. Furthermore, mitochondrial function improves after exercise training, increasing uptake and oxidation of glucose in parallel with an improvement in insulin sensitivity [230]. In addition, molecular studies have found a decrease in peroxisome proliferator coactivator 1a (PGC1α), the key co-activator of mitochondrial biogenesis, and a decrease in phosphorylation pathways in muscle mitochondrial of T2D patients compared with control without diabetes [231, 232]. Thus, these studies have suggested the possibility of a genetic predisposition for mitochondrial dysfunction already observed in the early stages of insulin resistance and diabetes. Although a compensatory attempt to increase mitochondrial oxidative activity that could deal with the increased lipid supply in the short term has been shown [233], a sustained exposure to high-fat diet, prolonged for more than 4–6 weeks, may not be able to be compensated by increasing the mitochondrial activity leading to ectopic lipid accumulation and IR [234, 235]. However these observations are not consistently shown [236, 237]. It is still unclear whether the observed defects in mitochondrial function could be due primarily to a decrease in their number in muscle or secondary to metabolic defects within the mitochondria. It is known that insulin sensitivity improves after weight loss, an effect that does not require mitochondrial function to improve or even to change. Drugs which inhibit mitochondrial function and ATP production (TZDs, metformin, etc.) improve insulin sensitivity [238]. Lipid infusion-induced insulin resistance also enhances mitochondrial β-oxidation [239]. In non-obese sedentary humans after a period of overfeeding, IR was increased without changes in mitochondrial function [240]. Also muscle mitochondrial function was not distinctively impaired in obese and T2D compared with control subjects [240, 241]. Finally, there is some evidence that decreased mitochondrial function may induce insulin sensitivity, whereas an increase mitochondrial function is associated with insulin resistance in transgenic mice [236, 237]. Thus the relationship between mitochondrial and insulin action remains complex and still not well established.

Oxidative Stress and Obesity-Induced Insulin Resistance

The mitochondria are an important source of superoxide generation in cells, having the greatest capacity for production in the electron transport chain (ETC). Under physiological conditions, mitochondrial superoxide contributes to mitochondrial function. Several studies have proposed a relationship between oxidative stress and IR. Lipid infusion increased the levels of oxidative damage markers such as plasma thiobarbituric acid reactive substance (TBARS) and was associated with a decrease in insulin sensitivity [242]. A decrease in intracellular reduced glutathione (GSH) is associated with a decreased insulin sensitivity in T2D patients. In addition, the infusion of GSH improved oxidative damage and insulin sensitivity [242, 243]. However, the physiological contribution of ROS to insulin sensitivity and metabolic response remains controversial, and several studies have been unable to reproduce consistently these observations [244, 245].

Endoplasmic Reticulum Stress and Obesity-Induced Insulin Resistance

The endoplasmic reticulum (ER) is an important biosynthetic organelle that regulates many biological processes required for nutrient storage and metabolization. If the surplus of nutrients is greatly increased, the synthesis, processing, and secretion of proteins may need to be increased, generating ER stress and dysfunction. Accumulation of unfolded or misfolded proteins is observed with ER stress [246]. ER stress is also induced by factors such as hyperglycemia, viral infections, hypoxia, and lipid over load or qualitative changes in membrane lipid composition [246]. ER stress has also been linked to the activation of chronic inflammation by activating JNK [247], raised oxidative stress, insulin resistance [248], and leptin resistance in obesity [249]. Moreover, the amelioration of ER stress with drugs directly improves insulin sensitivity in obese mice and recently also observed in insulin-resistant obese patients [250]. However, the specific mechanisms and process by which ER stress induces insulin resistance in humans still remains to be fully elucidated.

Skeletal Muscle Glucose and Lipid Metabolism

Adiponectin exerts direct effects in the skeletal muscle where it promotes fatty acid oxidation, decreases intramuscular lipid accumulation, reduces toxic deposit of ceramides, and results in improved insulin sensitivity [67]. Leptin may also play an insulin-sensitizing role in the muscle through the CNS or through the leptin receptors which are highly expressed on muscle and participates on its growth. Leptin's effect seems more related to the enhancement in FFA oxidation and amelioration of lipid deposition in muscle mediated by AMPK activation [251].

Liver Insulin Resistance and Hyperglycemia

As the key organ regulator of lipid and glucose metabolism, the liver is commonly affected by ectopic lipid accumulation (Fig. 14.4). Fatty acids accumulation in the liver results from

the imbalance of different sources: dietary fat, increase in lipolysis from adipocytes, and from de novo hepatic lipogenesis, without excluding defects in oxidation and on lipoprotein assembly and secretion. High-fat diets have been shown to produce fatty liver, whereas low-fat/high-carbohydrate diets have been shown to produce hyperinsulinemia in the context of selective insulin resistance and stimulation of de novo lipogenesis via SREBP-1c. Thus, dietary composition can have a major effect by affecting the relative sources of fat in the liver. However, an overproduction of FFAs from adipose tissue in the context of obesity is probably the most likely source of the excess triglyceride accumulating in the liver [110].

When an inflammatory environment is established in the adipose tissue, the whole body lipid metabolism becomes altered, initiating postprandial hypertriglyceridemia, because the liver overproduction of VLDL is not removed in time and remains for longer in plasma (postprandial hyperlipidemia). Further, because lipolysis from peripheral adipose tissue is exacerbated, the interstitial content of FFAs increases, which can be taken up by the adjacent muscle cells (↓ IS) or again transferred into lipoproteins to the plasma and could be taken up by the liver (↑ VLDL production) and other organs (lipotoxicity).

The ectopic accumulation of fat in the liver has been strongly associated with both hepatic and adipose tissue insulin resistance, an almost universal finding in nonalcoholic fatty liver disease (NAFLD) [66, 252]. Thus, whereas insulin sensitivity is reduced by ~45–50% (whole glucose disposal), the ability of insulin to inhibit endogenous hepatic glucose production is also decreased. However, not all obese individuals necessarily develop metabolic complications, as some remain insulin sensitive and do not develop fatty liver [111].

On top of all these factors, the link between obesity and associated metabolic abnormalities seems to be better related to the topography, anatomical distribution, and/or the functional peculiarities of the adipose tissue, a phenomenon which seems to be more relevant in patients with relatively normal weight (Figs. 14.3 and 14.4). The mechanism(s) that increased visceral adiposity is associated with insulin resistance is unclear, but circulating hormones secreted from adipose tissue have been implicated in modulating insulin sensitivity. Importantly, adiponectin receptors (adipoR1 and AdipoR2) are expressed in the liver. Adiponectin is associated positively with insulin sensitivity and associated negatively with intraabdominal and hepatic fat. Adiponectin stimulates glucose use and fatty acid oxidation in the liver by activating AMP-activated protein kinase AMPK) and PPAR-α [67]. Moreover, adiponectin exerts a protective action on liver fat accumulation, favoring lipolysis by promoting the action of CPT-1 and enhancing fatty acid transport into the mitochondria to undergo β-oxidation, while preventing the action of FAS, ACO, and TNF-α and decreasing the expression and action of CD-36 protein that promotes the transport of fatty acids [112]. Adiponectin induces suppression of sterol response element-binding protein-1C (SREBPC-1), a key factor regulating lipogenic gene expression in the liver. In addition, adiponectin lowers toxic hepatic ceramide accumulation by enhancing ceramidase activity. Recently it has emerged that FGF21, released by adipose tissue, the liver, and the skeletal muscle, increases adiponectin levels. Also the treatment of T2D subjects with pioglitazone also increases adiponectin levels, and this has been associated with decreases in hepatic fat and correlated positively with hepatic and peripheral insulin sensitivity both pretreatment and posttreatment [253].

Leptin prevents de novo lipogenesis while activating β-oxidation of fatty acids in the liver and has anti-inflammatory effects on the liver. Leptin increases inclusion of triglycerides into VLDL enabling the release of lipid from the liver. Clinical trial are currently ongoing to show the effect of leptin therapy for NAFLD.

With respect to the role of the inflammatory cytokines IL-6 and TNF-α, the plasma levels of these two inflammatory cytokines are increased in subjects with NAFLD and NASH [111]. Moreover, the peripheral blood monocyte production of TNF-α and IL-6 is increased in subjects with NASH [254].

β-Cell Dysfunction in Obese T2D Subjects

In obese insulin-resistant subjects, the pancreatic β-cells homeostatically increase insulin secretion to maintain glucose levels. The mechanisms involved in this β-cell compensation are not well known, but result in both increased generation of β-cells and enhanced β-cell functional responses (Fig. 14.5) [259, 260]. β-cell mass is increased in obese compared with lean subjects [256]. The signaling for compensatory β-cell mass expansion may include increased glucose and FFAs (probably the most important direct stimulus), insulin, and other growth factors [259]. Glucose is the natural stimulus to release storage granules and to synthesize insulin by β-cells. Glucose must enter the β-cell by a special glucose transporter (GLUT2), increasing pyruvate and ATP/ADP ratio (glucose oxidation) which trigger insulin release (first phase) [261]. The maintenance of hyperglycemia stimulates specific β-cell glucokinase (GK) activity which forms 6-P-glucose that increases insulin production (second phase) [261]. The expression of GK and GLT2 are directly associated with the differentiation of β-cells, and both are regulated by PDX1 [262].

In addition, FFAs are essential for amplification of glucose-stimulated insulin secretion (GSIS), and other nutrient and non-nutrient stimulus [263]. First, the binding of FFAs

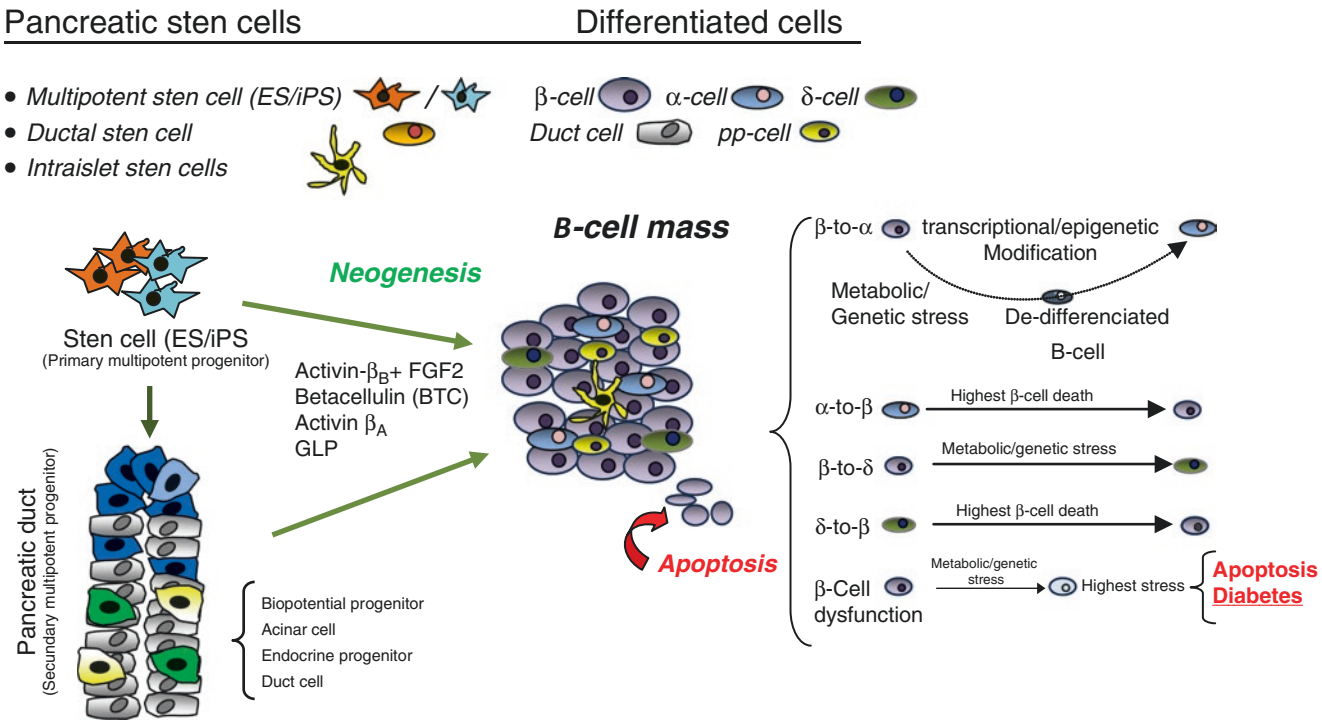

Fig. 14.5 Pancreatic β-cell failure appears as fundamental in the development of hyperglycemia in T2D, although insulin resistance may have been present for many years [255]. Insulin levels increase rapidly in relation with weight gain, probably associated with impaired insulin action; therefore hyperinsulinemia is frequently observed at diagnosis of T2D in obese subjects. However, only ~20% of obese subjects develop diabetes, while the remainder can maintain elevated insulin levels without hyperglycemia for many years. Thus, it appears that β-cell mass could progressively be reduced until it crosses a set point where insulin secretion is no longer sufficient to maintain the normal glycemic range in obese type 2 diabetic patients. Today, an increase in apoptosis of β-cells greater than a decrease in neogenesis is the most accepted cause for the loss of β-cell mass (Figure 14.5) [256]. β-cell death can be increased by an accumulation of high toxic lipids, a human islet amyloid polypeptide, and finally by the generation of high levels of glucose in the type 2 diabetes with obesity. In addition, in obese individuals, a high demand for insulin increases endoplasmic reticulum dysfunction (ER stress), and also hyperglycemia increases reactive oxygen species (oxidative stress)—both contributing to apoptosis of β-cells. Thus, if β-cell mass is lower than 50%, the remaining β-cells try to increase their function in order to compensate, which produces chronic β-cell stress. Therefore, proinsulin levels are frequently increased early in developing T2D, probably due to ER stress of β-cells. In addition, proinsulin levels after hemipancreatectomy determine the risk of developing diabetes, mainly in obese patients. Furthermore, the incretin effect is decreased in type 2 diabetes, affecting insulin secretion rates expressed as a percentage of insulin secretion. The incretin effect on total insulin secretion and β-cell glucose sensitivity and the GLP-1 response to oral glucose were significantly reduced in diabetes compared with NGT or IGT. Glucose tolerance and obesity inhibit the incretin effect independently [257]. In healthy subjects, infusion of physiological levels of GLP-1 increase insulin secretion. However, in patients with type 2 diabetes, physiological levels of GLP-1 had no effect on insulin release, whereas the infusion of GLP-1 at pharmacological levels (1 pmol/kg/min) increased just the "late-phase" (20–120 min) insulin response to levels similar to healthy subjects [258]. Furthermore, inflammatory pathways, such as increased interleukin-1β within islet β-cells, are involved in β-cell apoptosis in type 2 diabetes. Although the half-life and neogenesis rates of β-cells are difficult to establish in humans, it appears that β-cell can take several years to regenerate. However, interventions such as bariatric surgery can improve β-cell function in a few weeks in obese type 2 diabetes patients. In addition, β-cell function improved in obese T2D patients treated with a very-low-calorie diet (VLCD) weeks before insulin sensitivity was changed

to FFAR1/GPR40 receptors increases intracellular Ca^{2+} necessary for insulin release and second, through the generation of malonyl-CoA (inhibits fatty acid oxidation), which increases intracellular LC-CoA and diacylglycerol levels (DAG), in the malonyl-CoA/LC-CoA pathway [263, 264]. In addition, nutrients stimulate L-cells in the ileon, and higher fat content in food raises levels of glucagon-like peptide 1 (GLP-1) [265]. GLP-1 and FFAs can have synergistic actions, increasing GSIS [266], which may also stimulate β-cell growth [267, 268]. However, the incretin effect gets progressively impaired during the transition from IGT to diabetes. In addition, obesity and glucose tolerance each attenuate the incretin effect on β-cell function and GLP-1 response [257]. Pancreatic cells are connected with the parasympathetic system increasing insulin secretion, and its hyperactivity may be involved in the growth of β-cells [269]. Histological studies of the pancreas from necropsies and surgery have supplied important data for our knowledge of pathogenesis of islet β-cell dysfunction in T2D [256, 270]. An important research focused on the pancreas obtained from necropsies analyzed the total number of beta-cells (β-cell mass), the stage of beta-cell in regeneration and those

in apoptosis (Fig. 14.5). One hundred and twenty-four pancreases in total from lean and obese subjects were investigated, both groups having normal glucose tolerance and T2D and the obese group having the addition of impaired fasting glucose (IFG) [256]. In patients with normal glucose tolerance, the study found that relative cell volume was increased in obese versus lean cases ($P = 0.05$), increasing the mechanism of neogenesis ($P < 0.05$). However, a decrease of 40% and 63% in β-cell mass in IFG and T2D obese patients compared with obese normal glucose tolerance subject was also observed. Lean T2D patients compared with lean normal glucose tolerance subjects had a reduction of 59% in β-cell mass. The reduction of β-cell mass is evident in patients with impaired fasting glucose, suggesting that the loss of β-cell mass starts in the early stages. Finally, the study of mechanisms implicated in this loss of β-cell mass found no significant effect on β-cell neogenesis, but β-cell death by apoptosis was increased [256].

Underlying Mechanisms Implicated in β-Cell Failure in T2D

(a) **Glucotoxicity and glycation stress.** Insulin secretion is reduced during periods of hyperglycemia, while the partial recovery of β-cell function is achieved after the control of glucose levels in T2D patients. Glucotoxic mechanisms implicated in β-cell damage include increased glucosamine pathway activity and glycation stress, raised oxidative stress, increased ER stress, activation of inflammatory, and toxic accumulation of islet amyloid polypeptide (IAPP) [271, 272].

(b) **Mitochondrial dysfunction and reactive oxygen species.** Increased surplus of glucose and FFAs raises its oxidation in the mitochondria resulting in increased superoxide generation and production of uncoupling protein 2 (UCP2) in β-cell [273, 274].

(c) **Lipid effects on β-cell function.** An increased surplus of TG/FFA in β-cells induces glucose oxidation by which K+ATP channel pathway can be enhanced [266]. Thus, more than a direct lipotoxicity effect, elevated FFAs, and hyperlipidemia can be a major signal for a flexible adaptation of β-cell mass to obese-induced insulin resistance [266].However, the lipotoxicity effects of increased FFAs on β-cell can be seen more in combination with chronic hyperglycemia (glucolipotoxicity) [123, 264]. During hyperglycemia AMPK/malonyl-CoA signaling is stimulated, which slows down mitochondrial fat oxidation and promotes FFA accumulation in more complex lipids, some of which are lipotoxic [123, 264].

(d) **Islet β-cell exhaustion and ER stress.** The high requirements of insulin synthesis initiates mechanisms for compensating β-cell mass and generates high-endoplasmic-reticulum (ER) activity for the production of proinsulin. Continuous formation of proteins including insulin results in stress and dysfunction of the ER which affects the normal pattern of insulin secretion, a significant component of β-cell failure in T2D [275].

(e) **Differentiation of Undifferentiated Cells to Pancreatic β-cells.**

Hyperplasia, proliferation, and neogenesis of pancreatic β-cells may be adapted in relation to obese-induced insulin resistance and transitory β-cell damage. In humans pancreatic β-cell proliferation in pregnancy and T2D has not been observed. Therefore, similar to factors that induce multipotent stem cells (ES/iPS) to produce β-cells, we may be able to identify factors that inhibit pancreatic β-cell proliferation in various conditions. In humans, hyperglycemia progress is related with β-cell failure associated with a reduction of β-cell mass by increased apoptosis or dedifferentiation of β-cells during metabolic stressors such as is observed with obesity (Fig. 14.5).

Fate change between the different endocrine cells is observed under different conditions of stress. This may occur either directly or through a dedifferentiated state. Continued stress on the β-cell can lead to dedifferentiation that causes diabetes [276]. Future studies of some compounds that regulate endogenous stem cell differentiation could lead to drugs that stimulate β-cell neogenesis [277].

Multiple-Choice Questions

1. Talking about "Obesity, measurements, and assessment," which of the following statements is not correct?
   (a) Body mass index (BMI) is currently used to classify from low and normal weight to overweight and obese state in adults and is estimated by the weight/height squared ratio.
   (b) Deaths associated with a high BMI are ranked fourth behind deaths from hypertension, smoking, and unhealthy diets and ahead of deaths related to hyperglycemia, sedentary life style, high-salt intake, alcoholism, and high blood cholesterol level.
   (c) Several clinical parameters can be used to estimate central obesity, with the most widely being waist circumference (WC), hip ratio (HR), and waist-HR (WHR).
   (d) In research, to measure obesity and body fat distribution, more complex and more accurate techniques are used, such as dual energy X-ray absorptiometry

(DEXA), computed tomography (CT), and magnetic resonance imaging (MRI).

(e) **In research the single-voxel magnetic resonance spectroscopy is the gold standard for measuring distribution of body fat.**

2. With respect to the "Adipocyte and adiposity development," which of the following statements is not true?
   (a) In humans there are two types of well-differentiated adipose tissues, which have different distribution and functions, and are referred to as white adipose tissue (WAT) and brown adipose tissue (BAT).
   (b) The WAT is mainly related to the function of deposit of surplus energy as triacylglycerol, which could be mobilized and offered through hormonal signaling and has a tremendous ability to expand.
   (c) Adiponectin increases adipocyte lipid storage and prevents ectopic lipid accumulation. In addition, leptin decreases lipogenesis and increases lipolysis and fatty acid oxidation.
   (d) **Thermogenic function of BAT is mediated by the activation of a specific mitochondrial uncoupling protein 1 (UCP1), where the saturation of the production of ATP is dissipated as heat. Therefore, the activation of these sites with BAT decreases basal energy expenditure and increases onset of diabetes.**
   (e) The third fat cells, i.e., brown adipocytes, are also found infiltrating the skeletal muscle and in different areas of WAT. This could mean that the rate of lipid storage or lipid oxidation could be adapted and adjusted.
3. Which characteristics or pleiotropic effects of hormones and adipokines on adipogenesis and glucose metabolism is not correct?
   (a) Adipocyte differentiation and lipogenesis require insulin receptors and insulin action.
   (b) The infusion of hydrocortisone increases levels of circulating free fatty acids (FFA) associated with the activation mechanisms of lipolysis.
   (c) **The PPAR-γ agonists (thiazolidinediones, TZDs) increase central fat depots, decrease adiponectin levels, worsen lipid profile and insulin-sensitivity, and increase liver fat in NAFLD.**
   (d) Leptin is secreted by fat cells, establishing a negative feedback between the amount of adipose tissue and satiety centers in the brain.
   (e) Adiponectin is produced in mature adipocytes and is higher in peripheral adipose tissue than visceral adipose tissue.
4. Talking about inflammatory adipokines, all is true except for one.
   (a) Both TNF-α gene and its receptors are present in adipocytes and at higher levels in WAT. Increased release of TNF-α from adipose tissue may play a role in the impairment of insulin action.
   (b) **TNF-α increases the expression of PPAR-γ and increases the expression of genes involved in lipid and glucose uptake.**
   (c) A fatty acid-binding protein (aP2) could be the link between FFA and increased expression of TNF-α in obesity.
   (d) About one third of the total concentration of IL-6 is produced in adipose tissue, mainly in visceral adipose tissue compared with peripheral adipose tissue.
   (e) IL-6 levels are directly linked to obesity and insulin resistance and inhibit the activity of lipoprotein lipase (LPL).
5. Which of the "obesity effects on pathogenesis of type 2 diabetes" is not completely true?
   (a) Type 2 diabetes mellitus (T2D), at least at the beginning, is characterized by hyperglycemia, insulin resistance, and impairment in insulin secretion. The prevalence has increased as a result of obesity and sedentary lifestyle. But, can arise genetic or varying environmental factors, which complicates findings the cause in diabetic patients.
   (b) **The risk of T2D and cardiovascular disease rises not only with the amount of body fat and particularly increases when fat accumulation is in the peripheral depots.**
   (c) Increased and altered secretion of adipokines in obesity (TNF-α, adiponectin, leptin, etc.) contribute to insulin resistance.
   (d) Ectopic fat deposition, predominantly in the liver, skeletal muscle, and β-cell, contributes to altered fat and glucose metabolism.
   (e) Mitochondrial dysfunction and endoplasmic reticulum stress could be a link between obesity and diabetes, by decreasing insulin sensitivity and altering β-cell function.
6. In relation to "Obesity and Lipotoxicity Syndrome," all is true except for one statement.
   (a) Adipose tissue is the primary responsible for fat storage. Thus, a correctly functioning adipose tissue is necessary to maintain an adjusted delivery of surplus fuel to other tissues and nontoxic storage of lipids.
   (b) When the adipocytes enlarges, it develop insulin resistance; the antilipolytic effects of insulin is reduced. The increase of FFA in plasma results in more insulin resistance in the muscle and liver, inhibits insulin secretion, and induces β-cell apoptosis.

(c) **Leptin secretion decreases in parallel with fat accumulation, and as a result, the adipose tissue expands. Leptin action appears to be implicated in processes that increase lipotoxicity in non-adipose tissues.**
(d) Leptin regulates and increases β-oxidation through controlling peroxisome proliferator-activated receptor-α (PPAR-α) activity by minimizing ectopic accumulation of lipids.
(e) Adiponectin have a major role in improving insulin sensitivity, anti-inflammatory, anti-apoptotic, and pro-angiogenic effects that enhance the metabolic flexibility of adipose tissue.

7. In relation with "Pathogenesis of Obese Type 2 Diabetes," find out the statement that is not true.
(a) There are overweight subjects who maintain normal glucose tolerance. These can gain weight associated with insulin resistance (IR), but their acute insulin response (AIR) could be adjusted upward.
(b) The gastrointestinal tract is a large endocrine organ that releases two major incretin peptides. The glucagon-like 1 (GLP-1) by L-cells (distal small intestine) and glucose-dependent insulinotropic peptide (GIP) by k-cells (early small intestine) jointly rise by 60–70% insulin released in response to a mixed meal.
(c) GLP-1 reduces glucagon releases by α-cells on the pancreas and reduces appetite. In T2D patients the GLP-1 resistance results in hyperglucagonemia and increased HGP and weight gain by eating.
(d) **The kidney generates about a 15–20% of the endogenous glucose production, mainly in fasting period, and is controlled by insulin function. But the kidney in obese T2D is insulin resistant, and glucose production is decreased.**
(e) The glucose filtered is reabsorbed by sodium glucose transporter 2 (SGLT2) (80–90%) and SGLT1 (10–20%). When hyperglycemia is initiated, these capacity of reabsorption is increased and contributes to maintain elevated glucose levels and retention of sodium and water.

8. In relation with "β-cell dysfunction in obese T2D subjects," all are correct except one.
(a) In obese insulin-resistant subjects, pancreatic β-cells increases insulin secretion to maintain glucose levels. The mechanisms involved in this β-cell compensation are not well known, but implicate both increased generation of β-cells and enhanced β-cell responses.
(b) **The signaling for compensatory β-cell mass expansion includes increased glucose, while mainly FFAs, GLP-1, and insulin decrease β-cell mass, increasing apoptosis.**
(c) Glucose is the natural stimulus to release storage granules and to synthesize insulin by β-cells. Glucose must enter β-cell by a special glucose transporter (GLUT2) increasing pyruvate and ATP/ADP ratio (glucose oxidation) which trigger insulin release (first phase of insulin secretion).
(d) The maintenance of hyperglycemia stimulates specific β-cell glucokinase (GK) activity which forms 6-P-glucose that increases insulin production (second phase of insulin secretion).
(e) Pancreatic cells are connected by the parasympathetic system increasing insulin secretion, and its hyperactivity may be involved in the growth of β-cells.

9. Histological studies of the pancreas from necropsies and surgery have supplied important data for our knowledge of pathogenesis of islet β-cell dysfunction in T2D. Which of the following is not true?
(a) **In patients with normal glucose, tolerance has been found that relative cell volume is decreased in obese versus lean cases, decreasing the mechanism of neogenesis.**
(b) A decrease of 40 and 63% in β-cell mass in IFG and T2D obese patients compared with obese normal glucose tolerance subject has been also observed.
(c) Lean T2D patients compared with lean normal glucose tolerance subjects had a reduction of 59% in β-cell mass.
(d) The reduction of β-cell mass is evident in patients with impaired fasting glucose, suggesting that the loss of β-cell mass starts in the early stages.
(e) The study of mechanisms implicated in this loss of β-cell mass found no significant effect on β-cell neogenesis, but β-cell death by apoptosis was increased.

10. Talking about "the underlying mechanisms involved in the failure of β-cells in T2D," point out the incorrect one.
(a) Insulin secretion is reduced during periods of hyperglycemia, while partial recovery of β-cell function is achieved after the control of glucose levels in T2D patients (glucotoxic mechanisms).
(b) Glucotoxic mechanisms implicated in β-cell damage include increased glucosamine pathway activity and glycation stress, raised oxidative stress, increased ER stress, activation of inflammatory, and toxic accumulation of islet amyloid polypeptide (IAPP).
(c) An increased surplus of TG/FFA in β-cells induces glucose oxidation. Thus, more than a direct lipotoxicity effect, elevated FFAs, and hyperlipidemia can be a major signal for a flexible adaptation of β-cell mass to obese-induced insulin resistance.

(d) The lipotoxicity effects of increased FFAs on β-cell can be seen more in combination with chronic hyperglycemia (glucolipotoxicity).

(e) **Continuous formation of proteins, including insulin, results in stress and dysfunction of endoplasmic reticulum (ER) activity which does not affect the normal pattern of insulin secretion in T2D.**

11. The differentiation of undifferentiated cells to pancreatic β-cells plays a key role in the maintenance of the β-cell mass. Point out the incorrect of the following.

(a) Hyperplasia, proliferation, and neogenesis of pancreatic β-cells may be adapted in relation to obese-induced insulin resistance and transitory β-cell damage.

(b) In humans, hyperglycemia progress related with β-cell failure is associated with a reduction of β-cell mass by increased apoptosis and/or de-differentiation of β-cells during metabolic stressors such as is observed with obesity.

(c) Fate change of differentiation from multipotent stem cells (ES/iPS) between the different endocrine cells is observed under different conditions of stress.

(d) **Continued stress on the β-cell could lead to its dedifferentiation in α-cell, which will not affect the normal pattern of insulin secretion in T2D.**

(e) Future studies of some compounds that regulate endogenous stem cell differentiation could lead to drugs that stimulate β-cell neogenesis.

Conflict-of-Interest Statement The authors do not have potential conflict of interest.

Pathogenesis of Gestational Diabetes Mellitus

15

Evangelia Kintiraki, Gesthimani Mintziori, and Dimitrios G. Goulis

Introduction

According to the American Diabetes Association (ADA), gestational diabetes mellitus (GDM) is defined as hyperglycemia diagnosed in the second or third trimester of pregnancy that was not overt diabetes before gestation. It constitutes the most common metabolic disease of pregnancy, with a continuously increasing prevalence [1, 2]. It has been associated with several maternal and fetal/neonatal complications [3, 4]. Increased maternal age; increased pre-pregnancy body mass index (BMI); excessive weight gain during pregnancy; Aboriginal Australia, Middle East, and pacific island ethnicity; positive family history of GDM; and higher parity are established risk factors for developing GDM [5, 6]. GDM, similarly to type 2 diabetes mellitus (T2DM), is a multifactorial disease; its pathogenetic mechanisms are not yet fully understood. Genetic predisposition and acquired factors (lifestyle and environmental) that affect insulin sensitivity and β-cell function have been implicated in GDM development and determine the disease severity [7]. Hormonal, inflammatory, and immunologic factors contribute to insulin production, secretion, and action, resulting in uncompensated insulin resistance and GDM development. Suboptimal lifestyles, such as hypercaloric diet, unhealthy nutritional habits, and reduced physical activity, contribute to central obesity and acquired triggering factors for GDM [8, 9].

Insulin Sensitivity

Introduction

A major pathogenetic mechanism for GDM development is the reduced insulin sensitivity, called "insulin resistance," that progressively occurs in normal pregnancy. During the second half of gestation, the levels of placental and maternal hormones and pro-inflammatory cytokines increase in favor of fetal well-being and growth, thereby reducing maternal insulin sensitivity. In a healthy pregnancy, the expansion of the functional mass of β-cells compensates for the increased insulin demands resulting from the reduced insulin sensitivity. Insufficient β-cell compensation (see section "β-Cell Function and Insulin Secretion") or "excessive" decrease of insulin sensitivity results in GDM development.

Insulin action is impaired at hepatic, muscle, and adipose tissue levels in patients with GDM [10–12]. At the molecular level, insulin resistance is usually a failure of insulin signaling. Normally, insulin binding to insulin receptors causes phosphorylation of β-subunit of the receptor. It further leads to phosphorylation of insulin receptor substrate-I (IRS-I) at tyrosine residue, which acts as a docking site for other signal transduction molecules. Impaired post-receptor insulin signaling is mainly responsible for pregnancy-induced insulin resistance. Experimental studies showed impaired mRNA or protein expression of insulin signaling cascade components, such as insulin receptor substrate (IRS)-1 and IRS-2, a subunit of PI 3-kinase, as well as glucose transporter (GLUT)-1 and GLUT-4 in adipose tissue and muscle of women whose pregnancies were complicated by GDM. Decreased IRS-1 tyrosine phosphorylation, decreased GLUT-4 insulin-induced translocation to the cell surface, and decreased glucose transport into the cell were also found in muscle and adipose tissue of women with GDM [13–16]. Similar post-receptor insulin defects have been found in the placenta of GDM-affected pregnancies [17].

Chronic low-grade inflammation that characterizes obesity, which often accompanies GDM pregnancies, contrib-

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_15

utes to insulin signaling impairment and aggravates "normal" gestational insulin resistance [18] and oxidative stress [19]. Alterations in the composition of the gut microbiome and its metabolites also seem to contribute to decreased insulin sensitivity and GDM development.

Placental Hormones

The placenta is a temporary fetal organ that forms the functional interface separating the maternal and fetal circulations and is important for mediating adaptations in maternal physiology. A plethora of hormones secreted by the placenta mediates maternal metabolic alterations to ensure fetal survival, growth, and well-being. They facilitate nutrient, gas, and waste exchange between the maternal and fetal circulations. Placental hormones, such as human placental lactogen (HPL) and placental growth hormone (GH), are opposed to insulin action [20]. HPL is a peptide hormone produced by syncytiotrophoblast and is gradually increased during pregnancy until about the 30th gestational week when it reaches a plateau. It acts mainly via prolactin (PRL) and, to a lesser extent, GH receptors on a wide variety of tissues. It is correlated to fetal weight and well-being as well as placental function [21]. HPL is the main insulin-resistance mediator during pregnancy. It acts as an "anti-insulin" agent to ensure adequate glucose supply to the embryo [22, 23]. HPL raises maternal blood glucose concentrations by increasing insulin resistance and raised free fatty acid concentrations by increasing lipolysis [24]. A sudden drop in HPL concentrations could indicate fetal distress [25–27]. Growth hormone (GH) is an anabolic hormone involved in carbohydrate and lipid metabolism; when in excess, it has diabetogenic properties, opposing insulin action [28]. Human placental GH is the main GH molecule produced during pregnancy, affecting maternal insulin sensitivity [29]. It is produced mainly by placental syncytiotrophoblastic cells and, similarly to HPL, acts mainly via prolactin (PRL) and, to a lesser extent, GH receptors. Opposite to maternal GH, its production and secretion are not regulated by growth hormone-releasing hormone (GH-RH) and is secreted tonically rather than in a pulsatile fashion. It is gradually increased by mid-pregnancy to term. Studies in transgenic mice showed severe insulin resistance induction by placental GH overexpression [30]. Maternal obesity and diabetes in pregnancy may be associated with a disrupted balance in the placental expression of HPL and GH [31]. Progesterone, produced initially by the corpus luteum and later by the placenta, is gradually increased during gestation and reaches many folds of pre-pregnant levels. It is known that progesterone inhibits insulin action in vivo and in vitro, mainly by inhibiting the PI3-kinase pathway of the insulin signaling cascade in the adipocytes [32]. It seems to have a central role in mediating the metabolic changes in pregnancy. Evidence about the association of GDM development and progesterone levels is scarce and conflicting.

Maternal Hormones

Maternal serum GH, other growth factors, such as insulin-like growth factor 1 (IGF-1), also called somatomedin, their binding proteins, prolactin (PRL), progesterone, and cortisol are altered in women whose pregnancies are complicated by GDM as compared to unaffected pregnant women [33, 34]. PRL is produced mainly by anterior pituitary lactotroph cells and, secondary, the central nervous system, immune cells, nonpregnant uterus, placenta, amnion, decidua, and the mammary gland. The most well-known action of PRL is lactation. Other PRL effects are mammary epithelial proliferation, corpus luteum function, and immune response [35, 36]. Evidence about PRL's effect on insulin sensitivity is contradictory. As in patients with a prolactinoma, hyperprolactinemia exacerbates insulin resistance to the nonpregnant state [37, 38]. The latter effect regresses after treatment with a dopaminergic receptor agonist [39]. On the contrary, studies in nonpregnant healthy women (with normal prolactin concentrations) showed that lower prolactin concentrations were correlated to decreased insulin sensitivity and increased risk for diabetes [40, 41]. During pregnancy, PRL is also produced by decidual cells and the fetal pituitary. Maternal PRL is increased gradually by conception to term [42]. In pregnant rats, increased prolactin concentrations have been correlated to a post-receptor insulin defect [20]. In humans, higher concentrations of PRL during the third trimester of pregnancy have been associated with decreased glucose tolerance, implying a causative relationship between hyperprolactinemia and GDM [43]. A recent case-control study of 321 women (107 GDM and 214 non GDM) showed a positive association between PRL levels in the first trimester of gestation and risk of GDM development [44]. On the contrary, in other studies, no difference in PRL concentrations has been found between GDM and controls [32, 45]. It has also been suggested that prolactin receptor gene polymorphisms are associated with gestational diabetes [46]. Maternal, placental, and fetal adrenal steroids; progesterone; cortisol; estrogen; and androgens also contribute to pregnancy-induced insulin resistance [47]. Cortisol can induce insulin resistance through post-receptor insulin defects [20]. Androgen receptors are overexpressed in placentas of GDM-affected pregnancies as compared to controls [48]. Although it is known that estrogens regulate carbohydrate metabolism, the underlying mechanisms are not fully understood. In the nonpregnant state, estradiol (E_2) partially affects insulin signaling by modifying mitochondrial function [49]. In GDM-affected pregnancies, estrogen

concentrations are lower as compared to unaffected pregnant women [50].

Maternal Vitamin D

Vitamin D is primarily known for its vital role in calcium homeostasis, skeletal mineralization, and bone metabolism. Besides this, vitamin D exhibits several extra-skeletal effects. Hypovitaminosis D, defined as low serum concentrations of 25-hydroxy-vitamin D3 ($25(OH)D_3$), has been correlated to many diseases, including metabolic diseases such as diabetes mellitus (T1 and T2DM). Some of its extra-skeletal properties regulate glucose metabolism, possibly through a beneficial effect on both β-cell function and insulin sensitivity. The mechanism of vitamin D effect on the latter is not yet fully understood. It seems to be achieved via different and possibly synergic processes such as indirect antioxidant and anti-inflammatory action, direct action on vitamin D receptor (VDR) expression, and insulin signaling through activation of peroxisome proliferator activator receptor (PPAR-) pathway and genomic action (control of epigenetic genes expression) of vitamin D. Several studies, though not all, have shown an association between low levels of vitamin D and T2DM development, in the nonpregnant state [51, 52]. Regarding GDM, current evidence shows a possible association between vitamin D blood levels and the risk of GDM [53]. However, heterogeneity across studies and contradictory results do not allow for safe conclusions to be drawn. Finally, a recent meta-analysis of 19 RCTs showed that vitamin D supplementation of women with GDM improved their glycemic control and indices of insulin resistance [54].

Maternal Adipokines

Maternal adipokines that are produced by her adipose tissue have a significant effect on insulin action. Their impaired secretion has been associated with several metabolic disorders, including insulin resistance, obesity, and DM2 in the nonpregnant state. It is suggested that adipokines may contribute directly and/or indirectly to metabolic dysregulation by enhancing chronic inflammation, aggravating insulin resistance, and resulting in impaired carbohydrate metabolism. Regarding pregnancy, it seems that impaired adipokines secretion may be associated with GDM development.

Adiponectin, an adipose tissue-derived plasma protein, has, in general, an anti-inflammatory action. It is produced mainly by white adipose tissue (WAT) in the nonpregnant state. It exerts pleiotropic effects through three receptors, AdipoR1, AdipoR2, and T-cadherin. Adiponectin seems to express protective properties for the vascular endothelium and the heart through anti-inflammatory action and suppression of the atherosclerotic processes [55–57]. It also has a beneficial effect on carbohydrate metabolism by increasing insulin sensitivity partially due to her main anti-inflammatory action [58, 59]. Higher concentrations of adiponectin have been associated with a lower risk of T2DM development in nonpregnant women [60]. In pregnancy, evidence about adiponectin concentrations is not consistent; all investigators have not confirmed placental production of adiponectin [61, 62]. Some studies have demonstrated increased adiponectin concentrations in early pregnancy and a gradual decrease after that compared to the pre-pregnancy state [63, 64]. In contrast, others suggest constant [65] or "normal" lower levels of adiponectin (hypoadiponectinemia) during pregnancy as compared to the nonpregnant state. Although evidence regarding gestational concentrations of adiponectin and carbohydrate metabolism is less clear, a link between hypoadiponectinemia and insulin resistance exists [64, 66], as pregnant women with GDM have lower adiponectin levels than healthy controls [65, 67].

Another adipokine, leptin, the most well-studied one, plays a central role in neuroendocrine signaling, homeostasis, and metabolism. It acts via hypothalamic leptin receptors and is strongly involved in metabolic issues affecting insulin secretion and action and tissue insulin sensitivity [68, 69]. Leptin is produced mainly by WAT adipocytes, proportionally to adipose tissue mass [70]. To a lesser degree, it is produced by brown adipose tissue (BAT), placenta, skeletal muscle cells, ovaries, and gastric cells. Leptin's primary action is the regulation of energy homeostasis [71]. In contrast to adiponectin, leptin has pro-inflammatory actions and, if in excess, exerts a deleterious effect on carbohydrate metabolism. It reduces insulin synthesis and secretion via negative feedback, whereas simultaneously increases tissue sensitivity to it [69, 72]. Obesity is associated with resistance to leptin action [73]. Its secretion is gradually increased during pregnancy, reaching a plateau, and is decreased before delivery. Placenta-derived leptin results in nearly a 100% increase in maternal serum concentrations [74, 75]. Further increased leptin concentrations have been found in GDM-affected women compared to non-affected pregnant women [76, 77]. Moreover, increased expression of leptin receptors has been found in the placenta of GDM-affected pregnancies [78]. Both adiponectin and leptin gene polymorphisms have been correlated to GDM occurrence [79]. Low adiponectin and high leptin concentrations during the first trimester may predict GDM occurrence during later pregnancy [80, 81].

Other adipokines such as fetuin B, visfatin, resistin, and apelin have been lately implicated in GDM pathogenesis. It is known that fetuin B impairs insulin action. Women with GDM-affected pregnancies have higher fetuin B concentrations as compared to controls [82]. Visfatin, or pre-B cell colony-enhancing factor (PBEF) or nicotinamide phosphoribosyltransferase (NAMPT), is produced mainly by the

human visceral adipose tissue. Though its action is not yet fully understood, it seems to get involved in energy homeostasis. It has been shown that visfatin elicits insulin-mimetic effects via binding to and activating insulin receptors in hepatocytes, myocytes, and adipocytes. Moreover, it increased insulin sensitivity in diabetic mice. During pregnancy, it is also produced by the human placenta, although to a lesser degree. Current results about the association of visfatin levels and GDM development are conflicting [83]. Resistin is a polypeptide secreted by adipose tissue in rodents and by macrophages in humans. It elicits pro-inflammatory activity and induces insulin resistance. A meta-analysis of 18 studies showed a positive association between maternal serum resistin levels and the risk of gestational diabetes mellitus [84, 85]. Data on apelin concentrations and their association with GDM are not consistent. Other novel adipokines, such as omentin and chemerin, have been associated with GDM development, and a causal effect is implied by some investigators [86].

Immunological Changes and Low-Grade Inflammation

Normal pregnancy is accompanied by immunological changes and a low-grade inflammation to the fetus's benefit [87, 88]. Inflammation is exacerbated by obesity, a common risk factor of GDM, and affects insulin sensitivity through post-receptor signaling defects. Inflammatory cytokines, such as tumor necrosis factor-α (TNF-α), directly affect insulin action in healthy nonpregnant women, inducing insulin resistance [89]. TNF-α is a transmembrane protein produced mainly by activated macrophages in response to immunological stimulus [90]. To a lesser degree, it is expressed by other cells, such as lymphoid cells, cardiac myocytes, endothelial cells, and adipocytes. It expresses a cytotoxic effect on many cells; simultaneously, it regenerates tissues [91, 92]. TNF-α induces phosphorylation of the IRS-1, thus preventing the interaction of insulin with the insulin receptor and impairing insulin action. Interleukin-6 (IL-6) is a pro-inflammatory cytokine and an anti-inflammatory myokine expressed by immune cells, such as T cells and macrophages, visceral adipocytes, osteoblasts, and vascular smooth muscle cells. It is the main stimulator of the production of many acute-phase proteins. It impairs insulin-induced insulin receptor and IRS-1 phosphorylation, resulting in the inhibition of the insulin signaling cascade [93]. C-reactive protein (CRP) is an acute-phase protein of hepatic origin that is increased in response to inflammation and IL-6 secretion. It acts through activation of the complement system, triggering phagocytosis by immune cells. CRP is associated with insulin resistance in healthy individuals; high concentrations of high-sensitivity (hs)-CRP indicate a higher risk for metabolic, cardiovascular, and cerebrovascular disease [94]. The Generation R Study showed that increased CRP concentrations during early gestation are associated with a high risk of neonatal complications [95]. During normal pregnancy, low-grade inflammatory markers, such as CRP, IL-6, TNF-α, and GlycA, increase, suggesting an upregulation of systemic maternal inflammation [87, 96]. In contrast to this normal maternal adaptation, a further increase of some inflammatory markers is considered a risk factor for adverse pregnancy outcomes, including GDM. Specifically, it has been shown that women with GDM-affected pregnancies have increased IL-6 concentrations compared to controls [97]. In a recent meta-analysis, TNF-α is higher in GDM pregnancies compared to controls, independently of BMI [77]. CRP has been associated with GDM; an increase in its concentrations during early pregnancy is predictive of GDM development later in pregnancy [98, 99].

Oxidative Stress

Normal pregnancy is considered a condition of increased oxidative stress. Several pathologic conditions during pregnancy, including GDM, are associated with further aggravation of oxidative stress. It is believed that oxidative stress is caused either by increased reactive oxygen species (ROS) production or reduced antioxidant capacity [19]. Both increased oxidative stress markers and a decrease in antioxidative factors have been found in GDM-affected pregnancies. ROS induce an inflammatory response and inflammatory protein expression, aggravating the normal low-grade inflammation and insulin resistance during pregnancy. Furthermore, increased protein oxidation due to enhanced oxidative stress could be implicated in GDM pathogenesis [99, 100].

Maternal Gut Microbiome

Over the past few years, it has been increasingly indicated that alterations of the composition of the microorganisms colonizing the human gut, known as gut microbiome or microbiota, play a key role in developing metabolic disease. The gut microbiome has a pivotal role in regulating metabolic homeostasis. It is implied that a tripartite interaction between the intestine microbiome, immune system, and metabolism is a crucial participant in the pathogenesis of the metabolic disease, including type 2 diabetes mellitus (T2DM). It seems that an imbalance between commensal symbionts and pathobionts known as "gut dysbiosis" contributes to insulin resistance and chronic low-grade inflammation in T2DM patients. The production of metabolites during fermentation, activation of inflammatory cascades

leading to cytokine release, disruption of the permeability of the intestinal mucosal barrier, influx of toxins, and direct signaling action through incretin secretion are some of the implicated pathogenetic mechanisms [101]. Regarding GDM, although the impact of the microbiome on its development remains controversial, a growing body of evidence implies an association of gut microbiota dysbiosis to GDM. Alterations to microbial richness and composition, energy, and metabolic and transport pathways in the microbiome of GDM patients have been reported by some researchers. Because the diet is a powerful modulator of the gut microbiota, the latter represents a novel potential therapeutic target for GDM [102, 103].

β-Cell Function and Insulin Secretion

Introduction

The β-cell primary function is the production, storage, and secretion of insulin. β-cell dysfunction or failure can occur at any stage of the above processes, proinsulin synthesis, post-translational modifications, granule storage, sensing of blood glucose concentrations, and exocytosis of granules, resulting in hyperglycemia.

As mentioned above, during normal pregnancy, pancreatic cells adaptation occurs to compensate for the increased need for insulin. β-cell expansion and hyperfunctioning occur early in pregnancy to cope with the decreased insulin sensitivity after the second half of pregnancy [104]. Placental and maternal hormones, together with local regulators, like hepatocyte growth factor (HGF) and serotonin, work cooperatively to activate several signaling pathways, transcription factors, and epigenetic regulators to drive adaptations in β-cell mass and function during pregnancy. GDM is characterized by decreased insulin response to oral glucose and protein, sluggish first-phase insulin secretion, and delayed peak insulin secretion [105]. Subclinical pre-existing β-cell dysfunction and, to a lesser extent, a gradual decline of β-cell function during pregnancy due to the effect of maternal hormones and inflammatory mediators on its function constitutes the main mechanisms for the occurrence of GDM [106, 107]. Pre-existing β-cell dysfunction, due to genetic predisposition, does not allow for compensatory pancreatic β-cell hyperfunction to counter-regulate for the increased insulin resistance of pregnancy (Fig. 15.1) [108]. β-cell dysfunction in pregnancies complicated by GDM persists postpartum as compared to controls. Given the normalization of insulin sensitivity after delivery, only a small percentage of women with GDM remains within diabetic ranges; nevertheless, the risk for developing T2DM later in life remains increased (Fig. 15.2) [109]. An imbalance of hormonal and inflammatory factors, "glucotoxicity," "lipotoxicity," and oxidative stress have been associated with the aggravation of β-cell function and GDM development.

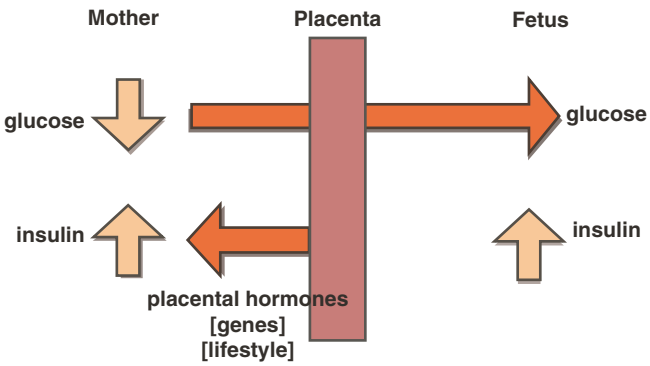

Fig. 15.1 Pathogenesis of GDM: the combination of maternal and placental hormonal alteration, genetic predisposition, and suboptimal lifestyle. (Adapted from: Poulakos P, et al. Comments on gestational diabetes mellitus: from pathophysiology to clinical practice. Hormones 2015;14:335–344)

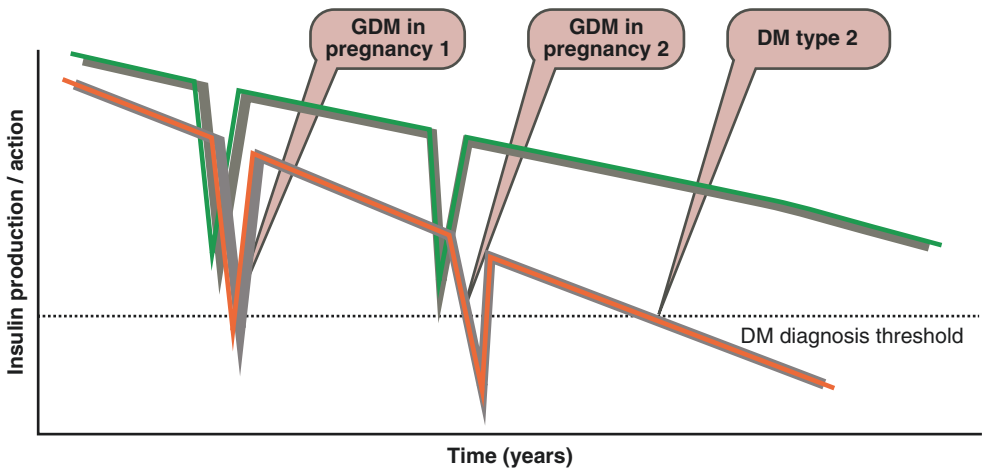

Fig. 15.2 T2DM development in women with prior GDM. Women with a history of GDM have an increased probability of developing GDM in later life due to genetic predisposition and suboptimal lifestyle. Maternal Hormones

The effect of maternal hormones on β-cell function and proliferation during pregnancy is still not completely understood. Although some results are contradictory, it is mainly suggested that they partially mediate β-cell proliferation, growth, neogenesis, insulin secretion, and apoptosis. Although PRL is considered a major regulator of β-cell expansion and hyperfunction during pregnancy, higher prolactin concentrations have been correlated to decreased glucose tolerance during late pregnancy [43, 110]. PRL receptor-null mice have shown β-cell maladaptation during pregnancy [111]. Moreover, PRL has been found to reduce menin concentrations, a known tumor suppression factor that suppresses β-cell proliferation and may be implicated in GDM development in pregnant mice [112]. 17β-estradiol seemed to be involved in β-cell adaptation and insulin secretion during pregnancy, specifically β-cell survival [113, 114]. Progesterone receptor-knockout mice have increased insulin secretion, probably due to increased β-cell mass [115]. The latter is in accordance with another experimental study that showed an apoptotic action of progesterone to pancreatic β-cells through an oxidative-stress-dependent mechanism [116]. Accumulating data have shown adipokines have a significant effect on β-cell function and survival. A leptin-induced decrease of insulin secretion by direct action on β-cells has been suggested. Moreover, leptin affects β-cell proliferation and apoptosis and inhibits insulin gene expression [117]. Another adipokine, adiponectin, seems to act directly on β-cell through its pancreatic receptors. It is known that adiponectin induces insulin release by β-cells through amplifying the exocytosis of insulin granules and increasing the insulin gene expression. Moreover, it reduces the rate of apoptosis in β-cells. Based on the evidence so far available, it is suggested that adipokines may have a crucial role in β-cell failure in the nonpregnant state [118]. Similarly, an imbalance of adipokines levels has been associated with GDM development [119].

Placental Hormones

Several hormones produced by the placenta have a key role in compensatory processes activated during gestation to maintain maternal euglycemia. It has been shown in animal studies that maternal β-cell compensation occurs before insulin resistance development and that the required β-cell expansion depends on secreted placental lactogens that signal through the prolactin receptors. Like maternal PRL, placental lactogens (PRL, PRL-like proteins, and HPL) seem to induce β-cell mass expansion by increasing β-cell proliferation and reducing their apoptosis in vivo and in vitro. Besides this adaptive increase in pancreatic β-cell mass, PRL and HPL also stimulate glucose-induced insulin secretion principally through upregulation of the glucose sensors [120]. Regarding GDM, polymorphisms or mutations in genes of the above hormones and their receptors have been reported in GDM-affected pregnancies. Other placenta-derived hormones, such as kisspeptin, are secreted into the maternal circulation, causing a significant increase in maternal blood concentrations, especially during the second and third trimester of pregnancy. Kisspeptin is a neuropeptide that in the nonpregnant state is most notably expressed in the hypothalamus and to a lesser extent in other areas such as pancreatic β-cells, liver adipose tissue, and brain. In addition to its known regulatory effect on human reproduction, novel peripheral roles for kisspeptin have been identified in metabolic pathways. Regarding GDM, low maternal concentrations of kisspeptin were observed in affected women [121].

Low-Grade Inflammation

As mentioned above, the low-grade inflammation that characterizes GDM affects glucose metabolism by increasing insulin resistance. Additionally, an impairment in adipokines production, possibly due to this inflammation, has also been correlated to β-cell dysfunction and decreased insulin secretion [77, 122]. Specifically, GDM-affected women have lower adiponectin concentrations as compared to controls [77, 123]. This hypoadiponectinemia of GDM pregnancy has been associated with β-cell dysfunction [124]. As part of the low-grade inflammation, GDM-affected women have increased TNF-α concentrations [77]. Beyond insulin resistance, TNF-α has a pro-apoptotic effect on β-cells [125]. The latter could contribute to the reduced insulin secretion of GDM. As mentioned above, GDM-affected women have lower concentrations of 25(OH)D_3. Vitamin D deficiency has also been associated with increased concentrations of inflammatory markers that could further deteriorate β-cell function [126].

Oxidative Stress

Beyond insulin resistance, oxidative stress per se or due to inflammation and hyperglycemia has been linked to decreased insulin secretion during the nonpregnant state [127]. GDM is characterized by increased oxidative stress as determined by increased concentrations of advanced glycosylated end products (AGEs) and other oxidative lipid and protein damage [100, 128]. Recently, a furan fatty acid metabolite, 3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid (CMPF), has been recognized as a possible negative

regulator of β-cell function, inhibiting insulin synthesis and secretion through oxidative stress and mitochondrial dysfunction in human and mouse islets. Women with GDM have increased concentrations of CMPF as compared to controls [129]. Moreover, in GDM-affected women, CMPF predicted lower β-cell function indices [107].

Glucotoxicity and Lipotoxicity

The term "glucotoxicity" has been coined to describe the harmful effects of increased glucose levels per se on β-cell function and survival. "Glucotoxicity" is a well-known aggravating factor of β-cell function and autophagy. It is known that insulin resistance leads to hyperglycemia, and hyperglycemia itself reduces the insulin secretion capacity of pancreatic β-cells in T2DM patients. The latter vicious circle may finally lead to the total incapacity of β-cells to secrete insulin. Oxidative and endoplasmic reticulum stress and mitochondrial dysfunction seem to be the main pathogenetic mechanism of hyperglycemia-induced β-cell failure. Reduced mass, insulin secretion, and compromised identity of β-cell are the potential alterations induced by glucotoxicity [130]. Given that T2DM and GDM share common pathogenetic mechanisms, glucotoxicity could also be implicated in GDM pathogenesis.

The term "lipotoxicity" has been coined to describe the harmful effects of lipid accumulation, due to the chronic elevation of free fatty acids, in non-adipose tissues that result in cellular injury, dysfunction, and apoptosis [131]. β-cell is susceptible to elevated concentrations of blood lipids. Lipotoxic conditions have been shown to alter several processes of its main actions, insulin production and release, as well as the process of its autophagy. Similar to "glucotoxicity," the molecular mechanisms of lipotoxic β-cell dysfunction and apoptosis include oxidative and endoplasmic reticulum stress, mitochondrial dysfunction, impaired autophagy, and inflammation.

Accumulating evidence implicates lipotoxicity in T2DM pathogenesis through the latter effects on β-cell [132]. Regarding GDM, it has been associated with increases in maternal blood lipid levels [133], raising the possibility that, similarly to T2DM lipotoxic β-cell dysfunction, may be involved in its pathogenesis.

Maternal Vitamin D

As mentioned above, vitamin D exhibits several extraskeletal or pleiotropic actions. Moreover, it has been found that vitamin D has receptors in pancreatic cells and seems to prevent β-cell dysfunction or apoptosis partially via immunomodulatory action [51, 52]. Low vitamin D levels have been associated with β-cell dysfunction in the nonpregnant state; vitamin D supplementation has been shown to improve insulin secretion in rats [134, 135]. During pregnancy, several studies though not all have shown an association between lower vitamin D concentrations and GDM. Whether this association is causal remains, however, unclear. Moreover, lower vitamin D concentrations postpartum have been associated with impaired β-cell function in women with a history of GDM [136]. Increased parathyroid hormone (PTH) concentrations have also been implicated in GDM pathogenesis, partially through insulin secretion impairment [137].

Autoimmunity

A rare cause of GDM is autoimmune destruction of pancreatic β-cells, similar to type 1 diabetes mellitus (T1DM). Autoimmune GDM consists in less than 10% of cases. GDM-affected women with an autoimmune form of diabetes often develop T1DM soon after pregnancy or latent autoimmune diabetes of adulthood (LADA) some years after delivery [138]. In a Swedish population, antibodies implicated in T1DM pathogenesis (glutamic acid decarboxylase antibodies (GADA), islet cell antigen-2 antibodies (ICA)/tyrosine phosphatase antibodies (IA2)) have been detected in 6% of women with GDM [139]. Specifically, the prevalence of GADA in GDM-affected women has been shown to extend between 0 and 11%, of ICAs between 1 and 35%, of insulin autoantibodies (IAA) between 0 and 6%, and that of anti-IA2 between 0 and 6% [140]. Moreover, pancreatic autoantibodies may be developed in some GDM women postpartum [138]. GADA was positively associated with the postpartum development of diabetes in women diagnosed with GDM [141]. Consequently, positive GADA and other pancreatic autoantibodies in GDM-affected women can predict postpartum T1DM development [142]. A recent meta-analysis has shown an association between HLA class II variants, up to 30–50% of the pathogenesis of T1DM and GDM. Specifically, DQB1*02 and DRB1*1302 alleles have been significantly associated with an increased risk of developing GDM. On the contrary, DQB1*0602 seems to be a protective allele against GDM development [143]. HLA-DR6 alleles were also positively correlated to GDM development, whereas other haplotypes, such as HLA-DR2 and HLA-DR51, seem protective. Besides HLA-DR3 gene and HLA-DR6/DR9 heterozygote were associated with GDM severity and prognosis [144]. Other studies found no significant differences in HLA class II polymorphism distribution between GDM, impaired glucose tolerance (IGT), and unaffected pregnant women [145]. The evidence about the relationship between GDM and autoimmunity is still controversial, and more studies are needed to establish it.

Genetic Causes

Linkage and association studies, including GWAS, have implicated genetic and epigenetic mechanisms in GDM development. Polymorphisms and variants of factors such as transcription factor 7-like 2 (TCF7L2), hepatocyte nuclear factor 4α (HNF4a), glucokinase (GCK), and glucokinase regulatory protein (GCKR) genes may predispose to GDM development. Mutations of maturity-onset diabetes of the young (MODY) gene constitute rare causes of GDM. Several MODY gene mutations are present in GDM-affected women. MODY is an inherited form of diabetes resulting from a single, autosomal, dominant gene mutation that disrupts insulin secretion. It may be inherited to the offspring by both maternal and paternal origin; less frequently, it can be caused by de novo gene mutation. Nowadays, several types of MODY have been recognized. Genes that are implicated in MODY development are hepatocyte nuclear factor-1 homeobox a (*HNF1a*) gene that is responsible for MODY 3 development, glucokinase (*GCK*) gene for MODY 2, hepatocyte nuclear factor-4 homeobox a (HNF4a) gene for MODY 1, hepatocyte nuclear factor-1 homeobox b (HNF1b) gene that causes diabetes and renal cysts (MODY 5), insulin promoter factor (HPF1) gene for MODY 4, insulin gene for MODY 10, ABCC8 gene (sulfonylurea receptor-1 (SUR1) subunit) for MODY 12, potassium inwardly rectifying channel subfamily J member 11 (KCNJ11) gene for MODY 13, neurogenic differentiation-1 gene (NEUROD1) for MODY 6, kruppel-like factor 11 (KLF 11) gene for MODY 7, carboxyl ester lipase (CEL) gene for MODY 8, paired box-4 (*PAX4*) *gene for MODY 9*, and *BLK gene for MODY 11* [146–154]. These monogenic forms of diabetes constitute less than 10% of GDM; MODY 2 is the most frequent type associated with GDM [155]. Several other mutations of MODY genes have been detected in GDM women, such as HNF1a, IPF1, insulin gene, and KCNJ11 gene [156–160]. However, a causal relationship between MODY and GDM has not been established yet. Further investigation is needed regarding the possible clinical implications of MODY gene mutations on maternal and fetal health [155].

An impairment of the complex system of epigenetic mechanisms (DNA methylation, histone modification, a miRNA gene silencing) has been associated with T2DM and possibly GDM development. Several studies have shown that epigenetic changes in GDM-affected women precede the development of GDM and could constitute a risk factor of GDM, whereas other suggest that similar alterations are consequences of GDM [161].

Conclusions

GDM is the most common metabolic complication of pregnancy. Its prevalence has been increasing over the years and parallels the increasing obesity trend. The main pathogenetic mechanism is insulin resistance due to maternal and placental hormone alteration, maternal adipokine alteration, low-grade inflammation, and oxidative stress accompanying pregnancy and obesity. An additional pathogenetic mechanism is a β-cell dysfunction either pre-existing due to occult genetic predisposition or hormonal and inflammatory effects of pregnancy and obesity. It seems that several maternal and placental hormones act via different signaling cascades, transcription factors, and epigenetic regulators that modify receptor density, cell cycle-related genes, and the threshold for glucose-stimulated insulin secretion. Less frequent causes of GDM are autoimmune destruction of pancreatic β-cells (similarly to T1DM) and impaired insulin secretion caused by genes mutations, such as MODY).

Multiple-Choice Questions

1. Levels of placental and maternal hormones and inflammatory cytokines
   (a) Increase at the end of pregnancy
   (b) Are stable throughout gestation
   (c) **Increase in the first half of gestation**
   (d) Increase at the second half of gestation
   (e) Are decreased throughout gestation
2. Factors contributing to insulin signaling impairment
   (a) Obesity
   (b) Low-grade inflammation
   (c) Alterations of the gut microbiome
   (d) None of the above
   (e) **All of the above**
3. Placental hormones
   (a) Reinforce insulin action
   (b) **Are opposed to insulin action**
   (c) Are irrelevant to insulin action
   (d) Continue increasing throughout pregnancy
   (e) Have no systemic effect
4. The main insulin-resistance mediator during pregnancy
   (a) **Human placental lactogen**
   (b) Prolactin
   (c) Placental growth hormone
   (d) Adipose tissue
   (e) Fetal beta-cells

5. Gestational diabetes impairs
   (a) Progesterone levels
   (b) Insulin-like growth factor
   (c) Prolactin levels
   (d) A and B are correct
   (e) **All of the above**
6. Hyperprolactinemia:
   (a) Improves insulin sensitivity
   (b) **Decrease glucose tolerance**
   (c) Increase insulin levels
   (d) Decrease insulin levels
   (e) Increase fetal adrenal steroids
7. Maternal vitamin D
   (a) Has not effect on pregnancy
   (b) **Improves glycemic control in pregnancy**
   (c) Impairs glycemic control in pregnancy
   (d) Increases insulin resistance
   (e) Inactivates the PPAR-pathway
8. Adiponectin
   (a) **Has an anti-inflammatory action**
   (b) Impairs endothelial function
   (c) Reduces insulin sensitivity
   (d) Has a pro-inflammatory action
   (e) Has not effects on carbohydrate metabolism
9. Autoimmunity occurs
   (a) Rarely, in 1% of pregnancies with gestational diabetes
   (b) **In 10% of pregnancies with gestational diabetes**
   (c) In 20% of pregnancies with gestational diabetes
   (d) In 30% of pregnancies with gestational diabetes
   (e) Never occurs in pregnancy
10. Epigenetic mechanisms involved in gestational diabetes include
   (a) DNA methylation
   (b) Histone modification
   (c) miRNA gene silencing
   (d) **All of the above**
   (e) None of the above

Nonalcoholic Fatty Liver in the Pathogenesis of Diabetes

16

Cristiane A. Villela Nogueira and Nathalie Carvalho Leite

Introduction

Nonalcoholic fatty liver disease is prevalent worldwide, and currently, it is a major cause of chronic liver disease due to obesity-related epidemic, sedentary profile, and metabolic syndrome [1–3]. NAFLD presents with different phenotypes and may progress to cirrhosis and hepatocellular carcinoma. Moreover, it may be the leading cause for liver transplant in the next decade [4]. NAFLD was formerly identified in 1980, when Ludwig et al. described a small series of patients with liver histology characterized by fat accumulation, hepatic necroinflammation, and, in most cases, fibrosis, in the absence of a history of excessive alcohol consumption [5].

Definition of NAFLD

Currently, NAFLD is defined as the presence of macrovesicular steatosis in ≥5% of hepatocytes in individuals who consume little or no alcohol. NAFLD is divided into two major subtypes that comprises different phenotypes histologically identified: nonalcoholic fatty liver (NAFL, also termed simple steatosis), the nonprogressive form of NAFLD associated with increasing cardiovascular mortality that rarely develops into cirrhosis, and NASH, the progressive form of NAFLD that can lead to cirrhosis and hepatocellular carcinoma and is associated to an increase of liver-related mortality [6, 7]. NASH is characterized by the presence of steatosis, ballooning degeneration, and lobular inflammation, with or without perisinusoidal fibrosis on liver histology [8].

In 2020, there was a consensus as a more appropriate name to describe fatty liver disease associated with metabolic dysfunction, ultimately suggesting that the old acronym nonalcoholic fatty liver disease (NAFLD) should be abandoned and replaced by Metabolic Non-Alcoholic Fatty Liver Disease (MAFLD). MAFLD might be defined based on the presence of liver steatosis plus some criteria linked to metabolic syndrome such as diabetes mellitus and obesity, among others [9]. Of note, the new nomenclature would not exclude other liver comorbidities like alcohol or viral hepatitis. However, this change is still under discussion [10, 11]. For this review, the name NAFLD will still be adopted.

Epidemiology

The rational for the high prevalence of NAFLD is multifactorial, being related to sedentarism, Western lifestyle worldwide, and obesity as well as to genetic and epigenetic factors. NAFLD is present in almost 30% of the general population [12]. The prevalence of NAFLD in Europe and the Middle East ranges from 20% to 30% [13]. In the USA, one-third of the population is obese, and one-third of American adults are thought to have NAFLD (Centers for Disease Control and Prevention *Overweight and Obesity* [online], http://www.cdc.gov/obesity/data/adult.html (2012)). NAFLD prevalence in Japan and China is similar to that in Europe (20–30% in Japan and 15–30% in China, respectively). In the Indian subcontinent, the prevalence of NAFLD in urban populations ranges from 16% to 32%; however, in rural India, where most people have traditional diets and lifestyles, the prevalence is around 9%, lower than in urban population [14]. In Latin America, the prevalence of NAFLD has been reported to range from 17% to 33% [15], but the increasing number of patients with type 2 diabetes mellitus is worrisome due to the association of these two diseases [16]. Data is lacking in the African continent; however, one study from Nigeria, which included patients with and without diabetes mellitus, identified a prevalence

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_16

of 9.7% [17]. Is sub-Saharan Africa fatty liver disease related to metabolic diseases has emerged as an important burden of noncommunicable diseases [18]. Regarding pediatric population, the prevalence of NAFLD varies from 3% to 10%, rising up to 40%–70% among obese children [19]. Globally, NAFLD/NASH incidence increased from 19.34 million in 1990 to 29.49 million in 2017 among children and adolescents with an annual increase of 1.35% [20].

Patients with NAFLD and metabolic syndrome share the same risk factors like obesity, type 2 diabetes mellitus, dyslipidemia, and insulin resistance. Diabetes has a huge impact not only on its prevalence worldwide but also on NAFLD severity [21]. The prevalence of ultrasonographic NAFLD on a cohort of diabetic patients was described as 69.4%. Patients with NAFLD were more obese, had a higher waist circumference and serum triglyceride, and had higher alanine aminotransferase levels than those without steatosis [21].

Although cardiovascular death is the most common mortality-related cause among the NAFDL population, increasing data regarding liver-related death due to liver dysfunction and hepatocellular carcinoma [22] has been increasingly reported. Although HCC is usually diagnosed in patients with NAFLD-related cirrhosis, it has also been detected in non-cirrhotic NAFLD. However, its true incidence and risk is still unknown [22]. Compared to viral hepatitis, the progression of liver fibrosis in NAFLD seems to be slower (patients developing cirrhosis 28 to 57 years) [23]; however, the burden of patients with NAFLD is higher than those with hepatitis C [24]. At present, NASH cirrhosis is the third leading indication for liver transplantation in the USA [25]. In the forthcoming decades, due to a projected increase in HCC incidence, a change in the burden of related cases of HCC is expected, moving from viral hepatitis to NASH-related cirrhosis as the major risk factor for HCC worldwide [13].

Clinical Manifestations

The clinical presentation of NAFLD is humble. Most patients are generally asymptomatic at diagnosis and are often referred from an internist with an ultrasound that demonstrates steatosis. Indeed, abdominal ultrasonography, owing to its noninvasive profile and easy accessibility, is the main screening and diagnostic method for NAFLD [26], although it is limited for patients that have more than 33% steatosis on liver biopsy. Patients who are symptomatic usually have unspecific symptoms like fatigue and a dull pain or heaviness in the right hypochondrium. However, a physical exam with signs of insulin resistance like acanthosis nigricans an enlarged waist circumference (usually over 88 cm in women and 102 cm in men) and overweight should also be a clinical clue to the diagnosis of NAFLD [27]. It's also important to be aware of some clinical conditions that may be associated with insulin resistance like polycystic ovarian syndrome in young women, which usually presents with obesity, hirsutism, acanthosis, and other diseases like hypothyroidism, sleep apnea disease, and psoriasis which are closely related to an increased prevalence of NAFLD [28–30].

Diagnosis

Most patients with NAFLD are diagnosed by incidental elevated liver enzymes or imaging studies suggesting hepatic steatosis [31]. When NAFLD is suspected, the first step to confirm its diagnosis is to exclude other known etiologies of chronic liver diseases like drug-related steatosis [32, 33], viruses [34], and alcohol. As previously described, a careful history of alcohol ingestion and medications that are related to steatosis must be taken. Of note, some NAFLD patients with excessive alcohol intake may have both alcoholic and nonalcoholic fatty liver disease [35]. The average amount of alcohol that is allowed for patients with NAFLD have been under debate, but so far, although small to moderate amounts of alcohol might be related to a decrease in cardiovascular risk, patients with NAFLD should refrain from drinking alcohol [36]. Generally, for the diagnosis of NAFLD, the upper limit for alcohol intake would be a maximum of three drinks a day for men and two for women [31]. However, if we consider the definition of MAFLD, higher amount of alcohol intake did not need to be excluded [37]. Further studies are needed to better understand the outcomes related to this new definition regarding the composite of NAFLD and alcohol-related liver disease.

The different phenotypes of NAFLD are simple steatosis, steatohepatitis, and fibrosis. However, so far, due to the lack of specific and accurate biomarkers, only liver biopsy can accurately identify steatohepatitis. Steatosis is the most prevalent phenotype, and most patients with simple steatosis have a benign course of the disease. Although NAFLD is the most common diagnosis in patients with incidental abnormal liver function tests [38], laboratorial tests are of minor value since most patients with NAFLD including those with more advanced disease may present normal inflammatory liver enzymes, even those with type 2 diabetes mellitus [39]. However, patients with persistent abnormal liver enzymes are those who usually present NASH on liver biopsy or other liver comorbidities like viral or autoimmune hepatitis. In conclusion, routine AST/ALT do not differentiate steatosis and NASH or help staging liver fibrosis [40].

Liver Biopsy and Noninvasive Markers of Fibrosis

As already stated, the gold standard to accurately diagnose the different phenotypes of NAFLD is still a liver biopsy. However, it is an invasive method prone to inter-observer and intra-observer disagreement. In addition, it is painful and difficult to be performed in such a high burden and widespread disease. However, although all this drawbacks are well-known, liver biopsy is still required for inclusion of patients in clinical trials [41]. The search for accurate noninvasive methods to identify the different spectrum of the disease is still under research. So far, steatosis and fibrosis can be identified by noninvasive methods that vary from serological scores to image methods, and since the presence of fibrosis is the most important prognostic marker of the disease [42], it is reasonable to develop noninvasive methods that accurately identify or exclude liver fibrosis. At present there are a great number of serological scores that can be used to assess patients with NAFLD (Table 16.1). They are usually applied as screening tools mostly to exclude patients with higher risk for advanced fibrosis at primary care settings. McPherson et al. have compared FIB-4 with NAFLD-fibrosis score (NFS) (1.675 + 0.037 × age + 0.094 × BMI + 1.13 × IFG/diabetes + 0.99 × AST/ALT ratio − 0.013 × platelets − 0.66 × albumin), and there was also a high negative predictive value to exclude advanced fibrosis with the cut-off of −1.455 (NPV of 93%) [43].

The most recommended serological noninvasive test to exclude advanced fibrosis at primary care is FIB-4 [(age AST)/(platelets* Sqrt (ALT)]. A result <1.3 excludes advanced fibrosis with a high negative predictive value of 95%. Patients with FIB-4 higher than this should be reevaluated with an additional serological marker like enhanced liver fibrosis (ELF) or an imaging noninvasive method such as vibration-controlled transient elastography (VCTE). FIB-4 followed by the evaluation of liver stiffness by VCTE or ELF test in those with indeterminate values (FIB-4 between 1.3 and 2.67) maintained an acceptable performance while reducing the rate of indeterminate results [44]. The ELF panel consists of the following three extracellular matrix turnover proteins: hyaluronic acid, tissue inhibitor of metalloproteinase 1, and N-terminal pro-collagen III-peptide. When used, ELF panel has had excellent performance to exclude advanced fibrosis in a low fibrosis prevalence setting like primary care. For a fixed sensitivity of 0.90, the best cut-off was 7.7 with a low specificity (34%) and a PPV of 7–26% but an excellent NPV of 95–99%. In a high prevalence fibrosis setting (above 30%), ELF can lead to a 75% PPV for a threshold of 10.51 [45].

If the patient has a FIB-4 less than 1.3 and a VCTE elastography less than 8 kPa or an ELF test <7.7, he might be kept in primary care and advised for lifestyle modification, assessment of cardiovascular risk, and serial measurement of noninvasive tests [46, 47].

NASH is the phenotype of NAFLD that points to a progressive form of the disease, and currently only liver biopsy is able to make this diagnosis. The histological definition of NASH comprises the triad of steatosis, cell injury (ballooning), or any amount of lobular or portal inflammation [48]. Of note, fibrosis is not required for the diagnosis of NASH. Semiquantitative histological scoring systems have been proposed for NAFLD, but they are not useful in clinical practice, and each has certain limitations. Recently, Bedossa et al. developed a new histological classification for NAFLD: the FLIP algorithm and the SAF (steatosis, activity, fibrosis) assesses separately the grade of steatosis, the grade of activity, and the stage of fibrosis. This algorithm and score may improve the agreement between pathologists when describing fibrosis stage [48]. However, the most used histological classification for NAFLD is still the NASH Clinical Research Network that considers the NAFLD activity score, NAS, that punctuates steatosis (0–3), ballooning (0–2), and lobular inflammation (0–2) and a separate classification for fibrosis (0–4). A NAS score of 5–8 is considered diagnostic for NASH, while a NAS of 3–4 is considered borderline [49].

Other noninvasive tools that have been useful as screening methods for the identification of patients with higher risk of fibrosis are VCTE, two-dimensional shear wave elastography (2D-SWE), acoustic radiation force impulse (ARFI), and magnetic resonance with elastography (MRE). Although MRE has been considered the most accurate method for the identification of liver fibrosis, its use is limited as screening method [50].

VCTE uses an ultrasound displacement M-mode and A-mode image produced by the system. It has two probes, M and XL. The XL probe was designed for obese patients, which has increased the success rate of the exam in patients with NAFLD since most are obese, and before the development of the XL probe, most exams were unreliable. Currently, all patients with a skin-to-liver capsule distance (SCD) of

Table 16.1 Diagnostic performance of serologic scores to evaluate fibrosis in NAFLD

Test	AUC	Cut-off	Se (%)	Sp (%)	PPV (%)	NPV (%)
NFS	0.81 (0.71–0.91)	−1.45	78	58	30	92
		0.676	33	98	79	86
FIB-4	0.86 (0.78–0.94)	1.30	85	65	36	95
		2.67	26	98	75	85
ELF[a]		7.7	93	34	26	95
ELF[b]		10.51	51	93	75	81

NAFLD nonalcoholic fatty liver disease, *NFS* NAFLD fibrosis score, *Se* sensitivity, *Sp* specificity, *NPV* negative predictive value, *PPV* positive predictive value

[a] Fibrosis prevalence <20%

[b] Fibrosis prevalence >30%

>25 mm should be assessed with the XL probe [51]. TE results under 7.9 kPa have a high negative predictive value for advanced fibrosis (97%) and should be employed in daily practice to decide about performing a liver biopsy in patients with NAFLD [52].

Two-dimensional shear wave elastography (2D-SWE) evaluation needs to be performed in a well-visualized area of the right liver lobe, without the visualization of large vessels, liver capsule, ligaments, and the gallbladder [53]. Obesity, which is one of the most prevalent findings in NAFLD patients, might limit a successful exam in addition to poor acoustic window or presence of artefacts and inability of the subjects to hold their breath [54].

In a study that compared the diagnostic performances of supersonic shear imaging (SWE) for the diagnosis of liver fibrosis compared to ARFI and TE in chronic liver disease, SWE, TE, and ARFI correlated significantly with histological fibrosis score; AUROCs of SWE, TE, and ARFI were 0.89, 0.86, and 0.84 for the diagnosis of mild fibrosis; 0.88, 0.84, and 0.81 for the diagnosis of significant fibrosis; 0.93, 0.87, and 0.89, for the diagnosis of severe fibrosis; and 0.93, 0.90, and 0.90 for the diagnosis of cirrhosis, respectively. Hence, all methods might be used to assess liver fibrosis in patients with NAFLD, since the reliability criteria are respected as well as its limitations [54]. Additional studies with 2D-SWE and ARFI are needed in order to better establish the best cut-offs for these methods.

NAFLD and T2DM Interplay

In order to better understand the interplay between NAFLD and T2DM, it is important to review epidemiological data and pathogenetic mechanisms accounting for this relationship.

As discussed before, T2DM is a risk factor for NAFLD and its progressive forms, NASH and advanced liver fibrosis [39, 55]. Interestingly, in addition to T2DM, a family history of diabetes was independently associated with NAFLD risk and with the presence of NASH and fibrosis in NAFLD patients [56, 57].

In our cross-sectional study, no diabetes-related variable (glycemic control, diabetes duration or the presence of long-term complications) was associated with the more severe stages of NAFLD [21]. In contrast, data are emerging to suggest that the presence and severity of NAFLD may be associated with the occurrence of macro- and microvascular complications in diabetic patients [7, 58, 59]. Some mechanisms could explain those epidemiological observations. Chronic hyperglycemia may promote or aggravate NAFLD in the same way it induces micro- and macrovascular diabetic complications. It accelerates the production of advanced glycosylation end ,products (AGEs) and interferes with the hepatocyte microenvironment, activating Kupffer and hepatic stellate cells (both have receptors for AGE) [60].

It has been demonstrated that over 85% of subjects with NAFLD have impaired glucose tolerance or T2DM by standard oral glucose tolerance test (OGTT) [61, 62]. Therefore, another issue to be considered is whether NAFLD is an important precondition for the development of T2DM. In this regard, several studies have shown an increased incidence of T2DM in patients with NAFLD diagnosed by ultrasonography or only by elevated liver enzymes. However, most of them were conducted in Asian countries, and few were properly adjusted for potential confounding variables [63, 64]. In a prospective cohort study of 3153 participants from the Multi-Ethnic Study of Atherosclerosis, high liver fat was independently associated with development of T2DM [65]. Two systematic reviews with different criteria for selecting studies of NAFLD patients obtained similar results. The two independent reviews demonstrated an increased risk for incident diabetes over a period of 4–10 years [66, 67]. Recently, Mantovani et al. performed a meta-analysis of relevant studies and concluded that NAFLD is significantly associated with a twofold-increased risk of incident diabetes [68]. Taken together, these observations have implied a role for NAFLD in T2DM pathogenesis.

Pathogenetic Mechanisms

During the course of human evolution, individuals who had more energy stores were more likely to cope with starvation. In modern industrialized societies, with unlimited access to caloric food, this evolutionary adaptation becomes maladaptive. An increased caloric intake exceeding rates of caloric expenditure promotes obesity, dysfunction of white adipose tissue, and accumulation of ectopic lipids. This relationship between the nutritional oversupply and NAFLD is reflected by the high prevalence of NAFLD and insulin resistance (IR) among obese individuals.

Metabolic Mechanisms Involved in NAFLD

Adipose Expansion and Inflammation

As obesity and the deposition of ectopic fat increase, adipose tissue is more likely to be infiltrated with macrophages and undergo inflammation. In fact, it is the tissue-specific distribution of fat from adipose tissue into ectopic depots and not the whole-body quantity of fat that determines insulin resistance. Visceral adiposity is known to be highly active in releasing adipocytokines that are implicated in NAFLD development. It has been demonstrated that VAT (visceral adipose tissue) has been associated with hepatic steatosis,

insulin resistance, and dyslipidemia because of its higher lipolytic rates [69]. Another hypothesis is that VAT was not a primary cause of NAFLD, but just a marker for an abnormal adipose tissue distribution related to a lower subcutaneous mass [70].

The expanded and dysfunctional adipose tissue triggers inflammation through recruitment and retention of macrophages and secretion of inflammatory cytokines such as tumor necrosis factor α (TNFα) and interleukin 6 (IL-6). TNFα activates pro-inflammatory pathways: the nuclear factor κB (NF-κB) and c-Jun N-terminal kinase (JNK) [71]. These pathways, via activation of various kinases, increase even more the release of inflammatory cytokines, modulate adipocyte transcription factors, and attenuate insulin signaling. TNFα-induced attenuation of insulin signaling is mediated by JNK and occurs via serine phosphorylation of insulin receptor substrate [72]. Adipokines provide an important link between adipose tissue and insulin resistance. Serum levels of adiponectin, a hepatoprotective adipokine, are reduced in patients with NAFLD, metabolic syndrome, and T2DM [73]. Adiponectin improves insulin sensitivity and decreases both steatosis and inflammation [74] and is inversely related to NAFLD development and progression [75]. All these adipose inflammatory events contribute to a systemic inflammatory and insulin-resistant state that predisposes to T2DM.

Insulin Resistance and Hyperinsulinemia

There is strong evidence of the association of NAFLD and insulin resistance (IR). Euglycemic hyperinsulinemic clamp studies, coupled with tracers infusion confirmed that the IR is the rule in main tissues even in nondiabetic and non-obese patients with NAFLD [76]. Insulin is a pleiotropic hormone that regulates different cell functions. Concerning lipid metabolism, insulin promotes triglyceride storage and inhibits lipoprotein lipase activity in adipose tissue. Insulin resistance at the level of the adipocyte seems to be the primary defect in NAFLD [77]. Impairment in insulin-mediated suppression of lipolysis leads first to elevated circulating non-esterified fatty acids (NEFAs) and subsequently to a sustained excess delivery of these fatty acids to the skeletal muscle and liver. In fact, there is growing evidence that chronically elevated plasma NEFAs concentrations can lead to insulin resistance in muscle and liver and impair insulin secretion by pancreatic beta-islet cells.

Adverse effects on the metabolism of carbohydrates are dependent on increased endogenous glucose production and reduction in peripheral glucose uptake. Chronic hyperglycemia induces insulin secretion by the pancreatic beta-islet cells, leading to compensatory hyperinsulinemia. The mechanisms of beta cell progressive failure are less well defined; however elevated levels of glucose and increased circulating NEFAs may be responsible for pancreatic beta-islet cells dysfunction and apoptosis [78]. The processes of beta-cell deterioration in response to elevated glucose and NEFAs levels are traditionally known as "glucotoxicity" and "lipotoxicity." Thus, with prolonged nutrients' toxicity, as metabolic capacity of beta-cells is overwhelmed, insulin production declines. It is the progressive loss of beta-cell insulin secretion in the setting of insulin resistance (IR)/hyperinsulinemia that leads to the development of T2DM.

Metabolic Consequences of NAFLD

Hepatic Lipogenesis and Hypertriglyceridemia

Interestingly, it has been argued that many of the adverse effects due to insulin resistance result much more from compensatory hyperinsulinemia in organs that remain sensitive to its action. In fact, there is selective insulin resistance even in different pathways within the same tissue or organ. In the liver, for instance, while insulin fails to suppress gluconeogenesis and to activate glycogenesis, it continues to promote FAs synthesis (de novo lipogenesis—DNL). The major direct effect of insulin on endogenous glucose production is the regulation of glycogen synthesis. With development of hepatic insulin resistance, insulin no longer stimulates glycogen synthase, and therefore glucose is redirected into lipogenic pathways, resulting in NAFLD and hypertriglyceridemia [79]. Insulin also regulates adipose tissue lipolysis and influences the amount of NEFAs for hepatic fatty acid esterification, independent of its hepatic action.

Hyperglycemia and compensatory hyperinsulinemia activate transcription factors sterol regulatory element-binding protein-1c (SREBP-1c) and carbohydrate response element-binding protein (ChREBP), which upregulate most genes involved in DNL [80].

The production of long-chain FAs is determined by the sequential action of various enzymes: acetyl-CoA carboxylase (ACC), fatty acid synthase (FAS), and fatty acid elongases and desaturases [81]. In turn, the key regulator SREBP-1c directly controls many of these enzymes and liver × receptor, which is also an important component of the nuclear receptor superfamily.

Hence, the action of these upregulated lipogenic enzymes and the increased delivery and uptake of FAs (adipose tissue and diet) play a critical role in the induction of NAFLD. Hepatic steatosis develops when the balance between hepatic triglycerides (TAGs) synthesis from free fatty acids (FAs) exceeds the liver capacity to oxidize FAs or export TG in the form of very-low-density lipoprotein (VLDL). FAs may be oxidized in the mitochondria, peroxisomes, and microsomal system. β-oxidation within mitochondria, however, is the most efficient source of energy

under normal circumstances. Patients with NAFLD/NASH can have impaired uptake and oxidation of FAs by mitochondria in the liver and throughout the body in other tissues [82, 83]. Fatty acid esterification into hepatic triglycerides results in increased VLDL production and hypertriglyceridemia present in most patients with NAFLD and T2DM. Defects in triglyceride export, as reduction in production of apolipoprotein B, can lead to liver steatosis but with extremely low VLDL and triglycerides levels [84].

Hepatic Insulin Resistance and Hyperglycemia

Although hepatic TAGs are thought to be inert or even protective for NAFLD progression, FAs metabolites such as diacylglycerol (DAG) may further contribute to IR and NASH development. The causal link between plasma membrane DAG-specific stereoisomers and IR is attributed to PKCε activation. Activated PKCε isoform binds and inhibits insulin receptor kinase, leading to reductions in insulin-stimulated tyrosine phosphorylation of insulin receptor substrate IRS-2 and insulin signaling [85]. In contrast to DAG, there was no consistent association between other lipid mediators, such as ceramides, and hepatic insulin resistance [86]. The selective insulin resistance (IR) in the liver is a key pathophysiologic event in the development of NAFLD and type 2 diabetes. Differences in insulin receptor (InsR) activation underlie the selective IR of glucose production relative to lipogenesis. Decreased (InsR) activation has been observed in the liver of patients with NAFLD and results from a cell-autonomous downregulation of receptor number and/or activity in response to chronic hyperinsulinemia. It has been shown that a greater degree of intact InsR signaling is required to suppress glucose production than to stimulate lipogenesis, one through Forkhead O transcription factor-1 (FOXO1) and the other through SREBP-1c [87]. These "bifurcation" of hepatocyte insulin signaling underlies the mechanisms by which one branch (i.e., glucose metabolism) becomes resistant to the effects of insulin, whereas the other (i.e., lipid metabolism) remains sensitive, or even stimulated by hyperinsulinemia. These molecular features of hepatocyte insulin signaling do not rule out the role of plasma membrane DAGs as the key cellular compartment and lipid species in hepatic IR. Recent data have shown that this is also the mechanism behind the insulin resistance in adipose tissue and skeletal muscle [88, 89].

Other Mechanisms Involved in NAFLD Pathogenesis

Genetics Factors

During last years, genome-wide association studies revealed a growing list of genetic variants associated with NAFLD pathogenesis. Patatin-like phospholipase domain-containing protein 3 (PNPLA3), transmembrane 6 superfamily 2 (TM6SF2), membrane-bound *O*-acyltransferase domain-containing 7 gene (MBOAT7), and glucokinase regulator (GCKR) single-nucleotide polymorphisms (SNPs) were validated in large and independent cohorts. The most well-described genetic risk variant is the I148M variant in PNPLA3 gene. The I148M allele leads to a loss of phospholipase lipolytic activity, which predisposes to increased hepatic fat content and progressive liver damage. In addition, I148M variant confers an increased risk of fibrosis progression and hepatocarcinoma in NAFLD patients. In the case of TM6SF2, (Lys E167K) T allele has been associated with hepatic retention of TAG and hepatic fibrosis and (Glu E167K) C allele with VLDL secretion and atherogenesis. However, both genetic variants in PNPLA3 and TM6SF2 have not been associated with IR or increased risk of T2DM [90, 91].

MBOAT7 rs641738 T allele was shown to increase the risk of the entire spectrum of NAFLD through changes in the phospholipid acyl chain remodeling [92].

The P446L variant in GCKR gene increases glucose uptake and DNL in hepatocytes. In this setting, hepatic lipid accumulation from constant glucose substrate favors liver disease but protects from T2DM development.

Recently, a new protective SNP was discovered. HSD17B13 (rs72613567:TA) gene variant is associated with loss of retinol dehydrogenase activity in hepatocytes. Interestingly, the presence of this loss of function variant seems to attenuate the risk liver injury of I148M allele in PNPLA3 gene [93].

Diet and Gut Microbiome

High-calorie diets and sedentary lifestyle have been linked to many pathological conditions including metabolic syndrome, type 2 diabetes mellitus, and NAFLD. In addition to the amount of calories, dietary composition may also contribute to NAFLD development. Recent data have suggested that increased consumption of fructose and sugar-sweetened beverages, saturated fatty acids (SFAs), and high trans-fat-containing ultra-processed food can have a dismal effect on the development and progression of NAFLD.

More emphasis is being placed on fructose consumption on NAFLD pathogenesis. Fructose can enhance liver steatosis via de novo lipogenesis—DNL through activation of SREBP1c, independently of insulin [94]. Fructose also inhibits fatty acids oxidation, reducing the action of PPARα - FGF21 hormone axis [95]. Moreover, fructose inhibits leptin expression, decreasing satiety [96]. Finally, fructose interferes with gut microbiota composition, increasing intestinal permeability, and endotoxinemia, which also promotes IR [97].

It is difficult to differentiate the effects of poor dietary habits and gut microbiome function and composition on NAFLD pathogenesis since they are both closely linked to obesity and its comorbidities. Patients with NAFLD have an altered gut microbiota composition and increased intestinal permeability, allowing LPSs and other products to enter the portal circulation. These observations have implied an important role for gut microbiota-induced inflammation in the development of NAFLD and insulin resistance [98, 99]. Toll-like receptors TLRs are a family of receptors that plays a critical role in innate immune systems. TLR4 received a particular attention because of its ability to recognize free fatty acids and lipopolysaccharides (LPSs) and activate the proinflammatory signaling pathway nuclear factor κB (NFκB). Thus, LPSs have an indirect effect on insulin sensitivity and inflammation [100, 101].

Gut microbiota may also contribute to NAFLD by increased production of branched-chain and aromatic amino acids, phenylacetic acid, ethanol, and short-chain fatty acids. Taken together, those gut metabolites increase nutrient absorption, fat accumulation, and generation of reactive oxygen species (ROS) and hepatic inflammation, leading to NAFLD progression [102–104].

Mechanisms Involved in NAFLD Progression

NAFLD progression results from a cascade of cellular and signaling events between hepatocytes, macrophages and other immune cells, and hepatic stellate cells. Metabolic mechanisms and other factors (genetic, diet, and gut microbiome) involved in NAFLD pathogenesis may influence the propensity for cell injury and liberation of proinflammatory and fibrogenic signals. Hepatocellular injury in NASH is characterized by activation of nuclear receptors, altered insulin signaling, mitochondrial dysfunction, enhanced endoplasmic reticulum stress, lipogenesis, and lipotoxicity [105]. Hepatocyte injury is a cornerstone of progressive NASH since it serves as a trigger for increasing inflammation and fibrosis [106].

Soluble and extracellular vesicles signals from hepatocytes lead to proinflammatory activation of macrophages and other immune cells. Activated macrophages release cytokines and chemokines which further contributes to hepatocyte apoptosis and recruitment of immune cells into the liver. Hepatic stellate cells are activated by stressed or apoptotic hepatocytes and by inflammatory and immune cells. Activation of stellate cells results in increasing extracellular matrix production and fibrogenesis [107].

The current concept is that not all patients with NASH share, in the same intensity, the same mediators and signaling pathways to develop inflammation and fibrosis. Future knowledge of different pathways will open up new diagnostic strategies and therapeutic interventions.

Multiple-Choice Questions

1. Among the options below, mark the one that contains the findings that must be present in liver biopsy in order to make the diagnostic of steatohepatitis.
   (a) Steatosis, fibrosis, and lobular inflammation
   (b) Fibrosis, ballooning and steatosis
   (c) Steatosis, ballooning, and lobular inflammation
   (d) Fibrosis, ballooning, and portal inflammation
   Correct answer: (c)
2. Patients with NAFLD usually have metabolic syndrome. Mark the option that includes other risk factors for NAFLD.
   (a) Polycystic ovarian syndrome
   (b) Graves' disease
   (c) Chronic hepatitis B
   (d) Gaucher disease
   Correct answer: (a)
3. Patients with cirrhosis have an increased risk of hepatocellular carcinoma. Mark the correct sentence.
   (a) In NASH, hepatocellular carcinoma may develop without cirrhosis.
   (b) Currently it is recommended to screen patients with diabetes for hepatocellular carcinoma.
   (c) Pioglitazone is associated with a higher risk of hepatocellular carcinoma in NASH patients.
   (d) Metformin should be quit in diabetic patients with NASH due to the risk of hepatotoxicity.
   Correct answer: (a)
4. The noninvasive method for the detection of fibrosis that has the best accuracy in patients with NAFLD is
   (a) Transient hepatic elastography
   (b) APRI
   (c) BARD
   (d) The combination of FIB-4 and elastography
   Correct answer: (d)
5. Mark the correct sentence regarding NASH.
   (a) NASH may be diagnosed in patients with a NAFLD score >0.675.
   (b) So far the only way to diagnose NASH is by performing a liver biopsy.
   (c) Metformin is linked to improvement of NASH.
   (d) In order to improve NASH, patients should lose 5% of their body weight.
   Correct answer: (b)

Diabetes Burdens in Asia: Morbidity and Mortality

Asia is considered as the epicenter of the global diabetes epidemic [1]. The major implications to the existing diabetes burden in Asia are the rising burden of young-onset diabetes mellitus and a higher risk of diabetes complications [2, 3]. According to the 10th edition of IDF Diabetes Atlas 2021, 1 in 11 adults in Southeast Asia (SEA) and 1 in 8 adults in the western pacific (WP) are living with diabetes. Further, one in two adults living with diabetes is undiagnosed, thus contributing to increased risk of micro- and macrovascular diabetes complications [4]. The proportion of all-cause deaths attributable to diabetes is 14.1% in SEA region and 11% in WP region [5]. Asia region has one of the highest age-standardized disability-adjusted life years (DALYs) associated with diabetes mellitus [6]. Figure 17.1 shows the global trend in the age-standardized DALYs attributed to diabetes by World Bank regions between 1990 and 2019. Both East-Asia and Pacific and South Asia regions have experienced a sharp increase in the diabetes-related DALYs over the last two decades.

Early-onset diabetes among children and adolescents is now emerging as a major public health concern in Asia. An interplay of higher rates of central obesity, insulin resistance, and genetic predisposition is implicated to contribute to rising burden of young-onset diabetes among Asians. In addition to this, conventional risk factors like smoking, alcohol, and diets rich in sugars, lack of physical activity among the middle class and rural populations has also contributed to the increase in the diabetes burdens in Asia [7]. Figure 17.2 shows the relative contribution of metabolic, behavioral, dietary risk factors, tobacco, and air pollution. Compared to other regions, air pollution has emerged as a novel risk factor contributing to the diabetes DALYs burden in Asia.

Prevalence and Incidence of Diabetes and Related Complications

The top-ranked countries in 2019 with the largest number of adults with diabetes were Asian countries including China (116.4 million) and India (77 million). Also, recent data suggest an increasing prevalence of type 1 diabetes in Asia region with a prevalence of 9.6 per 10,000 and incidence of 15 per 100,000 [8]. Further, a study from India reported the secular trends over 10 years and found that the prevalence of diabetes increased from 18.6% to 21.9% in cities, 16.4% to 20.3% in towns, and 9.2% to 13.4% in peri-urban villages. Abdominal obesity was significantly associated with the increased trend in diabetes prevalence, even among the villagers [9]. Another 2018 study by Geldsetzer et al. analyzed National Family Health Survey (NFHS-3) dataset to determine the prevalence of diabetes and hypertension in India and its variation by state, rural vs. urban location, and individual-level sociodemographic characteristics found that diabetes prevalence was highest in the middle and old age across all geographical areas and sociodemographic groups in India [10].

In 2019, global estimates for the number of incident cases of type 1 diabetes in children and adolescents aged 0–14 years were ~98,200 and ~128,900 for aged 0–19 years. India with 15.9 thousand cases ranked first for the estimated number of incident cases of type 1 diabetes in children and adolescents (0–14 years) per annum. The prevalence of diabetes complications among people with diabetes in select Asian countries is shown in Table 17.1. The prevalence of diabetic neuropathy appears to be significantly higher in Sri Lanka (63%) and Indonesia (59%) compared to other countries in Asia.

Table 17.1 Prevalence of diabetes complications in people with diabetes in select Asian countries

Country (year), (source)	Diabetic retinopathy (%)	Diabetic neuropathy (%)	Diabetic nephropathy (%)	Diabetic foot	Amputation	CHD	Stroke
China (2019) [11]	8.1	11.1	20.7	NA	NA	NA	NA

Socioeconomic Burden

Diabetes is associated with significant social challenges and economic impact at the individual, family, society, and national level [17]. Southeast Asian countries like India and Bangladesh had a higher diabetes risk among the higher socioeconomic groups with lower education levels [18]. A recent report from India suggests that the direct cost of diabetes was estimated to range from INR 1198 per annum to INR 45,792 [19]. Per the IDF 9th edition, the mean annual expenditure per person for diabetes in Asia is reported in Table 17.2. These data indicate that economic burden owing to diabetes is huge; therefore, low-cost sustainable strategies and effective public health policy are warranted to curtail the growing diabetes burden.

Special Types of Diabetes in Asia

Of all diabetes, monogenic diabetes is estimated to represent 1–6% in Asians [20]. It includes maturity-onset diabetes of the young (MODY), maternally inherited diabetes with deafness (MIDD), neonatal diabetes, and other genetic syndromes such as lipodystrophies, Bardet-Biedl syndrome, and Wolfram syndrome [21, 22]. In an East Asian study (2019), 109 participants with diabetes out of 2090 were suspected to have monogenic diabetes of whom 23 (21.1%) harbored the pathogenic genetic variants of monogenic diabetes. Around 14 had pathogenic/likely pathogenic variants of common maturity onset diabetes of the young (MODY) genes which were identified in GCK, HNF1A, HNF4A, and HNF1B [21].

Identifying monogenic diabetes cases is challenging because genetic testing can be expensive and awareness is low. Appropriate clinical approaches for proper diagnosis are vital including history collection—onset of disease, family history, physical examination, biomarkers—C-peptide, pancreatic autoantibodies, lipid profiles and high-sensitivity C-reactive protein (CRP), and genetic risk scores. Further, screening and diagnosis for monogenic forms of diabetes require high-quality testing methods, including multiple gene sequencing tests, and knowledge of database searches related to genomes, exomes, and alleles [23, 24]. However, population-based studies in monogenic diabetes are limited. Focus on population-wide prevalence studies across all age groups could aid in better understanding its epidemiology [23].

Fibrocalculous Pancreatic Diabetes (FCPD)

FCPD is another rare form of diabetes secondary to chronic calcific pancreatitis, with no alcohol abuse and mainly concentrated in the tropical regions among malnourished young individuals [25, 26]. For example, an Indian study conducted between 2014 and 2016 involving 891 patients with diabetes found 0.34% cases to have FCPD. All FCPD patients were aged between 35 and 45 years, from low socioeconomic strata, and consumed a high percentage of carbohydrates [27].

Disparities in Diabetes Care in Asia

It is well known that socioeconomic inequality exists in diabetes with higher incidence and mortality among lower socioeconomic groups. A recent study from Japan found that lower income and older age increased the risk of hospitalization and in-hospital mortality. Further, sex-specific health inequalities were observed. Males with lower socioeconomic status had greater hospital morbidity, mortality, and poorer oral hypoglycemic agent medication adherence as compared to females [28]. Irregular visits to the physician and lower socioeconomic status tended to have poor glycemic control among patients. Larger inequalities in health and healthcare utilization were seen among patients with diabetes in China. Demographic structure, consumption behavior, and occupational socioeconomic status were found to be major contributors to higher rates of underdiagnosis and under-medication [29]. The prevalence of diabetes and treatment was influenced by socioeconomic factors leading to inequalities among diabetic middle-aged and elderly adults in China [30].

The coverage of recommended pharmacological and non-pharmacological diabetes treatment in selected Asian countries is shown in Table 17.3. In a secondary analysis of cross-sectional surveys from 55 low- and middle-income countries (LMICs), researchers assessed coverage of three pharmacological and three non-pharmacological treatments among people with diabetes [31]. The self-reported diabetes treatment coverage was based on population-level monitoring indicators recommended in the 2020 WHO Package of Essential Noncommunicable Disease Interventions. Overall, *4.6% (3.9–5.4) of individuals with diabetes self-reported meeting need for all treatments recommended for them*. Coverage of glucose-lowering medication was 50.5% (48.6–52.5); antihypertensive medication was 41.3% (39.3–43.3); cholesterol-lowering medication was 6.3% (5.5–7.2); diet counseling was 32.2% (30.7–33.7); exercise counseling was 28.2% (26.6–29.8); and weight-loss counseling was 31.5% (29.3–33.7). Asian countries at higher-income levels tended to have greater coverage. Female sex and higher age, body mass index, educational attainment, and household wealth were also associated with greater coverage. In summary, this

Table 17.3 Coverage of essential diabetes treatment in selected Asian countries

Country	HAQ-index (diabetes)	Glucose lowering medication	Antihypertensive medication	Cholesterol lowering medication	Diet counseling	Exercise counseling	Weight-loss counseling
Bangladesh	56	64.3	59.5	NA	NA	NA	NA
Bhutan	57	40.2	43.7	1.7	37.5	33.8	40.4
Cambodia	52	59.8	57.3	5.4	46.8	45.8	53.6
China	85	57.1	50.7	NA	16.9	NA	11.9
India	65	29.2	30.4	NA	NA	NA	NA
Indonesia	34	19.6	19	4.8	19.5	14.2	14
Laos	52	55.9	42.3	1.2	46.4	46.4	53.7
Myanmar	48	56.8	48.8	1.9	39.3	30.5	27.8
Nepal	58	53.8	36.7	0	33.7	28.5	28.3
Timor-Leste	65	14.3	44	0	10	10	9.5
Vietnam	64	64.2	36.6	16	42.8	39.3	31.9

Source: Flood et al. Lancet Healthy Longevity, 2021 [31]. Coverage for each indicated is reported in percentage. *HAQ* = healthcare access and quality for diabetes sourced from the GBD 2018 Lancet paper [32]

analysis concluded that fewer than *one in ten people with diabetes in LMICs receive coverage of guideline-based comprehensive diabetes treatment*. Given that diabetes is considered a tracer condition for examining health systems, these findings indicate that many countries face challenges in achieving universal health coverage.

Furthermore, a 2019 study uncovered poor management of diabetes along the care cascade (i.e., diabetes diagnosis, treatment, and control rates), indicating large unmet need for diabetes care across 28 LMICs. This analysis showed that the performance across the diabetes care cascade varied by World Bank income group and individual-level characteristics, particularly age, educational attainment, and BMI. Figure 17.3 shows the various stages of the care cascade as diagnosed, lifestyle advice, and/or medication given ("treated") and controlled (HbA1c <8.0%). Total unmet need for diabetes care (defined as the sum of those not tested, tested but undiagnosed, diagnosed but untreated, and treated but with diabetes not controlled) was 77.0% (95%CI: 74.9–78.9%). Older age, education, and higher BMI were associated with higher odds of being tested, being treated, and achieving control [33].

Several reports from the Asian region suggest an inadequate access, quality, and coverage of health services related to diabetes prevention and treatment. Figure 17.4 summarizes the key barriers to diabetes care in Asia.

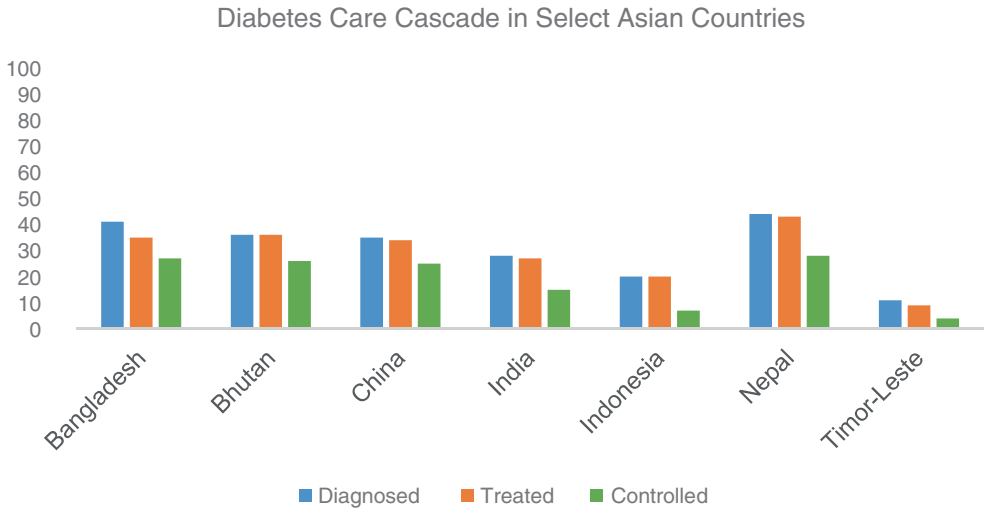

Fig. 17.3 Diabetes diagnosis, treatment, and control rates in selected Asian countries

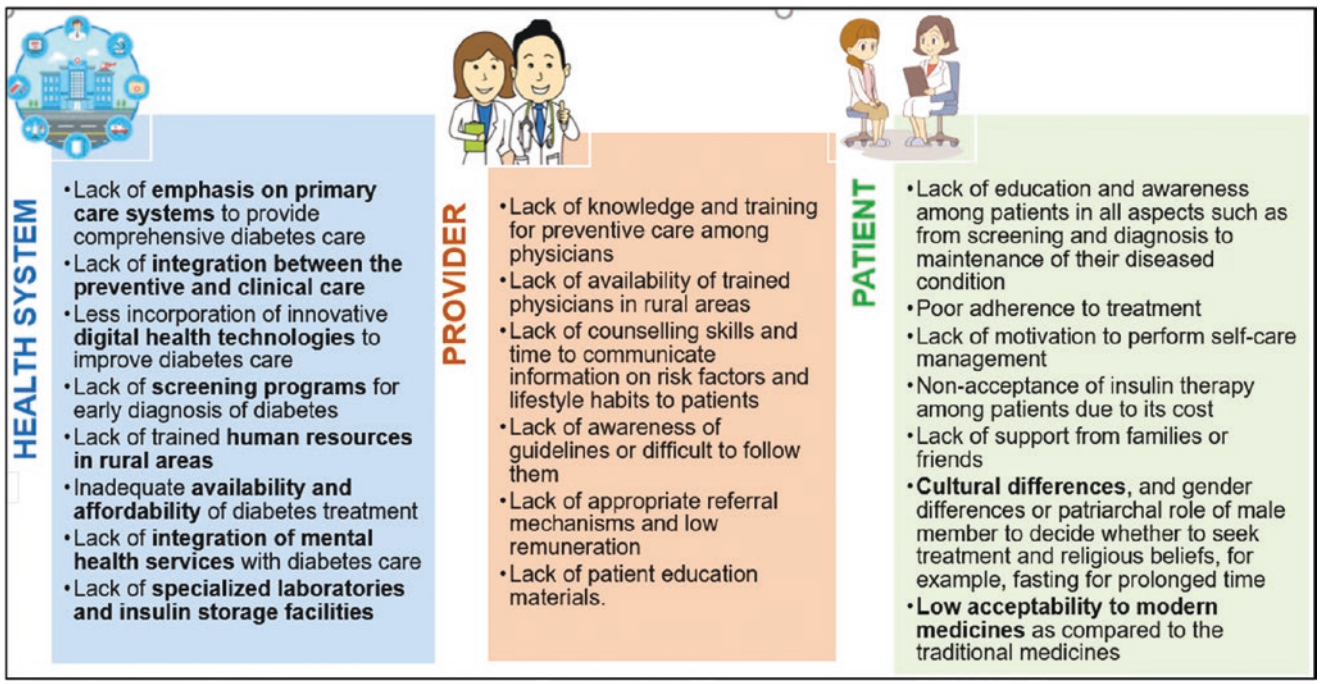

Fig. 17.4 Patient, provider, and health system level barriers to diabetes care in Asia

Management of Diabetes in Asia

Diabetes management involves both non-pharmacological and pharmacological approaches to prevention and treatment. Below we briefly describe the key recommendations for the prevention and management of diabetes in Asian context.

Non-pharmacological Approaches

Lifestyle Modification

Type 2 diabetes can be effectively controlled by simple lifestyle modification including the change in lifestyle habits (tobacco cessation, healthy diet, physical activity, and moderate alcohol consumption). Lifestyle advice should be given to all people with diabetes at the time of diagnosis. A systematic review and meta-analysis found that a low-carbohydrate diet and daily moderate- to high-intensity physical activity results in clinical improvements in people with type 2 diabetes [34].

Medical Nutrition Therapy (MNT)

MNT is beyond calorie restriction and dietary portion control. MNT is a lifestyle-transforming process in the management of diabetes. Asian countries such as India, China, Japan, Korea, and Thailand have huge cultural and culinary diversity which can be challenging. Therefore, designing individualized diet plan as a part of MNT should consider cultural, regional, and economical factors which will motivate individual to engage in healthy dietary habits. In the Asian context, guidelines recommend that carbohydrates should be limited to 50–60% of total calorie intake. Complex carbohydrates should be preferred over refined products. Fiber intake should be 25–40 g/day. The protein intake should be maintained at about 15% of total calorie intake. The quantity of protein intake depends on age, sarcopenia, and renal dysfunction. Nonvegetarian foods are sources of high-quality protein; however, intake of red meat should be avoided. Further, fats should be restricted to <30% of total calorie intake. Oils with high monounsaturated fatty acid (MUFA) and polyunsaturated fatty acid (PUFA) should be used. The use of two or more vegetable oils is recommended in rotation. Saturated fat (butter, coconut oil, margarine, ghee) intake should be less than 10% of total calories/day (<7% for individuals having high triglycerides). The use of partially hydrogenated vegetable oils (Vanaspati) as the cooking medium should be avoided. Reheating and refrying of cooking oils should be avoided. Diet rich in fruits, leafy vegetates, nuts, fiber, whole grains, and unsaturated fat is recommended. Food plate should include pulses, legumes, unprocessed vegetables, and low-fat dairy. Sugar-sweetened beverages are best avoided. Artificial sweeteners may be consumed in recommended amounts. Overall salt consumption should be <5 g/day (with sodium consumption <2300 mg/day). Smoking cessation should be advised to all. Smoking cessation therapies may be provided under observation for patients who wish to quit in a step-wise manner.

Further, a structured model of care (MOC) has been proposed for resource-constrained settings to improve pregnancy outcomes of Asian Indian women with gestational diabetes mellitus (GDM). Under the MOC, 212 women with GDM were followed through pregnancy, of whom 33 (15.6%) required insulin and 179 (84.4%) were managed with MNT and physical activity which reported that implementation of a structured MOC for women with GDM helped achieve improved pregnancy outcomes similar to those without GDM [35].

Physical Activity

Adoption of physical activity is very critical part of prevention and management of type 2 diabetes and its complications. A recent systematic review with meta-analysis assessed the effect of physical activity interventions in prediabetes and found that physical activity can help to slow down the progression of disease in individuals with prediabetes and thus reduces the morbidity and mortality associated with type 2 diabetes [36]. A minimum of 150 min/week of physical activity is recommended for healthy Asians due to the high predisposition to develop T2DM. The exercise regimens may consist of (a) ≥30 min of moderate-intensity aerobic activity each day, (b) 15–30 min of work-related activity, and (c) 15 min of muscle-strengthening exercises (at least 3 times/week). Further, recent Indian diabetes guidelines also recommend yoga practices including asanas (involving postures), pranayama (involving breath), and dhyana (involving meditation) as a part of holistic management of type 2 diabetes [37]. The use of monitoring tools like accelerometers, GPS units, pedometers, mobile-based apps, or devices to measure the intensity and duration of physical activity may be encouraged.

Pharmacological Approaches

The pharmacological management of diabetes is mainly divided into oral antidiabetic drugs (OADs), insulin therapy, and non-insulin injectable therapy.

Oral Antidiabetic Drugs (OADs)

Most commonly used OADs for the management of diabetes among Asians include biguanides (e.g., metformin), sulfonylureas (e.g., glimepiride), meglitinides (e.g., repaglinide), thiazolidinediones (e.g., pioglitazone), dipeptidyl peptidase IV inhibitors (e.g., sitagliptin), and α-glucosidase inhibitors (e.g., acarbose). As the first-line treatment for diabetes, metformin is recommended in combination with lifestyle interventions at the time of diagnosis. Further, initiation or dose increment of OADs requires monitoring the response through blood glucose monitoring every 2–3 months. Further, customization of OAD therapy depends up on the individualized target HbA1c for each patient based on age, duration of diabetes, comorbidities, cost of therapy, hypoglycemia risk, weight gain, and durability. Further, a recent meta-analysis of randomized trials assessed the impact of ethnicity on the glucose-lowering efficacy of the newer oral agents, sodium–glucose cotransporter 2 inhibitors (SGLT-2i), glucagon-like peptide 1 receptor agonists (GLP-1RA), and dipeptidyl peptidase 4 inhibitors (DPP-4i), which found that the glucose-lowering efficacy of SGLT-2i, and to a lesser extent DPP-4i, was greater in studies of predominantly Asian ethnicity compared with studies of predominantly White ethnicity. There was no difference seen by ethnicity for GLP-1RA [38].

Insulin Therapy

The choice of injectable insulin in type 2 diabetes mellitus is based on clinical, pharmacological, and psychosocial factors. In the Asian Indian context, factors like cost, quality of insulin, and cold chain maintenance must be considered. Patients who are failing to achieve glycemic targets on oral agents should be given insulin therapy. Evidence from clinical trials suggest that insulin glargine combined with oral antidiabetic drugs in the Asian and Chinese population with type 2 diabetes mellitus at a lower HbA1c can potentially lead to greater glycemic control [39].

Non-insulin Injectable Therapy (Glucagon-Like Peptide 1)

GLP-1 analogues are viable second-line or third-line option for the management of patients with uncontrolled hyperglycemia. Glucagon-like peptide 1 can be considered in overweight/obese patients as second-line therapy in patients with metformin inadequacy and as first-line therapy in patients with metformin intolerance. Glucagon-like peptide-1 receptor agonists (GLP-1RAs) reduce HbA1c, fasting plasma glucose, and in particular postprandial glucose levels, and slow gastric emptying while minimizing the risk of hypoglycemia and weight gain and may be considered as a treatment option for East Asian patients with inadequately controlled diabetes by oral antidiabetic drugs (OADs) or basal insulin [40].

Management of Special Types of Diabetes (Monogenic Forms and FCPD)

Patients with monogenic diabetes are sensitive to low doses of sulfonylureas in the initial stages. A few patients may need insulin as the beta cell defect progresses [41]. However, most patients with FCPD require insulin injections. Early diagnosis and treatment of FCPD patients, in tropical as well as nontropical countries, along with adequate glycemic control with regular monitoring, pain relief, management of macro- and micronutrient requirements, and monitoring of pancreatic function are essential to improve quality of life in FCPD patients [26, 41].

Newer Approaches to Diabetes Management in Asian Context

In the first edition of the book chapter on Diabetes Management in Asia, we have previously described in detail about both diabetes prevention and care models including successful examples from Asia. Here we present an updated information on the evidence from randomized trials on the newer strategies that have been evaluated to prevent or manage diabetes in Asia.

The Japan Diabetes Optimal Integrated Treatment for three major risk factors of cardiovascular diseases (**J-DOIT3**) study, a multicenter, open-label, randomized controlled trial involving 81 clinical sites in Japan, randomly assigned 2542 patients with type 2 diabetes aged 45–69 years to receive conventional therapy for glucose, blood pressure, and lipid control or intensive therapy. Over a median follow-up duration of 8.5 years (IQR 7.3–9.0), the primary outcome defined as a composite of myocardial infarction, stroke, revascularization, and all-cause mortality occurred in 109 patients in the intensive therapy group and in 133 patients in the conventional therapy group (hazard ratio [HR] 0.81, 95% CI 0.63–1.04; $p = 0.094$). Although the trial showed inconclusive benefits of further intensified multifactorial intervention compared with usual care for the prevention of a composite of major adverse cardiovascular events, the trial results suggest a potential benefit of an intensified intervention for the prevention of cerebrovascular events in patients with type 2 diabetes [42].

Another randomized, open-label, multicenter trial (**INDEPENDENT**) conducted among type 2 diabetic patients at four urban diabetes clinics in India evaluated a collaborative care model designed to improve depression and diabetes and

its microvascular and macrovascular complications. Patients with diabetes and depression symptoms were randomized to intervention group and control group. Intervention group received collaborative care which included 12 months of self-management support from nonphysician care coordinators, decision support electronic health records (DS-EHR) facilitating physician's treatment adjustments, and specialist care reviews. This trial showed that with the 12 months of collaborative care, significant improvements were seen in depressive symptoms and cardio-metabolic measures at 24 months among intervention group vs. control group [43]. Further cost-effectiveness analysis results from the INDEPENDENT Trial and CARRS-Translation Trial in India are underway and will be available in the near future. Preliminary findings from the cost-effectiveness analysis suggest that these diabetes care models are likely to be cost-effective to manage poorly controlled type 2 diabetes and depression in resource constraint settings.

A 2020 trial-based economic evaluation of **D-CLIP trial** conducted in India found that a stepwise approach for identification of high-risk individual and diabetes prevention would cost Parity Adjusted International Dollars (Int$) 145 to screen for and reduce diabetes incidence by 1% point, and Int$ 14,539 per diabetes case prevented and/or delayed, and Int$ 14,986 per quality-adjusted life-year gained, suggesting that a stepwise diabetes screening and prevention strategy is likely cost-effective, even in a low-income to middle-income country setting [44]. The findings of this economic evaluation can support more effective allocation of scarce healthcare resources for screening and stepwise approach to manage screen-detected diabetes in South Asia.

Impact of COVID-19 Pandemic on Diabetes Care and Potential Role of Digital Health Technologies

Since the World Health Organization's declaration of the COVID-19 pandemic in March 2020 [45], COVID-19 has remained rampant globally. In global case studies, older age, men, and the presence of comorbidities such as diabetes, cardiovascular diseases, chronic kidney disease, as well as regional differences in healthcare access and resources were identified as risk factors for mortality due to COVID-19-related factors [46]. Further, the mobility restrictions and lockdowns implemented to control COVID-19 have placed unintended direct and indirect stress on healthcare access by limiting access to healthy foods, exacerbating food insecurity among vulnerable populations, and limiting regular physical activity. A study from India found an association between state-level COVID-19 cases and deaths with diabetes, among other chronic conditions [47]. Another study found that the largest reductions in primary care contacts have been observed for contacts for diabetes-related emergencies (OR 0.35 [95% CI 0.25–0.50]) [48, 49].

Therefore, we need to reimagine the current healthcare system to provide alternative approaches to deliver care beyond COVID-19 and more investment in preventive care, building resilient primary healthcare systems as well as expanding financial protection through universal health coverage, to improve outcomes for patients with chronic conditions and prevent more people from developing these diseases amidst the current COVID-19 crisis [49]. Digital health technologies have transformed the way of delivering health services, particularly for chronic conditions to improve health outcomes. Mobile health (m-health) is the most promising and expanding approach in high-income countries to support the achievements of health goals and self-care management. mHealth strategies include short messaging services (SMS), remote monitoring devices, and other mobile-based applications. m-Health is a user-friendly health technology that enables and empowers people in capturing and monitoring health data. m-Health can foster patient engagement in diabetes self-care and potentially improve the interactions between patient and healthcare providers, particularly in resource constraints settings of Asia region.

For example, in India, a cluster randomized trial in 40 community health centers involving 3698 patients evaluated an android application used on a tablet computer that was capable to store health records electronically, enabling long-term monitoring and follow-up, and generated tailored management plan for hypertension, diabetes and comorbid depression, alcohol, and tobacco use. Further, SMS reminders were sent to the intervention group patients for follow-up and medication adherence. At 1-year follow-up, there was a greater reduction in the systolic blood pressure in the intervention group, but it did not reach statistical significance [50]. More recently, the researchers have successfully translated the mHealth intervention from research to service delivery mode in India, and it has been adopted by the state government of Tripura in India to manage hypertension and diabetes at the community health center level. Future work on mHealth to improve diabetes care should utilize consumer facing design thinking principles involving key stakeholders (patients, caregivers, physicians, and health administrators) to improve the acceptability, adoption, and effectiveness of mHealth strategies in patients with diabetes.

Conclusions

After three decades of intensive research, the benefits of blood glucose, blood pressure, and blood cholesterol lowering in patients with diabetes cannot be undervalued. Although proven and safe drugs now exist to meet treatment goals for people with diabetes, there remain enormous care gaps, especially in young patients and socially disadvantaged population. In view of the complexity of diabetes and patients'

pluralistic needs in Asia region, doctors and patients need to be fully informed and given time and support to build trusting relationships, supported by periodic assessments with access to free medications and self-monitoring tools, to minimize clinical inertia and nonadherence to prescribed therapy. The recent trials aimed to improve cardiovascular outcomes in patients with diabetes reminds us once again of the urgency of using advocacy, polices, and systems to ensure that patients with diabetes are managed by trained multidisciplinary healthcare teams, with regular feedback and monitoring of treatment targets to make optimal diabetes care a reality.

Further, constructing a regional infrastructure with guidelines, policies, and regional and centralized electronic health records to promote routine clinic-level diabetes patients' data collection, storage, and management along with diabetes-specific registries by professional societies and organizations will be effective to advance diabetes care. Research toward population-based management of both classical and special forms of diabetes will pave path toward a systematic approach to screening, diagnosis, and precision treatment of diabetes overall.

Points to Remember

- Asia region has one of the highest age-standardized disability-adjusted life years (DALYs) associated with diabetes mellitus.
- Southeast Asian countries like India and Bangladesh had a higher diabetes risk among the higher socioeconomic groups with lower education levels.
- Diabetes management involves both non-pharmacological and pharmacological approaches to prevention and treatment.
- Pharmacological management of diabetes is divided into oral antidiabetic drugs (OADs), insulin therapy, and non-insulin injectable therapy.
- Non-pharmacological management of diabetes is divided into lifestyle modification, medical nutrition therapy (MNT), and physical activity.

Multiple Choice Questions

1. Which region of world has the highest age-standardized disability-adjusted life years (DALYs) associated with diabetes mellitus?
   (a) Central Europe
   (b) Mediterranean and Middle East
   (c) **Asia**
   (d) Western Europe
2. Which Asian country has the largest number of adults with diabetes?
   (a) North Korea
   (b) **China**
   (c) Japan
   (d) Sri Lanka
3. Prevalence of diabetic neuropathy appears to be higher among which Asian country.
   (a) Pakistan
   (b) **Sri Lanka**
   (c) Iran
   (d) Malaysia
4. Which is the rare for, of diabetes among the malnourished young individuals with no alcohol abuse?
   (a) **Fibrocalculous pancreatic diabetes**
   (b) Maternally inherited diabetes with deafness
   (c) Neonatal diabetes
   (d) Maturity-onset diabetes of the young
5. What are the non-pharmacological approaches for diabetic management in Asia?
   (a) Lifestyle modification only
   (b) Lifestyle modification and insulin therapy
   (c) Medical nutrition therapy (MNT) only
   (d) **Lifestyle modification, medical nutrition therapy and physical activity**
6. Most commonly used oral antidiabetic drugs in Asia:
   (a) Biguanides
   (b) Thiazolidinediones
   (c) Biguanides and sulfonylureas
   (d) **All of the above**
7. As a part of medical nutrition therapy (MNT), what are the recommendations for the Asian population?
   (a) Carbohydrates should be limited to 50–60% of total calorie intake along with <5 g/day of salt consumption.
   (b) Fiber intake should be more than 40 g/day.
   (c) Diet rich in fruits, leafy vegetates, nuts, fiber, whole grains, and unsaturated fat.
   (d) Oils with high unsaturated fatty acid should be used.
   (e) **Both a and c**.
   (f) Only c option.
8. Exercise regimens among Asian diabetic population:
   (a) <30 min of moderate-intensity aerobic activity each day
   (b) >15 min of moderate-intensity aerobic activity each day
   (c) **≥30 min of moderate-intensity aerobic activity each day**
   (d) 20 min of moderate-intensity aerobic activity each day

9. Identify the barriers to diabetic care in Asia at healthcare system level.
   (a) Lack of integration between preventive and clinical care
   (b) Lack of patient education materials
   (c) Lack of emphasis on primary care systems to provide comprehensive diabetes care
   (d) **Both a and b**
10. What are the intervention components of the INDEPENDENT trial for type 2 diabetes patients?
   (a) Self-management support from nonphysician care coordinators
   (b) Decision support electronic health records
   (c) **Both a and b**

Epidemiology of Type 1 Diabetes Mellitus in Latin America and the Caribbean

The International Diabetes Federation estimates that in 2019, there were a total of 14,750 incident cases of type 1 diabetes in the age group 0–19 years (11,970 in the age group 0–14 years) and 153,700 prevalent cases in the same age group (83,240 in the age group 0–14 years) in Latin America [1]. The International Diabetes Federation data does not provide any data on the incidence or prevalence in older age groups. Many authors have stated that there is a paucity of data on the epidemiology of type 1 diabetes in Latin America [2, 3].

Temporal Trends

Globally, a 3–4% increase in incidence has been found for type 1 diabetes [4]. In Latin America, different studies have shown different trends. An increase (4%) in incidence was seen in Brazil over the period 1986–2006 [5]. In Mexico, a decrease in incidence was found between 2000 and 2018 (3.4–2.8 per 100,000) [6]; in contrast, another study by Gomez-Diaz et al. [7] also in Mexico showed an increase (3.4–6.2 per 100,000) between 2000 and 2010. Studies in Chile from 2000 to 2004 [8] and 2006 to 2014 [9], respectively, found increase of 5.4–8.3 per 100,000 population and 10.2–13.8 per 100,000 population, respectively. The studies by Negrato et al. [5] in Brazil, Garfias et al. in Chile [9] and Wacher et al. [6] in Mexico show wide variations in incidence rates over the periods studied.

Determinants and Drivers of Incidence of Type 1 Diabetes in Latin America

As in other world regions, the determinants and drivers of the incidence of type 1 diabetes are varied and as of yet unknown [4]. Various studies in Latin America have investigated different factors leading to changes in the condition's epidemiology. It has been noted that in Latin America, there is a link between the incidence of type 1 diabetes and European origin versus people of indigenous or African origin [2, 9–12].

Geographical differences in incidence have been noted in Brazil. In the Northeast, an incidence rate of 1.8 per 100,000 person-years was found in contrast to 10.4 per 100,000 person-years in the Southeast and 12.7 per 100,000 and 12 per 100,000 persons-year in 2 Southern Regions [3]. Peaks in incidence in Mexico were found to correspond to years of influenza outbreaks [6]. In an ecological model in Chile influenza, respiratory infections and environmental particulate matter were found to lead an increase with developing type 1 diabetes [13].

Differences in incidence based on gender were found in Mexico [6]. No seasonality of incidence is found in Cuba [14]. Shorter duration of breastfeeding equalled an increased risk of type 1 diabetes in a study in Brazil [15]. Enterovirus infection was found to be a risk factor for type 1 diabetes in different studies in Cuba [16]. Collado-Mesa et al. [10] found

a strong correlation between per capita supply of milk and incidence and prevalence of type 1 diabetes, as in other non-Latin American settings, as well as a correlation of wealth-related indicators for prevalence, but not for incidence. With regard to wealth as a determinant of type 1 diabetes, in Brazil and Chile, an increase in incidence was found in higher socio-economic groups [17, 18].

Genetic traits known to be a risk for increased incidence of type 1 diabetes were identified in Mexico [19] and Uruguay [20] (HLA-DQ allele), Colombia (RNASEH1) [21], Argentina and Colombia (rs763361 in CD226 and rs6822844 at the IL2-IL21 region) [22, 23], Chile (gene polymorphisms of PD-ligands (PD-L1 and PD-L2)) [24] and Brazil (rs763361 variant of CD226 gene (TT genotype) and HLA DQ2.5 and DQ8 haplotypes) [25–28]. In studying the HLA region which is a known genetic risk factor for type 1 diabetes globally, Conte Santo et al. [29] suggested that these alleles come mainly from the European population in Brazil through colonization and migration.

Age at Diagnosis

Most studies in Latin America show variations in the incidence rates for different ages [5, 7, 9, 17, 30]. A study in Brazil found that the incidence rate in infants and toddlers decreased during the period 1980–2014 but increased in children above the age of 10 [30]. Different mean ages at diagnosis were found in different Brazilian studies: 6.8 [30], 8.9 [5] and 11.3 [17] years. In Chile, the incidence was found to have increased especially in children under the age of 4 [8].

Delivery and Quality of Care

In many Latin American countries, type 1 diabetes care is predominantly provided in a hospital setting [3, 31, 32]. Diabetes control as measured by HbA1c in many Latin American countries is relatively poor, with, for example, in Mexico 18% of subjects having an HbA1c less than 7% and 35% more than 9% [33]. The problems with quality of diabetes care in Latin America have been identified for quite some time, with the QUALIDIAB network in 2001 already presenting data on the low quality of diabetes management in the region [34]. More recent studies in Brazil show that children, adolescents and adults with type 1 diabetes do not receive the necessary tests and screening for complications in comparison to international guidelines and ideal management of type 1 diabetes [35–37]. It could be argued that the poor delivery and quality of care is responsible for low levels of adherence found in Latin America [38].

Access to Care and Insulin

Cost of diabetes care can be a burden for the family. In some Latin American countries, some elements of diabetes care are provided for free, for example, insulin and consultations in Nicaragua [31]. In Mexico, it was found that average family costs of treatment and monitoring for type 1 diabetes were US$ 1690 which represents a substantial cost [39]. The highest cost was for self-monitoring representing 53% of total cost and insulin 15% of total cost. From a nationwide study in Brazil, similar results were found with insulin administration supplies and self-monitoring representing 53% of total costs of US$ 1319 per year [40]. Regional differences in the average annual per capita spending for type 1 diabetes care were found in Brazil with a range from US$ 1148 to US$ 1466 [32]. Although many aspects of diabetes care are provided for free in the public sector in Latin American countries, these are often not available [41]. With different populations accessing different services dependent on their family or their income or employment status, different outcomes for type 1 diabetes are seen with, for example, in Brazil, people with private insurance having better diabetes management than those in the public health system [42]. These socio-economic and educational differences were also linked to better access to insulin analogues and insulin pumps, with Caucasians, those with higher economic status and more years of schooling having better access in Brazil [43]. In other Brazilian studies, socio-economic [32, 44–46] and education [47] levels impacted diabetes care. Similar results were also found in Argentina with socio-economic and familial factors associated with poor control [48].

This challenge of overall access in the context of Universal Health Coverage and inequality is addressed in a study in Chile, highlighting that although coverage exists in Chile, people still face challenges accessing the care they should receive [49].

Complications

Due to challenges in the delivery of care and barriers to access, poor management and high rates of complications have been found in Latin America. In a nationwide survey of glycaemic control in people with diabetes, 87% of people with type 1 diabetes had an HbA1c above 7% [50]. Regarding complications, in a nationwide, cross-sectional study in Brazil of people with type 1 diabetes, 35% presented diabetic retinopathy and 12% presented vision-threatening diabetic retinopathy [51]. A cohort study in Brazil found that 70% of deaths were due to end-stage renal disease, macrovascular disease or acute complications of diabetes, mainly diabetic ketoacidosis, with a threefold increase in mortality [52]. Another study in Southern Brazil found that the leading

factor in people presenting diabetic ketoacidosis was non-compliance to their treatment [53].

Epidemiology of Type 2 Diabetes Mellitus in Latin America and the Caribbean

The region of Latin America and the Caribbean is highly heterogeneous. Although sharing geographic, language and some ethnic similarities, it presents a significant diversity regarding genetic ancestry and environmental exposures. In addition, this region presents major inequalities [54, 55] which often manifest themselves as health disparities [56], including differences in the obesity burden [57] and life expectancy [58] which influence the development of type 2 diabetes.

The NCD Risk Factor Collaboration (NCD-RisC) proposed the following sub-regions, which are helpful in terms of comparison [59]: Andean Latin America, Caribbean, Central Latin America and Southern Latin America. A similar sub-region classification is available when analysing the Global Burden of Disease (GBD) data [60].

Diabetes data, especially country-specific, are scarce for most of the region, but increased effort has been made to aggregate and synthesize the available data by global collaborations such as the International Diabetes Federation, which produces biannually the International Diabetes Federation Diabetes Atlas [61], the GBD Study, with its multiple publications on disease and risk factor frequency and burden [60], and the NCD-RisC, with its multiple and insightful studies, predominantly of prevalence [62]; finally, there has been a constant increase of systematic reviews and meta-analyses.

Prevalence

According to the International Diabetes Federation, in 2019, among those between 20 and 79 years old, 463 million people were living with diabetes worldwide, which is expected to increase to 700 million by 2045 based on population ageing and urbanization. Of these, 90% are estimated to have type 2 diabetes, and a total of 31.7 million were living in the South America and Central America region (including only the Spanish-speaking Caribbean nations), representing an 8% (95% CI: 6–11%) age-adjusted comparative diabetes prevalence, and ranking fifth among the seven world regions considered [61]. This estimate is expected to increase to 9% (95% CI: 7–13%) by 2045. The International Diabetes Federation aggregates Mexico with the non-Spanish-speaking Caribbean and North America to create the North America and Caribbean region. Discounting the United States and Canada, the remaining countries of this region were home to 13.8 million living with diabetes in 2019 [61]. It is worth noting that many individuals with diabetes do not know their diagnosis, which includes an estimated 36% of all individuals living with diabetes in Latin America and the Caribbean in 2019. Despite scarce country-level data being available for the region, the highest proportion of undiagnosed diabetes was found for Haiti (52%) and the lowest for Chile (21%) [61].

The Global Burden of Disease (GBD) estimated a type 2 diabetes prevalence of 6% (95% CI: 6–7%) for all low- and middle-income countries of the Latin America and Caribbean region in 2019 [60]. Over the last 10 years, Mexico and the two GBD sub-regions of Central Latin America and the Caribbean have consistently shown a considerably higher age-standardized prevalence than the global estimate (Fig. 18.1).

Brazil and Mexico had the highest absolute number of people living with diabetes in 2019 in Latin America: 16.8 and 12.8 million, respectively [61]. As for the International Diabetes Federation age-adjusted comparative prevalence, Belize was the country with the highest (17%; 95% CI: 14–19%) and Ecuador the one with the lowest (5%; 95% CI: 3–8%). Considering the countries with the largest populations, Brazil ranked 19th in age-adjusted prevalence (10%; 95% CI: 9–11%) and Mexico 4th (13%; 95% CI: 8–16%) [61] (Table 18.1). Brazil experienced an increase in diabetes crude prevalence of 91% over recent decades (from 1990 to 2019), according to the GBD data. The increase was primarily due to population ageing, as the age-adjusted increase was only 15% [60, 63]. Mexico's crude and age-adjusted prevalence increased somewhat more—by 114% and 22% [60]. Mexico's greater prevalence is believed to be principally due to its greater prevalence of risk factors, especially obesity. The Mexican 2018–2019 National Survey on Health and Nutrition (ENSANUT) estimated that 39% (95% CI: 37–40%) of adults were overweight and an additional 36% (95% CI: 34–37%) were obese, with the obesity prevalence having increased 42% from the year 2000. The latest increase (9% between 2012 and 2018) was higher than the previous one (6% between 2006 and 2012), indicating that the obesity and, consequently, the diabetes prevalence will likely continue to increase [64].

Except for Mexico (ranked 4th), the remaining top 10 countries, in terms of International Diabetes Federation age-adjusted comparative prevalence (Table 18.1) were all from the Caribbean region: Belize, British Virgin Islands, Puerto Rico, Barbados, Saint Kitts and Nevis, Antigua and Barbuda, Suriname, US Virgin Islands and Saint Vincent and the Grenadines [61]. Despite the scarcity of quality country-level data for the Caribbean region, resulting in higher estimate uncertainty, NCD-RisC reported that the largest increases in obesity and diabetes in the Americas between 1980 and 2014 were for the non-English-speaking (obesity

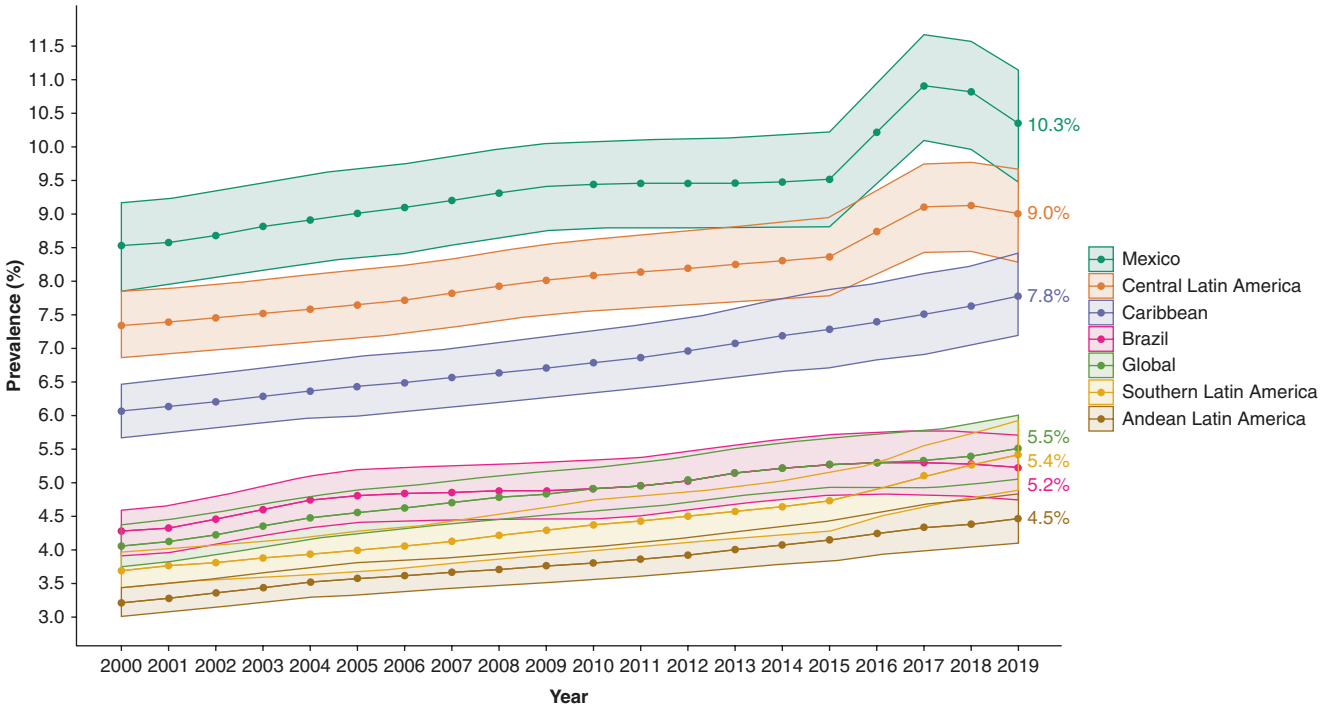

Fig. 18.1 Age-standardized prevalence (%) of type 2 diabetes on Latin American and Caribbean sub-regions for 2000–2019, data from the Global Burden of Disease

increase by 377% in men and 150% in women) and the English-speaking (diabetes increase by 23% in men and 22% in women) Caribbean sub-regions, respectively [62].

Three countries (Bolivia, Ecuador and Peru), usually classified together as the Andean Latin America sub-region, presented the first (5%; 95% CI: 3–8%), fourth (6%; 95% CI: 4–10%) and sixth (6%; 95% CI: 5–10%) lowest age-adjusted comparative prevalence, respectively [61] (Table 18.1). However, even though they presented the lowest rates, diabetes prevalence and management in these countries still represent major public health issues. A recent analysis estimated that the proportion of diabetes in these three countries attributable to each 5-unit BMI increase rose from 29% in 1980 to 50% in 2014 [65].

Incidence

Although of high importance to measure risk and changing risk over time for diabetes, the estimation of diabetes incidence usually requires much larger studies with a long-term follow-up and higher costs involved. Thus, there are scant diabetes incidence data available for Latin America and the Caribbean.

Age-period-cohort models are applied to the Mexico National Health and Nutrition Survey projected age-specific incidence estimates for 2010. For both men and women, the highest rate was in the 50–59 age interval (27.0/1000 in women and 23.3/1000 in men) [66]. The cohort study PERUDIAB estimated the diabetes incidence in urban areas of Peru as 19.5 per 1000; in contrast, the PERU MIGRANT study, in which more than half of the participants are from rural areas, estimated an incidence 50% lower [67]. The ELSA-Brazil (Longitudinal Study of Adult Health) cohort reported a diabetes incidence estimate of 2.0 per 100 person-years for Brazilian adults from six large capital cities [68].

Interventions focusing on improving known lifestyle and socioeconomic diabetes risk factors have demonstrated efficacy in decreasing the incidence of diabetes [69–71]; therefore, studies that address trends, current burden and management of these factors can be of great help in understanding the future risk of type 2 diabetes.

Mortality

Type 2 diabetes is well known to lead to increased mortality [72], disability and a lower quality of life [73] and, at the same time, to impose a heavy economic burden on the healthcare system [74], especially on low- and middle-income countries, such as most of those in Latin America and the Caribbean [75]. However, data on diabetes-related mortality in the region are scant. A recent meta-analysis reported that in Latin America, all-cause mortality in patients with self-reported diabetes was 149% (RR = 2.49; 95%CI: 1.96–3.15) higher than that of people without diabetes. For

Table 18.1 Number of individuals with diabetes, age-adjusted comparative prevalence of diabetes, and number of individuals with undiagnosed diabetes for Latin American and the Caribbean, data from the Diabetes International Diabetes Federation, 2019

Country or territory	GBD sub-region	Number of adults 20–79 years with diabetes in 1000s (95% confidence interval)	Diabetes age-adjusted comparative prevalence (%) in adults 20–79 years (95% confidence interval)	Diabetes age-adjusted comparative prevalence rank	Number of adults 20–79 years with undiagnosed diabetes in 1000s (95% confidence interval)
Bolivia	Andean Latin America	411.4 (337.5–636.3)	6.8 (5.6–10.4)	36	114.3 (93.8–176.8)

Table 18.1 (continued)

Country or territory	GBD sub-region	Number of adults 20–79 years with diabetes in 1000s (95% confidence interval)	Diabetes age-adjusted comparative prevalence (%) in adults 20–79 years (95% confidence interval)	Diabetes age-adjusted comparative prevalence rank	Number of adults 20–79 years with undiagnosed diabetes in 1000s (95% confidence interval)
Panama	Central Latin America	206.1 (171.0–295.1)	7.7 (6.4–10.7)	29	67.0 (55.6–95.9)
Venezuela	Central Latin America	1403.6 (1052.2–2017.7)	7.0 (5.0–10.8)	35	727.1 (545.0–1045.2)
Argentina	Southern Latin America	1837.4 (1309.6–2712.4)	5.9 (4.4–8.5)	40	597.2 (425.6–881.5)
Chile	Southern Latin America	1262.2 (1081.3–1550.0)	8.6 (7.4–10.7)	27	271.5 (232.6–333.4)
Uruguay	Southern Latin America	196.0 (148.3–247.1)	7.3 (5.7–9.4)	31	63.7 (48.2–80.3)
Brazil	Tropical Latin America	16,780.8 (15,045.1–18,697.9)	10.4 (9.2–11.5)	20	7719.2 (6920.7–8601.0)
Paraguay	Tropical Latin America	372.7 (340.4–411.3)	9.6 (8.8–10.6)	22	146.1 (133.4–161.2)

[a] Not included on the Global Burden of Disease (GBD) sub-region classification

cardiovascular mortality, the increased risk observed was a 176% (RR = 2.76; 95% CI: 1.99–3.82) [76].

According to the GBD, Mexico was the country with the highest type 2 diabetes mortality rate in those less than age 70 in 2019 (28.9 per 100,000; 95% CI: 24.5–33.4), followed by Central America (20.4 per 100,000; 95% CI: 17.7–23.2) and the Caribbean (18.2 per 100,000; 95% CI: 14.7–22.3) sub-regions (Fig. 18.2). The lowest estimate was observed for Southern Latin America (7.9 per 100,000; 95% CI: 7.3–8.5) [60].

Local Quantification of Risk Factors

The aetiologies of type 2 diabetes are complex, involving nutritional, genetic and environmental factors. Over the last two decades, there were many surveys in Latin America and the Caribbean to assess diabetes prevalence and status of management, treatment and care goals. There is, however, still the need for more data to extend the understanding of diabetes prevention and high-quality care achievements across countries [77].

Globalization and urbanization have led Latin America and the Caribbean to experience a major dietary shift to less-healthful low-nutrient/high-density foods and sugary beverages, which contributed to the remarkable rise in obesity [78]. Globalization and urbanization also led to a more sedentary lifestyle [79], which may have contributed to the increasing burden of obesity and diabetes.

Glycaemic and weight control of those with diabetes are the main factors usually associated with better morbidity and mortality outcomes. Obesity has consistently increased in all sub-regions in the last decades [60]. A review of the glycaemic control in Latin America and the Caribbean reported that it varies across the region. However, no study reported a percentage above 54% for the attainment of HbA1c lower than 7%. The percentage of those achieving optimal glycaemic, blood pressure and LDL-cholesterol altogether was not higher than 9%. This review also observed that the glycaemic control attainment over the region was associated with higher socioeconomic status, having health insurance, and better access to healthcare services [77].

The genetic ancestry of those living in Latin America and the Caribbean is diverse and highly admixed. For example, African ancestry has been described as having a higher frequency in Puerto Rico or Dominican Republic, while in Mexico or Bolivia, it was Native American ancestry, and in Chile and Argentina, European [80]. While there have been studies indicating an association of African and Native American ancestry with type 2 diabetes, a high portion of this association may be due to socioeconomic inequalities [81].

Socioeconomic disparities in the region are known to be a subjacent cause of diabetes. They can cause diabetes through food insecurity, which is a barrier to healthy eating habits, and by leading to unsafe neighbourhood environments which impose obstacles to augmenting physical activity, as well as through more difficult access to health care and medication

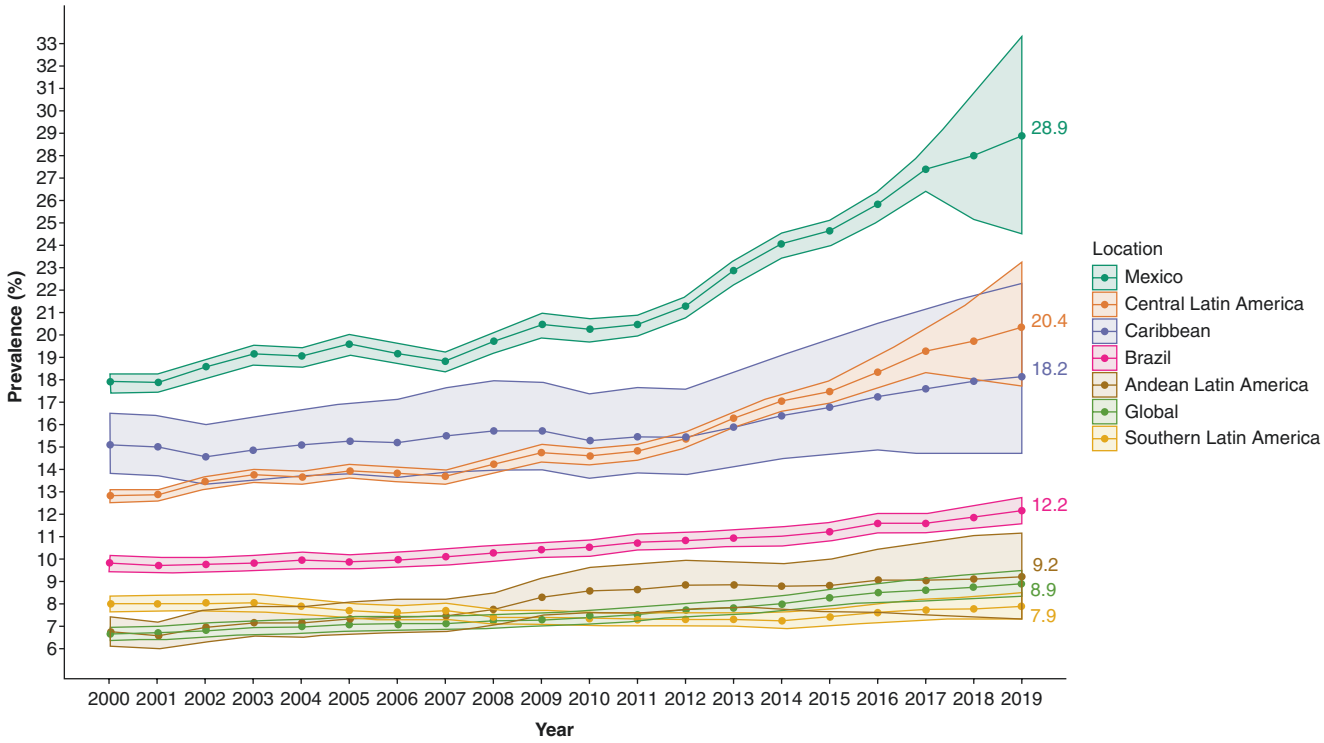

Fig. 18.2 Type 2 diabetes age-standardized mortality (per 100,000) in the Latin American and Caribbean sub-regions for 2000–2019, data from the Global Burden of Disease

[82]. Therefore, the high inequality observed in this region, within and between countries, needs to always be considered when planning public policies [83] which should be capable of reaching all those who can benefit from them.

Chronic Diabetes-Related Complications

Chronic diabetes-related complications can be divided into two major groups: microvascular (e.g. retinopathy, nephropathy and neuropathy) and macrovascular (e.g. cardiovascular diseases including coronary heart disease and stroke). The onset and prevalence of these chronic diabetes-related complications are closely related to metabolic control (e.g. optimal HbA1c levels), time since diabetes diagnosis and the synergic presence of other risk factors (e.g. smoking) and diseases (e.g. hypertension). While globally the mechanisms of these diabetes-related complications have been well defined along with prevention strategies and treatment [84–88], in Latin America and the Caribbean, quantifying the local burden and geographic distribution of these chronic diabetes-related complications is still an area of active research. Thereby, health authorities and practitioners still require a thorough understanding of the local epidemiology of chronic diabetes-related complications in order to set policies and interventions as well as to inform clinical practice guidelines for prevention and treatment.

Epidemiology: Microvascular

The large burden of microvascular diabetes-related chronic complications in Latin America and the Caribbean is likely linked to a twofold phenomenon: (a) on one hand, a large share of cases with type 2 diabetes is unaware of their diagnosis, particularly cases with a younger age at onset, who may have diabetes for longer without any proper treatment [89], and (b) a large number of cases live without adequate metabolic control, likely due to intrinsic deficiencies in access to treatment and disease monitoring throughout Latin America and the Caribbean [90]. These two factors interact and increase the likelihood not only of incident diabetes-related chronic complications but also increase the likelihood of disability related to improper long-term management of these conditions [77].

Despite the relevance of these microvascular diabetes-related chronic complications, currently there are no large-scale or multi-country prevalence studies of the epidemiology of chronic microvascular diabetes-related complications in Latin America and the Caribbean [91]. However, global analyses already suggest there is a large burden of microvascular complications in Latin America and the Caribbean [92]. For example, there are more years lived with disability due to diabetes-related lower extremity complications in Andean Latin America, the Caribbean and Central Latin America (second largest in the world) than the global average [92].

Evidence from community studies (i.e. not national and not in healthcare facilities) in Brazil revealed a diabetic retinopathy prevalence of 38% [93]; similarly, other studies in Brazil showed a 7% prevalence of diabetic retinopathy among people who are aware they had type 2 diabetes mellitus, and interestingly, 35% of those diagnosed with diabetic retinopathy did not know they had diabetes [94]; also in Brazil, of 533 patients with diabetes followed for retinopathy examination, 152 developed diabetes retinopathy or worsened their retinopathy over 9 years of follow-up in average [95]. In Ecuador, a community study showed that of 110 people with diabetes, 24% had peripheral arterial disease, 59% had peripheral neuropathy and 15% had both [96]. In the Republic of Suriname, a community study showed that among people with diabetes, 21% had diabetic retinopathy or maculopathy; furthermore, 8% had diabetic retinopathy at such a degree that would threaten their sight [97]. A study in Costa Rica found that diabetic retinopathy would be responsible for 6% of blindness cases [98]; following a similar methodology, researchers in Mexico found that diabetic retinopathy would explain 8% of blindness cases [99]. Another study in Mexico revealed that among people with diabetes, there was 15% prevalence of diabetic retinopathy; unfortunately, all these diabetic retinopathy cases had their sight threatened [100]. In Puerto Rico, the age-standardized incidence rate per 100,000 people with diabetes of end-stage renal disease was 196 in 2007 and 203 in 2010 [101, 102].

Studies in healthcare facilities also revealed heterogeneous results. An endeavour with inpatients in selected hospitals in nine countries in Latin America and the Caribbean showed that the prevalence of diabetic foot classified as Wagner 1 or above ranged from 3% in Bolivia to 13% in Chile [103]. In Argentina, the prevalence of diabetic foot in several healthcare centres with inpatient facilities was 14% [104]. In Brazil, a study with patients referred to specialized diabetes centres showed 46% retinopathy prevalence and 52% stage 1 nephropathy prevalence; regarding foot care, 18% had an active ulcer, 25% had a previous ulcer, and only 37% had foot without signs of risk [105]. Also in Brazil, a study in rural Basic Health Units with people with diabetes revealed that 63% of men and 36% of women had their feet foot with high risk of ulcers [106]. A study in Mexico based on administrative data informed that there were 100 major amputations per 100,000 people with diabetes in 2004, and this rate increased to 111 major amputations in 2013; these rates for minor amputations were 168 and 162 in 2004 and 2013, respectively [107]. In Peru, an analysis of a referral network for diabetic retinopathy showed 24% prevalence [108]; in addition, a surveillance programme in 18 hospitals in Peru informed that the most common complications were neuropathy (21%), diabetic foot (5%), nephropathy (3%) and retinopathy (2%) [109].

Epidemiology: Macrovascular

Cardiovascular diseases, with coronary heart disease and stroke at the top, are the leading cause of death in people with diabetes. Evidence suggests that people with diabetes have threefold risk of cardiovascular mortality (pooled relative risk = 2.7; 95% CI: 1.9–3.8) than people without diabetes [76]; apparently, this risk estimate is larger than that of other world regions [76]. A multi-country study in Latin America and the Caribbean with patients in healthcare centres gathering information from medical records showed that 7% also had coronary artery disease, 3% had myocardial infraction, 3% underwent percutaneous coronary intervention and 2% had stroke [110]. A lack of systematized information or a common registry of macrovascular complications in people with diabetes complicates the epidemiological characterization for this group of complications [111]. More data is required to evaluate specific risk factors, particularly those related to inequalities and intrinsic deficiencies in preventive care for people with diabetes, and which may inform preventive regimes and likely contribute to a reduction in the burden of cardiovascular disease in people with diabetes in Latin America and the Caribbean [112].

Final Remarks

In this section, we have summarized epidemiological evidence about chronic microvascular and macrovascular complications among people with diabetes in Latin America and the Caribbean. Evidence suggests that there is a large burden of these complications in Latin America and the Caribbean; nonetheless, much more research is needed to have a strong quantification of the burden of these complications at the national and sub-national levels in all countries of the region and to evaluate potential contributors of this phenomenon to inform future changes in public policy. A key factor to prevent or delay these complications is to reach optimal metabolic control. Unfortunately, metabolic control rates among people with diabetes are still low in Latin America and the Caribbean [113], and a large share of these patients is currently unaware of their diagnosis [113]. Ongoing and future work should strengthen the epidemiological and clinical evidence about these complications in the region while also securing optimal care for people with diabetes and timely detection of cases, particularly those with young disease onset so that they reach metabolic control and receive preventive care for these chronic complications.

Diabetes Interventions in Latin America and the Caribbean

Successful interventions are required to prevent and manage diabetes in Latin America, a region with significant increase in the number of people with this chronic condition. There are benefits achieved by preventive care among patients with diabetes. Although many of the interventions are focused on type 2 diabetes, some of them are being conducted enrolling type 1 diabetes cases.

Interventions in Type 1 Diabetes Mellitus

A limited number of interventions focused on type 1 diabetes have been evaluated in Latin America and the Caribbean. A randomized cluster trial was carried out to improve the quality of diabetes care in ten primary healthcare centres in Mexico using the chronic care model and the breakthrough series collaborative methodology [114], with an improvement in glycaemic control rates from 28% to 39%. Similarly, the proportion of patients achieving three or more quality improvement goals increased from 16% to 69%.

Two different programmes were also conducted in Brazil. One of them included a structured education programme on glycaemic control, knowledge and skills associated with diabetes care with workshops using the Dose Adjustment for Normal Eating (DAFNE) guidelines and subsequent reduction on HbA1c levels (20% in the first year and a further 11% reduction 8 months later) [115]. The second programme included an educational intervention tool and its potential impact on diabetes knowledge and behaviour of caregivers and school professionals. The intervention achieved the goal of informing and changing the behaviour of parents and school staff, improving the care provided to children with type 1 diabetes in schools [116].

Finally, in a pre-post evaluation, a coaching programme was implemented as part of the interdisciplinary care of individuals with type 1 diabetes in the Brazilian public health system, including weekly 60-min individual sessions for a total of eight sessions [117]. With ten patients in this pilot study, results suggested a reduction of HbA1c after 3 months and no further change at 6 months.

Interventions in Type 2 Diabetes Mellitus

Primary Prevention

There are relevant reasons why primary prevention of type 2 diabetes should be the dominant strategy for Latin American countries, mainly related to younger age group, female preponderance and high overweight and obesity prevalence. Interventions have been based on young subjects with impaired tolerance or fasting glucose, or with factors dramatically increasing the risk of developing type 2 diabetes, to improve lifestyle behaviours and potential risk factors. In an intervention in Colombia, using a three-arm randomized trial, two groups received early intensive lifestyle intervention compared to a control group (DEMOJUAN Project) [118]. One group received first a nutritional intervention for 6 months, physical activity intervention later for 6 months and then 12 months of a combined nutritional and physical intervention with specific goals, whereas the second group received only the physical activity intervention for 6 months plus the nutritional intervention for other 6 months. Despite of the 772 participants randomized and followed for 24 months, there was no significant difference between groups in the rates of reversion to normoglycaemia.

Nevertheless, two other clinical trials conducted in Brazil and enrolling subjects in high risk of type 2 diabetes have shown contrary results. One of them included group sessions twice per month and individual sessions once per month for 12 months and showed a decline in cholesterol, fasting and postprandial glycaemia and HbA1c [119]. The second study consisted of an interdisciplinary intervention with three visits plus an individual appointment with a dietitian and two-hour group sessions (four sessions in the first month, two sessions in the second month and one session monthly up to 9 months) [120]. This intervention reduced waist circumference, systolic and diastolic blood pressure as well as some domains in the 36-item Short Form Survey (SF-36).

Two quasi-experimental studies using a pre-post approach have showed benefits. One of the studies, conducted in Chile, assessed the results of an interdisciplinary pilot programme for overweight adults at risk of type 2 diabetes with reduction in body mass index, systolic and diastolic blood pressure, blood glucose, plasma insulin and HOMA [121]. The second study, carried out in Mexico, adapted the Diabetes Prevention Program with intensive sessions the first 3.5 months (weekly group and individual sessions) for lifestyle behaviour change and nutritional advice [122]. Intensity, however, lowered from 3.5 to 6 months, and only group sessions were done from month 6 to 12. The intervention group has significant weight loss, from 3 to 8 kg, at 6 months, but retention was only 40% at month 12.

Secondary and Tertiary Prevention

Different studies have been conducted in Latin America to address type 2 diabetes secondary and tertiary prevention. Many of the studies using a secondary prevention approach have been based on education programmes and, for instance, behavioural change. Thus, in Argentina, Gagliardino et al. conducted a randomized trial to assess four structured group education programmes (control, physician education, patient

education and both physician and patient education) using the Training Course for Physician and the Diabetes Structured Education Courses for People, with a follow-up of 3.5 years [123]. In this study, HbA1c decreased significantly from 4 to 10 mmol/mol by the end of the study, being the largest and more consistent reduction in the physician and patient group. Nevertheless, in Brazil, a 5-week educational group course (10 h), mainly focused on self-management, with reinforcements every 4 months for a total of 12 months, did not find differences between groups in HbA1c at 4, 8 and 12 months of follow-up [124].

In the case of behavioural change, in a clinical trial conducted in Trinidad and Tobago, the intervention consisted of identifying each patient's Stage of Change for managing their diabetes by diet, exercise and medications and using personalized, stage-specific care during consultations [125]. This intervention reduced HbA1c levels depending on the favourable movement to better stage of change in diet and exercise after 48 weeks. de Sousa et al. in Brazil used individual nutritional counselling every 2 weeks to reinforce and support dietary adherence and monitor caloric intake compared to such intervention with football training (3 weeks per week) [126]. A reduction in blood triglycerides, total cholesterol, LDL-cholesterol and VLDL-cholesterol was achieved in the football and dietary intervention during the 12 weeks of duration of the study. Similarly, West-Pollak et al. in Dominican Republic using a quasi-experimental design implemented a community-based lifestyle intervention programme developed by lay people perceived as leaders by community members and trained as healthcare champions [127]. Significant improvement in systolic, diastolic blood pressure and HbA1c levels was found after 6 months; however, only HbA1c improved after 1 year of follow-up.

In a randomized cluster trial in Mexico, a 13-week secondary prevention intervention, MetaSalud Diabetes, was implemented within the structure of a support group in government-run community health centres [128]. The programme consisted of two-hour participatory workshop-style session with educational information and empowerment-building discussions to promote long-term behavioural change. Participants' follow-up was carried for 12 months with reduction on cardiovascular disease risk at 3 months of follow-up in the intervention compared to the control group, but not significant change at month 12. In addition, diabetes distress was lower in the intervention group compared to controls.

In Costa Rica, using a quasi-experimental design, an educational community intervention for primary health care including type 2 diabetes patients, their family members and healthcare providers, was adapted to local conditions and patient's needs and implemented [129]. Providers improved their knowledge in diabetes prevention, treatment and education by a mean of 85%, whereas patients receiving the intervention improved their glycaemic control, without changes in body weight or lipid profile. In Mexico, an educative intervention comprising 12 modules with three 60-min sessions per week focused on self-monitoring, diet, exercise, complications, behaviour modification, self-care, family and sexuality, reduced fasting and postprandial glucose as well as HbA1c and cholesterol after 12 months [130]. Similarly, in Nicaragua, a prevention and self-management intervention delivery in interactive group format, including a one-on-one coaching component, for a total of 8 weeks, was conducted. This latter intervention reduced HbA1c from baseline to 3 months, and the greater reduction was found among those with HbA1c >7.5% at baseline [131].

On the other hand, two studies have reported findings using community health workers to deliver the intervention. A culturally adapted education intervention for type 2 diabetes patients was developed and implemented in rural communities in Guatemala using a one-group pretest post-test design and community health workers [132]. There was a significant decrease in the mean of HbA1c levels from baseline to 4 months of follow-up. In Brazil, salaried community health agents received a 32-h training in motivational interviewing-based counselling and behavioural action planning [133]. With support of booster training sessions, the community health agents used these skills in their regular monthly home visits over a 6-month period with patients with type 2 diabetes. Participants reported improvements in quality of diabetes care received, increase in physical activity levels, consumption of fruits and vegetables and medication adherence, with a subsequent reduction of HbA1c levels and improvement on LDL-cholesterol and triglycerides levels.

Some studies have utilized technology to improve the intervention to be implemented. In Peru, Lazo-Porras et al., using a clinical trial, conducted an education programme for preventing foot ulceration using reminders and foot-care promotion messages as SMS or automatic phone calls, and foot thermometry [134]. However, the addition of mHealth to foot thermometry was not effective in reducing the risk of ulceration after 18 months of follow-up. In Mexico, the Project Dulce model was evaluated using a randomized trial with three arms: control, educational sessions for self-management with, and without, wireless technology [135]. Such educational programme included eight 2-h weekly sessions led by peer diabetes partners during the first 2 months of the intervention, with a subsequent drop in HbA1c levels from baseline to month 10 of the intervention groups compared to the control, being greater among those using wireless. In addition, a single group, pre-post study was conducted to evaluate the feasibility and potential impact of an interactive voice response programme using a cloud-computing model to improve diabetes management in Honduras [136].

After 6 weeks, participants reported that because of the programme, they improved diabetes management, including glycaemic control or foot care; there was also a reduction of HbA1c levels.

One study in Latin America tried to improve glycaemic control by using monetary incentives. This three-arm randomized clinical trial was a small pilot conducted in a tertiary level public hospital in Peru [137]. All participants received diabetes education and tailored goal setting for weight and HbA1c levels and assigned to one of the three arms: individual incentives, mixed incentives—altruism and mixed incentives—cooperation. After 3 months, participants in all three arms showed reduction in weight and HbA1c level.

From the tertiary prevention perspective, only one randomized clinical trial, conducted in Argentina and Chile, was carried out comparing percutaneous transluminal coronary angioplasty versus stent among patients with type 2 diabetes to reduce the incidence of angiographic restenosis, with no differences between group after 30 days and 9 months of follow-up [138].

Final Remarks

As diabetes increases in Latin American and the Caribbean region, innovative and effective interventions are required to improve health outcomes. In this section, we summarized several initiatives in Latin American and the Caribbean countries that focused mainly on diabetes risk reduction and diabetes management, some of them showing promising results. Evidence supports than education programs may be relevant but not enough to improve glycaemic control. Thus, a multidisciplinary approach may be efficacious for diabetes management, including community health workers, using a self-management approach, and including the use of technology.

Implementation Science for Type 2 Diabetes Mellitus in Latin America and the Caribbean

Implementation science is usually defined as "the scientific study of methods to promote the systematic uptake of research findings and other evidence-based practices into routine practice, and, hence, to improve the quality and effectiveness of health services and care" [139], and it has the objective to close the know-do gap, the differences between what we know works and what we do, by addressing barriers and facilitators to the uptake of interventions [140].

For diabetes, this science is essential due to the complexity of this chronic condition in terms of the different levels of influence and the multiple interactions between them (individual level, family, community, health system, environment and policies) [141, 142]. In that sense, it is relevant to translate the knowledge to daily practice and to understand how the intervention was implemented in the field [143, 144]. Latin America had previous experiences implementing context-adapted interventions, and they will be explained as case studies. Additionally, using implementation science, it is possible to identify some barriers and facilitators to achieve an adequate management, and this information will be presented too.

Examples of Successful Experiences

Case 1: The VIDA Project

The aim of this project was to improve the quality of care in people with diabetes at the primary healthcare level in Mexico [114]. The intervention was a quality improvement project that included three learning sessions for the primary healthcare teams and personnel from the local hospital. The chronic care model was used to let health personnel to identify their problems to provide care, and the "plan, do, study, act" was used to co-develop solutions. Also, they received training in patient's education, foot care and diabetes management in primary care.

The study was a pre-post design conducted in the state of Veracruz, and the intervention was delivered in ten centres with ten other centres receiving usual care. Quality improvement was measured by changes in the proportion of patients achieving the diabetes care goals such as metabolic control (HbA1c <7%), total cholesterol <200 mg/dL, blood pressure <140/90 and to have received foot and eye examination.

After 18 months of study, they found an increase in the proportion of the management of three or more treatment goals in the intervention group from 16% to 69%, whereas the usual care group did not present such difference. The proportion of those who achieved the blood pressure goal did not present a difference in neither of the groups.

Also, patients that participated in the education sessions provided feedback and mentioned that they found the support groups very useful to increase physical activity and they indicated that activities need to be tailored to different types of patients. Additionally, the health personnel selected objectives for improvement activities, and the implementation of the "plan, do, study, act" was successful.

Case 2: The Meta Salud Diabetes Implementation Study

This project evaluated the effectiveness of Meta Salud Diabetes to reduce cardiovascular risk [128]. They used a clustered randomized trial in urban and rural areas from Sonora, Mexico. The intervention included 13 sessions of

two hours each in support groups (Grupo de Ayuda Mutua—GAM) to provide education and hold empowerment discussion and also included blood pressure and glucose monitoring, games and the design of a physical activity routine. The intervention was delivery by diverse health professionals trained to guide the session. The comparison group was participants of the usual care activities of the GAM that includes sessions with invited speakers to provide general information about diabetes. The outcome was cardiovascular disease risk using a score, and the follow-up was at month 3 (at the end of the intervention) and at 12 months (to measure sustainability).

Cardiovascular disease risk was lower in the intervention arm in comparison with the control arm at 3 months, but the difference was not maintained at 12 months. The effect was modified by gender (having a positive effect in male and not in female at 3 and 12 months) and baseline HbA1c (having a positive effect in people with HbA1c <8 and not in those with higher HbA1c).

The project also included a qualitative study to explore the willingness of the staff, their capacity and the resources available to implement Meta Salud Diabetes within the existing GAM structure. Some characteristics were identified that could boost the adoption of the intervention such as management, staffing and local environment. Barriers included the absence of standardized training and capacity building in chronic disease and health promotion, a need for supervision and feedback to the programme, scarce medical supplies and lack of interdisciplinary support. Modifications are possible to adapt the intervention to realities of the health centre environment [145].

Case 3: Combined Diabetes Prevention and Disease Self-Management Intervention for Nicaraguan Ethnic Minorities: A Pilot Study

The study assessed the feasibility, acceptability and preliminary efficacy of a community-based participatory research [131]. A pilot study was conducted in two groups considered ethnic minorities from Nicaragua (Miskitos and Creoles). The setting was a rural area, and the intervention was developed in collaboration with local church and community leaders to prevent and promote self-management of diabetes and complement with input from community nurses and physicians. The intervention included two main components: (a) group sessions led by a nurse with motivational interview and goal settings for diet and exercise (eight sessions of one hour) and also (b) one-on-one meetings to individualized diabetes prevention or promote self-management (four sessions of 30 min).

The pilot study intervened in 42 participants and follow-up 33 of them. The mean HbA1c improves from 8.8% to 8.3% in 3 months, and the impact was slightly higher in those that had a higher HbA1c at baseline (from 9.7% to 9.0%). Also, the intervention was acceptable, and the feasibility was good with successful research capacity building and achievement of sampling goals.

Other implementation studies can be found in the literature [146] and included diverse intervention approaches, e.g. one study evaluated the challenges of implementing a clinical practice guideline in public hospitals in Mexico [147]; other study in rural Guatemala implemented a quality improvement strategy at the household, clinic and institutional level [148]; also, a study in Brazil evaluated the introduction of an application for decision system support used by health professionals. It included clinical evaluations and blood glucose measurements and generated specific recommendations based on the data provided [149]; finally, an intervention to prevent diabetic foot ulcers through the implementation of foot thermometry and mHealth achieved good adherence to temperature measurements, but the intervention was not superior to the control arm (foot thermometry alone) [134].

A recent systematic review identified the barriers and facilitators to achieve a successful management of type 2 diabetes using the Theoretical Domain Framework [150]. They included 60 studies and found that 54 studies (90%) identified factors related to the environmental context and resources. Challenges due to "social influences" (40 studies) such as lack of support from family members were found. Additionally, clinician's paternalistic attitudes as well as other negative attitudes (37 studies) were frequently addressed. Other barriers were related to the patient's beliefs (25 studies) that end up in low patients' trust in the treatment and/or physician and the use of alternative therapies.

Know-Do-Gaps for Type 1 Diabetes Mellitus

In the case of type 1 diabetes, guidelines have identified key priorities to improve type 1 diabetes care such as education and information, blood glucose management, insulin therapy, awareness of hypoglycaemia and detection and management of psychological and social issues, among others [151, 152].

There are no implementation science studies conducted in Latin America for type 1 diabetes. However, we will describe one model to integrate implementation science into paediatrics psychology developed in the USA and the implementation of a social support event for children with type 1 diabetes and their families conducted in the USA. These examples might help the reader grasp important concepts related to implementation science and might also motivate them to use implementation science methods within their research.

Price et al. propose a model for integrating implementation science into paediatric psychology for type 1 diabetes [153]. The model has four steps: (a) identifying the gap of psychological management of patients with type 1 diabetes, (b) identifying barriers and facilitators using the Consolidated Framework for Implementation Research (CFIR) framework

[154], (c) developing implementation strategies using those identified in The Expert Recommendations for Implementing Change (ERIC) project [155], and (d) evaluating implementation outcomes as acceptability.

Education and psychoeducation interventions have proven effective to reduce HbA1c and increase children's self-efficacy to manage type 1 diabetes [156]. However, Price et al. identified a gap in management of psychological issues in patients with type 1 diabetes, as they cite, only 18% of families with these patients attended at least one psychology visit within a 2-year period in Boston, USA [157]. He proposed some barriers using the CFIR framework: outer setting (patient needs, patient and family perspectives, stigma associated with psychological care and insurance coverage), inner setting (staffing and space), characteristics of the individuals (lack of awareness of the effectiveness of paediatric psychology care among patients, families, providers and payers), intervention characteristics (length and number of sessions) and process (need to have a plan for implementing paediatric psychology care). Based on this information, they expect to develop targeted implementation strategies to then test them.

It is important to note that the proposed model uses implementation science methods that could be used in different contexts, including Latin America. Thus, following the proposed four steps of the model could help researchers develop a clear research plan from the identification of a research gap to the development and evaluation of implementation strategies.

Shea et al. conducted a study to assess the implementation of the "Diabetes Day" [158], a social support event for children with type 1 diabetes and their families, as they noticed that only 25–50% of the families who confirmed participation actually assisted to the event. Shea used the Rogers's diffusion of innovation theory to assess the dissemination and acceptance of the "Diabetes Day" event. This framework was used to evaluate each step of the event, and information on programme success, barriers to participation and suggestions for future sessions were collected through surveys to families and healthcare providers. Then, the staff planned the next session meeting children and parents' expectations such as including outdoors activities in the summer when children will be out of school. Additionally, to improve recruitment of families, flyers were designed and pasted in the hospital, and the "Diabetes Day" information was added to the discharge sheets that providers use during patient visits.

Access to Treatment

Hypoglycaemic Medication

The access to hypoglycaemic medication is unequal around the world with greater disadvantage for low- and middle-income countries in the Latin American Region. According to an International Diabetes Federation survey which included 13 countries of South America and the Caribbean Region, metformin was available in 65% of middle-income and only in 20% of low-income countries and sulfonylureas in 46% and 10%, respectively [159]. Those numbers are far from the target of 80% availability of essential medicines for the prevention and treatment of diabetes recommended by the World Health Organization (WHO) in the Global Action Plan for the prevention and control of non-communicable diseases [160].

The survey methodology proposed by the World Health Organization and Health Action International (WHO/HAI) [161] to assess price, availability and affordability was applied in different countries in Latin America. For instance, Brazil, El Salvador and Peru as representative countries of South America reported a mean availability of glibenclamide 5 mg/tab of 79% in the public sector and 90% in the private sector, which are higher results than the result from Africa, Asia, the Eastern Mediterranean region and the Western Pacific but lower than the European region [142]. In terms of affordability, to supply a treatment for 30 days with glibenclamide 5 mg/tab, the lowest-paid unskilled government worker has to spend 1.6 day's wage to acquire a generic brand and 4.5 day's wage for an originator brand [162]. A medicine is considered affordable when the lowest-paid unskilled government worker spends less than 1 day's wage to pay for a regular treatment [161]. Data compiled from different countries showed that the availability of metformin 850 mg/tab in the public sector decreased in the following order: Colombia > Mexico > Ecuador > Bolivia > Brazil, while for the affordability of generic brand in the private sector decrease as follows: Bolivia > Ecuador > Mexico > Braz il > Colombia [163]. It is important to note that the price also varies depending on the brand; for example, in Peru, they found that the median price of metformin 850 mg/tab in private pharmacies was 0.12 USD for a generic brand and 0.53 USD for an originator brand [164]. This price difference may in part from the large number of generic manufacturers in the country and the pricing regulations.

It is true that in some countries, such as México, Brazil, Colombia, Ecuador and Peru, hypoglycaemic drugs are provided free of charge with public insurance; nevertheless, the low availability in the public sector force patients to go to the private sector where the price may be up to ten times higher generating high out-of-pocket expenses with significant impact on the most disadvantaged ones [162–164]. For example, in Mexico, it was reported that even though older adults have public insurance, they faced out-of-pocket expenses, and these are greater among rural populations, mainly because some medicines are not covered by the public insurance [165, 166]. Besides the public insurance, other factors associated with limited access to medicines for chronic conditions in Latin American countries include people who live in rural areas or with less proximity to health-

care facilities; where the household head is retired or belong to an ethnic minority; being older than 65 years; and worse economic household level and with equal or less than elementary education [167].

There are also positive initiatives, for example, the government of Brazil implemented subsidy policies for essential medicines for hypertension and diabetes (the Farmácia Popular Program) that in 2004 started just with public pharmacies but in 2006 was expanded to private ones. This programme improved the availability of essential medicines and the affordability but also increased the number of dispensations and sales of generic medicines [168]; unfortunately, an adequate access to medicines did not assure adherence to pharmacological treatment [169].

Insulin

The expenditure for insulin in Latin American and the Caribbean is estimated between USD 6 and USD 11 billion, almost twice the expenditure for oral antidiabetics [170]. In this region, between 13% and 36% patients with type 2 diabetes use insulin, either alone or in combination with oral antidiabetic drugs, being the most prescribed insulin the human intermediate-acting or isophane [41, 171].

Using the WHO/HAI methodology [161], a study in 2007 in Brazil reported an availability of 40% for regular insulin and 50% for isophane insulin and an affordability of 2.8 day's wage for isophane insulin in the private sector [172]. Another study with the same methodology in 2019 showed that the availability of isophane insulin improved to 80% in the public sector, while its affordability in the private sector remained stable [173]. From 2006, the Brazilian federal government provided free of charge human insulins (regular and isophane) in the public sector and through patient's co-payment with government subsidy in the private sector. In 2011, the programme "Health has no Price" (Saúde Não Tem Preço, in Portuguese) established a partnership with private pharmacies to provide regular and isophane insulin free of charge, with a government reimbursement. In the first 12 months of "Health has no price", the number of units dispensed in private pharmacies increased by 97% for regular insulin and 78% for isophane insulin, while the dispensing of fixed-dose combination (regular/isophane) decreased which may indicate a preference for using medicines provided by the programme [174]. The different efforts of the Brazilian government generated an investment of USD 1027 billion between 2009 and 2017 and benefited thousands of patients; however, it also implied important expenses in reimbursement [175].

Regular and isophane insulins are listed in the WHO model list of essential medicines [176] as well as in the National List of Latin American countries; this denomination facilitates the procurement through public tendering at national level which take advantage of economies of scale and achieve lower prices. The no inclusion of analogue insulins in National List of Medicines prevents their acquisition through tendering in some countries such as Peru and Brazil, but this does not hinder their existence in public hospital since analogue insulins may be procured at a local level [164, 175]. This increases inequity because these analogue insulins are only available for a small proportion of the population, and the expenses in their procurement are high. For example, in Peru, it was found that 10% of public hospitals have analogues, but their acquisition price (USD 57) represented almost ten times the acquisition price of human insulins (~USD 4) [164].

Price differences not only occur between human and analogues insulins; there is also important price variation between originator brand and biosimilar [173]. Price regulation led to less variability in markups, but not necessarily lower prices [177]. For example, in Peru, ingredients for the manufacture of medicines for diabetes and the medicines itself are free of import taxes, but the price of the same type of insulin may vary between USD 49 and USD 107 [164].

Cardiovascular Treatment in People with Diabetes

It is described that antihypertensive treatment achieves cardiovascular risk reduction if treatment starts as soon as possible and the goals are reached soon [178]. In relation to lipid-lowering medication, a systematic review and meta-analysis published in 2010 explored the effect of statin use vs. placebo and more intensive lowering of LDL cholesterol regimen against less intense regimen in major cardiovascular events. The study found that comparing statin/more intense regimen vs. control/less intense regimen for type 1 diabetes, the effect (rate ratios) on first major vascular event (first occurrence of any major coronary event, coronary revascularization or stroke) per 1.0 mmol/L reduction in LDL cholesterol was 0.77 (95% CI: 0.58–1.01) including 337 events, whereas for type 2 diabetes, it was 0.80 (95% CI: 0.74–0.86) including 5414 events [179].

However, there is no pooled data from Latin America to know the proportion of people with diabetes that achieve the blood pressure or lipid lowering goals as well as the percentage of people who have access to their medication. Only some studies usually conducted within the health system setting explored these data and found that between 25% and 67% of patients reached the goals for blood pressure (considering different definitions) and between 12% and 52% reached the goals for LDL cholesterol [180].

In terms of access to cardiovascular medication, there is data from the PURE study that evaluated availability and

Table 18.2 Availability and affordability of four cardiovascular medicines by country income group

	Availability of four cardiovascular medicines		Unaffordable for population (%)
	Urban	Rural	
High-income countries	61 (95%)	27 (90%)	0.14
Upper middle-income countries	53 (80%)	43 (73%)	25
Lower middle-income countries	69 (62%)	42 (37%)	33
Low-income countries, excluding India	8 (25%)	1 (3%)	60

affordability of 4 cardiovascular disease medicines including aspirin, β-blockers, angiotensin-converting enzyme inhibitors, and statins in 18 countries (4 from Latin America); and they found differences by income status of the countries [181]; and differences between urban and rural areas were identified as well (Table 18.2). Also, affordability of the four cardiovascular medicines were defined if the cost was less than 20% of household capacity-to-pay, and Chile and Brazil were under the 20% cut-off point, whereas Colombia and Argentina were around 45% [181].

Prediction Tools

Countries within the Latin America and the Caribbean region have high rates of patients with undiagnosed diabetes, and many of whom do not have adequate glycaemic control and are at high risk of acute metabolic events and chronic micro- and macrovascular complications [112]. In an effort to promote prompt identification of cases with suspected type 2 diabetes, predictive modelling approaches have been proposed as triage or screening methods to identify patients who are likely to have undiagnosed diabetes and would benefit most from additional screening methods including serial fasting glucose measurements, oral glucose tolerance tests or HbA1c measurements in an effort to improve resource allocation in rural or limited resource settings [182]. In this section, we will discuss evidence regarding the utility of diagnostic and prognostic tools for type 2 diabetes and diabetes-related complications.

Diagnostic and Prognostic

Given some described differences in onset, progression and treatment response of patients with type 2 diabetes in Latin America and the Caribbean, there is a need for the development of predictive modelling approaches which incorporate metabolic particularities of these populations [112, 183]. To be useful, predictive models for type 2 diabetes need to satisfy certain requirements including: (1) They need to be simple and widely applicable to justify its use instead of a simple (but arguably invasive) fasting glucose measurement; (2) need to consider items which make diabetes unique in the region, including earlier age at disease onset, lower degree of obesity required compared to similar ethnicities and unique genetic susceptibility for development of diabetes independent of additional risk factors; and (3) need to show that its use could lead to improved outcomes or more precise public policy planning. To date, no single model has shown to be cost-effective to be widely recommended as a tool to promote effective screening and diagnosis of diabetes in the region [183, 184].

A 2019 systematic review summarized at least five diagnostic tools which have been developed in different countries, which have primarily focused on prevalent but previously undiagnosed diabetes cases in Brazil, Mexico and Peru [183]. These models are driven primarily by consideration of age, obesity traits (assessed by body mass index and waist circumference), family history of diabetes and secondary predictors including sex, blood pressure levels and individual components of the metabolic syndrome, which have had limited assessment regarding its incidence in countries outside of Mexico [185]. Additional modelling approaches not considered in the systematic review include two incidence models for prediction of 3-year risk of diabetes mellitus in Mexico based on convenience sampling and an additional model based on the population-based ENSANUT, with similar characteristics to the tools appraised in the systematic review [186–188]. Finally, models developed in other populations such as FINDRISK have been externally validated in the region but have failed to show adequate calibration or be cost-effective in comparison to simpler screening techniques [184, 187]. Additionally, few of these diagnostic and prognostic models have been externally validated, and none have been validated for all countries within the Latin America and the Caribbean region, opening up opportunities for further research in validation studies [183].

A main limitation of current modelling approaches includes that ascertainment of the outcomes is standardized using fasting glucose measurements, with only one model in Peru assessing the outcome based on an oral glucose tolerance test [183, 184]. This may underestimate the true prevalence of potentially undiagnosed diabetes, given the low concordance between fasting glucose levels, impaired oral glucose tolerance and abnormal HbA1c levels [189, 190]. In addition to these concerns, models developed for a specific population in the region may not have external validity for other countries. To mitigate this, modelling approaches should consider including regional predictors or may need to incorporate habits or region-specific traits as candidate pre-

dictors which may be applicable for the overall region in order to tailor predictions to better represent the epidemiologic landscape of diabetes. As of the time of this writing, no model can be considered to be widely applicable for the region, and most models have shown limited performance as screening tools in the population. Models for incident type 2 diabetes have not been developed using population-based samples, opening a need for the development of prospective development and validation studies in the region [183, 184]. These models may offer a unique opportunity to inform preventive regimes aimed at ameliorating the impact of specific risk factors on diabetes incidence, which may have better long-term public health implications beyond the individual benefits usually expected for predictive modelling [182].

Diabetes-Related Complications

As commented in the preceding sections, the epidemiology of chronic diabetes-related microvascular and macrovascular complications for countries in the Latin America and the Caribbean region is incompletely characterized, with no systematized approaches to describe at a larger scale its prevalence or incidence or to characterize unique risk factors for this region [112]. Given these limitations in the characterization of chronic micro- and macrovascular diabetes-related complications, predictive modelling for prevalent or incident chronic complications is scarce [191]. Few approaches have dealt with prevalent diabetic retinopathy, diabetic kidney disease, diabetic neuropathy and chronic diabetes-related cardiovascular complications, with only one study incorporating omics technologies as complementary in prediction to traditional measures and risk factors for diabetic kidney disease [192–195]. To be useful, models for diabetes-related complications need to show superiority compared to commonly used predictors including HbA1c and years of diabetes exposure to be clinically useful. Despite the existence of models for identification of chronic complications in selected populations, no model has been developed for prognosis of incident complications at national scales across the region besides few studies assessing convenience and non-population-based samples to varying degrees of success [191].

To be cost-effective and potentially clinically applicable, further modelling approaches for chronic diabetes complications in Latin America should consider (1) evaluating ethnic-specific traits which may increase risk of developing chronic micro- or macrovascular complications or decrease age of onset or at lower HbA1c levels, (2) demonstrating its superior performance compared to commonly used predictors including HbA1c and years of diabetes exposure and (3) showing that its implementation either at individual of population level has the potential to lead to improvements in diabetes-related outcomes, beyond its informative nature. Current approaches have not been externally validated across the region, rigorously tested and must be considered at moderate to high risk of bias if implemented outside of its origin population. Therefore, prospective and planned modelling approaches need to consider that low-cost models need to be developed if they are expected to be used for diagnosis, prognosis or follow-up for cases with type 2 diabetes in Latin America and the Caribbean.

New Research Trends

Population Health

Diabetes is a complex disease which needs synergic work whereby practitioners and public health officers work together, while the former deliver high-quality care to patients, and the latter provide good understanding of the epidemiology and design policies and interventions for primary (i.e. to prevent or delay diabetes onset), secondary (i.e. to secure effective treatment) and tertiary prevention (i.e. to improve health and well-being after a complication has occurred). Research in population health related to diabetes could provide evidence to inform these three stages of care.

A study in Brazil showed that in 2013, 9% of all deaths were attributable to diabetes when diabetes was self-reported (i.e. people aware they had diabetes) [196]; when unknown diabetes was considered, this figure rose to 14% [196]; conversely, when diabetes mortality was ascertained from death certificates (i.e. underlying cause of death), this figure was 5% (and 10% when diabetes was anywhere in the death certificate) [196]. These findings imply that diabetes mortality based on death certificates may underestimate the real mortality burden attributable to diabetes. This could have a few pragmatic implications: (a) national and regional health authorities in Latin America and the Caribbean could agree on how to quantify the mortality attributable to diabetes and provide tools and guidelines for that; (b) there is a need to improve death certificate registration when the underlying cause may be diabetes; and (c) improving prompt identification of cases with type 2 diabetes may have relevant implications not only for short- and long-term disease monitoring but also for quantifying the true impact of the disease and required policy changes.

A work in Andean Latin America (Bolivia, Ecuador and Peru) computed the number of diabetes cases attributable to high body mass index since 1980 [65]. They showed that, during the study period, the number of diabetes cases attributable to class I obesity increased the most followed by those attributed to class II obesity [65]. Moreover, there were substantial differences between countries [65]. From these findings, one could gather that reducing obesity is paramount

and that even class II obesity is now found with higher frequency. To reduce the impact of obesity on diabetes incidence, a combination of medical and public health interventions would require (a) medical interventions to provide treatment and counselling to people who already have obesity; (b) public health (population-wide) interventions so that the mean body mass index in the population would reduce; and (c) to evaluate public policies related to promotion of healthier lifestyles beyond weight loss to reduce overall metabolic burden. The fact that there were differences among three countries with similar epidemiological background is also interesting and calls to study all countries to find country-specific patterns of diabetes prevalence and incidence, or similarities between countries which could address the heterogeneity of type 2 diabetes. This could help to find countries where similar interventions can be delivered with the support from regional or global health organizations.

Novel Analytic Approaches

Novel research and analytical approaches are developed every day, and they can be incorporated in our research toolbox to provide answers to relevant research questions in the fields of clinical medicine and public health in Latin America and the Caribbean. A main goal of data-driven methods in diabetes is to address the high heterogeneity of diabetes by providing an analytic framework which builds from advances in knowledge regarding the pathophysiology of type 2 diabetes, novel insights into disease monitoring and follow-up and incorporation of improved treatment regimes.

As discussed above, risk prediction tools are useful for risk stratification and to inform treatment allocation and clinical management. Similarly, data-driven clustering of people with diabetes can deliver equivalent information by finding groups of patients with similar characteristics, with similar response to a given treatment, or that would have the same (or similar) disease progression. Research outside Latin America and the Caribbean has shown that clustering patients with metabolic and clinical characteristics could be useful in identifying groups for risk stratification and treatment response [197–199]. One study in Mexico proved that this approach would also be feasible in Latin America and the Caribbean, with relevant implications for clinical management of patients with diabetes [193]. For example, patients in the same diabetes cluster could receive similar treatment, or patients in the same cluster of disease progression could receive similar treatment to avoid or delay unfavourable outcomes. These clustering methods, which aim to systematize previously identified differences in the pathophysiology and evolution of type 2 diabetes at an individual level, may have relevant implications for the advancement of personalized medicine; however, these individualized approaches may fail when applied to large-scale epidemiological efforts because they do not adapt to the population of origin. At the population level, another study in Latin America and the Caribbean analysed national surveys and found cluster of patients with shared profiles; they also described the frequency of these clusters in nine countries from this region [200]. This information at the population level could be used to plan interventions or policies. For example, a cluster had people with diabetes and high blood pressure; in places where this was the most frequent cluster, they should secure effective cardiovascular treatment for people with diabetes. Likewise, in places where the most frequent cluster was that with diabetics with high body mass index or waist circumference, they should secure effective weight management for patients with diabetes. These two approaches—clusters of patients and populations—are complementary and could create a synergistic approach to both further treatments tailored for individual patient characteristics while pushing for population-level interventions informed by specific traits of the population.

Other research innovations include deep learning, a group of techniques within the remit of artificial intelligence. Deep learning can be used to analyse images like photos. In the global literature, there are several examples in which deep learning has been used to classify (i.e. diagnose) images of diabetic retinopathy with good accuracy [201]. Deep learning has also been used for diabetes diagnosis and glucose monitoring based on sequential follow-up glucose measurements [201]. For these analytical tools to perform, accurately good and large data sources are needed. Latin America and the Caribbean should improve their data collection standards and availability, particularly of administrative data. This way, researchers can explode these sources to inform decisions, interventions and clinical guidelines. Electronic health records are useful source of data, though these are still not available in all countries in the region largely due to technical difficulties of lack of systematization of these approaches in individual countries. Efforts are needed to strengthen these and other sources of administrative data.

Finally, longitudinal studies are required to inform different aspects of disease progression, monitoring and prognosis. Since ethnic-specific differences in the pathophysiology of type 2 diabetes have been reported for countries within the Latin America and the Caribbean region, many commonly accepted paradigms of treatment, prevention and monitoring need to be confirmed for feasibility and wider applicability in these populations, calling for studies conducted in the region to validate findings or adapt them to fit the reality of the region to maximize its potential impact. This will require a conjoined effort between many research teams and will likely require several years to realize, but its utility in advancing the understanding of diabetes in the region makes these efforts of uttermost importance.

Multiple-Choice Questions

1. Regarding genetic traits known to be a risk for increased incidence of type 1 diabetes, please choose the incorrect statement.
   (a) HLA-DQ in Mexico and Uruguay
   (b) RNASEH1 in Colombia
   (c) CD226 in Argentina and Colombia
   (d) DQ8 in Brazil
   (e) **PD-L1 and PD-L2 in Peru**
2. In relation to other world regions and regarding the age-adjusted comparative diabetes prevalence, South America and Central America rank:
   (a) 1st (out of seven world regions considered)
   (b) 2nd (out of seven world regions considered)
   (c) **5th (out of seven world regions considered)**
   (d) 4th (out of seven world regions considered)
   (e) 3rd (out of seven world regions considered)
3. The highest and lowest proportions of undiagnosed diabetes appear to be in ___ and ___:
   (a) **Haiti and Chile**
   (b) Peru and Colombia
   (c) Panama and Chile
   (d) Haiti and Costa Rica
   (e) Nicaragua and Mexico
4. In 2019 in Latin America, the two countries with the highest absolute number of people living with diabetes were:
   (a) **Brazil and Mexico**
   (b) Argentina and Mexico
   (c) Mexico and Chile
   (d) Panama and Mexico
   (e) Brazil and Peru
5. In Latin America, the risk of cardiovascular mortality in people with type 2 diabetes (compared with diabetes-free people) is:
   (a) 0.5-fold
   (b) 1.7-fold
   (c) **2.7-fold**
   (d) 3.7-fold
   (e) 4.7-fold
6. Regarding the VIDA Project, choose the incorrect statement.
   (a) **Blood pressure treatment goals were improved after the intervention.**
   (b) The outcomes were measured after 18 months.
   (c) Study design: pre-post.
   (d) Metabolic control was defined as HbA1c <7%.
   (e) The total cholesterol goal was <200 mg/dL.
7. The research on implementation science for type 1 diabetes in Latin America have addressed:
   (a) Timely diagnosis.
   (b) Treatment access.
   (c) Treatment adherence.
   (d) **There are no implementation science studies conducted in Latin America for type 1 diabetes in particular.**
   (e) Metabolic control.
8. The expenditure for insulin in Latin America and the Caribbean is estimated at:
   (a) **Between USD 6 and USD 11 billion**
   (b) Between USD 6 and USD 11 million
   (c) Between USD 5 and USD 10 billion
   (d) Between USD 5 and USD 10 million
   (e) Between USD 7 and USD 12 billion
9. To be useful, predictive models for type 2 diabetes need to satisfy certain requirements; select the correct statement.
   (a) Simple and widely applicable.
   (b) It considers unique features of diabetes in the region along with general risk factors.
   (c) It leads to better outcomes and more precise public police planning.
   (d) (a) and (c).
   (e) **(a), (b) and (c).**
10. Regarding diabetes incidence in Latin America, choose the incorrect statement.
   (a) PERUDIAB estimated the diabetes incidence in urban areas of Peru as 19.5 per 1000.
   (b) **In Peru, the PERU MIGRANT study found a higher incidence that the PERUDIAB study.**
   (c) The ELSA-Brazil cohort reported a diabetes incidence estimate of 2.0 per 100.
   (d) In Mexico, the highest incidence has been found in the age group 50–59.
   (e) In Mexico, the incidence in men 50–59 was 23 per 1000.

Diabetes Management in the United States

19

Megha K. Shah, Farah Naz Khan, and Mohammed K. Ali

Introduction

Prevalence and Cost Burdens

In the United States (USA), diabetes affects approximately 11% of the population, and in 2020, this equated to an estimated 34.2 million Americans with diabetes [1]. Type 2 or insulin-independent diabetes accounts for the majority (~90 to 95%) of cases in the United States [2]. Furthermore, approximately one-third of US adults have prediabetes, an identifiable precursor phase in which blood glucose levels are above normal but not yet in the diagnostic range for diabetes, and one's risk of developing type 2 diabetes increases 5- to 12-fold [3].

The diabetes epidemic has evolved considerably over the last quarter century. At every counting, the growth in prevalence and absolute numbers of people with diabetes has far exceeded statistical projections. Further, over time, larger proportions of those affected by diabetes are people of minority race/ethnicities and from lower socioeconomic backgrounds, and onset and first diagnosis appear to be younger than in decades past [4].

Diabetes is associated with billions of dollars in health expenditures and lost productivity [5–7]. Using a compilation of national data sources, diagnosed and undiagnosed diabetes accounted for over $400 billion in economic burden, which includes medical expenditures and reduced labor force participation, early mortality, and lower productivity in 2017. As a result, diabetes is one of the leading contributors to rising healthcare costs in the United States [8, 9].

Health Impacts

Type 2 diabetes typically develops over many years. The slow progression and lack of symptoms in the early stages of disease often delay requests for a screening test, preventive care, and/or medical attention. Other issues, such as lack of insurance or access to timely preventive care, may compound these delays. As such, even in high-income country settings like the United States, approximately 21% of people with diabetes are not aware of their diagnosis [1]. This is problematic as the pathophysiology of diabetes and its impacts on organs continues unabated despite the individual's awareness (or lack thereof) of their glycemic status.

The health impacts of diabetes vary by the type of disease. Type 1 or insulin-dependent diabetes, which accounts for about 5% of cases in the United States, is more commonly associated with acute fluctuations in blood sugar levels. Episodes of severe acute hyperglycemia (e.g., diabetic ketoacidosis [DKA] [10] and hyperosmolar nonketotic coma) or, conversely, severe hypoglycemia most often require immediate medical management. When treated in a timely and appropriate manner, the mortality from acute hyperglycemic episodes such as DKA is extremely low in the United States [11, 12]. Individual patient (e.g., age, additional comorbidities) and resource (e.g., healthcare facilities, experience of staff) characteristics can influence outcomes and risk of mortality.

Both type 1 and 2 diabetes are associated with chronic, progressive damage of the nerves, eyes, kidneys, and/or vasculature [13–15]. Target organ damage of this nature can be life-threatening and/or seriously disabling [16]. In a large proportion of persons with diabetes, other cardio-metabolic

risk factors (hypertension, dyslipidemia, proinflammatory, and procoagulant states) often co-occur [17] which increases the risk of end-organ damage [18]. The frequency of these end-organ diseases varies according to the underlying phenotype, pathophysiology, as well as care and control of glycemia and other cardio-metabolic risk factors (i.e., blood pressure, cholesterol, and tobacco use) [19].

In this chapter, we provide an overview and update of diabetes management in the United States from a national perspective and examine several aspects of diabetes care including detection, health maintenance, and achievement of cardio-metabolic care goals. We further describe where and how diabetes has been managed over the past few decades in the United States and examine previous and ongoing disparities. We examine and report what local care delivery, payer, and policy interventions have been evaluated to improve quality of care and their respective impacts.

National Trends

Screening

As the national prevalence and absolute numbers of people with diabetes have grown, the proportion with undiagnosed disease has not changed dramatically [1, 20]. This has implications for disease burden as undiagnosed people are less likely to have a usual care provider or seek care, further lowering their likelihood of being diagnosed, and the progression toward end-organ damage continues [21]. In some cases, recognition of underlying diabetes is only confirmed when diabetes complications are evident. Indeed, national data show that approximately 40% of adults with previously unrecognized diabetes have some form of chronic kidney disease [22].

Similarly, with regard to prevention of diabetes, it is estimated that only about 1 in 5 of the 80 million adults with prediabetes in the United States are aware that they are at high risk of imminently developing diabetes [23]. This awareness gap is likely a major barrier to engaging people at risk of diabetes in evidence-based lifestyle or pharmacotherapeutic interventions to prevent diabetes [24, 25].

There are well-accepted glucose tests to diagnose prediabetes and diabetes and evidence-based lifestyle and pharmaceutical interventions to prevent and manage diabetes. There is also consensus that universal screening—i.e., offering glucose tests to the whole population—is not cost-effective, but rather, targeted screening of individuals at high risk for diabetes is both appropriate and economically sound [26–28]. To promote appropriate testing, expert committees at the American Diabetes Association (ADA) and US Preventive Services Task Force (USPSTF) regularly review the evidence and set recommendations for healthcare providers regarding whom to test and when [29, 30].

The ADA recommends glucose testing adults age ≥45 years or at any age with a body mass index (BMI) ≥25 kg/m^2 and one other diabetes risk factor (people who are physically inactive, have a family history of diabetes, are of minority race/ethnicity who did not identify as non-Hispanic white, have history of gestational diabetes or delivering a macrosomic baby, hypertensive [blood pressure ≥140/90 mmHg or antihypertensive medication use], have dyslipidemia [HDL-cholesterol <35 mg/dL, triglycerides >250 mg/dL, or lipid-lowering medication use], polycystic ovarian syndrome, known prediabetes, or known myocardial infarction, coronary heart disease, or stroke) [29].

The USPSTF previously recommended glucose testing in individuals with blood pressure >135/80 mmHg or antihypertensive medication use [31]. In 2021, the USPSTF changed their guideline and now recommend glucose testing between age 35 and 70 years in those who are overweight or obese [30]. The USPSTF guidelines also note that clinicians should consider screening earlier in persons with one or more additional risk factors (i.e., family history of diabetes, history of gestational diabetes, members of certain racial/ethnic groups such as African Americans, American Indians or Alaskan Natives, Asian Americans, Hispanics or Latinos, or Native Hawaiians or Pacific Islanders) since they may be at increased risk for diabetes at a younger age or at a lower body mass index.

In terms of the extent to which screening guidelines achieve their intended purpose, a study using national survey data showed that, during the period 2007–2012, only half of all US adults that would be eligible for glucose testing based on either the ADA or the older USPSTF criteria were actually offered a glucose test [32]. There is also a sizeable proportion of people (approximately 15%) that receive glucose tests despite not meeting sufficient criteria. Furthermore, in terms of guideline performance, findings suggest that the ADA and USPSTF guidelines are very different in their ideological focus: the ADA guidelines require a lower threshold for glucose testing with the aim of higher sensitivity, while the USPSTF recommendations are more focused on specificity. Despite this difference, the positive predictive value (or yield of people with dysglycemia of those eligible for screening) associated with each guideline was broadly similar—approximately 54–58% for identifying prediabetes or diabetes and around 5–7% for identifying undiagnosed diabetes.

More recent analyses examining the performance of the newer USPSTF guideline show that only 25% of patients would be eligible for screening. Though the newer guideline is more sensitive (~45%) and less specific (~72%), racial/ethnic minorities are less likely to be eligible for screening, perhaps due to their higher risk of diabetes at lower weight levels [33].

Management of Cardio-Metabolic Risks

It is encouraging that people with diagnosed diabetes do seek care. Nationally, 95% adults with diagnosed diabetes report having a healthcare provider and almost 92% report visiting the care provider twice or more in the past year [21].

Furthermore, over the past four decades, the scientific community has made important advances in clinical research. Large robust randomized controlled trials have shown that comprehensive management of cardio-metabolic risk factors, including glucose, blood pressure, and lipids, and avoiding tobacco, can delay both micro- and macrovascular diabetes complications [34–39]. It is on the basis of these trials and meta-analyses that diabetes management guidelines are set and revised by professional agencies (e.g., the ADA and the American Association of Clinical Endocrinologists [AACE]). These same guidelines are used to benchmark quality of care at local and national levels.

Using clinical care goals as targets, national survey data have been used to develop cross-sectional snapshots of how average adult Americans with diabetes are managing their cardio-metabolic risks. The data from consecutive national reports from the 1999–2002 to 2015–2018 surveys show that the proportion of adults with diabetes achieving glycated hemoglobin (HbA1c) levels <7.0% grew from 44.0% to 50.5%. The proportion of adults with diagnosed diabetes with BP <140/90 mmHg grew 64.0–70.4%, while the proportion meeting non-HDL-cholesterol <130 mg/dL increased dramatically from 25.3% to 55.7%; however, the proportions have leveled off since 2007. Though the proportion of adults with very poorly controlled glycemia (A1c <9.0%), blood pressure (BP >160/100 mmHg), and/or cholesterol (LDL >160 mg/dL), all declined. Of note, however, the proportions achieving control of all three risk factors have remained low, at 22.2% for 2015–2018, with little improvement since 2007 (Fig. 19.1) [40].

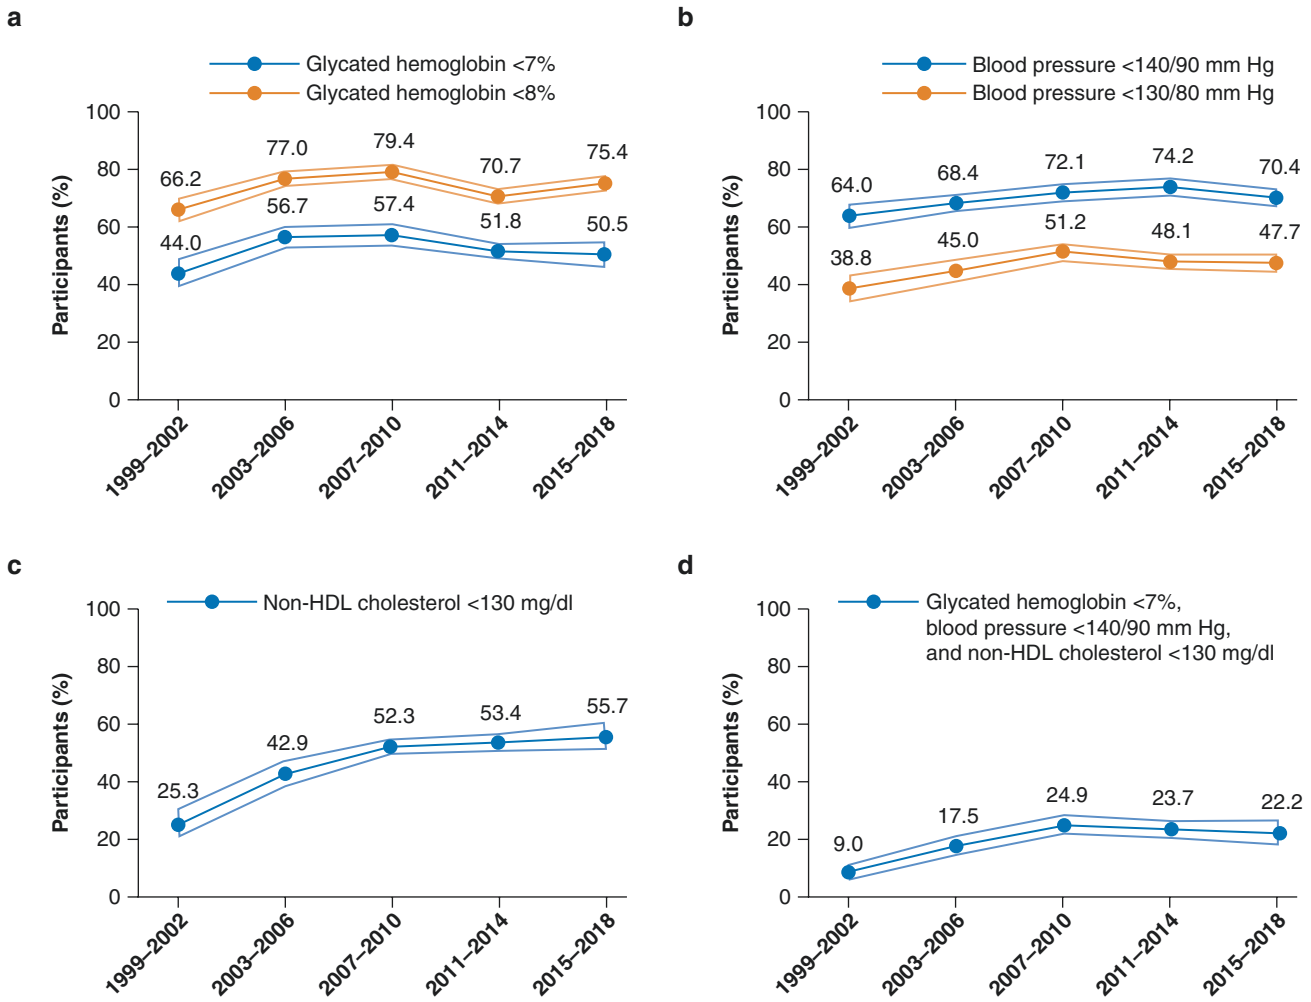

Fig. 19.1 Prevalence of glycemic, blood pressure, and lipid control among adult NHANES participants with diagnosed diabetes, 1999–2002 to 2015–2018. (**a**) Glycemic control, (**b**) blood-pressure control, (**c**) lipid control and (**d**) all risk factors controlled. (From Fang M, Wang D, Coresh J, Selvin E. CVD cardiovascular disease, *y* years, *HI* high intensity, *MI* medium intensity

[a]Suggested targets by several authors; no formal guideline has endorsed specific targets other than generally supporting individualized glycemic goals [44, 45]

[b]More or less stringent glycemic goals may be appropriate for individual patients

National- and state-level efforts that drew greater attention to diabetes through measurement and action may have influenced trends in diabetes care. Movements like the National Committee for Quality Assurance (NCQA) and National Quality Forum have made major impacts through setting quality metrics, encouraging accreditation, and establishing performance measurement for healthcare systems. In turn, these processes may have facilitated [41, 42] better achievement of diabetes care goals. Similarly, individual states have used performance measures effectively—in Minnesota; for example, the Community Measurement initiative has reported on healthcare quality annually for a decade and can demonstrate performance for each of 1247 clinics or provider groups [43], and the state's average for meeting diabetes and cardio-metabolic care goals (38%) is higher than the national average (14%). These same successes are unlikely to be ubiquitous across all states, but no formal state-level analyses have examined this.

Other factors that may have contributed to these gains either positively or negatively include newer medications, provider education, changes in physician practice norms, the use of information technology, and electronic health record data, such as clinician decision support and the use of diabetes registries to track management of diabetes and performance measures and to couple audits with feedback. Payers for healthcare and hospital systems have also tracked and offered financial incentives (and disincentives) for care goal achievement (or lack thereof). On the patient side, there have been sustained efforts to educate patients and promote self-management. Each of these quality improvement efforts is discussed in greater detail later in the chapter.

There are limitations to using guideline treatment targets as performance metrics for health systems, localities, and the country at large. Although they are evidence-based, recommended treatment targets are not always what patients desire, and there can sometimes be a tension between quality of care from the health system and provider perspective and patient desires and satisfaction. Treatment targets are subject to change as new evidence is generated (Table 19.1), and these "moving targets" make it hard to understand whether there is any consistency in the patterns being observed. Furthermore, targets are usually dichotomous and can only convey part of the picture—for example, the mean levels of cardio-metabolic indices may be clustered around the target, but because of the single dichotomous metric, they get counted as "good" or "bad." Indeed, patients may also fare worse on specific aspects of their care, but better on others. As such, more "global" measures of disease risk (e.g., Framingham risk score, hospitalizations, quality of life, patient satisfaction, hypoglycemias) may provide alternative indicators than single dichotomous treatment targets.

Screening for Diabetes Complications

Aside from managing glycemia and cardio-metabolic risk factors to prevent diabetes complications, care guidelines [46–48] also recommend regular screenings to detect and treat diabetes complications. Earlier detection is aimed at identifying risk before irreversible target organ damage is incurred. All the microvascular complications of diabetes have a preclinical latent phase and well-accepted, sensitive, and specific eye, foot, and urine checks.

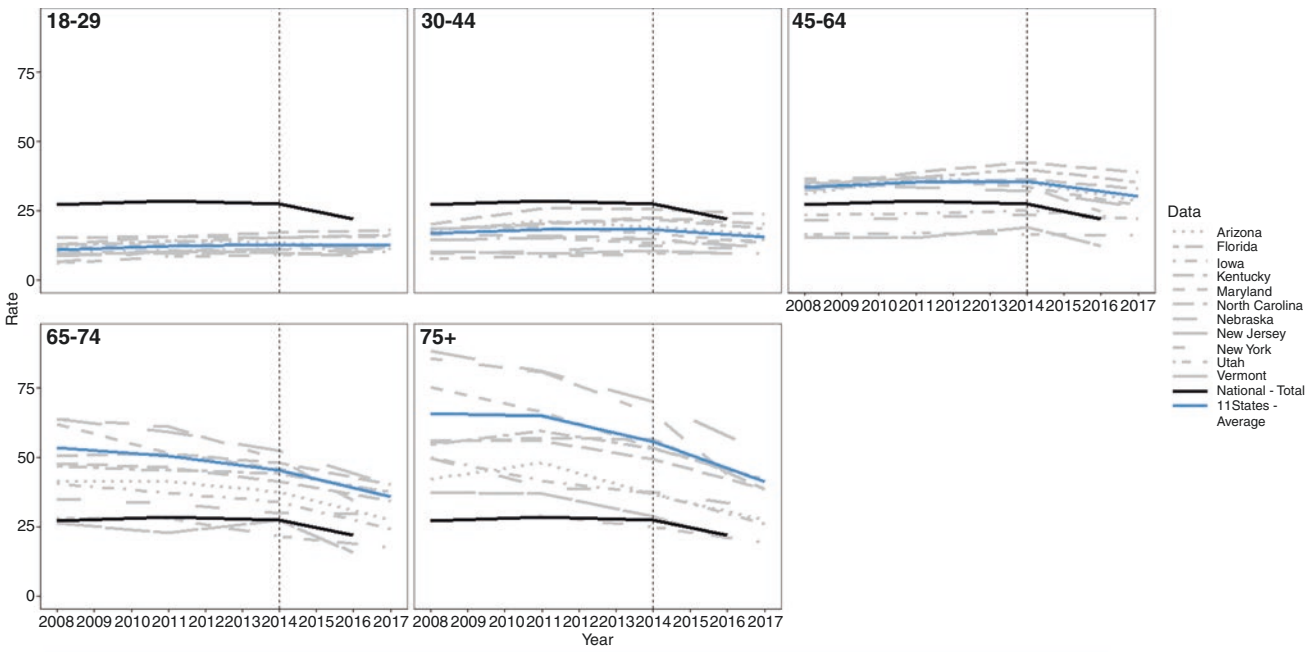
Diabetic retinopathy is very common and occurs in all people with diabetes, given sufficient duration of disease [49, 50]. Retinal screening [51] followed by photocoagulation therapy has been shown to significantly preserve vision [52, 53]. Neuropathy is also a common consequence of diabetes, and combined with compromised peripheral vascular circulation and poor wound healing [54, 55], ulceration [56], and infections [57, 58], can increase one's risk of gangrene and limb amputation. Regular foot checks and foot care are

considered invaluable to prevent foot ulceration and gangrene in people with diabetes [59, 60]. Regarding deterioration of kidney function, annual urine screening and the use of ACEi/ARB medications once micro-albuminuria sets in are both recommended [60]. Lastly, to lower infections, people with diabetes benefit from annual influenza vaccination and a lifetime pneumococcal vaccination [29, 61–65]. Repeated snapshots of national survey data between 2003 and 2018 show a plateau in the proportions of adults with diagnosed diabetes receiving all of these preventive screenings [20].

Incidence of Complications

The limitations of performance metrics notwithstanding the average 10-year cardiovascular event risk among Americans with diagnosed diabetes has declined over the past three decades, from 16.5% to 11.3% [66]. In keeping with this, between 1990 and 2010, nationally, there were substantial reductions in incidence rates of diabetes complications [67] and increases in life expectancy among people with diabetes [68]. There were marked decreases noted in incidence rates of acute myocardial infarctions (~68% decline), strokes (~53% decline), lower extremity amputations (~51% decline), and hyperglycemic death (~64% decline). The incidence of end-stage renal disease declined more gradually (~28% decline). However, more recent data suggests a reversal of this trend, with increasing hospitalizations for hyperglycemia from 2009 to 2015, and an increase in diabetes-related lower extremity amputations [69, 70]. Although visual impairment due to cataracts and retinopathy remain an important complication of diabetes, there are no reliable national estimates of trend patterns for these complications to date.

Another recent analysis of national and state-specific inpatient utilization data demonstrated a decline in diabetes-specific hospitalization rates by about 20% from 28.6 hospitalizations per 10,000 adults (n = 683,968) in 2011 to 22.0 hospitalizations per 10,000 adults (n = 537,394) in 2016/2017. This varied by age—older adults (65–74, 75+) had the greatest decrease in diabetes-specific hospitalizations (37.0–43.1% decrease), while we observed an increase in hospitalizations among the youngest age group (18–29) (18.5% increase, 95% CI 11.7, 25.3). See Fig. 19.2.



Hospitalization rates were calculated using numerator data from the HCUP Nationwide Inpatient Sample and State Inpatient Databases and denominator data from the IPUMS USA American Community Survey from years 2008-2017.

Two benchmark lines are highlighted: the black National-Total line shows national hospitalization rates across all US adults of all age groups and the blue 11 States-Average line shows average hospitalization rates across all states by age group.

The dotted vertical line delineates the point within our data that the data transitioned from rates generated using ICD-9 codes to ICD-10 codes. Rates post-transition may not be directly comparable to rates prior to the transition.

Fig. 19.2 Rates of diabetes-specific hospitalizations among US adults by age group; years 2008–2017. (Unpublished work from Turbow, S; et al. Trends and Sociodemographic Disparities in Diabetes Hospital Admissions: Analyses of Serial Cross-Sectional National and State Data, 2008–2017)

Gaps in Care

There are a number of ongoing concerning trends related to diabetes nationally. The absolute number of people with diabetes has grown substantially, approximately threefold over the past three decades [6, 71]. Large numbers of people still do not meet their care goals; the absolute numbers affected by disabling complications have increased; costs of care double every decade; and though excess mortality associated with diabetes has declined, there has been an expansion in the number of years people with diabetes live with disabilities [72]. Many of these concerns are at least partly attributable to gaps in access, suboptimal organization and delivery of healthcare and preventive services, and workforce shortages. We further examine these and other barriers and provide data from program and policy intervention studies as possible future directions for diabetes management to progress toward.

Outpatient Settings in the United States

Over the last 30 years, there has been a shift from hospital-based diabetes management to outpatient primary care. While earlier studies showed that hospital-based care provided better outcomes, health systems began shifting away from hospital-based diabetes management, and several studies showed that diabetes management in primary care setting was as good as hospital-based care and provided greater adherence to guideline-based preventive services [73–75]. Almost all of diabetes management is now in the ambulatory setting by primary care providers, and only 20% of patients with diabetes may be referred to an endocrinologist [76, 77].

Though fewer patients are managed in hospital-based settings for diabetes, admission rates for diabetes-associated complications (such as amputations, cardiovascular disease, and blindness) are still higher in the United States than in comparable countries [78]. Despite the availability and evidence of effective clinical guidelines, wide variation of the treatment of patients with diabetes remains in primary care [79]. Moreover, care gaps remain for many patients with diabetes [80].

Several challenges exist to achieving optimal diabetes care in the outpatient setting, which can be divided in three main areas: the patient, the provider, and the system.

The Patient

Patients must be able to access care, adhere to treatment, afford the care, and have the knowledge and skills to manage their condition on a daily basis. Access to care can often be determined by socioeconomic status and insurance status. Several studies have demonstrated that lower SES is associated with less access to specialist care, to diabetic preventive services, and worse control of diabetes [81–83]. Patients with private or public insurance are most likely to have met quality of care measures than those with no insurance [84]. A study using national data over the 1998–2008 period found that an estimated 16% of known patients with diabetes were uninsured and tended to have worse outcomes [85, 86].

Physical access to care continues to be a barrier. Lack of transportation, location in rural areas, and availability of healthcare personnel all play a role in a patient's ability to access care. Rural residents have higher rates of diabetes than urban residents and significantly greater barriers accessing reliable transportation. Moreover, rural residents can often spend more time trying to access care, thus creating higher cost from missed wages and time spent away from families to have improved quality of care [87]. Data from NHANES, 1999–2018, suggests that while there are no differences in diabetes care goal achievement in rural versus urban areas, adults with diabetes in rural areas were more likely to have multiple comorbid chronic health conditions [88].

Treatment adherence continues to be a major challenge in achieving adequate glycemic control. In one study of over 160,000 patients in Northern California, over 20% of patients with uncontrolled diabetes had poor medication adherence [89]. While the cause of this can be multifactorial, several challenges exist from the patient's perspective. First, lack of diabetes education can lead to poor understanding of the disease process and empowerment of the patient to play an active role in their care process [90]. While evidence supports the efficacy of diabetes self-management education in improving glycemic control, access is still limited [91]. Complex medication regimens and side effects from medications can also lead to poor adherence. Simplifying medication regimens can help address patient barriers to medication adherence [92]. The ADA Standards of Care guidelines recommend that providers address medication factors when reviewing treatment plans with patients to insure that they are simple, affordable, and manageable for the patient [29].

The Provider

Several provider level factors can influence diabetes care. Assessment of adherence can often be overestimated or missed by providers [92]. Patients are often asked to self-report their medication use without any objective assessment of actual medication adherence. In addition, providers are often reluctant to intensify therapy, though it may be clinically indicated; this is known as clinical inertia. Clinical inertia appears to be particularly common with regard to initiating insulin therapy and may also come into play with recent updated guidelines and initiation of novel antihyper-

glycemic medications (discussed below in "Diabetes Medical Management Updates" section) [93, 94].

Though clinical inertia is multifactorial and can be due to system and patient-level factors, one key area is patient-provider communication. Studies have shown that the quality of provider communication and patient's trust of their providers was associated with better outcomes. Better communication was associated with fewer misconceptions about insulin; thus, patients were more likely to begin insulin therapy, and this was associated with improved outcomes [95]. Several studies have also shown that providers who recommend individualized barrier assessment and tailored communication to patients can improve care [96].

The System

Several system-level factors create challenges to optimal diabetes care. First, dissemination of evidence-based practices can be slow. While evidence exists for optimal diabetes care, including processes of care, implementation of these evidence-based guidelines can vary. This can greatly improve through the use of guidelines to drive care, structured care management, and performance feedback [95].

Second, coordination of care can greatly improve outcomes. Evidence shows that optimal diabetes management in the outpatient setting requires a coordinated, systematic team-based approach. This strategy can help address several of the processes that create barriers to diabetes management. This is supported by team-based approaches where there are focus planned visits, education, and appropriate specialty care. Several models have been effective at demonstrating improved care coordination; these are discussed in detail later in this chapter. Many of these system level factors rely on accurate clinical data; this can also be improved by implementing electronic health records to track diabetes care outcomes and processes of care [95, 97].

Next, addressing financial barriers to patients for medications, health services, and education can greatly improve adherence and outcomes. Studies have consistently found that shifting costs to patients negatively affect outcomes in diabetes care. Increased cost to the patient resulted in lower medication adherence and lower rates of preventive care [98]. Those patients with full cost coverage were more likely to have appropriate diabetes-related care (such as dilated retinal exams), attended diabetes education, and practiced blood glucose monitoring.

Disparities in Diabetes Prevention and Management

Despite considerable evidence for preventing diabetes complications [34–39] and important advances in clinical care, there remain significant gaps in translating this evidence into policy and practice, specifically for vulnerable subpopulations (e.g., some age, race/ethnicity groups, and those with associated comorbid conditions) [21, 68]. Additionally, burdens of diabetes are not uniformly distributed across the United States; the Southeastern United States, for example, is disproportionately affected by diabetes and its complications [6, 99, 100].

Demographic Disparities

With reference to vulnerable populations, African-Americans, Hispanics, Native-Americans, and Asians/Pacific islanders all have higher rates of diabetes prevalence as compared to non-Hispanic Whites. The prevalence of diabetes among African-Americans is around 12.5% and for Hispanics is around 13%, compared to around 10% for non-Hispanic whites [20, 101]. These disadvantaged groups are less likely to receive diabetes-related preventive services, less likely to have access to care [21], and have lower health literacy. This lack of care leads to delayed diagnosis, advanced disease, and poor outcomes among these groups [102]. As the US population continues to become more diverse and the number of people with diabetes increases, addressing disparities in care will be increasingly vital.

While some studies have found no significant difference in most of the processes of care (including periodic hemoglobin A1c, lipid, microalbuminuria testing), those of racial/ethnic minorities and low-income groups tend to have poorer glycemic control [4, 103]. Furthermore, African-Americans and Hispanics have higher rates of diabetes-related complications resulting in hospitalizations, end-stage renal disease related to diabetes, and amputation [95, 104, 105].

Disparities also exist in care based on age. Younger adults with diabetes are less likely to receive periodic testing and more likely to have lapses in recommended care [21, 77]. Younger adults are less likely than older Americans to receive treatment when diabetes care goals are not achieved for glycemic and blood pressure control [40].

Socioeconomic Disparities

Socioeconomic factors contribute greatly to disparities in diabetes. Poverty, low education, and adverse neighborhood characteristics are often interrelated and continue to be concentrated in minority race/ethnic groups [106].

While numerous factors contribute to disparities in diabetes care, there are several potentially modifiable factors. One major contributing factor to poor diabetes outcomes is low health literacy and numeracy among minorities and patients of lower socioeconomic status. Defined as "the degree to which individuals have the capacity to obtain, process, and understand basic information and services needed to make appropriate decisions regarding their health," low health literacy can lead to low self-efficacy and disease knowledge and ultimate low diabetes self-management skills [107, 108].

Inherent to diabetes management is the ability of the patient to comprehend and apply diet and lifestyle instructions, measure and dispense medications, and quantify aspects of their care. Thus low literacy, which is often not assessed, can have major implications for patients' self-efficacy in diabetes management [108].

As mentioned above, access, especially insurance coverage, can greatly affect disparities in care. For example, a national study found that after controlling for demographic and health status characteristics, insurance coverage was more likely to determine whether a patient received diabetes services rather than race/ethnicity or socioeconomic status. It has been argued that expansion of insurance coverage would have the biggest impact of improving the quality of diabetes care and reducing disparities [109]. Studies have highlighted the implications that health policy can have on addressing disparities [110].

Disparities in Care Delivery

Unconscious bias at the provider and health-system level can also contribute to health disparities. Studies have shown that within the same provider panel, white patients had better glycemic control than African-American patients, independent of other sociodemographic characteristics, provider performance, or the number of African-Americans on their panel [103]. That said, while a majority of providers endorsed that racial disparities exist in diabetes care, only a small percentage of providers acknowledged the presence of racial disparities in their own practice [111]. Thus, unconscious stereotypes may be influencing physician behavior and ultimately the quality of the care provided.

Since the Institute of Medicine's 2002 report, "Unequal treatment: Confronting racial and ethnic disparities in healthcare," the evidence is growing that provider-level and system-level interventions that streamline processes of care and improve cultural competency can improve disparities in care [102]. For example, continuing medical education programs and personal feedback has shown to significantly improve diabetes process measure achievement (e.g., foot exams). Furthermore, assessment of health literacy, provision of culturally competent care, and improved awareness of disparities in care have been shown to be effective strategies improving diabetes care [112]. However, diabetes care disparities persist; further research and work to develop targeted patient-, provider-, and systems-level approaches to mitigate disparities in care for vulnerable populations are still needed.

Diabetes Medical Management Updates

Medical Management of Diabetes

Currently in the United States, most diabetes management is in the ambulatory setting. Primary care providers see a majority of the patients with type 2 diabetes in the United States [113]. Given the growing shortage of endocrinologists in America, this trend will likely continue into the future [114]. Studies have shown that there is a gap in adherence to the American Diabetes Association (ADA) guidelines when you compare primary care to endocrinology, with endocrinologists being more likely to adhere to the ADA guidelines [115]. Given the ongoing updates to outpatient management guidelines for type 2 diabetes, it will be crucial to change this pattern going forward given evidence that unstructured care has been noted to have worse outcomes for patients with diabetes [73].

Most Recent Changes in Guidelines

The ADA Standards of Medical Care in Diabetes has most recently been updated to reflect the growing body of literature that centers on adjusting cardiovascular risk [116] and mitigating risk of microvascular complications [117] with highly individualized diabetes treatment regimens. This segmentation may help clinicians with regard to choosing between the wide array of medications to lower glycemia that are currently available. To support this process, professional guidelines for glucose-lowering medications in type 2 diabetes have shifted to include specific guidance based on whether or not patients have either coronary vascular disease, heart failure with reduced ejection fraction, or chronic kidney disease [118]. Below we will review in detail some of the landmark trials that have shaped this shift in our management approach.

SGLT2-Inhibitors

In general, SGLT2 inhibitors have been associated with reductions in major adverse coronary vascular disease events and reductions in progression to end-stage renal disease. Specific trials are discussed in detail below.

1. Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients (EMPA-REG OUTCOME)—Empagliflozin reduced the risk of death

from cardiovascular causes (38% relative risk reduction (RRR)) and reduced risk of heart failure hospitalizations (35% RRR) in type 2 diabetes patients with established heart disease when compared to placebo [119].
2. Canagliflozin Cardiovascular Assessment Study (CANVAS)—Canagliflozin reduced the risk of major adverse cardiovascular events (~15% RRR; $P < 0.001$ for noninferiority; $P = 0.02$ for superiority) and was associated with renal benefits in patients with type 2 diabetes [120].
3. Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation (CREDENCE) Trial—Canagliflozin reduced the risk of kidney failure and cardiovascular events in patients with type 2 diabetes and kidney disease (~30% RRR) [121].
4. Dapagliflozin Effect on Cardiovascular Events-Thrombosis in Myocardial Infarction 58 (DECLARE-TIMI 58)—Dapagliflozin reduced the rate of cardiovascular death or heart failure hospitalization in patients with type 2 diabetes with or at risk for atherosclerotic cardiovascular disease (RRR 17%) [122].

DPP-4 Inhibitor and GLP-1 Agonists

A systematic review and meta-analysis of cardiovascular outcome trials for GLP-1 agonists noted that treatment with this class of medications has cardiovascular benefits, reduced mortality, and improved renal outcomes [123]. DPP-4 inhibitors have not been shown to have the same effects as noted below.

1. Trial Evaluating Cardiovascular Outcomes with Sitagliptin (TECOS)—Sitagliptin had no clinically significant impact on either cardiovascular or renal outcomes [11.4% of the sitagliptin group vs. 11.6% of the placebo group [RRR <2%] (p for noninferiority <0.001)] [124].
2. Saxagliptin Assessment of Vascular Outcomes Recorded in Patients with Diabetes Mellitus—Thrombolysis in Myocardial Infarction 53 (SAVOR-TIMI 53) Study—Saxagliptin did not significantly affect the rate of ischemic cardiac events (7.3% and 7.2% [RRR ~1%], respectively, $P = 0.99$ for superiority; $P < 0.001$ for noninferiority) [125].
3. The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) Trial—Liraglutide lowered the rate of first occurrence of death from cardiovascular causes and the rate of nonfatal MI and stroke (12% RRR) in patients with type 2 diabetes [126].
4. The Trial to Evaluate Cardiovascular and Other Long-term Outcomes with Semaglutide in Subjects with Type 2 Diabetes (SUSTAIN-6)—Semaglutide reduced the rate of cardiovascular death and nonfatal MI and stroke (26% RRR) in patients with type 2 diabetes with high cardiovascular risk [127].

There is recent positive data for the dual GLP-1 receptor agonists and glucose-dependent insulinotropic polypeptides (GIPs) tirzepatide [128] and for the newer long-acting GLP-1 agonist efpeglenatide [129]. We may soon see these medications integrated into routine diabetes care in the United States.

Advancements in Diabetes Technologies

Technologies have advanced significantly over the years to include a wide range of insulin pumps and continuous glucose monitors (CGMs) that can help our patients with both type 1 and type 2 diabetes better manage their diabetes. Clinical guidelines recommend that the use of these technologies be tailored to individual patient circumstances [130]. The future advancement of these technologies will likely include improved hybrid-closed loop algorithms that allow for insulin pumps and CGMs to work more efficiently and effectively to improve glycemic control. The use of these technologies may be limited by insurance coverage and patient affordability.

Challenges and Barriers to Medical Management

Access to and affordability of diabetes medications, particularly insulin, remains of significant concern in the United States. A study looking at nationally representative data found that the cost of insulin had tripled from 2002 to 2013 [131]. Even with only three insulin manufacturers serving the market in America (Eli Lilly, Novo Nordisk, and Sanofi), there is a significant lack of transparency about the insulin supply chain which contributes to the excessive cost of insulin for patients [132]. The total patient expenditure on non-insulin antihyperglycemic medications has historically been lower than the total expenditure on insulin, but this may change as new patented medications emerge in the future [131] (Fig. 19.3). Ultimately, the true patient-facing cost of other glucose-lowering medications is difficult to ascertain due to the variability of insurance coverage of these medications.

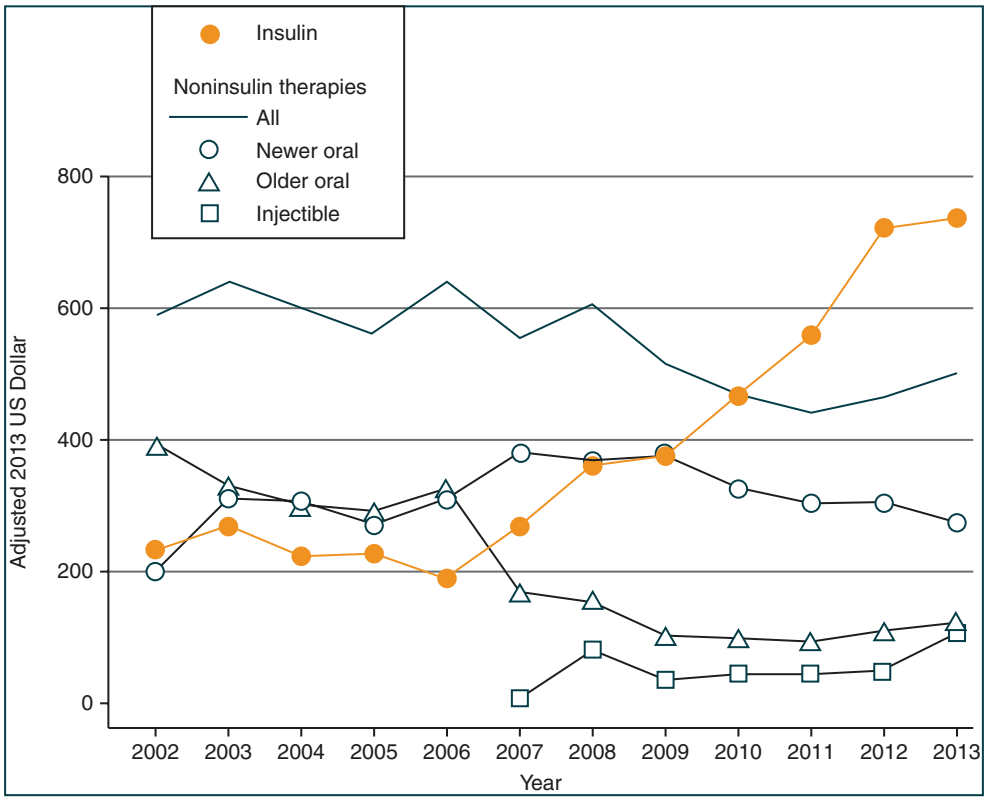


Fig. 19.3 Mean expenditure per patient for antihyperglycemic medications, 2002–2013. (From Hua X, Carvalho N, Tew M, Huang ES, Herman WH, Clarke P. Expenditures and Prices of Antihyperglycemic Medications in the United States: 2002–2013. JAMA. 2016;315(13):1400–1402. Quality Improvement Initiatives in Outpatient Diabetes Care

As mentioned above, there are barriers to achieving diabetes care goals at the patient- (e.g., low motivation), provider- (e.g., lack of therapy intensification), and/or system-level (e.g., fragmented care) [89, 133]. There are a number of patient-, provider-, and practice-level quality improvement (QI) interventions that have been devised to address these barriers [134, 135]. QI interventions include reminders, audits, and other tools to facilitate better self-management by patients and better care delivery by providers. The literature regarding QI interventions for diabetes management remains dominated by studies testing single interventions, usually focused on patients or providers, but not both. On aggregate, these interventions are associated with incrementally greater clinical benefits than routine care. A meta-analysis of 48 cluster and 94 individual randomized controlled trials [135] showed that, compared to usual care, QI interventions were associated with a 0.37 percentage point larger reductions in HbA1c; 3.1 and 1.6 mmHg larger reductions in systolic and diastolic blood pressures, respectively; and 3.9 mg/dL greater declines in LDL-cholesterol. On aggregate, even control arms experienced benefit, suggesting that more attentive follow-up alone may confer benefit in diabetes care.

Similar benefits were noted in a large pragmatic, cluster-randomized, parallel-group trial that assigned 343 European practices to screening and intensive treatment of multiple risk factors (i.e., small group educational meetings with family physicians and nurses to discuss treatment targets, algorithms, and lifestyle advice) versus usual care. Over 5 years of follow-up, the intervention clinic patients experienced greater improvements in cardiovascular risk factors (HbA1c, cholesterol, and blood pressure), but this was not associated with significant reductions in the incidence of cardiovascular events and deaths [136].

Though these single QI interventions are promising, diabetes patients usually face multiple interacting barriers, and sustaining risk factor control is challenging. As such, multicomponent QI interventions or "integrated" care models are recommended [137–143]. Integrated care attempts to address barriers by leveraging existing facilities, infrastructure, and human resources. Integrated clinical care models can be based in primary care or specialist care settings, and some examples of tested models include the chronic care model, collaborative care, and their more formal, contemporary patient-centered medical homes (PCMH) and accountable care organizations. The use of multicomponent QI interventions has shown some promise, even in randomized trials in low- and middle-income countries like India. One such trial enrolled patients with

mean HbA1c's of 9.9% and used nonphysician care coordinators to support patient self-management and decision-supported electronic health records to support treatment modifications by clinicians. This study showed sustained larger improvements in cardio-metabolic indices (0.5 percentage points larger HbA1c, 4/2 mmHg larger BP, and 7.9 mg/dL larger lipid reductions) than the control arm, as long as the intervention was continued (average of 30 months) [144].

Clinical Care Models and Practice Redesign

Conceptual Basis

Integrated clinical care models all embody similar principles. For example, collaborative care applies the principles of the chronic care model [137]. Collaborative care interventions have been shown to be of particular benefit in individuals with multi-morbidities like diabetes and depressive symptoms. Key components of the model include (1) focusing on defined patient populations and improving self-care among patients, (2) targeting depressive symptoms with medications and behavioral therapies, and (3) measurement-based treatment ("treating to target": regular review of patient population data, discussion of challenging cases, and recommending treatment modifications until clinical targets are achieved) [145].

A large number of randomized controlled trials have demonstrated that collaborative care is effective in the treatment of depression and anxiety in people with diabetes [146–151]. This has even been demonstrated in a randomized trial in India [152]. Collaborative care leads to greater adherence, larger reductions in depressive symptoms, more depression-free days, and better control of cardio-metabolic indicators [146, 151, 153–156]. However, there are two caveats. First, if the intervention is given for a defined period (e.g., 12 months in the INDEPENDENT study), there was no difference between the intervention and control groups in HbA1c at 24 months post-randomization, suggesting that persistent QI efforts are needed to sustain cardio-metabolic benefits. Second, there is a tension in collaborative care models as they have (sometimes conflicting) ideals: that of "treating-to-target" and of being "patient-centered." Very little is known about patient perspectives on these aspects of QI strategies in general—in a review of 554 qualitative research articles related to diabetes over 30 years [157], none used mixed methods to gather patient and provider perspectives on QI.

Regarding the value of multicomponent QI or integrate care models, cost-effectiveness studies have noted that upfront investments are offset by savings for future acute medical care [153, 158]. As such, collaborative care models do incur an upfront cost; it remains unclear whether US health delivery systems and payers view this as a worthy upfront investment [159, 160].

Application of Care Models for Diabetes

The chronic care model [137, 161] and collaborative care [162] concepts have inspired significant practice redesign to enhance diabetes care and outcomes over the past few decades [163]. A notable example has been the growing endorsement of medical homes [164]. Medical homes, also referred to as Patient-Centered Medical Homes (PCMHs) [165], were initially used in pediatric practices and later implemented more broadly after the American Academy of Family Physicians (AAFP) and the American College of Physicians (ACP) released position statements in 2004 and 2007 [166]. As mentioned above, the PCMH concept is based on the Chronic Care Model [167] and incorporates several core elements, such as team-based care, information technology, and payment reform, with the goal of providing more patient-centered approaches to the management of chronic health conditions (Table 19.2).

Within the Veterans Administration (VA) Healthcare System, medical homes are referred to as Patient Aligned Care Teams (PACTs) and have been used to help provide "patient-driven, proactive, personalized, team-based care focused on wellness and disease prevention resulting in improvements in Veteran satisfaction, improved healthcare outcomes, and costs" [170]. A typical VA PACT core team consists of a primary provider, a RN care manager, a clinical staff assistant, and an administrative staff member who work with a Veteran patient over time. The core team may also refer the patient to specialists as needed. Previous evaluations have shown that achievement of diabetes care goals in the VA system is as good or even better than in commercially insured programs [171].

In 2008, the NCQA developed a PCMH Recognition Program in collaboration with the AAP, ACP, AOA, and AAFP. An estimated 12,000 practices nationwide have now achieved recognition status [172]. On an annual basis, participating practices use an online platform to submit documentation on their performance in six categories, including (1) patient-centered access, (2) team-based care, (3) population health management, (4) care management, (5) care coordination and care transitions, and (6) performance measurement and quality improvement. The NCQA provides resources, such as training, education, and tools, to groups participating in the program [172].

Table 19.2 Features of PCMH and applications in diabetes care

PCMH feature	Description	Diabetes example
Team-based care with coordination and continuity	• Physician and nonphysician providers provide collaborative care	Physician refers patient on multiple medications to pharmacist for medication reconciliation and co-management
	• Team arranges care with subspecialists and consultants and guides the patient through the health system	
Information technology and quality tracking	• Incorporation of EHR → use of patient registries and clinical decision support based on updated practice guidelines, quality metrics	Use EHR data to identify patients with poor blood sugar control (i.e., HbA1C >9.0%) to provide targeted interventions (diabetes education, self-management, etc.) [168]
	• Checklists to ensure consistency	
	• Use of patient registries to review quality and performance data for entire system	
Enhanced access and comprehensive care	• Flexible scheduling system; easy access to the healthcare team	Clinic staff contact patient after complicated hospital stay to ensure patient has a follow-up visit within 7 days of hospital discharge
	• Comprehensive care including preventive care, education services, and end-of-life care	
Payment reform	• Quality-based payment and fee-for-service reimbursements	Payment incentives for meeting specified quality measures for diabetes care
	• Sharing of savings from reduced healthcare costs	

Adapted from references [164, 169]

Evidence

There is now an extensive and growing evidence base to support the PCMH model [173], especially for improving delivery of preventive services, patient satisfaction, and staff experiences, and reductions in emergency room visits [174]. A study of the Southeast Pennsylvania Multi-Payer Advanced Primary Care Practice Demonstration included 25 practices and showed improvements in lipid, blood pressure, and blood sugar control among patients receiving care for cardiovascular disease and diabetes [175]. A 2011 review of medical home demonstration projects also concluded that PCMH has been associated with improvements in quality and cost of diabetes care [164].

In more recent years, some medical home evaluations have shown less dramatic changes in quality and costs of care. For example, a 2014 study examined changes in the quality, utilization, and costs of care among 32 primary care practices in the Southeastern Pennsylvania Chronic Care Initiative between 2008 and 2011 [176]. Among 11 quality measures, significant differences were only observed in nephropathy screening in diabetes, and there were no significant changes in utilization or costs of care. However, the NCQA notes this study should be interpreted with caution since it was based on the NCQA's "earliest PCMH standards" with "only half of practices achieving the highest recognition level" [173]. In a recent observational study of primary care practices across Minnesota in 2020, building upon the experiences of demonstration practices, certified PCMH practices were more likely to meet composite diabetes care goals than uncertified practices (79.2% vs. 74.9%, $P = 0.01$) [177].

Lessons Learned

Demonstration projects have highlighted several important implementation challenges for medical homes [178]. These include (1) scheduling issues (i.e., time-limited visits and long wait times), (2) increased staffing needs, and (3) costly investments needed in EHRs [179]. It is worth noting that these challenges are often amplified for smaller practices, where resources may be more limited. A 2010 review also highlighted the "decline of the primary care workforce" (i.e., higher numbers of physicians, physician assistants, and nurse practitioners pursuing non-primary care specialties) and "lack of full patient engagement" (meaningful participation of patients in their own care) as other important challenges [163].

Policies and Incentives to Address Accountability and Quality in Diabetes Care

Polices and incentives focused on accountability and quality in diabetes care have increased significantly since the late 1990s. In particular, there has been an increased emphasis on the use of standardized performance measures, such as the Health Plan Employer Data and Information Set (HEDIS). HEDIS incorporates 81 measures across 5 domains of care and is used by most healthcare plans to measure performance of care and services [180]. The HEDIS diabetes measures originated from the Diabetes Quality Improvement Project (DQIP), which was a collaboration between the NCQA, the ADA, and Centers for Medicare and Medicaid Services (CMS) in 1997 [181]. The goal of the DQIP was to develop new QI measures for diabetes care and one of the first examples of the application of disease-specific measures on a national level. The DQIP measures included clinical measures of accountability (i.e., proportion with HbA1c testing

annually), quality improvement (i.e., self-management care), and patient survey data that are still used today in national assessments.

The HEDIS measures are now assessed annually including several diabetes-specific measures such as the percentage of patients receiving comprehensive diabetes care (i.e., annual HbA1c testing, glycemic control, retinal screening, LDL screening, etc.). Health plans are incentivized to use HEDIS measures since they are required to collect and submit this information in order to receive reimbursement. For example, the CMS requires health maintenance organizations (HMOs) to submit HEDIS data in order to get reimbursed for services provided to Medicare enrollees under the Medicare Advantage program [182, 183].

Pay-for-Performance Policies

Pay-for-performance programs, which also incentivize the use of quality measures, have been increasingly disseminated. The term pay-for-performance describes the use financial incentives to encourage health systems or providers to increase quality while decreasing costs (i.e., increase value) of health care and service delivery [184]. Quality measures may focus on processes, outcomes, structure, and/or patients' experiences with healthcare delivery. These incentives have been delivered in both the private (i.e., between a specific health plan and provider groups) and public (i.e., the CMS Value-Based Purchasing Program to provide incentives for providers) sectors. Financial penalties (i.e., no payment for service that does meet a specified quality metric) have also been included in some instances.

Studies evaluating the effects of pay-for-performance programs have shown mixed results [185, 186]. For example, a study of 1040 matched hospitals (n = 260 pay-for-performance hospitals and n = 780 control hospitals) found that while performance initially improved in pay-for-performance hospitals compared to control hospitals, there were no significant differences between groups at 5-year follow-up [187]. A recent review of 49 studies examining the effect of pay-for-performance on physicians, hospitals, and other settings also showed mixed results. Out of the 49 included studies, the only study rated as "good quality" did not find any significant improvements in diabetes outcomes (i.e., proportion with HbA1c and lipid control) [188]. Despite these mixed findings, there has been strong support for the use of pay-for-performance incentives as a means of aligning profits with improvements in patient care and "strengthen[ing] the business case for quality and safety" [189].

Several pay-for-performance programs, including accountable care organizations (ACOs) and Medicare's Hospital Re-admissions Reduction Program, were expanded under the Affordable Care Act (ACA). Some of the concerns regarding expansion of pay-for-performance programs include scope (i.e., will payments be large enough for providers to recoup their upfront costs in EHR/information technology to support data collection); unintended effects on the physician-patient visits and relationships (i.e., disruptions in clinical flow or forced disenrollment of noncompliant patients); and the potential impact on safety-net providers and existing race/ethnic and socioeconomic disparities (i.e., will providers avoid higher-risk patients which will further exacerbate of disparities in care) [190–193].

In addition to expanding pay-for-performance programs, the ACA also included several important provisions related to diabetes care [194]. A recent review highlighted several potential improvements in (1) diabetes screening rates, (2) access to diabetes care, and (3) structure of diabetes care resulting from ACA provisions [195]. The authors argue that up to 2.3 million out of 4.6 million adults with undiagnosed diabetes between 2009 and 2010 may have gained access to preventive care under the ACA as a result of provisions requiring health plans to provide free diabetes screening to those at risk and the establishment of the health insurance marketplaces, which makes health insurance more accessible. However, many states with higher prevalence rates of diabetes have not yet expanded Medicaid as of 2021, and more studies are needed to fully understand ACA impacts on diabetes care at the state and county levels.

COVID-19 and Telehealth

The COVID-19 pandemic required strict lockdowns and social distancing that prevented the routine care for adults living with diabetes. This led to the rapid adoption of telehealth, with support from all payers to provide these services [196], while the full impact of the pandemic on diabetes care is yet to be seen. Data suggests that patients with diabetes may have benefitted from telehealth services. In a survey conducted by the ADA, 73% of people with diabetes have used telehealth services during the pandemic, compared to just 11% prior to COVID-19. Of those who have utilized telehealth, 40% report that it has made it easier to manage their diabetes, compared with 37% who reported no change [197]. Thus, fueled by the pandemic, telehealth may be a potential care delivery platform for future diabetes care.

Research Gaps

Ultimately, success in addressing diabetes and related disparities will be contingent upon how rapidly, efficiently, and effectively existing evidence-based care programs can be translated, adopted, and sustained in clinical and community venues. More and rigorous theory-based translation/imple-

mentation research is needed. Implementation sciences involve studying the barriers and processes that lead to effectiveness of interventions (already proven in efficacy trials) in real-life clinical and community settings, as well as investigating the adaptations required to embed these interventions into routine practice. These data can help support communities, clinicians, and decision-makers to become increasingly skilled and comfortable with implementing programs and policies [198–200].

It must also be said that, to truly realize the "triple aim" of better health, better care, and lower cost for the nation with regard to diabetes [201], we cannot ignore the importance of prevention and the health policies needed to support this. The current growth in absolute numbers with diabetes, leveling off of achievement of diabetes care targets, and associated healthcare costs is untenable, and bending the cost curve requires greater adoption of interventions to prevent diabetes, whether they are targeted at the individual (e.g., intensive lifestyle interventions) or at the population (e.g., sugar-sweetened beverage taxes). However, more rigorous evaluation of population-based policies and interventions like taxation is needed. Studies assessing the long-term impacts of recent policy changes are also needed. The use of rigorous quasi-experiments has increased, and it is hoped that these shed light on appropriate and cost-effective policies and programs for employers, communities, counties, states, and even the federal government to adopt and invest in.

Concluding Remarks

The story of diabetes in the United States over the past 30–40 years is one of good and bad news. The evidence base for diabetes prevention and management has grown, and with that, there have been improvements in care and control of diabetes [80] and associated comorbidities. However, major gaps persist: (1) The proportion of people with undiagnosed diabetes and prediabetes has not improved; (2) engagement in prevention is exceedingly low; (3) rising costs of care and medications make achievement of targets out of reach for many Americans; and (4) young adults and disenfranchised populations with diabetes fare poorly in terms of control.

Furthermore, while incidence rates of "classical" diabetes complications like myocardial infarction, stroke, and amputations have dramatically declined in the last 20 years, the overall burden continues to rise due to growing numbers with diabetes and its complications, and there have been recent signals of increases in diabetes complications. Again, declines in incidence were less impressive for young adults, minorities, and low socioeconomic populations, and there have been increases in other diabetes complications like cognitive decline, depression, and heart failure. As such, it appears that younger people with diabetes will contend with classical complications earlier in life, and older Americans with diabetes will contend with more years of physical and mental disability. This has profound implications for US health care in terms of the volume, complexity (i.e., multimorbidity) of cases, and health system costs related to diabetes.

The changing demographics of people with diabetes in the United States has implications for care in terms of how those affected culturally and psychologically view their illness, if and how they access care, and progression of disease. Equally, the changing nature of how and where diabetes is managed will influence the impacts that this devastating disease places on this nation.

Multiple-Choice Questions

1. Which of the following statements is correct about trends in diabetes in the United States over the period 1999–2018?
   (a) Nearly 90% of people with diabetes remain undiagnosed.
   (b) The absolute numbers of people with diabetes complications like heart attacks and strokes has declined.
   (c) **The proportion of people with diagnosed diabetes achieving glycemic control has improved.**
   (d) All of the above are true.
2. Regarding quality of diabetes care in the United States, which of the following statements is false?
   (a) Since the 1990s, there have been concerted state, federal, and nongovernmental efforts to improve diabetes care goals through measurement and action.
   (b) **Treatment targets for diabetes are static and do not change as more and newer evidence is uncovered.**
   (c) Most of diabetes care is delivered in outpatient settings.
   (d) Comparing outpatient primary vs. specialty care for diabetes, studies have found no major difference in quality of care.
3. **True** or False: The United States experiences disparities in terms of diabetes-related health outcomes between people of different race/ethnicities, age, gender, and geographies.
4. Regarding the factors related to quality of diabetes care in the United States, which of the following statements is false:
   (a) **All gaps in quality are due to patient noncompliance.**
   (b) There are reports of unconscious biases that physicians have toward some of their patients which result in some patients doing better than others.

(c) Clinical inertia is a term to describe how physicians might be reluctant to prescribe certain therapies or intensify certain therapies—for example, insulin.
(d) System-level barriers to care like limited financial coverage for care have been associated with poorer health outcomes.

5. Which of the following statements best characterizes quality improvement interventions for diabetes?
   (a) Quality improvement interventions have no supporting evidence base and are mostly discovered by trial and error.
   (b) Quality improvement interventions mainly target patients since most of quality gaps are due to patient noncompliance.
   (c) **Gaps in diabetes care are usually multifactorial, and so interventions that address several barriers and are "integrated" are more likely to be effective.**
   (d) None of the above is correct.
6. Regarding delivering quality improvement interventions for diabetes, which of the following statements is most correct:
   (a) Quality improvement programs are only aimed at specialty care and have no place in primary care.
   (b) Each of the theories (e.g., the chronic care model, collaborative care, etc.) that underpin integrated care delivery is very different and does not have any common features.
   (c) The evidence to support quality improvement interventions for diabetes is weak (i.e., there are no randomized controlled trials or meta-analyses).
   (d) **None of the above is true.**
7. Patient-Centered Medical Homes (PCMHs) include which of the following features:
   (a) **Care coordination using physician and nonphysician providers**
   (b) Paper-based charting for most patient visits/encounters
   (c) Avoiding costly referrals to subspecialists and consultants
   (d) Enrolling healthier and younger subsets of patients to the practice
8. Regarding pay-for-performance programs, which of the following statements is false?
   (a) Pay-for-performance programs are used to incentivize the use of quality measures.
   (b) Pay-for-performance programs were expanded under the Affordable Care Act (ACA).
   (c) Pay-for-performance programs are used by both private and public insurance programs.
   (d) **Pay-for-performance programs have consistently led to improvements in patient care and outcomes.**
9. All of the following are associated with a lower likelihood of achieving diabetes care goals in the US except:
   (a) Black or Hispanic ethnicity
   (b) **Older age**
   (c) Younger age
   (d) Neighborhood characteristics
   (e) Low health literacy

Diabetes Management in Africa

20

Simeon Pierre Choukem, Christian Akem Dimala, Camille Mba, and Jean Claude Mbanya

Objectives

- To discuss the current issues related to diabetes management in Africa
- To review the most frequent treatment strategies and protocols for diabetes in Africa
- To discuss the challenges to the adequate management of diabetes in Africa

Introduction

Beside the fact that Africa is facing the most severe increase in the number of people with diabetes over time as compared with other regions of the world [1], Africans with diabetes face specificities that should be taken into consideration when approaching diabetes management in this area of the world. The most prominent specificities are (1) the absence of global healthcare insurance and coverage and the limited number and distribution of equipped healthcare facilities in most countries, both of which certainly account for the high frequency of acute and chronic complications; (2) the clinical heterogeneity marked by atypical phenotypes such as ketosis-prone type 2 diabetes [2].

As a chronic disease, the management of diabetes in Africa as in other parts of the world has greatly evolved from the traditional protocols to a more holistic and patient-centered approach. However, the health systems in Africa are often ill-equipped to manage chronic diseases, because these countries still face significant mortality and morbidity from infectious diseases which take priority on most health policy agendas [3, 4]. Nevertheless, there has been significant progress in the types and coverage of diabetes care services.

It is, however, worth noting that despite the aforementioned specificities of diabetes, there are still limited contextualized guidelines, specific to the management of diabetes in Africa, as many countries still rely on guidelines essentially used in developed countries [5, 6]. The integration of diabetes care programs in the health system has been one of the innovative methods adopted by a number of countries in Africa to improve the management of diabetes. Alongside these programs, associations are being set up in several countries to coordinate actions at national level, all in a bid to control the burden of this disease [4].

Regarding the pharmacological means to treat diabetes, most oral antidiabetic agents are available in Africa, though the newest ones may not be financially accessible to most patients. While traditional formulations of human insulin are more accessible in most countries, insulin analogs in pens, though present in most markets, are still very expensive. Finally, attempts to define the role and include African traditional medicine and phytotherapy in the management strategy of diabetes seem to be of great interest, as these alternatives are often the recourse of many patients, because of their limited financial means and the chronic nature of the disease.

As in other parts of the world, the objectives of management of diabetes in Africa are centered on improving the quality of life of patients, reducing morbidity and mortality through prevention of disease progression, and development of complications [7]. Despite the lack of general guidelines for the management of diabetes in Africa as a whole due to the specificities of this chronic disease, some countries like South Africa, Tanzania, and Nigeria among others have produced context-specific national guidelines [8–10]. The

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_20

importance of these guidelines cannot be overemphasized, given the fact that they provide a contextualized framework for rational management decisions and a guide for training healthcare providers on up-to-date evidence-based practices for diabetes management. Overall, these guidelines help to improve on the quality of care delivered to patients and reduce diabetes-related mortality and morbidity [8].

The management of diabetes in Africa can be approached from the following four perspectives:

1. Health beliefs and perceptions relating to diabetes
2. Management of blood glucose
3. Prevention and management of acute metabolic and chronic complications of diabetes
4. Management of comorbidities

Health Beliefs and Perceptions Relating to Diabetes in Africa

For a better approach to the management of diabetes in Africa, it is important to understand the beliefs, knowledge, and perceptions relating to diabetes and related risk factors. In this first section, we shall describe the health-seeking behaviors of people with diabetes in Africa and how this influences the prevention and control of diabetes.

Health-Seeking Behaviors of People with Diabetes in Africa

In Africa, although most patients believe that the ideal place to seek treatment for general health care including diabetes is a modern healthcare facility, patients often seek alternative or complementary treatment from folk healers and other sources, mainly because they lack money to pay health service bills. Money is seen as a major determinant of where, when, and which kind of treatment is sought during illness. Patients tend to use traditional therapies because of beliefs about the causes of their ill health and a strong cultural attachment to initial home management and only access modern health services during a crisis. Concerning some of the risk factors for diabetes, some people believe that obesity is a sign of good living and/or good health and that eating healthy is hard to sustain because of practical difficulties. Others consider less strenuous activities such as walking to be a sign of poverty and therefore see this as demeaning.

Figure 20.1 describes the behavioral factors and beliefs associated with the development and progression of diabetes in Africa. This highlights on the relative importance of various health beliefs toward a cultural understanding of diabetes in Africa.

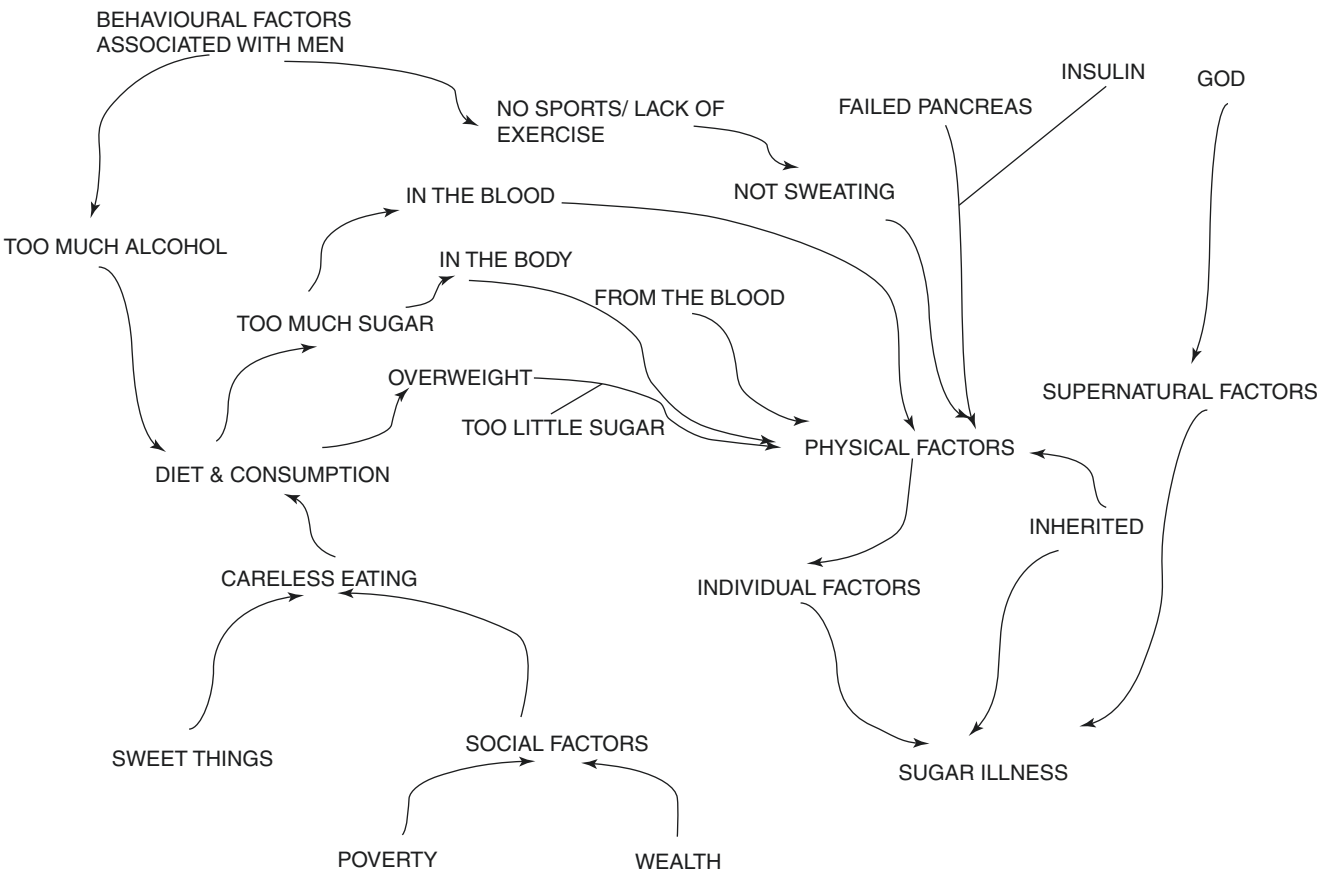

Fig. 20.1 Causal Web of Diabetes in Africa (Professor Jean Claude Mbanya, personal communications 2014)

Impact of These Beliefs on the Prevention and Control of Diabetes in Africa

Due to the beliefs described above, many people are not motivated to take action to reduce their risk of diabetes by increasing activity, changing their diet, and losing weight. In addition, home management for symptomatic relief is accepted as essential because patients taken to the hospital are thought to be likely to die. This lack of knowledge, lay beliefs about causation and treatment, and financial barrier, increase the likelihood of diabetes and its complications to be managed at home or consultation of traditional healers, thereby delaying presentation to health services. Since the diagnosis of diabetes is late in Africa, most patients already present with complications at the time of diagnosis.

Figure 20.2 illustrates the strong interplay between health beliefs, knowledge, lay perceptions, and health behavior of patients with diabetes in Africa and how this influences its prevention and control. This shows that health outcomes of patients with diabetes in Africa are highly dependent on knowledge and cultural beliefs.

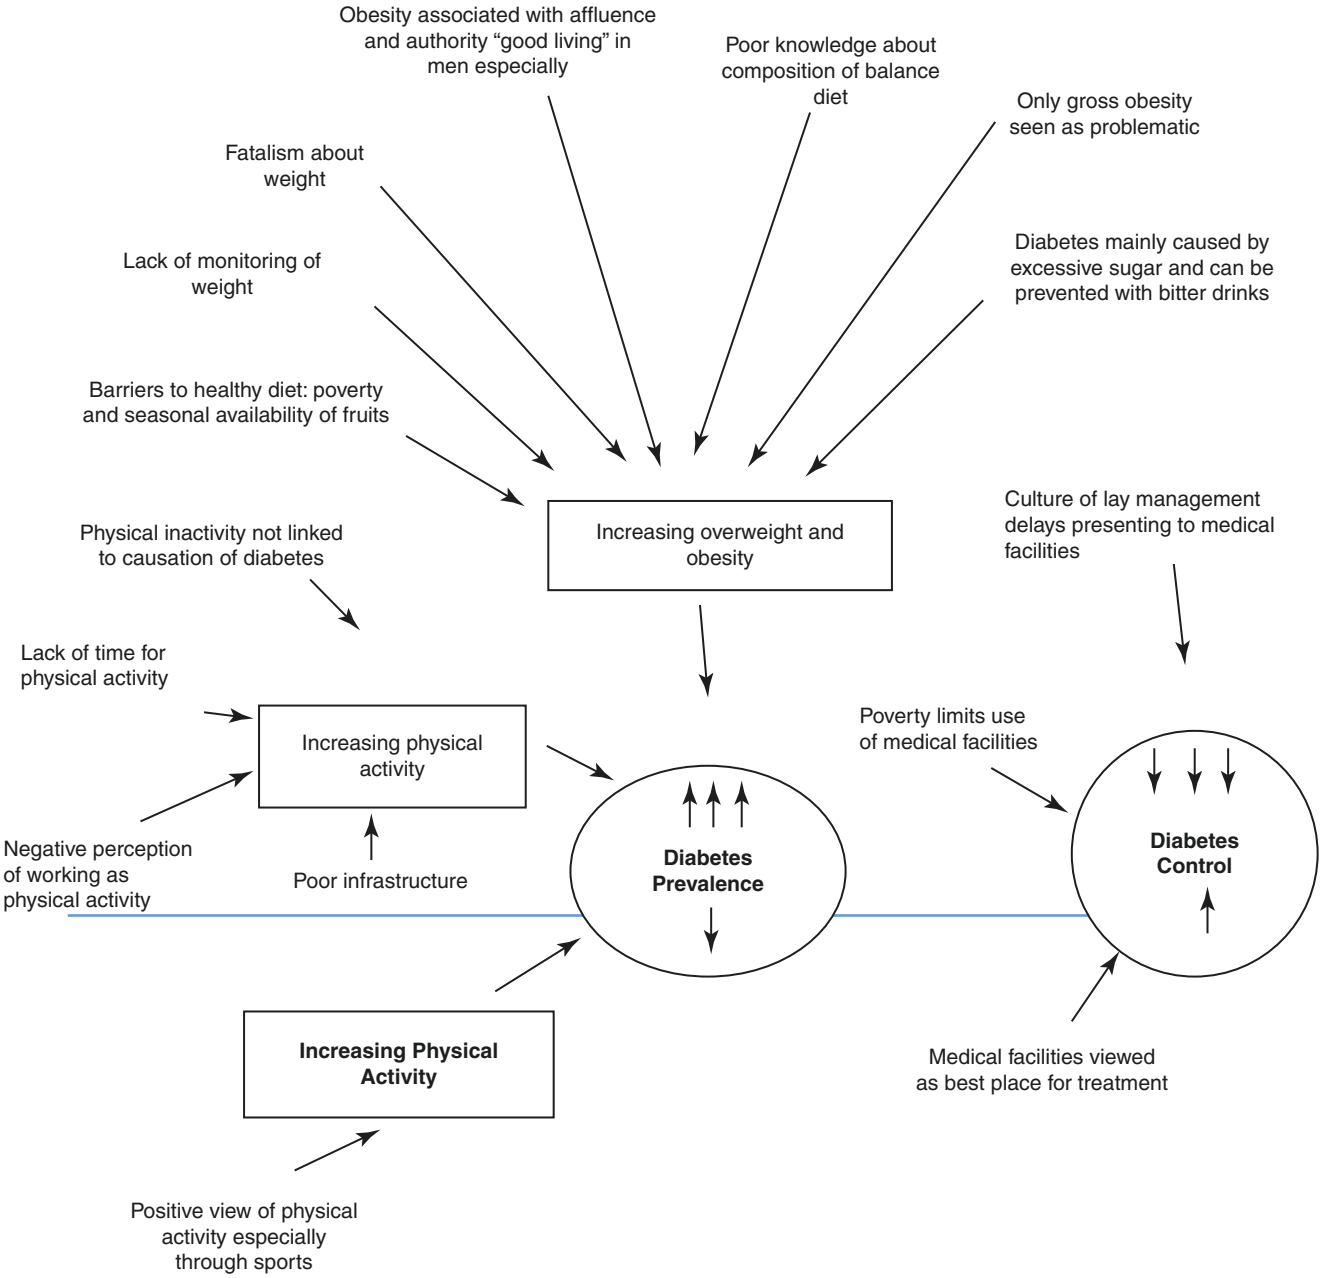

Fig. 20.2 Impact of lay health beliefs on the prevention and control of diabetes in Africa [11]

Management of Hyperglycemia

Maintenance of an optimal blood glucose level is fundamental to managing diabetes. This is because the complications of diabetes arise when the chronic hyperglycemia that characterizes diabetes mellitus remains untreated. Normal glycemic control can be achieved using non-pharmacologic and pharmacologic means. Non-pharmacologic means are the first line of treatment, and pharmacologic means are employed in combination. Medical nutrition therapy is the first line of treatment among the non-pharmacologic options [7]. It is worth noting that the therapeutic benefits of pharmacologic therapy are optimal when used alongside medical nutrition therapy.

Objectives of Management of Diabetes Mellitus

- Improve on the early detection of disease in affected individuals.
- Improve the quality of life of patients with diabetes.
- Prevent disease progression to complications.
- Empower patients and encourage self-care practices.

Screening and Diagnosis

The asymptomatic presentation of diabetes in its early stages compromises health-seeking behavior, even among susceptible individuals. It has been estimated that a quarter of patients with diabetes at the time they seek medical attention already have complications resulting from the disease [8]. Less than 50% of participants from most studies conducted in sub-Saharan Africa were known to have diabetes with reported within-country variations; the higher percentages reported in urban areas compared to rural areas [5]. Screening is important in the early detection of disease before the occurrence of complications, thereby reducing disease morbidity and mortality [8]. Even though the Anglo-Danish-Dutch Study of Intensive Treatment in People with Screen-Detected Diabetes in Primary Care (ADDITION)-Cambridge study found that screening for type 2 diabetes is not associated with a reduction in mortality, the careful interpretation of these findings in a resource-limited context as sub-Saharan Africa has been strongly recommended to avoid drawing faulty conclusions and inferences [12]. This is because the socioeconomic context makes Africa the area where screening is most likely to be beneficial.

Nevertheless, the implementation of large-scale population-based screening in the African context is limited by the scarcity of both human and financial resources, since well-organized clinics with suitably trained staff in diabetes screening and care are necessary for an effective screening program. Targeted screening conducted at local healthcare facility level and focused on individuals with increased disease risk is therefore preferred. Logistically less-demanding screening methods, such as risk scoring systems and questionnaires with minimal or no laboratory testing required, have been proposed for identifying people at high risk of developing diabetes [13]. The screening of diabetes is often undertaken alongside other cardiovascular risk factors such as hypertension and hyperlipidemia to ensure a holistic approach to patient care. The Society for Endocrinology, Metabolism and Diabetes of South Africa (SEMDSA) guidelines recommend screening for type 2 diabetes mellitus in all overweight adults at any age so long as they have another risk factor for diabetes, all other adults with no risk factors and aged 45 and above, with rescreening after 3 months to 3 years depending on individual risk [10]. The International Diabetes Federation, however, recommends screening for type 2 diabetes mellitus in individuals aged 40 and above, with familial predisposition, elevated body mass indices, and other cardiovascular risk factors such as high blood pressure and dyslipidemia [14].

Screening of Type 2 Diabetes Mellitus

For who?

- Age ≥ 45 if no risk factor
- Any age if overweight or obese with one other risk factor:
  - Family history of diabetes mellitus
  - Hypertension
  - Hyperlipidemia
  - Physical inactivity
  - Pregnancy/gestational diabetes

Methods

- Fasting blood glucose measurement
- 2 h blood glucose (oral glucose tolerance test)
- HBA1c

Review durations

- 3 yearly in case of negative screening test
- Yearly follow-up in case of positive screening test but negative diagnostic test results.

Adapted from the 2017 SEMDSA Guidelines for the Management of type 2 Diabetes [10]

The criteria for diagnosis of diabetes in Africa are similar to those recommended by the international guidelines [15]. Most patients present with acute hyperglycemia with undoubted clinical manifestations; others are diagnosed through campaigns screening or labor health screening. Oral glucose tolerance test is seldom performed, whereas using HbA1c as a means of diagnosis seems illusive because of the absence of the recommended method (high-pressure liquid chromatography) in most African countries.

Lifestyle Modification

The principal components of lifestyle modification in the African context just as in other parts of the world are diet control, weight control, physical activity, cessation of alcohol consumption, smoking, and other factors known to favor hyperglycemia or to increase the risk of complications.

Components of Lifestyle Modification
Healthy diet:

- Reducing carbohydrate, saturated fat, cholesterol, and salt intake

Weight reduction:

- Target BMI: 18.5–24.9 kg/m^2

Regular physical activity:

- Aerobic exercises (brisk walking, cycling, swimming, dancing, water aerobics)
- Resistance exercises (free-weight lifting, exercises with weight machines)
- At least three times/week and between 20 and 30 min per session
- Reconsider insulin and secretagogues dosing to prevent hypoglycemia
- Consider cardiovascular assessment before and contraindications to physical activity

Reduction of alcohol consumption
Cessation of smoking

Adapted from the 2012 and 2017 SEMDSA Guidelines for the Management of type 2 Diabetes [8, 10]

Medical Nutrition Therapy

The effects and benefits of medical nutrition therapy are two-pronged to maintain glycemia within normal limits and also to help reduce body weight which is a modifiable risk factor of diabetes. Adjustments of the diet revolve around a personalized diet based on an assessment of the patient's nutritional status within the context of sociocultural and psychological influences and tailored to the patient's needs based on ongoing monitoring of glycemia and patient support to maintenance of this plan with allowance for flexibility. Even though most patients with diabetes in Africa are aware of the importance of a healthy diet in its management, some are not aware of the specific components of the healthy diet [16].

In addition to this, lack of adherence even when the healthy diet is initiated remains common [10]. Regular medical nutrition therapy contact sessions with dietitians specialized in diabetes management are therefore recommended over the generic nutritional advices and messages often given to patients [10]. Restrictive diets consisting of protein-rich, carbohydrate-free, and fat-free items are not recommended due to no proven long-term benefit [8].

Specific dietary requirements in patients with type 2 diabetes mellitus are as follows:

1. Healthy diet:
   (a) Increasing daily water intake and having meals at regular times daily
   (b) Avoiding binge eating
   (c) Variety of vegetables and fruits excluding fruit juices
   (d) Low-fat dairy products, meat alternatives, and fish
   (e) Limiting processed food
2. Carbohydrate:
   (a) Constitute 45–60% of total energy intake
   (b) Monitoring carbohydrate intake and limiting sugar alcohols
   (c) Reasonable sucrose and fructose and artificial sweeteners intakes are acceptable
3. Fats:
   (a) Should be <35% of the total energy intake
   (b) Limiting saturated and poly-saturated fats intake
   (c) Consume monounsaturated fat and omega-3 fatty acids from both plant (flaxseed, walnuts, and canola) and marine (fatty fish) sources instead of saturated fat
4. Proteins:
   (a) Should make up 15–20% of total energy intake
5. Salt:
   (a) Reducing dietary salt intake to control blood pressure (<2300 mg/day)
6. Vitamins and minerals:
   (a) Routine supplementation not required unless in some specific groups such as elderly patients or lactating pregnant women

7. Alcohol:
   (a) Moderate alcohol consumption for individuals who consume alcohol (1 unit per day for women and 2 units per day for men)

These dietary requirements often difficult to accurately measure have been simplified in the healthy diabetes plate concept (Fig. 20.3a, b).

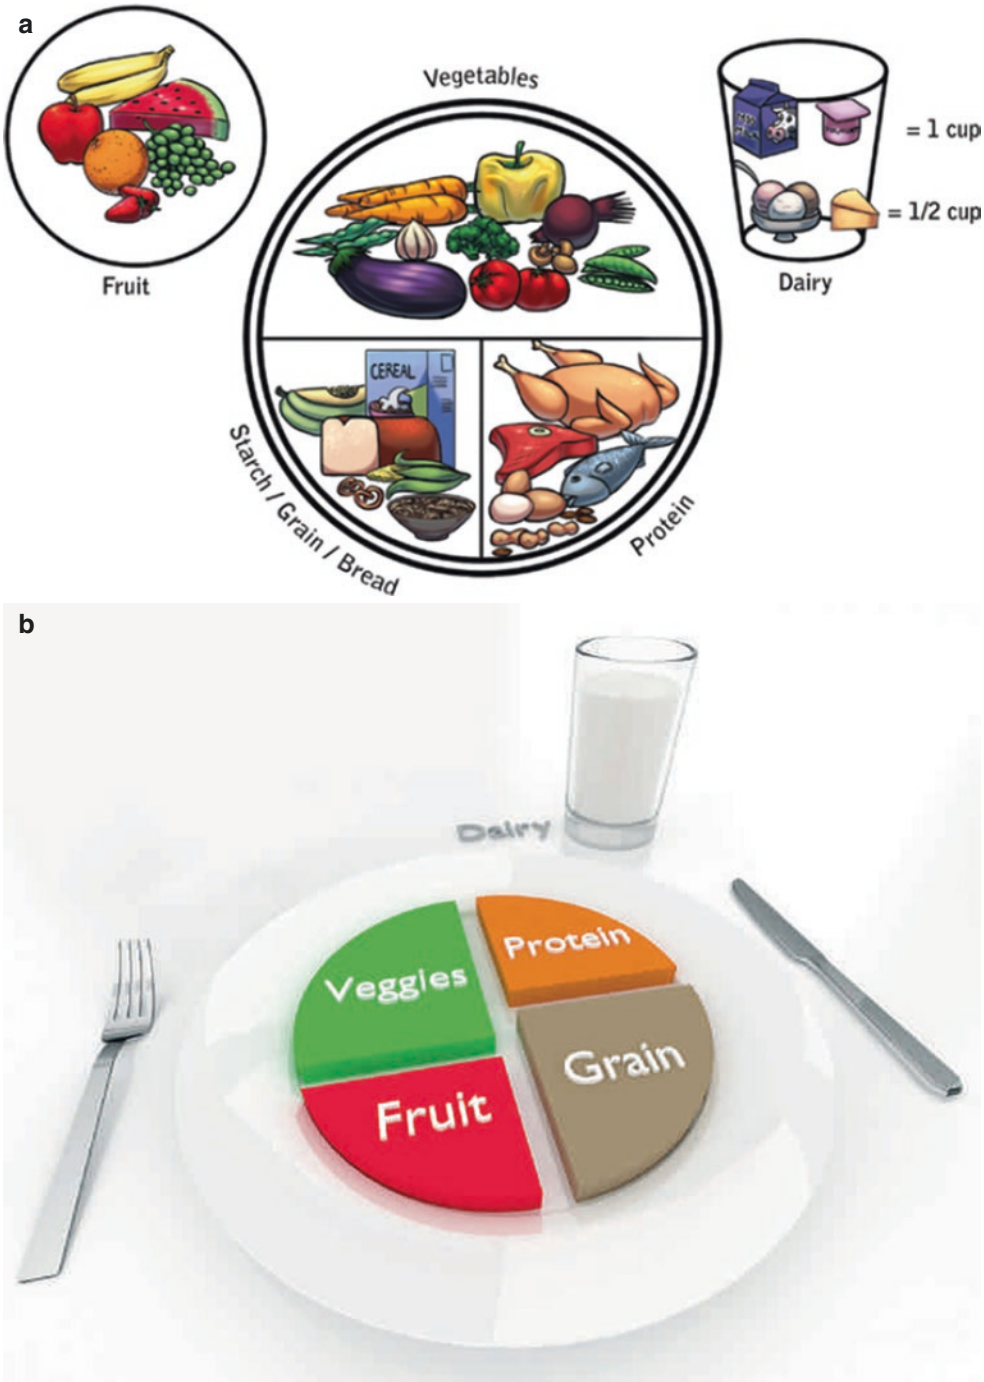

Fig. 20.3 (**a**) The healthy diabetes plate. (*Source: The 2012 SEMDSA Guideline for the Management of type 2 Diabetes* [8]). (**b**) The healthy diabetes plate (*Source: Management of Gestational Diabetes in the Community. Training manual for community health workers* [17])

The Healthy Diabetes Plate

To constitute the healthy diabetes plate:

- Divide into two equal halves, and then divide one of these halves into two equal sections.
- The undivided half section should consist of a variety of non-starchy vegetables, such as spinach, carrots, lettuce, and other greens, cabbage, green beans, broccoli, cauliflower, tomatoes, cucumber, beets, mushrooms, and peppers.
- One of the quarters should contain starchy foods, such as whole-grain breads (e.g., whole wheat or rye), whole-grain high-fiber cereal, cooked cereal (e.g., oatmeal), brown or long-grain rice, pasta, baby potatoes, green peas, sweet potatoes, whole-grain crackers, and fat-free popcorn.
- The other quarter section should contain meat and meat substitutes, such as skinless chicken and Turkey portions, fish and other seafood, lean cuts of beef and pork (e.g., sirloin, fillet or pork loin), tofu, soya, eggs, and low-fat cheese. Avoid processed meats (e.g., salami, Vienna sausages, and polony), which are high in fat and salt.
- A glass (240 mL) of nonfat or low-fat milk, or 180 mL of light yoghurt (at least 2 servings per day).
- A medium portion of fruit (such as oranges, apples, pears, or small bananas), or two small fruits (such as plums or peaches), or three quarters of a cup of fresh fruit salad. Instead of eating fruit with meals, these are eaten as snacks between meals.

Physical Activity and Other Lifestyle Measures

With obesity and overweight as risk factors for insulin resistance and type 2 diabetes mellitus, weight loss stands out as an important factor to be considered in order to prevent or manage diabetes mellitus. Adjustments in weight should therefore be tailored to match the individual's height to maintain a normal body mass index (18.5–24.9 kg/m^2). The place of patient education on weight loss and its importance in diabetes management cannot be overemphasized, since local perceptions in the African setting consider obesity as an indicator of affluence, status, and good living [11]. Significant reductions in diabetes mellitus-related mortality and morbidity have been reported with regular physical activity [18, 19]. As reported in the findings of a study on a cohort of diabetes mellitus patients in Cameroon, Central Africa, a 12-week aerobic exercise program monitored by a step counter was found to significantly improve the anthropometric and metabolic parameters, alongside the aerobic capacity of patients with diabetes mellitus [19]. The aerobic exercise here consisted of 45-min sessions holding thrice a week with each session consisting of a warm-up, brisk walking or light running, and a cooldown. Dancing was also introduced at some point during the follow-up period of the aerobic exercise [19]. Despite being aware of the importance of physical activity in preventing or managing diabetes, several patients in sub-Saharan Africa still do not engage into physical activity due to lack of time or access to appropriate infrastructure [11].

Overall, physical activity reduces cardiovascular disease risk; improves insulin sensitivity; controls glycemia, blood pressure, and lipid levels; and reduces the total body weight. It is worth noting that any recommendations to engage in a physical activity regimen should be preceded by an adequate assessment to ensure there are no contraindications to physical activity.

The multicenter Diabcare Africa conducted in six African countries study reported rather low rates of smoking and alcohol consumption among patients with diabetes mellitus in sub-Saharan Africa, with the highest figures detected in Central African regions [20]. Reduction in alcohol consumption to a maximum of 1 unit per day or less for women and 2 units per day for men is beneficial in preventing any alcohol-related hyperglycemia [8].

Pharmacologic Therapy

Pharmacologic therapy is considered in addition to lifestyle modifications or when the latter has failed to maintain optimal glycemic levels. In type 1 diabetes, and in any acute metabolic and non-metabolic diabetes presentation, insulin therapy is usually mandatory. As in other parts of the world, the two principal pharmacologic therapies used in Africa are oral antidiabetic medications and insulin therapy, used individually or in combination depending on the type of diabetes and patients' individual circumstances. Over the past decade however, non-insulin injectable antidiabetic drugs led by glucagon-like peptide-1 (GLP-1) have emerged as an essential part of diabetes management [21]. Many patients in

Africa, however, believe that diabetes can be treated using traditional therapy, making compliance to recommended pharmacologic therapy occasionally ineffective [11].

Treatment Targets

Blood Glucose

- Fasting plasma glucose (FPG): 4–7 mmol/L
- Two-hour postprandial plasma glucose (2-h PG) 4–8 mmol/L

Glycated Hemoglobin [10]

- Glycated hemoglobin A1c (HbA1c)c ≤ 7%
- HbA1c <6.5% in newly diagnosed patients in good health

Considerations [10]

Involve patient in discussion on glycemic targets

Three monthly HbA1c monitoring in patients not at target and six monthly if target achieved

Oral Antidiabetic Medications (OAD)/Oral Hypoglycemic Agents (OHA)

Majority of patients in Africa on pharmacologic therapy for diabetes are on oral antidiabetic medications [20], since they are generally the first line in type 2 diabetes treatment protocols. Monotherapy or combination therapy with different oral antidiabetic agents is used based on the potential factors underlying the hyperglycemia of the patient, and combination therapy should be based on agents from different classes. The multicenter Diabcare Africa study reported that more than half of patients on pharmacologic therapy were receiving two oral antidiabetic agents for treatment of their diabetes, and very few patients had up to three agents [20]. Nevertheless, treatment should be individualized, based on patient sociodemographic and clinical characteristics as well as economic status. The use of generic medications with proven efficacy is highly encouraged in the African context due to their relative affordability compared to proprietary brand [7]. The biguanide metformin and sulfonylureas agents are often used as first-line agents unless contraindicated. The most commonly used oral antidiabetic agents and their respective characteristics are summarized in Table 20.1.

Table 20.1 List of antidiabetic drugs available in Africa

Medication	Starting dose	Maximum dose	Adverse effects	Contraindications
Biguanides				
Metformin	500 mg	2550 mg	Abdominal pain	Renal failure
			Nausea	Hepatic failure
			Loose stool	Cardiorespiratory failure
			Lactic acidosis	Pregnancy
Sulfonylureas				
Glibenclamide	2.5 mg	20 mg	Hypoglycemia	Pregnancy
Gliclazide	40 mg	320 mg	Weight gain	Caution with hepatic and renal disease
Glimepiride	1 mg	8 mg	Skin rashes	
Glipizide	5 mg	40 mg		
Chlorpropamide	100 mg	500 mg		
Tolbutamide	500 mg	2500 mg		
Tolazamide	100 mg	1000 mg		
Acetohexamide	250 mg	1500 mg		
Thiazolidinediones[a]				
Rosiglitazone	4 mg	8 mg	Hepatic impairment	Renal failure
Pioglitazone	15 mg	45 mg	Fluid retention	Hepatic failure
			Weight gain	Cardiorespiratory failure
			Dilutional anemia	Pregnancy
Meglitinides				
Nateglinide	180 mg	360 mg	Hypoglycemia	Cardiac failure
Repaglinide	1.5 mg	16 mg	Weight gain	Hepatic failure
			Dyspepsia	Pregnancy
Alpha-glucosidase inhibitors				
Acarbose	25 mg	300 mg	Dyspepsia	None
Miglitol	25 mg	300 mg	Loose stool	

Source: Type 2 diabetes mellitus clinical practice guidelines for sub-Saharan Africa [7]

[a] This class is currently absent in most African countries because of the issues on the cardiovascular safety of rosiglitazone

Insulin Therapy

In general, insulin therapy is used in type 2 diabetes: when oral antidiabetic agents are inadequate to maintain optimal blood glucose levels; in cases of acute hyperglycemia requiring rapid correction; and in pregnancy where most oral antidiabetic agents are contraindicated. In type 1 diabetes, insulin is the compulsory treatment. Africa, however, faces the major problem of limited availability of insulin analogs and even unaffordability when available [5], and frequent run-out of human insulin formulation which are more accessible. Nevertheless, insulin therapy should begin as soon as indicated in the management of diabetes, whether in combination with oral antidiabetic agents or as monotherapy.

Insulin Therapy

Indications:

- Type 1 diabetes mellitus
- Poor glycemic control with OAD
- Contraindications of OAD
- Hyperglycemic emergency
- Severe glycemia at initial presentation
- Perioperative glycemic control
- Organ failure (cardiorespiratory, hepatic, renal)
- Pregnancy

Regimens:

Combination therapy:

- NPH (0.2 IU/kg of body weight/day – Administered at bedtime) +
- OAD (metformin and reduced or stopped sulfonylureas dose)

Monotherapy:

- Premixed insulin twice daily, given half an hour before morning and evening meals

(0.2 IU/kg of body weight/day)

OAD, *oral antidiabetic agents*; *NPH*, *Neutral Protamine Hagedorn*

Source: *Type 2 diabetes mellitus clinical practice guidelines for sub-Saharan Africa* [7]

Insulin preparations most used in the African setting are presented in Table 20.2.

Table 20.2 Insulin preparations used in Africa

Insulin preparation	Onset of action (min)	Peak action (h)	Duration of action (h)	Injections per day
Rapid-acting	10–20	1–2	3–5	Immediately before meals
Soluble	30–60	2–4	6–8	30 min before meals
Intermediate (NPH)	60–120	5–7	13–18	Once or twice
Lente	60–180	4–8	13–20	Once or twice
Biphasic mixture 30/70	30	2–8	Up to 24	Once or twice

Source: Type 2 diabetes mellitus clinical practice guidelines for sub-Saharan Africa [7]

Combination Therapy with Oral Antidiabetic Medications and Insulin

A combination of insulin and oral antidiabetic medications may be necessary to maintain blood glucose levels within optimal ranges. However, this combination therapy is used after failure of monotherapy with OAD, and insulin is required as a supplement to the OAD. An algorithm for the management of type 2 diabetes in Africa is shown below.

Algorithm for Type 2 Diabetes Mellitus Management

Step 1: (lifestyle modification)

1. Lifestyle changes: Diet, physical activity, smoking, and alcohol consumption cessation
2. Review in 3 months

   Note: If patient is unwell, with severe symptoms or pregnant, then refer to a tertiary hospital or admit patient and consider insulin therapy.

Step 2: (Oral monotherapy)

At follow-up visit after 3 months, if glycemic control is:

3. Adequate: Continue monitoring
4. Inadequate and patient is overweight: Start metformin at low dose, and increase three monthly as required until maximum dose reached
5. Inadequate and patient is not overweight: Start a sulfonylurea at low dose and increase every 3 months as required until maximum dose reached

Step 3: (Oral combination therapy)

At follow-up visit, if glycemic control is:

6. Adequate: Continue monitoring
7. Inadequate: Add another class of OAD, start at low dose, and increase every 3 months as required until maximum dose reached

Step 4: (Oral and insulin combination therapy)

8. At follow-up visit, if glycemic control is adequate, continue monitoring
9. Inadequate: Continue OAD and add bedtime intermediate acting insulin
10. Review in 3 months

Step 5: (insulin therapy in a secondary or tertiary service)

At follow-up visit in 3 months, if glycemic control is:

11. Adequate: Continue monitoring
12. Inadequate: More than once daily insulin is required, so refer to secondary or tertiary care

Adapted from type 2 diabetes mellitus clinical practice guidelines for sub-Saharan Africa [7]

Specificities of the Management of Ketosis-Prone Type 2 Diabetes

Ketosis-prone type 2 diabetes (KPD) is an atypical form of diabetes which is frequently seen in sub-Saharan Africa. Its management mandates some specific measures because of its dichotomic presentation: acute ketotic onset or relapse that resembles the clinical presentation of type 1 diabetes, further course that is similar to that of type 2 diabetes, and the high probability of near-normoglycemic remissions with risk of hypoglycemia if hypoglycemic agents are maintained in the treatment [22]. Though there is no consensual management strategy, expert opinion suggests the following [2]:

1. During the acute phase (onset or relapse)
   (a) Manage as any diabetes ketoacidosis
   (b) Assess autoantibodies to rule out type 1 diabetes
2. Early (first to second week) after the acute phase
   (a) Educate on hypoglycemia, adjustment of insulin doses and diet
   (b) Assess insulin secretion if possible
3. Few weeks after the acute phase
   (a) Close monitoring including close consultations and phone calls
   (b) Progressive insulin withdrawal, switch to oral antidiabetic drugs
4. Over months and years
   (a) Education on diet and physical activity, drug adherence, risk of hyperglycemic relapses
   (b) Standard follow-up similar to classical type 2 diabetes
   (c) Inpatient management in case of relapses

Prevention and Management of Acute and Chronic Complications of Diabetes

Prevention and Management of Chronic Complications

Populations of African origin are known to be more likely to develop microvascular complications of diabetes compared to the macrovascular complications of diabetes due to the limited access to adequate diabetes care and partly due to the high rates of hypertension in this population [23]. In most instances, the appearance of complications is the reason for patients seeking medical attention, making early detection of the disease very unlikely [24]. As a result of the higher frequency of microvascular complications of diabetes in patients in Africa, complications such as foot ulcerations, blindness, and renal failure are more frequent in these patients compared to complications resulting from large vessels involvement [25]. The African sociocultural context has a tangible impact on the management of these complications as some procedures such as amputations for chronic limb ulcerations are often unwelcomed [26]. The importance of patient education on the complications of diabetes and their management cannot be overemphasized.

As much as 50% of the patients with diabetes in the multicenter Diabcare study had their serum creatinine levels tested within the last year, with the highest percentages noted in Central Africa compared to East and West Africa. Of these patients tested, 54% had significantly raised serum creatinine levels [20]. Likewise, Central Africa compared to East and West Africa registered the highest proportion of patients tested for proteinuria in the last year [20]. These data show that diabetes complications are rare when adequately investigated for and therefore remain a major concern in the African setting.

With the appearance of complications, the risk of developing cardiovascular disease significantly increases, as well as disease-related mortality. Patients presenting with symptoms suggestive of a potential complication of diabetes should be referred to secondary or tertiary care for a proper assessment of complications. All associated complications of diabetes diagnosed following the full assessment should be promptly managed to prevent major sinister outcomes of diabetes that result in significant impairment such as amputation and blindness [7].

Management of Acute Complications of Diabetes

Poorly controlled diabetes can result in acute metabolic emergencies characterized by significant acute derangement in glycemic levels resulting in altered consciousness and even coma.

The reported acute metabolic complications of diabetic ketoacidosis and lactic acidosis, hyperosmolar states, and hypoglycemia are also common in Africa [25]. These life-threatening acute metabolic emergencies that require prompt life-saving interventions carry high mortality rates in Africa due to a constellation of reasons among which the late presentation at health facilities, delay in diagnosis, and even lack of insulin [7, 25]. Diabetes-related infections such as foot sepsis and hand infections have been proposed as acute complications of diabetes due to their high frequency and mortality in the African setting [25]. Clinicians should therefore be trained in diagnosing and managing these conditions.

Diabetic ketosis presents with elevated blood glucose levels, heavy and rapid breathing, raised serum, and urine ketones, with or without altered consciousness. Nonketotic hyperosmolar state that has a slower development of the hyperglycemic state presents with marked dehydration and uremia, with minimal or no ketonuria. The cornerstone of management of these conditions is prompt initiation of intravenous fluid resuscitation and gradual lowering of the blood glucose level using intravenous insulin [7]. This requires close monitoring of blood glucose levels, serum electrolytes, and creatinine levels, which is often challenging to implement. A protocol consisting of intramuscular insulin and rehydration was therefore proposed as an alternative to intravenous insulin use in the absence of appropriate monitoring facilities, based on its associated significant reduction in early deaths, simplicity, and inexpensive setup [27]. Hypoglycemia in revenge, characterized by extremely low blood glucose levels, often results from overdosing of diabetes medication and/or insufficient carbohydrate intake to maintain an adequate glucose level. In the African setting, this complication has been especially frequent with sulfonylureas agents [25]. Patients initiated on these agents and insulin should therefore be educated on the potential risks of hypoglycemia and how to prevent and/or manage it.

Management of Acute Diabetic Emergencies

Diabetic ketoacidosis and nonketotic hyperosmolar state

- Intravenous fluids: Minimum of 1 L in the first hour (if no contraindication)
- Insulin therapy: Short-acting insulin intramuscularly
- Immediate referral to an emergency unit (secondary or tertiary care)

Hypoglycemia

For conscious patient

- Oral glucose

For unconscious patient

- Intravenous fluids: 50% glucose bolus (40–50 mL) or 20% dextrose (100–150 mL) followed by 8–10% glucose if required
- Injectable glucagon
- Long-acting carbohydrate snack on recovery
- Continue intravenous dextrose 5–10% for 12–24 h as required
- Identify possible cause of hypoglycemia
- Review drug therapy and renal function and adjust antidiabetic treatment accordingly

Adapted from: Type 2 diabetes mellitus clinical practice guidelines for sub-Saharan Africa [7]

Management of Comorbidities

Management of diabetes entails managing associated comorbidities that tend to worsen the prognosis and overall quality of life of patients with diabetes by favoring disease progression to complications and target-organ damage. The principal comorbidities often associated with diabetes are cardiovascular risk factors and components of the metabolic syndrome such as hypertension and dyslipidemia. As much as 65% of patients with diabetes were being treated for hypertension, and 13% for hyperlipidemia in the Diabcare Africa study, with regional variations in these percentages [20]. Aggressive management of these comorbidities therefore forms an essential component of the management of diabetes in Africa. In individuals without these comorbidities, reducing their risk of developing these comorbidities is important. As with diabetes mellitus, the management of comorbidities is by both non-pharmacologic and pharmacologic means to achieve the desired treatment targets.

The main non-pharmacologic means for managing diabetes consist of lifestyle modifications and diet which also help in controlling the major comorbidities of diabetes such as hypertension and dyslipidemia. Failure of the non-pharmacologic means should prompt initiation of pharmacotherapy to control blood pressure, hyperlipidemia, and any other known co-comorbidities. Treatment should be individualized and special considerations taken for potential interaction between drug classes, diabetes, and antidiabetic medications. Regular monitoring of lipid profile and renal function of the patient should be ensured, and prompt referral to a specialist or for secondary/tertiary care should be

done in cases or poorly controlled comorbidities or suspicion of target organ damage [7].

Management of Comorbidities
Non-pharmacologic:

- Lifestyle modification
- Reduced salt and saturated fats in diet, regular physical exercise, weight loss

Pharmacologic:

- Antihypertensives (monotherapy, then combination therapy as required)
- Antihyperlipidemics

Treatment targets:

- Blood pressure
- Systolic blood pressure <130 mmHg (<125 if persistent proteinuria on dipstick)
- Diastolic blood pressure <80 mmHg (<75 if persistent proteinuria on dipstick)

Dyslipidemia:

- Total cholesterol <5.2 mmol/L
- LDL cholesterol ≤2.6 mmol/L
- HDL cholesterol >1.1 mmol/L
- Triglycerides <1.7 mmol/L

Interactions to consider:

- High-dose diuretics inhibit insulin release
- Beta-blockers may accentuate hypoglycemia
- Alpha-blockers may accentuate autonomic dysfunction
- B-beta-blockers and diuretics may worsen dyslipidemia
- ACE inhibitors may exacerbate hypoglycemia

Adapted from type 2 diabetes mellitus clinical practice guidelines for sub-Saharan Africa [7]

Follow-Up of Patients

Regular clinic follow-up is mandatory in the treatment and control of diabetes. The follow-up visits can range from weeks to months depending on the stage of the disease and other clinical and patient-related factors such as access to healthcare services. This has been a quite deficient arm of the overall diabetes care in Africa with patients often lost to follow-up due to several known and unknown reasons. Factors assessed at follow-up visits are shown in Table 20.3.

Monitoring of blood glucose control is best done by measuring the standard glycated hemoglobin levels (HbA1c). Unfortunately, the awareness and availability of this standard test are low in most African countries. As reported in the Multicenter Diabcare Africa study, access to HbA1c testing was as low as 47%, despite the variations across study centers [20]. There were, however, remarkable regional differences in the overall HbA1c awareness, being higher in the Central African countries compared to the West African countries. It is worth noting that in settings and centers where the HbA1c testing was available for monitoring of diabetes

Table 20.3 Factors assessed at follow-up visits

Initial visit	3-month visit	Annual visit
Primary level		
History and diagnosis	Relevant history	History
Physical examination	Weight	Physical examination
• Height and weight	Blood pressure	Biochemistry
• BMI	Foot inspection	(As at the initial visit)
• Waist and hip circumferences	Biochemistry	
• Blood pressure	• Blood glucose	
• Detailed foot examination	• Glycosylated hemoglobin	
• Tooth inspection	• Urine protein	
• Eye examination	Education advice	
– Visual acuity	Nutritional advice	
– Fundoscopy	Review therapy

control, a low proportion of patients achieved their HbA1c targets [20]. An acceptable alternative to the HbA1c in the monitoring glucose control in Africa is the laboratory measurement of fasting and postprandial blood glucose levels. The use of urine glucose testing though might be the only alternative available in some resource-poor settings is not advised [7].

Current Challenges to Diabetes Management in Africa

Despite the progress made in the management of diabetes in Africa, much still needs to be done on the care of patients with diabetes in Africa. Diabetes is an expensive chronic disease not only for the health systems of countries in Africa but also for individual patients given the organization and financing of healthcare systems and payment of healthcare services by patients [3]. The barriers to adequate management of this chronic disease are:

- The unavailability of logistics for diabetes care
- Population awareness about diabetes and its management and complications due to nontreatment or poor compliance
- Poor glycemic control and late presentation to health facilities especially in type 1 diabetes [28]
- Scarcity of health personnel as a whole and those trained in diabetes care
- Access to medications due to their cost [4]

Africa that was initially plagued solely by the communicable diseases burden now faces a double disease burden, with the increasing number of patients with noncommunicable diseases. As such, the healthcare systems of countries in this part of the world are faced with the challenge of resource reallocation from the traditional communicable diseases such as malaria, HIV, and tuberculosis toward the management of chronic noncommunicable diseases such as diabetes [3]. This therefore becomes extremely challenging for healthcare systems of these countries which by default are more adapted to managing acute conditions rather than chronic diseases [29].

As with other chronic conditions, cost stands out as a principal determinant of access and adherence to treatment. Access to antidiabetic medication therefore stands out as one of the major challenges faced by patients in Africa [25]. The lack of universal health coverage in most African countries implies out-of-pocket payments are the main way through which individuals pay for healthcare services, making access to treatment difficult given the high proportion of people living below the poverty threshold. This is particularly the case with insulin-based treatment of diabetes which is not always affordable when available [3]. As such, the prognosis of this disease in Africa has not often been satisfactory as in other parts of the world [30, 31]. In 2005, insulin was estimated to cost between $4.30 and $4.60 per 10-mL U100 vial, in Mozambique and Zambia, when bought by the national health systems. Insulin was even more expensive when bought by individuals from private wholesalers [3].

Other more specific problems faced with regard to the management of type 1 diabetes mellitus are the quantification of insulin needs, the storage of insulin under optimal temperature conditions, and timely ordering of medication stocks to ensure permanent availability at all levels of patient care [3].

Population awareness and education about diabetes is a major factor. Many people living with diabetes still resort to unconventional and alternative treatment means such as traditional healers who are generally unlikely to refer patients back to healthcare facilities [4, 32]. There is a need to conduct operational research on such alternatives with a bid to define their potential role in the management strategy of diabetes. Knowledge about diabetes, its complications, and how to manage it is still low [33]. This makes the control of this chronic disease difficult in Africa. This lack of awareness is not limited just to the patients and their caregivers but has been reported to extend to healthcare providers as well [34], with reported instances of coma as a result of diabetes being diagnosed as cerebral malaria or HIV/AIDS, all favored by the lack of appropriate diagnostic facilities [3]. Despite the adoption of the westernized lifestyles that could increase risk of developing diabetes in Africa, the sociocultural practices in this part of the world have not made adequate allowances for the accompanying practices that could reduce disease risk such as adequate physical activity and healthy diet [32]. This is even worsened by local perceptions of the African setting such as the fact that obesity is an indicator of affluence and good living [11]. Despite all the challenges and barriers to the effective management of diabetes in Africa, it is worth noting that there exist considerable within-country differences, with urban regions having more satisfactory systems in place to manage diabetes than the rural areas.

Newer Approaches to Diabetes Management in Africa

Newer approaches to diabetes management are increasingly being implemented in Africa such as the social support and self-management of diabetes that are currently in use in developed countries. Several countries in Africa have now created a national diabetes registry and diabetes associations and are implementing national diabetes programs alongside

other primary healthcare programs to cater for patients with this disease. The setting up of diabetes clinics across countries through joint efforts from national diabetes associations and ministries of health is consistently adopted due to their efficiency in disease management [35].

These approaches and programs have been aimed at improving patient education and awareness about diabetes, patient empowerment with regard to diabetes management, health personnel training, medication supply, diagnostic facilities, and overall improvement in healthcare systems across the continent [3].

Patient education and empowerment aims to educate patients on what diabetes is, how to take care of themselves to reduce their risk of having diabetes, and how to self-monitor their glycemia and adopt healthy lifestyles to reduce the risk of developing complications. The diabetes self-management support provided should be patient-centered, individualized, integrate cognitive-behavioral interventions, and involve the patient as much as possible in the decision-making process [10]. Patients should also be provided with the resources to be able to undertake self-care [7]. The adoption of less costly preventive measures such as physical activity and more precisely aerobic exercise known to improve metabolic and anthropometric parameters of patients with diabetes mellitus should be encouraged.

Points to be covered in a self-assessment education of diabetes patients are covered in Table below [8].

Basic Knowledge of Diabetes

- Basic knowledge of diabetes.
- Importance of good comprehensive control and methods to achieve this.
- Insulin injection techniques and sites of injection.
- Self-monitoring of blood glucose.
- Recognition and management of acute and chronic complications.
- Foot care.
- Smoking cessation and responsible alcohol use.
- Preconception care.
- Pregnancy: preparing, managing diabetes during pregnancy, and appropriate postnatal care.
- Psychosocial issues, stress management, and coping skills.
- Training of caregivers and family of people with diabetes.
- Managing diabetes emergencies.
- Importance of an identification disc or bracelet.
- Children with type 2 diabetes should be referred for specialist assessment and diabetes education.
- Management of elderly patients:
  - Assess knowledge and understanding of diabetes.
  - Evaluate ability to learn and apply new self-care skills.
  - Assess nutrition and physical activity.
  - Address polypharmacy and comorbidities.
  - Assess for cognitive dysfunction, depression, and physical disability.
  - Address quality of life versus life expectancy.

Adapted from the 2012 SEMDSA Guideline for the Management of type 2 Diabetes [8]

Healthcare providers should be trained on diabetes as a chronic disease and its management. They should also be trained on how to disseminate this information to the population that makes use of the health facilities and through other means of community engagement and communication [33].

Task shifting in the care and management of patients with diabetes is also gaining grounds in sub-Saharan Africa. There are reports of the successful implementation of nurse-led diabetes care [36, 37]. This has turned out to be cost-effective and has helped in solving the shortage of doctors treating patients with diabetes mellitus [38].

Concerning improving diagnostic facilities and medication supply, standardized means of assessing blood glucose levels should be available at the various levels of patient referral of the health system. Medications for treatment should be made available at all times through improvements in the supply chain dynamics of antidiabetes medications, and these medications have to be made affordable for patients [3].

Another important component of the newer approaches to diabetes management in Africa is the implementation of monitoring of care system, whereby, the quality of care offered to patients is periodically monitored to identify deficiencies and correct them as appropriate [7].

Above all, the availability of adequate data on disease burden and current level of treatment coverage remains fundamental to assessing the actual progress of the management of this disease and planning on measures to improve diabetes-related mortality and morbidity [28]. Likewise, extensive research should be funded to investigate on the presentation and specificities of this condition in this part of the world [28]. This will demand enormous coordinated actions between key stakeholders, ministries of health, and both government and nongovernmental organizations. A multidisciplinary approach to diabetes prevention and treatment is therefore necessary for effective

management of diabetes in Africa, with the involvement of all key stakeholders both at patient and community levels [3, 5, 28].

At the international level, the African regional branch of the International Diabetes Federation, through the African Diabetes Declaration, has summoned governments and agencies involved in diabetes care in Africa to uphold standards of diabetes care with regard to prevention, early detection, and availability and affordability of treatment [3].

The International Insulin Foundation has summarized adequate diabetes management in Africa in 11 keys points [3].

Diabetes Management in Africa

- Organization of the health system
- Prevention
- Data collection
- Diagnostic tools and infrastructure
- Drug procurement and supply
- Accessibility and affordability of medicines and care
- Training and availability of healthcare workers
- Adherence issues
- Patient education and empowerment
- Community involvement and diabetes associations
- Positive policy environment

Adapted from Diabetes care in sub-Saharan Africa [3]

Concluding Remarks

- The management of diabetes in Africa has significantly improved over the decades with management taking a more holistic approach.
- There are still limited contextualized guidelines specific to the management of diabetes in Africa, as many countries still rely on guidelines essentially used in developed countries.
- Treatment cost and medication availability remain as major barriers to effective treatment in Africa.
- The role of new drugs such as GLP-1 receptor agonists or sodium-glucose cotransporter 2 (SGLT2) antagonists is worth evaluating.
- A multidisciplinary approach to diabetes prevention and treatment is necessary for effective management of diabetes in Africa.

Multiple Choice Questions

1. Measures aimed at early detection of disease in affected individuals are known as:
   (a) Primary prevention
   (b) **Secondary prevention**
   (c) Tertiary prevention
   (d) Treatment
   (e) Management
2. The following are major objectives of the management of diabetes, except which one:
   (a) **Bring down HbA1c level below 7% for all.**
   (b) Early detection of disease in affected individuals.
   (c) Improve the quality of life of patients with diabetes.
   (d) Prevent disease progression to complications.
   (e) Empower patients and encourage self-care practices.
3. All the following apply to the management of ketosis-prone type 2 diabetes, except which one:
   (a) Patients usually require insulin at onset.
   (b) Patients may be insulin-free for years.
   (c) **Patients are insulin-dependent for life.**
   (d) Patients may keep an excellent glucose control without any treatment.
   (e) Patients are in high risk of hypoglycemia during the remission period.
4. Management of diabetes is centered on which of the following:
   (a) Early screening and diagnosis of diabetes
   (b) Management of blood glucose
   (c) Management of comorbidities
   (d) Prevention and management of acute and chronic complications of diabetes
   (e) **All of the above**
5. Which of the following is not a routine pharmacologic management option for diabetes?
   (a) Insulin therapy
   (b) **Vitamins and minerals**
   (c) Biguanides
   (d) Sulfonylureas
   (e) Meglitinides
6. Medical nutrition therapy recommends one of the following except:
   (a) Increasing daily water intake and having meals at regular times daily
   (b) Variety of vegetables and fruits excluding fruit juices
   (c) **Restrictive diets consisting of protein-rich, carbohydrate-free, and fat-free items**
   (d) Limiting daily fats consumption to <35% of the total energy intake

(e) Reducing dietary salt intake to control blood pressure (<2300 mg/day)

7. Which of the following oral antidiabetic class is recommended as the first line for outpatient care of type 2 diabetes?
   (a) Insulin
   (b) Sulfonylureas
   (c) Meglitinides
   (d) **Biguanides**
   (e) Thiazolidinediones
8. Well-known barriers to the management of diabetes in Africa consist of all of the following except:
   (a) The unavailability of logistics for diabetes care
   (b) Population awareness about diabetes and its management and complications due to nontreatment or poor compliance
   (c) **The use of oral antidiabetic agents instead of insulin in patient with diabetes**
   (d) Late presentation to health facilities
   (e) Access to medications due to their cost
9. Which of the following side effects of antidiabetic treatment is a major barrier to management?
   (a) Gastrointestinal side effects
   (b) Cardiovascular side effects
   (c) Skin side effects
   (d) Hematological side effects
   (e) **Hypoglycemia**
10. The following assessments are part of the annual evaluation of patients with diabetes, except which one:
   (a) **Blood urea nitrogen**
   (b) Urine dipstick
   (c) Serum creatinine
   (d) Electrocardiogram
   (e) Lipid profile

Answers

1. Secondary prevention consists of methods aimed at identifying patients with disease early before the progression of the disease, as opposed to primary prevention which entails adopting measures to reduce the risk of developing the disease, and tertiary prevention which entails treating the disease to reduce mortality and morbidity.
2. This question aims at raising the awareness of physicians taking care of diabetes, on the fact that people living with diabetes should not be restricted to HbA1c level. Targeting HbA1c level below 7% is indeed important; it is part of the objective "prevent disease progression to complications." Also, HbA1c target should be individualized.
3. Ketosis-prone type 2 diabetes is characterized by an acute ketotic onset that usually requires insulin therapy. This phase is usually followed by a long-term insulin-free remission, during which patients may keep an HbA1c level below 6.5% even without any treatment.
4. Management of diabetes entails preventing disease occurrence, management of the blood glucose level, preventing the progression of the disease to complications, and preventing or managing its acute and chronic complications in affected individuals.
5. Body needs in mineral and vitamins are generally obtained from a regular balanced diet. Mineral and vitamin supplements are not routinely administered to patients with diabetes unless they have other conditions requiring their supplementation such as in lactating pregnant women. An affluence of food supplements—usually merely made up of vitamins and minerals—in Africa over the past two decades has contributed in disturbing diabetes management. The marketing message conveyed by companies selling these products is that food complements can "cure" diabetes and many other epidemics. These food supplements are not recommended in diabetes management.
6. Medical nutrition therapy which is the first-line treatment of diabetes mellitus consists of all the options mentioned in the question except restrictive diets consisting of protein-rich, carbohydrate-free, and fat-free items which are no more recommended due to no proven long-term benefit. Restrictive diet is not recommended and may be dangerous.
7. Metformin, which is a biguanide, is recommended by most guidelines as the first-line pharmacologic agent in the management of type 2 diabetes.
8. Even though oral antidiabetic agents are the first-line pharmacologic options to use in patient with diabetes, there are instances in which insulin is preferentially used. Nevertheless, using oral antidiabetic agents instead of insulin is not reported as being one of the reasons for suboptimal management of diabetes in Africa.
9. Hypoglycemia is the major side effect of antidiabetic treatment. Fear of hypoglycemia by patients or healthcare personnel is a factor for nonadherence to treatment and therapeutic inertia.
10. Blood urea nitrogen (BUN) is not part of the routine assessment of diabetes. Routine BUN test is a waste of money. The other tests stated in the question are mandatory as they help identify chronic complications or cardiovascular risk factors associated with diabetes.

Joel Rodriguez-Saldana

The sick suffer enough We must avoid adding insult to injury by denying them a proper role in determining their future

Jerome P. Kassirer, M.D.

Introduction

Current models of health care continue to be designed to address every type of health problem from an acute disease approach, based on episodic face-to-face interactions between healthcare providers and patients; this approach does not address the multiple needs of patients with chronic diseases like diabetes [1]. In contrast, participation of patients has become increasingly important; they are assuming new roles as active agents, managers, and producers of their own health; involvement of patients is a new way to understand the relationship between patients, health professionals, and health systems, not only to recognize that they are the main responsible of their health control but they also have an undeniable influence in policy planning [2]. Healthcare providers should ensure to meet the information needs of patients because their perceptions of quality of care and quality of life are associated with the physicians' ability to transfer key information to them [3]. The professional ideal of the physician-patient relationship claims that doctors are directors of care and decide about treatment; the patient's principal role was to comply or obey "doctor's orders" … while the patient (supposedly) had only a minimal role in making decisions [4]. We have come a long way from the paternalistic view of medicine that excluded patients from discussions about their own health [5]. The enhanced capacity to address patients' needs increases loyalty and persistence, reduces complaints, increases the efficiency, and is also profitable [6]. Improvements in health care can be accelerated and evaluated developing patient-based measurement systems able to provide direct measures of success and failure, strengths and weaknesses, improvements, and declines in the provider's capacity to produce the desired health outcomes [7]. In sharp contrast with these realities, examples of doctors who reject patients not because of time limitations, but on far more questionable grounds, including sexual orientation, ethnicity, or specific health problems such as HIV infection, diabetes, and obesity, have been described and highly publicized as causes of rejection [8]. One of the drivers of the health disparities observed in diabetes is discrimination; discrimination is associated with decreased feeling of patient-centeredness and increased dissatisfaction with care [9]. Discrimination affects health through psychological and physiological stress responses; it is associated with loss of trust, lack of adherence, and poor diabetes management; reduces the use of diagnostic tests including A1c testing and cholesterol checks, using clinical services such as eye examinations and immunizations; and produces dissatisfaction with care [9]. Patient dissatisfaction is significantly associated with lower general dieting, higher HbA1c levels, and lower mental quality of life component [10]. The results of a study published by Cykert and colleagues reinforce a need for patient-provider communication that is inclusive, eliminates perceptions of discrimination and bias, increases patient-centeredness, and improves overall clinical care [9]. Physician empathy is significantly associated with clinical outcomes, including lower rates of acute metabolic complications. Empathy should be considered an important element in patient care and a significant factor of physician competence [11], but in the real world, coverage denial, lack of access, or delayed access to health care are highly preva-

lent [12]. In the United States, for example, Pearson reported a 7% rate of denial of coverage within a mixed model HMO [12]. In countries like Mexico, the percentage of out-of-pocket medical expenses, even in recipients of social security, has been estimated to be as high as 75% [13]. Denial of coverage or denial of services is associated with lower ratings of quality of health care and less trust on physicians [12]. A report from a nationally representative sample showed that patients with the highest levels of satisfaction had lower rates of visits to emergency departments, while people at the lowest levels had higher rates of hospitalization, greater expenditures in medications, and higher risks of mortality [14]. Patient-centeredness is an important issue in health care; it is highly dependent on patient's values and preferences, the professionals' behavior, and the interactions of both and seven key elements: (1) uniqueness, (2) autonomy, (3) compassion, (4) professionalism, (5) responsiveness, (6) partnership, and (7) empowerment [15]. Health beliefs and the self-reported capacity to adhere to treatment regime or to follow general advice are consistently predictive of glycemic control and reduction of cardiovascular risk factors [16]. The crucial role of patients and their families on the intermediate- and long-term outcomes is an essential component of diabetes management. Diabetes has become a representative model of the patient-centered medical home and should be properly addressed in clinical practice.

Milestones of Patient-Centered Care

Western health systems were initially dominated by a paradigm that considered "diseases" as basic elements of pathology. Since the seventeenth century, diseases were considered as functional or structural abnormalities of cells or body organs, with each abnormality added in linear fashion to the extent of illness. Barbara Starfield claimed that "medicine is still practiced this way…in this outdated scheme there is no room to recognize that diseases are not distinct biological entities that exist alone and apart from the person [17]."

The pathological model of disease was challenged in recent decades by a new form of clinical practice that stresses the centrality of the person (not the patient), her or his risk factors and personal priorities, and the role of medical surveillance to understand health and illness. In 1971, DC Taylor brilliantly described three components of sickness: (1) diseases, referring to abnormalities in diagnostic tests; (2) illnesses, unique combinations of symptoms and signs in an individual; and (3) predicaments, the personal, social, and economic consequences of being sick [18]. The paradigm of the pathological model of disease claimed that if mankind could master nature through science, every clinical problem would have a single explanation and solution. Nevertheless, a "whole patient"-oriented view of disease is more accurate and more equitable than a disease-oriented view [18]. Medical care must evolve to meet the healthcare needs of patients in the twenty-first century; clinical decision-making should focus on the attainment of personal goals, identification, and treatment of all modifiable biological and non-biological factors, instead of solely relying on the diagnosis, treatment, and prevention of individual diseases [19].

Primary Care as the Site of the Medical Home

A new paradigm in health care was announced by Freyman in 1989, in which the focus of health care would have shifted to the community [20]. Diagnosis and treatment would be managed in ambulatory settings including home, and the hospitalized fraction of the population needing medical care would be smaller…primary physicians would be the key personnel of vertically integrated systems to become the first contact of patients and would be responsible to coordinate services; to provide continuing, comprehensive, and up-to-date medical care; and to refer "the relatively few" who need the services of specialists [20]. These visionary predictions met strong resistance in many countries; reasons include the natural resistance to innovate, the perception of this innovative model as a threat to current interests, particularly economic, of physicians and health organizations, and perceptions of low value by providers of "solutions" of high cost [21]. Although some nomadic patients prefer to navigate through episodic encounters with emergency departments and specialists, most people want a medical home, in which responsibility of care and care coordination resides in the personal medical provider working with a healthcare team according to patient's needs and including specialists, midlevel providers, nurses, social workers, care managers, dietitians, pharmacists, physical and occupational therapists, family, and community [22]. Primary care, in which physicians address most of the patients' healthcare needs through their lifetime, was conceived to become the medical home [23]. One of the first descriptions of the attributes and the roles of primary care was made by Scheffler and colleagues in 1978 and included (1) accessibility, (2) comprehensiveness, (3) coordination, and (4) continuity, delivery by accountable providers of personal health services associated with the care of the whole person, rather than of particular illnesses, and distinguished from other levels of health care by the nature of the services, not by the particular training of the provider (i.e., not necessarily provided by physicians [23]). In 1998, Barbara Starfield described the four essential functions or major features of accountability of the primary care medical home [24] (Table 21.1):

Table 21.1 Attributes of primary care

Function	Description
1. Accessibility, first contact, gatekeeping	A place of easy access for health care; a gate to start receiving care from health professionals, nurses, or physicians
2. Comprehensiveness	Arrange and provide the full range of health-related needs including preventive, acute, chronic, rehabilitative, and palliative services
3. Sustained, longitudinal care	Dealing with changes in the health status of individuals or groups of people over years from a regular source of care, in one place, by an individual or team
4. Coordination	Harmonized referral: integration of all types of care, regardless of provider, including specialists and hospitals

Modified from [24]

Roots and Milestones of Patient-Centered Care

Historically, excellence in western medicine was based on the application of anatomy and physiology on the care of patients, but many years ago, this idea was challenged [25]. In 1882, Nothnagel in Vienna claimed that "medicine is about treating sick people and not diseases," in 1892 Sir William Osler declared that "It is more important to know what sort of patient has a disease than to know what kind of disease has the patient" and in 1926 Crookshank pointed out that "since the origins of the clinical method in ancient Greece, there have been two meanings of diagnosis: to diagnose a disease and to diagnose a patient [26–28]." The term "patient-centered medicine" was introduced by Balint and colleagues in 1970 in contrast to "illness-centered medicine [29]," and patient-centered medicine had its roots in 1967, when the American Academy of Pediatrics (AAP), under the leadership of Calvin Sia, introduced the term "medical home" in the book *Standards of Child Health Care* to describe an approach to taking good care of children with special care needs [30]. According to Reach and McWhinney, the idea of person-centered or patient-centered care is a "rediscovery [26, 27]." The doctor-centered model is the doctor's attempt to interpret the patient's illness in terms of medical explanations in order to assign the patient's illness to one of conventional disease categories [26]. From this perspective, success depends on the accurate classification of illness, the capacity to link the patient's symptoms and signs with organic pathology and to identify causal agents, and its etiology [26]. These two approaches are clearly different; they represent two ways of thinking, two attitudes to life, two different mental sets, and probably two personality types for practicing medicine [26]. Disease-centered recommendations do not address what matters most to patients, who have different health priorities… patient's goals and preferences are rarely translated into actual care decisions [31].

The Link Between Primary Care and Patient-Centered Care

Primary care probably dates back to the Dawson Report published in the United Kingdom in 1920 which introduced three levels of care: (1) primary, (2) secondary health centers, (3) teaching hospitals, which are still the basis of the pyramidal regionalization of health services [32]. Primary care found its roots in the 1960s and 1970s when the vertical approach to health care and the efforts to *transplant* hospital-based healthcare systems to developing countries in the absence or lack of emphasis on prevention were criticized [33]. At the 1976 World Health Assembly, Halfdan Mahler proposed the goal of "Health for All by the Year 2000," which became crucial in the history of primary care, and that would be confirmed at Alma Ata in 1978 [33]. As already mentioned, the AAP defined the medical home as the repository of medical records for chronically ill children and expanded the definition to include primary care accessible, continuous, comprehensive, coordinated, family centered, and culturally effective [34]. In 1978, the World Health Organization incorporated several concepts currently described as part of the Patient-Centered Medical Home (PCMH) at the Primary Care Conference of Alma Ata in 1978, including (1) access and continuity to care, (2) comprehensiveness and integration of care, (3) patient education and participation, (4) team-based care, and (5) public policies supporting primary care [35]. Since Alma Ata, promotion of primary health care stressed the need to address the health needs of all people and to recognize family physicians as the primary providers of health care albeit disillusionment about its real contribution to health improvement still persist [36]. Achievements continue to fall short of expectations; it is time to launch renewed efforts to strengthen health systems and integrate primary health care [36]. The "missing link" to translate the principles of Alma-Ata from idealism to practical effective public strategies has been the incapacity of health systems to integrate personal and public health, but the challenge continues to be shifting personal health care at the expense of population health [36]. By stating that health is a fundamental human right, the declaration of Alma-Ata was a landmark in public health [37]. In 2017, a similar declaration was made for experts in the field of diabetes. The Berlin Declaration called for early action to address the dangers of the type 2 diabetes pandemic in accordance with the World Health Organization's vision to decrease the expected rise in type 2 diabetes and obesity by 2025 [37–39]. The Berlin Declaration involves prevention and management

policies, including encouragement of primary care physicians to prioritize screening "despite having to address multiple health problems during short consultations [39]." Unless these limitations are realistically addressed devoting additional resources and overhaul of health systems to increase the time for medical visits and multidisciplinary care, the status quo of primary diabetes care will prevail.

The Paradox

It has been shown that primary health care contributes to reduce the adverse impact of social inequalities of health and is more effective to achieve better health outcomes, at lower costs, than systems oriented to disease management and specialized care [40]. The turning point in primary care is to recognize the inescapable fact that patients with chronic conditions self-manage their illness, and while physicians are experts about diseases, patients are experts about their lives [40]. Traditional views regard physicians and health professionals as experts, with patients bringing only their illness to receive and obey medical orders. In chronic diseases like diabetes, a paradigm shift has emerged: patients are their main caregivers ("the experts of their disease" in the words of Elliot Joslin), and the role of physicians is as supporting consultants [41]. The literature about the benefits of primary care has shown greater effectiveness, efficiency, equity, and understanding of the mechanisms by which its benefits are achieved [41]. The following attributes in combination produce better services: (1) greater first contact access and use, (2) more continuing person-focused care, (3) greater range of services, and (4) coordination [42].

Primary care rapidly evolved but also became an endangered species: doctor's duties changed, influenced by advances in medical knowledge and technology, the increasing use of computers, handheld devices, and electronic records, and the growing trend to track and measure clinical data [43]. The pressure on physicians to accomplish multiple goals has intensified worldwide; many patients describe their doctors as hurried and unresponsive, while nurse practitioners are perceived more willing to take time to talk to patients and answer questions; most of the time, physicians' days are spent on administrative tasks, paperwork, and data entry [43]. Overwhelmed by large patient workloads, many primary care practices are performing poorly: patients are interrupted after 23 s trying to explain their problems to a physician, 50% of patients leave office visits not understanding what the physician has told them, and evidence-based care is provided on a limited basis [44]. Two possible solutions are a very difficult one, devoting more time per patient, and a more feasible one, pioneered by Bodenheimer and colleagues: reorganizing primary care as a team-based endeavor, in which many functions currently in the hands of physicians are provided by other staff members, including nurses or medical assistants [45].

Primary care physicians are central and core components of any high-quality healthcare delivery system [46]. The Academy of Clinical Excellence (MCACE) at Johns Hopkins University states that clinical excellence involves achieving distinction in six plus-one areas related to patient care [46]:

1. Communication and personal skills promoting successful physician-patient relationships
2. Professionalism and humanism supporting development and maintenance of strong physician-patient relationships
3. Diagnostic acumen, the "science and art" of using information gathered from the history and physical examination to make the correct diagnosis
4. Skillful negotiation within the healthcare system, to overcome fragmentation with providers, sites of care, and record systems
5. The ability to find, interpret, and apply information to solve clinical problems
6. A scholarly approach to clinical practice to ensure that physicians remain informed about the best practice
7. Plus a passion for patient care [46]

Challenges to Implement the Patient-Centered Medical Home

In the medical home, responsibility and care coordination reside in the patient's personal medical provider working with a healthcare team and including specialists, midlevel providers, nurses, social workers, care managers, dietitians, pharmacists, physical and occupational therapists, families, and communities. Patient-centered medical homes and primary care are at a crossroads in many countries: family medicine appears to be largely devalued as a professional activity among medical students, who are more interested into specialty care, and primary care physicians are discouraged and even leaving practice [47, 48]. In most medical schools, students spend time in the offices of primary care physicians, where they observe the reality of this type of practice and gain insight into the challenge of caring for patients with a wide range of conditions, including chronic diseases [49]. When they observe patients with chronic diseases like diabetes who were hospitalized because of inadequate treatment, medical students cannot help but notice how little attention is devoted to avoid hospitalization through better outpatient management and the scarcity of team-based, patient-centered models for chronic disease [49]. Time pressures, chaotic work environments, increasing administrative and regulatory demands, an expanding knowledge base, fragmentation of

care delivery, and the high expectations placed on primary care are multiple contributors to the strain [21]. Burnout is an additional threat to primary care; high levels of emotional exhaustion are endured by staff and clinicians, resulting in low professional competence, cynicism, and denial [50]. Tight team structures and greater team cultures are associated with less clinician stress and burnout [51]. Under the leadership of Thomas Bodenheimer, the Center for Excellence in Primary Care at the University of California in San Francisco has clearly and since a long time demonstrated that the current practice model of primary care is unsustainable [52]. They described barriers and limitations to deliver high-quality primary care and the following solutions: (1) expanding the role of health assistants to deliver pre-visit and post-visit activities; (2) adding capacity, sharing care with other team members; (3) reducing or eliminating time-consuming administrative work; (4) prescription renewal to save time; (5) return tasks corresponding to receptionists, pharmacists, and nurses; and (6) improving team communication and functioning within a systems-approach redesign [52, 53]. In the face of a growing gap between the supply and demand of primary care, the practice should provide prompt access to high-quality care that maximizes patient's experiences, minimizes healthcare costs, makes primary care more attractive for physicians, and engages nonphysician members in the care process [54]. Improvements in the delivery of high-quality primary care result in higher proportions of patients achieving targets of HbA1c, triglycerides, and high-density cholesterol and significant reductions in HbA1c, blood pressure, LDL cholesterol, triglycerides, body mass index, reducing clinical inertia and the incidence of complications [55]. Delivering high-quality primary care for patients with diabetes is feasible but requires reinforcements in structure and process that most health systems across the world do not perceive or are unwilling to carry out. Primary care is the backbone of health systems and countries aspiring to universal, effective health coverage; a strong primary care system is the essential building block [45].

Transitioning from Primary Care to the PCMH

Patient-centered medical homes represent an updated model of primary care that recognizes and rewards the diverse but necessary activities for a population of patients [48]. Actions taken by policy-makers and payers to recognize the essential role of primary care physicians such as Medicare and Medicaid payments under the Affordable Care Act in the United States were tempered by continuing divisions between supporters of primary care and specialty care over the relative value of their services and the decreasing interest of medical school graduates for primary care [56]. Most developed nations assure access to primary care physicians who are paid based on guidelines and outcomes established by consumers and providers, but others have created and nurtured the perception that universal access to care is too expensive and unaffordable [56]. The National VA Primary Care Survey on Primary Care directors identified 16 moderate-to-extreme challenges to implement patient-centered medical homes, including access, preventive care screening, chronic disease management, "challenging medical conditions," mental health, special populations, coordination of care, and informatics [45]. A primary care practice that wants to deliver health care effectively must interact with patients where, when, and how they want to be served [54]. According to Berry et al. and Tayloe, its building blocks include physical and remote visits [57, 58]. The former include office visits with physicians and health professionals and visits to satellite clinics; remote practice involves at-home visits, telemedicine, and web-based services [58]. Additionally Tayloe described ten key components of the PCMH: (1) a visionary leadership with an outcome approach to health care, (2) a team of providers who are able to provide state-of-the art care, (3) minimization of unnecessary emergency and hospital admissions, (4) integration of hospital and office care, (5) business expertise of physicians and staff, (6) user-friendly electronic medical records, (7) physicians and staff trained and able at implementing quality improvement projects, (8) community-based coordination, (9) support from private and public third-party providers, and (10) a clear understanding of the community needs [58].

Patient-Centered Care Defined

Table 21.2 shows definitions of patient-centered care [59–61]:

Table 21.2 Evolving definitions of patient-centered care

Year	Author(s)	Definition
2001	Institute of Medicine [59]	Health care that establishes a partnership among practitioners, patients, and their families to ensure that decisions reflect patients' wants, needs, and preferences and that patients receive the required education and support to make decisions and participate in their own care
2010	Epstein et al. [60]	Personal, professional, and organizational relationships; an approach to care perceived as the right thing to do, in order to understand a series of outcomes, including feeling understood, trust, or motivation for change
2012	Valko et al. [61]	Team-based, comprehensive primary care, involving multiple professionals, including physicians, assistants, nurses, social workers, pharmacists, and behavioral specialists. Not just a place but a model of health care designed to reliably and reproducibly implement the core functions of primary care

Attributes of Patient-Centered Care

Over three decades, several visions about the attributes of centered care have been described, each one with different, enriching patient perspectives (Table 21.3) [62–67]:

The origins of these dimensions are variable; for example, the principles proposed by the Picker Institute were developed from surveys to evaluate patients' experiences with many clinical conditions and in every setting of health care, "with the dream to transform health

Table 21.3 Attributes of patient-centered care

Year	1983	1993	2005	2007	2010	2010
Authors	Levenstein et al. [62]	The Picker Institute [63]	Davis et al. [64]	American Academy of Family Physicians [65]	Battersby et al. [66]	Epstein et al. [67]
Attributes or principles	1. Entering the patient's world to see the illness through the patients' eyes	1. Respect for the patient's values, preferences and manifest needs	11. Superb access to care	1. Enhanced access and continuity	1. Brief targeted assessment	1. Healing personal relationships between clinicians, patients, and family members; bridging demographic, social and economic differences between clinicians and patients
	2. Invitation and facilitating openness by patients	2. Coordination and integration of care	12. Patient engagement in care	2. Identification and management of patient populations	2. Evidence-based information to guide shared decision-making	2. Teamwork from a coordinated community of healthcare professionals, including preparations before office visits and eliciting patient's concerns early in the visit
	3. Main objective: allowing patients to express all the reasons of visit	3. Information, communication, and education	13. Clinical information systems supporting high quality of care, practice-based learning and quality improvement	3. Planned and managed care	3. Nonjudgmental approach	3. Shared tailored information, shared deliberation considering patient's needs and preferences, care beyond informed consent or treatment
	4. Aim: to understand each patient expectations, feelings, and fears	4. Physical comfort	14. Care coordination	4. Self-care support and community resources	4. Collaborative priority and goal setting	
	5. Key aspect: allowing as much possible the flow from the patient	5. Emotional support, alleviating fear and anxiety	15. Integrated, comprehensive care and smooth information transfer	5. Track and coordinated care	5. Collaborative problem-solving	
	6. Crucial skill: be receptive to verbal and nonverbal cues from patients	6. Involvement of family and friends	16. Ongoing, routine patient feedback	6. Measurement and improved performance	6. Self-management support by diverse providers	
		7. Transition and continuity			7. Self-management interventions by diverse formats	
					8. Patient self-efficacy	
					9. Active follow-up	
					10. Guideline-based case management for select patients	
					11. Linkages to evidence-based community programs	
					12. Multifaceted interventions	

Table 21.4 Joint Principles of the Patient-Centered Medical Home (PCMH) integrating behavioral health care

Principle	Description
Personal physician	To guarantee that each patient has an ongoing relationship with a personal physician trained to provide first contact, continuous and comprehensive care, with a whole person orientation
Physician-directed medical practice	Physicians lead the PCMH, supported by a team of health professionals to integrate the physical, emotional, and social aspects of the patient's health needs
	Facilitative leadership involves shared responsibility, seamless teamwork, honoring the unique abilities of each member, and enabling members to work to their full potential
Orientation to the whole person	Responsibility to provide all the patient's healthcare needs and arrange care with other qualified professionals, including care for all the stages of life, acute care, chronic care, preventive services, end-of-life care, psychosocial dimension, and resulting behavior changes in the provision of all the patient's healthcare needs
Coordinated and/or integrated care across all the healthcare system and the patient's community	Assurance that patients receive the indicated care when and where they need and want it. Avoid fragmentation and separation of primary from behavioral health care
	Shared registries, medical records, decision-making, revenue streams, and responsibilities. Clarification of real and perceived barriers to communication and regular sharing of information
Quality and safety as hallmarks	Support the attainment of optimal, patient-centered outcomes by care planning processes driven by partnerships between physicians, behavioral health professionals, patients and their families
	Support from evidence-based medicine and clinical decision support tools
	Accountability for continuous quality improvement and performance measurement
	Active participation of patients in decision-making and feedback to ensure that their expectations are met
	Appropriate use of information technology to support optimal patient care, performance measurement, patient education, and enhanced communication; incorporate behavioral health, mental health screening, and health outcomes
	Recognition by nongovernmental entities to document the capacity to provide patient-centered services and behavioral care within the medical home model
Enhanced access	Access to patients, families, and physicians to medical and behavioral care through collaboration, shared problem-solving, flexible team leadership, and enhanced communication
Appropriate payment	Recognition of the added value of behavioral health care; payment in addition, not separate from primary care. Pay per-member and per-month primary care capitation

Modified from [65, 68]

care systems into a real system that provides effective and compassionate care for everyone [63]." The American Academy of Family Physicians and associates developed their principles based on the chronic care model and the medical home model promoted by the Institute of Medicine [65]; the principles proposed by Battersby and colleagues were organized within the framework of the chronic care model developed by Wagner and colleagues [66]. The Joint Principles of the Patient-Centered Medical Home, formulated and endorsed by the AAFP, the AAP, the ACP, and the AOA in 2007, and integrating behavioral care in 2014, are summarized in Table 21.4 [65, 68]:

To be feasible, the rewards for implementing the PCMH must exceed the cost of change: the AAFP, the AAP, and the ACP considered a three-component fee consisting of (1) an initial fee for service or visit, (2) a monthly management fee for practices providing medical home services, and (3) an additional bonus for reporting quality performance goals [65].

Effectiveness of the Patient-Centered Medical Home

Evaluations of several patient-centered medical home models have confirmed earlier findings about improved outcomes and satisfaction; patients report very positive experiences with patient centeredness, including being treated with courtesy and respect and communication with providers in a way that could be easy to understand [69]. The PCMH results in improvements in process measures, reduction in errors, and higher levels of satisfaction when patients identify with a medical home, but the evidence about its effects on clinical and economic outcomes is still scarce [70, 71].

The Patient-Centered Medical Home and Diabetes

Transforming the approach to patients with diabetes starts with the model of health care [72]. Despite the uncertainty about the effectiveness of the patient-centered medical home, identifying and overcoming barriers to achieve glycemic targets will become more important, not only to prevent diabetes complications but also to ensure reimbursement for diabetes management. In this scenario, the role of patients will also change; they will become "health care consumers" as health systems shift toward a model of value-based care, paramount of the patient-centered medical home [72]. Table 21.5 shows the effectiveness of interventions to implement the patient-centered medical home in diabetes management [73–87]:

Evidence about the effectiveness of the PCMH in diabetes management from meta-analysis and systematic reviews is even more limited. Ackroyd and Wexler selected and described the most effective interventions for diabetes care identified in a meta-analysis of 48 cluster randomized trials and 94 patient-level randomized trials attempting to determine the effect of individual quality improvement strategies for diabetes [88–91]. Albeit the studied strategies were not embedded in PCMH models, they provided some effect about the magnitude of the benefits expected on A1c levels [88]. The study showed larger effects at higher HbA1c base-

Table 21.5 The patient-centered medical home in diabetes management

Author(s), year and reference	Intervention	Size	Results
Kinmonth et al. 1998 [73]	Randomized controlled trial Routine care vs. routine care plus additional training	41 practices, 21 in the intervention group (250 patients), 20 in the comparison group (360 patients)	Better communication with doctors, greater treatment satisfaction and wellbeing in the intervention group
	One-year analysis, including practice effects and self-reporting by patients including communication with practitioners, satisfaction with treatment, style of care, and lifestyle		Nonsignificant differences in lifestyle and glycemic control
Steiner et al. 2008 [74]	Observational study: Community health networks organized and coordinated by physicians, hospitals, health departments, and social services	1200 primary care practices	Patients with A1c <7.0%: 47%
		750,000 patients	Patients with A1c >9.0%: 21%
		Each patient linked to a medical home	Blood pressure control ≥140/90 mmHg: 34%
		In addition to the Medicaid fee, a management fee to guarantee ongoing comprehensive primary care, 24-h on-call coverage and arrangements with other health professionals	Blood pressure control <130/80 mmHg: 37%
			LDL control ≥130 mg/dL: 19%
			LDL control <100 mg/dL: 5%
			Moderate reduction of unnecessary emergency department and specialty care
			No effect on costs
Paulus et al. 2008 [75]	Observational study Effectiveness of an innovation strategy for care model redesign	55 clinical practices	Goals achieved: Patients with HbA1c <7.0%: 34.8%
		450 physicians	Patients with HbA1c >9.0%: 21%
		20,000 patients with diabetes from a community of	Blood pressure control <130/80 mmHg: 43.9%
		2.5 million people poorer, older, and sicker than national benchmarks	Patients satisfying all nine quality indicators: 6.5%
		Components:	Low applicability
		Clinical leadership, Innovation team	
		Electronic record for ambulatory services	
		Financial alignment of incentives	

Table 21.5 (continued)

Author(s), year and reference	Intervention	Size	Results
Reid et al. 2010 [76]	Observational study	One prototype and two control clinics	Patients in the medical home reported better care experiences on six scales at 12 and 24 months
	Assessment of ambulatory care experiences and chronic illness care	6187 adults	Quality composite aggregate measures for 22 indicators, including diabetes, showed significant improvements within 2 years
		Quality measures included	Significant lower rates of staff burnout, emergency department visits, and hospitalizations
		HbA1c testing, HbA1c >9.0%, retinal examination, LDL-C screening, LDL-C <100 mg/dL, nephropathy monitoring	
Nutting et al. 2011 [77]	Observational study	36 small independent family practices selected to become PCMH and randomized into two groups: "facilitated" and "self-directed" intervention	Adoption of more components of the PCMH when using practice coaches
	Demonstration of the PCMH through a model with eight domains: access to care and information, practice services, care management, continuity of care, practice-based teams, quality and safety, health information technology and practice management		A composite score including HbA1c, blood pressure, lipoproteins, and retinal examination showed improvements in both groups
			Two years was not enough to implement the entire model and to transform work process
			Implementing discrete model components is easier than modifying existing roles and work patterns
Calman et al. 2013 [78]	Observational study	4595 patients with diabetes, including a subsample of 545 patients with HbA1c improvement	The transition to a PCMH increased number of encounters with outreach, diabetes education, and psychosocial services
	Changes in patterns of healthcare use throughout a 9-year period of practice transformation including recognition of centers at level 3 PCMH practices		All patients had visits with a primary care physician
			Annual levels of HbA1c decreased steadily during the 9-year period:
			Patients with A1c ≤9.0% showed increases of outreach services from 59% to 95.3%, diabetes education from 0.0% to 53.3%, psychosocial care from 9.0% to 27.4%, and small reductions in primary care from 99.7% to 99.4%
			Patients with HbA1c ≥9.0% showed increases of outreach services from 60.2% to 98.5%, diabetes education from 0.0% to 77.8%, psychosocial care from 11.2% to 35.3%, and primary care from 99.4% to 99.5%
			Patients with HbA1c ≥9.0% showed decreases from 10.72% to 8.34%

(continued)

Table 21.5 (continued)

Author(s), year and reference	Intervention	Size	Results
Slingerland et al. 2013 [79]	Cluster randomized clinical trial	13 hospital clusters, 506 patients with type 2 diabetes 237 randomized to patient centered, 269 to usual care	Patient-centered care was most effective and cost-effective in patients with baseline HbA1c >8.5%
	Effectiveness and cost-effectiveness of patient-centered care within specific HbA1c ranges	Primary outcomes: changes in HbA1c, quality-adjusted life years (QALYs), costs and incremental costs at 1 year	HbA1c reduction after 1 year: 0.83%, incremental cost-effectiveness ratio: $261.00 USD per QUALY
			Over a lifetime, 0.54 QALYs were gained at a cost of $3482.00 USD
			Care was not cost-effective at an HbA1c baseline level <7.0%
			Patient-centered care is more effective in patients with higher HbA1c levels
Pagán et al. 2013 [80]	Observational study	Analysis of the cardio-metabolic risk (CMR) data set including results of 19 simulated controlled trials for 100,000 individuals representative of the US population, comparing standard care to interventions targeting diabetes, obesity, and cardiovascular disease	The PCMH model has the potential to reduce the proportion of bilateral blindness, foot amputations, myocardial infarction, and death rate and is cost-effective ($7898.00 USD per quality-adjusted life)
	Long-term health and cost outcomes of implementing a PCMH model for adults with poorly controlled diabetes (A1c >9.0%) based on simulated data obtained from the Archimedes model of disease progression and health care		The PCMH model has potential long-term benefits to patients with poor diabetes control, health systems, and providers
Shah et al. 2015 [81]	Retrospective study	1038 patients, 713 from clinics with diabetes registries, and 325 from clinics without diabetes registries	Patients treated at clinics with diabetes registries did not have greater overall improvement in HbA1c levels than patients treated without diabetes registries in PCMH
	HbA1c values for patients from clinics with established diabetes registries vs. patients from clinics without diabetes registries in patient-centered medical homes		Additional research is needed to determine if diabetes registries are effective tools for the PCMH
Page et al. 2015 [82]	Observational study	10,000 patients treated by a centralized team of nurses and patient navigators who reach out to patients with scheduled appointments, motivational reminders and focus on patient encouragement, identification of barriers to keep appointments and communicate patient feedback to care teams	Ten of 11 measures of adherence improved from baseline to 12 months post-implementation, a 23.6% increase
	Effectiveness of the PCMH on improving access, quality of care, and adherence in patients with diabetes		Significant improvements in the number of patients receiving recommended care
			Centralized care coordination is effective for improving care in poor and underserved populations

Table 21.5 (continued)

Author(s), year and reference	Intervention	Size	Results
An 2016 [83]	Observational study	3334 adult patients with diabetes identified in the Medical Expenditure Panel Survey	11.4% of patients were classified in the PCMH group at baseline and only 3.6% remained in the PCMH for 2 years
	Associations between PCMH and process measures of diabetes care and adherence to oral antidiabetics (OADs)	Patients in the PCMH group vs. patients without PCMH features	Only 26.9% of the patients met all the diabetes care process measures, with a higher proportion in the PCMH (33.8%) vs. the non-PCMH group (26.0%)
		Process measures of diabetes care included ≥2 A1c tests, ≥1 cholesterol tests, foot examination, dilated eye examination, and flu vaccination at 1-year follow-up	No differences in the weighted mean MPR in the two groups
		Medication possession rate (MPR) was calculated for patients receiving OADs	Overall adherence rate: 47.7%
			Patients receiving PCMH had improvements in process measures of diabetes care, but not in adherence to OADs
Williams et al. 2016 [84]	Relationship between patient-centered care (PCC), diabetes self-care, glycemic control, and quality of life (QOL) in adults with type 2 diabetes	615 patients from 2 primary care clinics	PCC was significantly associated with physical and mental QOL, medication adherence, general diet, specific diet, blood sugar testing and foot care, but not in glycemic control
			Changes in clinical outcomes such as glycemic control need to expand throughout healthcare systems
Ratner et al. 2017 [85]	Relationship between patient-centered care (PCC), empowerment, and modification adherence in type 2 diabetes	Cross-sectional survey	PCC was significantly associated with medication adherence and diabetes empowerment
		166 patients completing a survey	
Brorsson et al. 2019 [83]	Effectiveness of a person-centered communication and reflection education model (GSD-Y) on young people with type 1 diabetes	Randomized controlled trial	Nonsignificant differences in glycemic control at 6 and 12 months in females and males, except for males at 12 months
		71 adolescents with type 1 diabetes starting continuous subcutaneous insulin infusion (CSII) and their parents	
		37 in the intervention group attending 7 group training sessions over 5 months using the GSD-Y model	
		34 patients in the control group received standard care	
Solberg et al. 2020 [84]	Effectiveness of practice systems primary care practices certified as medical homes on diabetes outcomes	Cross-sectional, observational study	92% of participating practices had data on diabetes care measures
		416 adult primary care practices completing questionnaires about the presence of medical home practice systems and 6 standardized measures of diabetes care including access, registry, coordination of care, care plans, and quality improvement	Practices certified as medical homes were more likely to meet a composite measure of optimal diabetes care

line and found that in addition to clinician education, patient education facilitated relay of information, electronic patient registries, and patient reminders, which are three major components of the PCMH: (1) team changes, (2) case management, and (3) promotion of self-management had significant effects reducing A1c levels [88]. Regarding non-glycemic outcomes, these strategies were associated with increases in aspirin use, the use of antihypertensives, lower levels of blood pressure, and LDL cholesterol [88]. Two systematic reviews and an integrative review addressed analyzed the effectiveness of the PCMH on diabetes outcomes [90–92]. In the study of Morgan and colleagues, each PCMH principle reached the following results:

Principle 1 (personal physician): a minimum of two visits to the same physician over 3 years and continuity of care result in lower HbA1c levels.

Principle 2 (physician-directed medical practice): nurse care managers and pharmacist care significantly reduce HbA1c levels compared to controls.

Principle 3 (whole person orientation): achieves significant reductions of HbA1c compared to controls.

Principle 4 (coordinated and integrated care): (a) two studies using technology enhancements to supplement care coordination showed reductions of HbA1c from a baseline of 7.35%; two smaller studies had no impact on HbA1c; (b) two studies providing cognitive behavioral therapy did not reduce HbA1c; (c) integration of nurse case managers reduced HbA1c by 2.0% from a baseline level of 10.0%.

Principle 5 (quality and safety): five studies assessing self-monitoring of blood glucose showed no reductions in HbA1c.

Principle 6 (enhanced access): (a) increased frequency of visits (every 2 weeks) achieved fastest control of HBA1c; (b) each 10% increase in missed appointments increase the odds of poor HbA1c control.

Principle 7 (payment): additional payments to physicians reduce HbA1c levels by 0.55% over 9 years.

The authors conclude that applying the PCMH in diabetes management improves glycemic control, and principles 2 and 3 are the most influential [90]. By comparison, albeit the systematic review by McManus and colleagues reported positive clinical outcomes, decreased use, and cost savings with the PCMH, it also recognized inconsistencies in the methods selected to study PCMH variables and the need to incorporate standardized instruments, reliable and valid, and measurements for PCMH research [91]. Finally, the review of 22 eligible studies by Olesen and colleagues demonstrated that the application of person-centered approaches is largely successful and superior to didactic diabetes self-management education to achieve outcomes, including psychosocial improvements and glycemic control [92].

Conclusion

Patient-centered care entered the health policy lexicon until 2001, when it was featured as one of the six aims to improve the quality of health care by the Institute of Medicine in the United States [59]. The IOM described patient-centered care as care that "is respectful to individual patient preferences, needs and values, and ensuring that patient values guide all clinical decisions [59]." The central role of the PCMH emerges from the growing body of data demonstrating that systems of care based on a strong foundation of primary care outperform systems of care based on specialty practices [61]. Patient-centered care is not simply capitulating to patients' requests nor it is "throwing information at people and leaving them on their own" [60]. Recent advocacy for the patient-centered medical home has arisen worldwide interest, and countless organizations have proposed steps to achieve such type of care, albeit many still do not understand the meaning of patient-centered care or are unwilling to accept it and even less implement it. The patient-centered medical home has become a worldwide initiative to reform health care and has advanced from pediatrics to involve internal medicine, geriatrics, palliative care, and collaborative disease management in diabetes, cancer, HIV infection, and patients with complex healthcare needs. Achieving a 2020 vision of patient-centered care will require champions among primary care leaders, employers, insurers, and politicians [64]. Patient-centered care matters because it is "the right thing to do," regardless of its contribution to achieve other goals, such as improved quality, patient well-being, or fair distribution of resources [93]. From the perspective of medical ethics, patient-centered care fulfills the obligation of healthcare professionals to place the interests of patients above else and to respect their personal autonomy [93]. Leading institutions in the advance of quality of health care such as Virginia Mason Medical Center in Seattle and Planetree, a nonprofit organization devoted to implement a comprehensive, patient-centered model of care with associates in America, Europe, Africa, and Australia, have successfully linked this approach to quality improvement and patient safety and satisfaction [93, 94]. In personalized care, patients and physicians work in collaboration to use the available evidence to select between a series of diagnostic and therapeutic options [95]. Shared decision-making recognizes the influence of patients' preferences and cultural values on clinical decisions; it is demanding and time-consuming and requires the integration of generalists and specialists, who may have competing interests [95]. Elevating patients' values, preferences, and needs over those of physicians or the healthcare organization is absolutely necessary [96]. Patient-centered and person-focused care are important but also different: in contrast with patient-centered care, person-focused care is based on the accumulated knowledge of people to improve recognition of

health problems and needs and facilitate the appropriate care for these needs with an specific focus on the whole person [96]. Patient satisfaction is an innovative approach. It has its roots in consumer marketing and is a measure of the capacity of products or services to meet or exceed the anticipated expectations of the customer [95]. The evidence of the effectiveness of the satisfaction-profit chain has stimulated the commercial use of monitoring and measurement of patient satisfaction; if accepted as a valid outcome, patient satisfaction should become and be held in the same standard as any other health intervention [95]. Patient satisfaction should be embraced as a desirable goal, but it must undergo a critical analysis [95]. After more than four decades and despite huge resistance to its principles from the advocates of fragmented, high-cost medical care, the patient-centered medical home is receiving worldwide acceptance, but at the same time, its strengths, weaknesses, opportunities, and threats have been recognized [97]. According to Rogers, its main strengths include (1) commitment to evidence-based medicine, (2) quality improvement, (3) the use of information technology, (4) application in routine medical care, and (5) understanding and facilitating the process of change. Its main weaknesses lie in the infrastructure including (1) the inability to provide universal provision of desired communication skills and shared decision-making, (2) the scarcity of health systems to document personal relationships between physicians and team members, and (3) the absence of formal care planning processes [97]. The PCMH is an opportunity for recognition, increasing compensation and reimbursement to individual physicians that will fund the development of infrastructure, and the perceived threats to family medicine involve programs emphasizing infrastructure, focusing on cost savings, the emergence of PCMH imposters, and the risk to deviate its focus in disregard that patient-physician relationships are at the core of the PCMH [97].

In 2013, the Institute of Medicine sponsored a workshop in which recommended the implementation of "strategies and policies at multiple levels to advance patients, in partnership with providers, as leaders and drivers of care delivery improvement through the protected use of clinical data, informed, shared decisions and value improvement," based on the premise that "prepared, engaged patients are a fundamental precursor to high-quality care, lower costs and better health [98]." The distinction between patient-centered care and better customer service lies in that it involves actions undertaken in collaboration with patients, not just on their behalf and requires clinicians to appropriately share power even when sharing feels uncomfortable [99]. According to Millenson, "prepared, engaged patients are the fundamental precursors to transform health care…patients and providers must change at the same time…a framework that enables a deeper partnership between patients and providers is more important than having "better patients" [99]." The momentum for widespread adoption of the PCMH has steadily built, and accumulating empirical evidence has shown that being attentive to the human experience improves quality, empowers patients, and improves health outcomes and engaging patients and family members as essential partners of the healthcare team has the potential to reduce costs [100]. Persisting barriers to widespread adoption are based on a relentless demand for solid evidence about the efficacy of the PCHM from traditional experts who are usually distanced and indifferent from patients and family experiences [100]. The future of the PCMH is still uncertain and involves several scenarios: from an increase in patient-centeredness as a function of current trends such as the Joint Principles of the Patient-Centered Medical Home to the extreme where health systems leave behind the PCHM from financial pressures pursuing lowering costs in acceptance of the negative consequences on the quality of health care [93]. To become a reality, the PCMH requires adopting new roles for patients and providers to achieve balanced levels of collaboration, positive activation, health literacy, and empowerment of patients and their families [101]. By putting patients—our customers—at the center in our practice, in our use of language and in our thoughts, the patient-centered medical home accomplishes one of the most legitimate aspects of medical practice and the most important outcomes for patients and their families: from "clinically relevant" to "patient or humanly important [102]." In a moving account of a dying man by Archie Cochrane, an act of brotherhood to another person is not medical, just human. Probably above science, this is what patients and their families expect and appreciate the most [103].

Multiple Choice Questions

1. Historically, the professional ideal of the physician-patient relationship is:
   (a) That patients have the most important role in making decisions
   (b) **That patients have a minimal role in making decisions**
   (c) That patients and physicians have equal roles in making decisions
   (d) That patients have very important roles in making decisions
   (e) That patient's relatives are most important in making decisions
2. The enhanced capacity to address patients' needs:
   (a) Is a waste of time
   (b) Increases the economic burden of health systems
   (c) Distracts physicians from their priorities
   (d) Has no effects on the outcomes
   (e) **Increases the efficiency and is also profitable**
3. Patient discrimination:

(a) Is unavoidable and necessary in some cases
(b) Reinforces the patient's compromise to adhere to therapy
(c) **Increases the use of diagnostic tests and services**
(d) Does not affect satisfaction with care
(e) Reduces the use of A1c measurements

4. The attributes of primary care include all of the following, except:
   (a) **Medical expertise**
   (b) Accessibility
   (c) Comprehensiveness
   (d) Longitudinal care
   (e) Coordination
5. A medical home was originally defined:
   (a) As the medical setting were patients are more comfortable
   (b) **As the repository of the medical record of children with chronic diseases**
   (c) As the patient's home with adaptations according to individual needs
   (d) As a "patient friendly" medical environment
   (e) As the place within clinical settings were physicians organize meetings
6. By comparison to disease management and specialized care, primary care:
   (a) Is less effective than specialized care
   (b) Is less professional
   (c) Is not supported by academic centers
   (d) **Is more effective to achieve better health outcomes**
   (e) Is exclusively empiric, not evidence-based
7. Clinical excellence involves all of the following, except:
   (a) **Expertise in the use of the most recent medications**
   (b) Promoting successful physician-patient relationships
   (c) Ability to find and apply information to solve clinical problems
   (d) Skillful negotiation within the healthcare system
   (e) Diagnostic acumen
8. In patients with diabetes, improvements in high-quality primary care result in significant reductions of:
   (a) A1c
   (b) Systolic and diastolic blood pressure
   (c) LDL-cholesterol and triglycerides
   (d) None of the above
   (e) **All of the above**
9. The principles of the patient-centered medical home:
   (a) Increase the costs of medical care
   (b) **Reduce HbA1c levels**
   (c) Increase physician burnout at unmanageable levels
   (d) Achieve nonsignificant reductions in HbA1c levels
   (e) Increases the use of diagnostic tests
10. The strengths of the patient-centered medical home include:
    (a) Commitment to evidence-based medicine
    (b) Quality improvement
    (c) Information technology
    (d) **All of the above**
    (e) None of the above

Outpatient Diabetes Management and the Chronic Care Model

22

Joel Rodriguez-Saldana

Introduction

In the 1960s, diabetes was considered a common disease, even when it was much less common than today. The average practitioner treated 15 or 16 patients and hospital clinics admitted approximately 1000 patients each year [1, 2]. The first diabetes clinics were established in North America and Europe in the years following the discovery of insulin with the main objective of teaching patients the technique and principles of its use; only in Britain, 500 had been established from 1924 to 1973, even in isolated geographical locations [1, 3]. Hospital surveys showed that diabetes was controlled by diet and insulin, and early diabetic complications and patient education were overlooked by physicians, and involvement of nurses and dietitians was considered ineffective [4]. Successful clinics were the ones that had the vision, ability, and resources to institute comprehensive diabetic services coordinating activities of physicians, nurses, and dietitians to deliver multidisciplinary outpatient care, specialties (foot, eye, pregnancy, children, and adolescents), and diabetes education as essential components of their services [4–7]. These types of programs showed marked improvements in all areas of diabetes care, including diagnosis, assessment, hypoglycemia prevention, diet, and referrals [4]. In most of the hospitals, patients with diabetes admitted to hospitals were seen mostly by specialists, but the sharp rise in the prevalence of type 2 diabetes made this unpractical [8]. Hospital diabetes programs including telephone support for patients, screening by nurses, and a mixture of outpatient and inpatient services showed reductions in emergency room visits, decreases in the incidence of acute complications (ketoacidosis, hypoglycemia) and amputations, lower rates of broken appointments and complaints, and higher levels of patient and professional satisfaction [9, 10]. Most of the other hospitals told a different story: once referred, patients were supposed to be treated for life, doomed to take time out of work, and travel and wait to be seen by a different physician at almost every visit at the diabetes clinic. This approach of fleeting consultations was—and still is—unrewarding from every perspective [1]. Even when the estimated incidence of diabetes was 1.2–1.3% in England, diabetic clinics had such a large load that they became unable to devote sufficient time to difficult cases; medical manpower to deal with the growing workload was (and currently more than ever) met with increasing use of junior staff, resulting in large dropout rates, lack of adherence, high levels of patient dissatisfaction, and abysmal levels of quality of care [1, 2]. Taking into account that the average diabetic required seven to ten clinical visits every year, hospital demands meant establishing huge diabetic clinics with dissatisfaction and depersonalization for patients and staff [1]. In Germany and other countries, diabetes management was paternalistic; patients were admitted to stabilize blood glucose, and the lack of self-care support had negative consequences: glycosuria was preferred to prevent hypoglycemia, routine therapy consisted in one or two daily injections of medium-acting insulin, self-monitoring and changes in insulin dosage were not allowed, and education had degraded to "obedience training" to follow rigid dietary prescriptions consisting of six to seven meals with fixed amounts of carbohydrates, proteins and fats, and prohibition of sugar [11]. This approach was never assessed, but acute and late complications were frequent [11]. Hospital wards overflowed, resulting in patients treated in hallways, untimely access to appropriate medical advice, hospital resources largely devoted to episodic care for acutely and severely ill patients, low supervision by specialists, and high rates of acute complications [8, 9]. In-patient hospital care represented >80% of the direct costs of diabetes and was devoted to manage cardiovascular complications and renal disease [12]. At the same time, understaffing and low resources to outpatient facilities were associated with an excess in hospital admissions and direct costs [13]. With the increasing rates of diabetes occurring in recent decades, the number of patients admitted to hospitals continues to rise, with higher probabilities to die in the hospital, to occupy more bed days, and to incur in higher

costs than people without diabetes [14]. The aim of diabetes care should be enabling patients to lead normal lives, with good metabolic control and free from complications. For many patients across the world, such an ideal is still far away [13].

Lessons Learned and Lessons Still Unlearned

Cumbersome clinics developed into adequate appointment systems and excessive waiting times and continuity was hampered by a multiplicity of doctors with limited experience and adequate supervision [15]. Failure of clinics established at hospitals, which rapidly became overwhelmed, obliged to increase the role of primary care physicians in diabetes management. General became aware of the importance of tailoring management to the patient's lifestyle, their expectation to be actively involved in their treatment, and their unwillingness to continue accepting medical advice without questioning [8]. General physicians from the United Kingdom were among the first to see that they could manage many aspects of diabetes in their own practice [2, 15–22]. Albeit the pace to provide ambulatory diabetes care was initially slow, many innovative schemes were described and initiated [23]. Combination of need and opportunity prompted the creation of "small clinics (mini-clinics) of general practice" where groups of general physicians were organized to assist groups of 80 to 100 patients to stop the flow of patient to hospital-based clinics devoted to difficult cases [2, 19–24]. Pioneering reports from Malins, Wilkes, Thorn, Russell, Hill, Singh, and colleagues showed that:

1. Diabetes could be looked after by family doctors [1].
2. General practice seemed the proper place to look after many diabetics, allowing general practitioners to become increasingly competent in diabetes care, to develop new expertise, able to contribute and notice that patients are willing to accept their professional competence [2–16].
3. Patients welcome being treated by general physicians; apart from attending close to their homes, they are glad to come into an atmosphere which is familiar and to be greeted by staff whom they know and that their personal and social circumstances are taken into account [16].
4. Coordinating and sharing "the diabetic workload" with hospital clinics raised community awareness about diabetes, allowing family physicians to deal with problems for which they were trained [18].
5. Diabetes care delivered by organized general physicians achieved similar levels of metabolic control to the ones reached in hospital clinics [19].

To summarize, increases in the number of patients with type 2 diabetes, longer life expectancy, and sophistication of treatment produced overcrowding and inadequacies of delivery in hospital-based diabetes care [25, 26]. Home and Walford reflected that "though some activities required expertise and resources only available in hospitals, most of them did not require them, as long as general physicians had access to blood glucose monitoring, dietetic, chiropody and nurse educational services" [25]. The need to reappraise the role of diabetes clinics was recognized by Thorn and Russell since 1973, but it was also essential to increase the access to effective diabetes management, because only a small proportion of patients attended hospital and outpatient clinics [25, 26]. Since 1985, it was acknowledged that the huge amount of people with diabetes in the community made it unrealistic to treat them in specialist outpatient clinics [26]. On the same year, Ling and colleagues proposed an analogy between traditional diabetes clinics and dinosaurs [27]:

> "Theories abound to explain the extinction of dinosaurs…perhaps they became too big to maintain efficient life…to adapt to the changing circumstances of the environment…or were unable to cope with all that was demanded to them. Whatever the reasons, perhaps the diabetic clinic could meet a similar fate." [27]

Four decades ago, ample evidence about the disadvantages, lack of efficiency, and high cost of specialist diabetes clinics had been documented, by comparison with the success of outpatient clinics in the United Kingdom, Germany, New Zealand, and the United States. Despite these observations, many other countries still breed and proudly maintain their "diabetes dinosaurs."

Transforming Diabetes Care

Surveys at facilities demonstrated (and continue to show) large discrepancies with recommended national and international guidelines [28]. A survey carried out by the Medical Advisory Committee (MAC) in Britain showed a scarcity of diabetes clinics or even examination rooms, resulting in lack of referrals; a variety of deficiencies in access to professional services, including obstetricians, ophthalmologists, dietitians, chiropodists, and nurses; a scarcity in the availability of resources to measure glucose and A1c; and absent or inadequate facilities to deliver diabetes education [29]. Nineteen recommendations were endorsed by the MAC, and a follow-up report 10 years later showed significant improvements in all the previously described deficiencies, albeit there was still room for improvement [30]. Even when resources were insufficient, reorganization and integration of services produced great improvements in healthcare standards. From its inception in the 1970s, the concept of diabetes centers evolved to a number of "different breeds in the 1990s, including depictions of structure and process" [15, 27, 31–33]. Dunn and colleagues identified four priority areas to be considered for implementation of the Diabetes Control and Complications Trial (DCCT) in Australia: (1) allocation and effective use of resources, (2) standards of care and quality assurance, (3) training and continuing education, and (4) research and evaluation [33].

Effectiveness of Diabetes Outpatient Management: The Evidence

The main objective of diabetes management became preventing or delaying the physical and social consequences of the disorder [26]. Early reports showed that transforming traditional to modern management methods was feasible, acceptable, and effective and produced significant improvements in A1c levels without higher risk of hypoglycemia [33]. Recent emphasis on cost-effectiveness came to realize that diabetes is a disorder that rarely warrants hospitalization; awareness to these facts reinforced the concept of diabetes ambulatory care [33]. Nevertheless and despite demonstrations of cost-effectiveness of ambulatory management, funding of ambulatory services remained (and continues to be) in huge disadvantage with hospital care [33]. The 1980s witnessed the emergence of multiple initiatives devoted to shift the focus of diabetes management from hospitals to outpatient clinics in Europe, North America, and Australia. Table 22.1 shows examples of outpatient diabetes programs manually collected or through a Pubmed search from 1971 to 2021 [19, 34–71]:

Table 22.1 Worldwide experiences about outpatient diabetes management

Year, country, and reference	Objectives	Type of study and intervention	Results
1984, UK [19]	Compare the degree of metabolic control achieved by mini-clinics with that achieved by a hospital clinic	Randomized controlled trial 57 patients receiving at mini-clinics 57 patients receiving treatment at hospital clinics	No significant differences were found between patients attending mini-clinics and those attending hospital clinics in blood glucose or HbA1c concentrations
1984 UK [34]	Compare routine care by a hospital diabetes clinic with routine care in general practice	Randomized controlled trial 97 patients treated at hospital clinic 103 patients treated by general practitioners	13.6% of patients in general practice were regularly reviewed and 4.8% had blood glucose measurement once a year All patients attending the hospital clinic were seen at least and had blood glucose measurements once a year HbA1c levels at the end of the study: General practice: 10.4% Hospital clinic: 9.5%
1988 United States [35]	Comparative effectiveness of community diabetes care and education on clinical outcomes	Prospective, randomized study 261 patients treated by 61 primary care physicians from 1980 to 1985 from four large and four small communities randomly selected Intervention: Four group sessions delivered by paramedical personnel Five-year follow-up	Significant changes in healthcare practices, including increasing use of multiple injections of insulin and self-monitoring of blood glucose Decrease in hospitalizations related to diabetes, probably representing changes in healthcare practices rather than changes in health status A1c levels unchanged
1988 Germany [36]	Efficacy of structured treatment and education on pharmacological therapy, A1c levels, triglycerides, and body weight	Prospective randomized study 114 patients with type 2 diabetes, 65 in the intervention group and 49 in the control group from five general practices Intervention: Preparatory course for physicians and assistants; four group monthly education sessions delivered by health professionals	A1c levels remained unchanged in the intervention group; significant decreases in triglycerides and weight loss Percentage of patients receiving sulfonylureas decreased from 68% to 38%
1993 Germany [37]	Feasibility and efficacy of structured treatment and teaching on routine primary health care	Observational study of a random sample of 17 physicians and their office staffs Remunerations to physicians and staff upon completion of a postgraduate training course 179 patients with type 2 diabetes Four 90- to 120-min sessions; groups of four to ten patients, partly based on the Grady memorial diabetes medical and education program [10] and previously participating in a controlled trial [36] program delivered by the office staff	Acceptance by physicians Significant decreases in A1c levels from 8.11% to 7.47%, body weight (mean 2.8 kg), use, and percentage of patients treated with oral antidiabetics

(continued)

Table 22.1 (continued)

Year, country, and reference	Objectives	Type of study and intervention	Results
1994 United States [38]	Follow-up of a structured treatment and education program on selection of pharmacological therapy, A1c levels, triglycerides, and body weight	Prospective, randomized study 440 patients with type 2 diabetes, 61 in the intervention group and 355 in the control group Ten-year follow-up 1981–1991	Positive changes in diabetes care and education Nonsignificant decreases in A1c and total cholesterol, significant increases in HDL cholesterol, significant decreases in hospital admissions, and small increases in percentage of patients receiving formal diabetes education Most of patients with type 2 diabetes managed on diet alone had never seen a dietitian Nonsignificant changes in ophthalmologic examinations Less patients managed with insulin
1997 United States [39]	Effectiveness and safety of intensive insulin therapy on outpatient, endocrine-based, multidisciplinary practice in patients with type 1 and type 2 diabetes	Longitudinal cohort study, 14 years duration 780 patients, 209 receiving long-term comprehensive treatment including cardiac screening with exercise treadmill tests, noninvasive thallium scan, and cardiology referrals if necessary 571 declined continuing care	Patients with prolonged exposure to comprehensive therapy had significant reductions in overall and cardiac mortality and lower incidence of renal failure Lower comorbidity scores associated with higher survival Two thirds of the patients declined receiving multidisciplinary, intensive care
1997 United States [40]	Compare the quality of ambulatory diabetes care delivered in a specialist clinic versus a general medicine clinic	Retrospective observational study; review of medical records 56 patients cared in the general medicine clinic 56 patients cared in the specialist clinic	Statistically significant differences in the percentage compliance in process of care criteria between the clinics including self-monitoring of blood glucose, foot and eye examination, and referral for diabetes education None of the records from either clinic achieved good quality of care criteria 52% of the general medicine clinic and 73% of the specialist clinic passed
1998 United Kingdom [41]	Changes in the percentage of patients receiving primary and secondary diabetes care over 5 years	Longitudinal study, 1990–1995 Seven general practices, five of them with organized diabetes programs	The proportion of patients treated in general practice doubled from 17% in 1990 to 35% in 1995 Patients treated in secondary practice fell from 35% in 1990 to 30% in 1995 Patients treated both in general and secondary practice fell from 6% to 2% Newly diagnosed and treated patients in general practice also increased Greater activity in primary care did not increase pressure on hospital services
1998 United Kingdom [42]	Effectiveness of training on a patient-centered intervention for general practitioners and nurses on outcomes	Randomized controlled trial 29 general practices receiving training about patient-centered care 252 type 2 diabetic patients 2-year duration	High initial levels of professional adoption by professionals Persistence after 2 years: 19% No significant biochemical or functional improvements
1998 United States [43]	Implementation of a diabetes improvement program in order to increase intermediate outcomes including retinal screening, foot inspection, risk-related education, testing for microalbuminuria and HbA1c and patient satisfaction	25 primary care clinics	Prevalence of HbA1c testing: 77% before the program; 80% afterwards changes in process measures before and after the program: Access to retinal screening: 66–86% Foot examination: 20–50% Smoking prevention and cessation: 14% to 10%

Table 22.1 (continued)

Year, country, and reference	Objectives	Type of study and intervention	Results
1999 Poland [44]	Effectiveness of a disease management program on A1c and fasting glucose, appropriateness of treatment modalities, and timing of therapeutic choices	Prospective study in outpatient clinics, 18-month duration Randomly selected patients: 88 with type 1 diabetes 132 with type 2 diabetes 177 pregnant women with type 1 diabetes, 81 received the structured program, 74 non-recipients 155 infants from women treated in these two groups	Patients with type 1 diabetes showed significant decreases in A1c, fasting and postprandial blood glucose, without severe hypoglycemia Nonsignificant body mass changes Patients with type 2 diabetes had significant decreases in A1c, fasting and postprandial blood glucose, without severe hypoglycemia, significant body mass decrease pregnant women not receiving the structured program had higher rates of hyperglycemia, preeclampsia, ketoacidosis, polyhydramnios and cesarean sections Recipients of the structured program showed higher APGAR scores in infants
2000 Israel [45]	Improving effectiveness of primary care providers to control glycemic levels	Retrospective cohort study of a 2-year national program conducted by a health maintenance organization based on continuing medical education, establishing guidelines and diabetes registries. One patient randomly selected for review from each of the physicians' diabetes registries	National response: 72.7%, 876 participating physicians Statistically significant improvements in performing all the monitoring parameters including weight: 35–60%, foot inspections: 40–63%, fundus examinations: 38.5–68.3%, HbA1c measurement: 38.5–68.3% Significant improvements in HbA1c: >9.0% decreased from 33.2% to 22.5%; HbA1c increased from 45.1% to 50.5%
2001 United States [46]	Effectiveness of a comprehensive diabetes management program including risk stratification and social marketing on clinical outcomes and patient satisfaction	Prospective trial, 12-month duration Two outpatient primary care clinics from a managed care organization 370 patients in the intervention group, 193 with available information at 12 months 623 patients in the control group	Significant improvements in glycemic control: Patients at low risk (A1c < 7.0%) increased by 51.1% Patients at moderate risk (A1c 7.0–8.0%) increased by 2.5% Patients at high risk (A1c ≥8.0%) decreased by 58.3% and 97.4% had changes in therapy Patients with blood pressure < 140/90 mmHg increased from 38.9% at baseline to 66.8%; 63.0% of patients with blood readings >130/85 mmHg at baseline had changes in medication Patients receiving lipid profile tests increased from 66% at baseline to 100% Patients with LDL >130 mg/dL decreased from 25.4% at baseline to 20.2% 76.7% of patients at the highest risk of nephropathy had a change in medications Patients receiving dilated eye examinations increased from 53.9% to 80.3% Foot examinations increased from 0 to 100.0%, 100% of patients and providers were satisfied with the program Patients in the control group remained unchanged

(continued)

Table 22.1 (continued)

Year, country, and reference	Objectives	Type of study and intervention	Results
2001 Denmark [47]	Effectiveness of a multifaceted intervention for general practitioners on 6-year mortality, morbidity, and risk factors of patients with type 2 diabetes	Open controlled trial randomization of practices to structured personal care or routine care 311 Danish practices, 474 general practitioners 243 in intervention group 231 in comparison group 459 patients randomized to structured care 415 patients randomized to routine care Regular follow-up and individualized goal setting supported by prompting of doctors, clinical guidelines, feedback, and continuing medical education	Equal rates of nonfatal outcomes and mortality in both groups Patients in the intervention group showed significantly lower fasting plasma glucose, HbA1c levels, systolic blood pressure, and total cholesterol levels More frequent use of metformin, doctors arranged more follow-up visits, referred fewer patients to hospital clinics and set more optimistic, individualized goals, education, and surveillance in primary care for at least 6 years, bringing risk factors of type 2 diabetes to a level to reduce diabetic complications without weight gain
2001 Netherlands [48]	Comparative effectiveness of a disease management to a shared diabetes care model	Observational non-randomized trial In the traditional care model, patients were seen by endocrinologists In the disease management model, patients were seen by nurse specialists, organized, and coordinated with specialists and health professionals in general practice 22 general physicians accepted the shared care model; 29 endocrinologists continued using the traditional model 74 patients agreed to participate in the shared care model; 47 patients continued using the traditional model	No differences were found between groups in quality of life, knowledge of diabetes, patient satisfaction, or consultation with caregivers Glycemic control improved in patients receiving shared care and deteriorated in patients receiving traditional care Factors influencing implementation of the shared care model: project management, commitment, power, and structure
2001 United States [49]	To evaluate the impact of primary care group visits based on the chronic care model on diabetes process and outcomes	Randomized controlled trial 57 primary care practices with at least 20 patients with diabetes per clinic 14 clinics were randomized to establish the chronic care model 21 clinics were randomized to deliver usual care 707 patients ≥30 years old randomly selected from an automated diabetes registry who completed baseline and follow-up information Intervention group: Periodic day chronic care clinics for groups of eight patients	At 24 months and compared with control patients, the intervention group received significantly more recommended preventive procedures and diabetes education; general health and bed disability days were significantly better, along with fewer specialty and emergency room visits Identical HbA1c levels in both groups
2002 United States [50]	Effectiveness of community-based diabetes care and a diabetes electronic management system (DEMS)	Observational study Three primary care practice sites Implementation of planned care and DEMS with 16 primary care providers	Improvements with planned care in A1c, cholesterol, microalbuminuria, tobacco advice DEMS associated with improvements in all indicators including microalbuminuria, retinal examination, foot examinations, and self-management support Organization and delivery of healthcare services improve documentation of clinical practice, adherence to performance measures and metabolic outcomes

Table 22.1 (continued)

Year, country, and reference	Objectives	Type of study and intervention	Results
2003 United States [51]	Effectiveness of diabetes care delivered by nurses and supervised by a diabetologist to meet the American Diabetes Association process and outcome measures versus usual care	Randomized observational trial 504 patients from two county clinics: 252 receiving nurse-directed diabetes care 252 patients receiving usual care as controls	Patients under nurse-directed diabetes care received almost all process measures significantly more frequently than control patients A1c levels fell 3.5% by comparison to a 1.5% decrease in patients under usual care After 1 year under nurse-directed care, A1c levels decreased to 7.1% and the median value fell from 8.3% to 6.6%
2003 United Kingdom [52]	Effectiveness of specialist diabetes clinics receiving patients from primary and secondary care	Observational prospective study, 2-year duration 19 specialist clinics 2415 patients referred to 19 specialist diabetes clinics led by GPs with special interest in diabetes, to alleviate increasing waiting times for secondary care Training: 2-day workshops for GPs, follow-up workshops and case reviews Multidisciplinary support from specialist nurses, podiatrists, dietitians, and retinal screening cameras	Significant increases in patient attendance Significant reductions in hospital attendance Main benefits: geographical accessibility, availability in community setting, short waiting times at most clinics and continuity of staff Reservations: lack of strategic planning in the location of clinics, long waiting times in some of them, poor communication for referrals Advantages: convenience to patients, acceptability, increased capacity of physicians
2004 United States [53]	Effectiveness of community-based, nurse case management and peer education to improve diabetes care, patient knowledge and satisfaction, reduce adverse beliefs in undeserved patients	Prospective study, 1-year duration 153 patients from six community clinics 76 non-randomized patients from the same clinics with A1c values ≥9.0% as controls	Patients in the intervention group: significant improvements in A1c, total cholesterol, LDL cholesterol, and diastolic blood pressure Nonsignificant changes among patients in the control group
2004 France [54]	Effectiveness of a local adaptation of a structured program on primary care to encourage intensive treatment of diabetes as routine practice	Prospective, randomized, controlled trial in a suburban and semirural area, 12-month follow-up allocation of all general physicians from a suburban and semirural area, 35 in the intervention group, 32 in the control group 192 patients in the intervention group 148 patients in the control group Three-day training and follow-up of physicians in the intervention group	Patients in the intervention group: more adequate management according to guidelines and referrals Significant decreases in A1c in the intervention group (0.86%) No significant differences in other clinical outcomes, incremental costs from the intervention No significant changes in quality of life
2008 South Africa [55]	Effectiveness of a nurse-led protocol and education-based system on diabetes management in a rural setting	Prospective non-comparative intervention 326 patients, 96% with type 2 diabetes Two rural nurses received 12-month training from a diabetes specialist One weekly hospital diabetes clinic, 14 monthly peripheral diabetes clinics Cornerstones: Patient education, drug dose titration, clinical outcomes	High levels of acceptance by patients and staff 980 patients enrolled within 9 months Significant decreases in A1c from 11.1 ± 4.2% to 8.7 ± 2.6% at 6 months Patients with baseline A1c >10.0% showed a mean 5.8% fall Diabetes education associated with significant A1c improvements Rates of hypoglycemia did not increase
2008 United States [56]	Effectiveness of a multicomponent organizational intervention in diabetes care and outcomes in primary care	Controlled clinical trial Components of the intervention: Electronic diabetes registry Visit reminders Patient-specific physician alerts	Over 24 months, 69,965 visits from 8405 adult patients with type 2 diabetes treated by 238 healthcare providers were recorded Significant net improvements in diabetes process measures in the intervention group including foot examination (35.0%), annual eye examination (25.9%), renal testing (28.5%), HbA1c testing (8.1%), blood pressure monitoring (3.5%), LDL testing (8.6%) Mean HbA1c levels and comorbidities decreased significantly and intervention practices had significant greater improvements to achieve HbA1c, systolic blood pressure, and LDL goals

(continued)

Table 22.1 (continued)

Year, country, and reference	Objectives	Type of study and intervention	Results
2008 Australia [57]	Compare clinical outcomes of patients attending diabetes clinics with different models of care	Diabetes centers participating in a national diabetes information audit were invited to nominate if they provided (A) routine diabetes care only, (B) routine care and structured annual complications screening, (C) annual review and complications screening in a shared-care system with specialized diabetes clinic	Analysis of 3052 patients from 18 diabetes centers showed that patients receiving management under models B and C had higher rates of attainment of HbA1c and blood pressure targets and higher rates of nephropathy and lipid screening
2010 United States [58]	Effectiveness of systems-based care in an undeserved population to reduce disparities in care for cultural, ethnic, commercial, and socioeconomic minorities	Implementation of disease registry and management system in four community health centers from a suburban practice network	Community health center patients meeting guidelines showed significant improvements in clinical outcomes except percentage of patients with A1c >9.0% Statistically significant discrepancies persisted between community health clinics and suburban practices in percentage of patients with A1c <7.0%, LDL <100, retinopathy, and microalbuminuria screening Community health centers lagged in all comparisons
2010 United States [59]	Comparative effectiveness of nurse-directed diabetes management between a nonintegrated model in which patients were removed from primary care clinics and followed by supervision from endocrinologists versus an integrated model in which patients were seen by nurses under supervision of primary care physicians	Observational study, 9–12 months 387 patients randomly assigned to the nonintegrated model 178 patients referred to the integrated model	25% of patients in the nonintegrated model used insulin (mostly bedtime), 75% of patients in the integrated model used intensified insulin regimes A1c decreased 1.9% in the nonintegrated model and 3.9% in the integrated model in the integrated model: 90% of patients met blood pressure goals, 96% met LDL goals, and 47% met all three goals of treatment (A1c, blood pressure, LDL)
2010 Mexico [60]	Effectiveness of structured diabetes management on the quality of primary diabetes care	Seven-year statewide diabetes program Training, feedback, and reminders to general physicians, nurses and health professionals to implement 43 outpatient multidisciplinary diabetes clinics at urban and rural health centers Organizational arrangements to reduce waiting times, avoid rotation of staff and increase time for baseline and follow-up visits Statewide diabetes registry	4393 patients with type 2 diabetes After five visits, significant increases in the percentage of process indicators were documented in the diabetes registry, including body mass index, blood pressure, A1c, total cholesterol, and foot examination Outcome measures showed significant decreases in A1c and fasting blood glucose Nonsignificant changes in systolic/diastolic blood pressure and lipoprotein levels
2011 Netherlands [61]	Effectiveness of structured diabetes care from the perspective of patients and healthcare professionals in routine practice	Quasi-experimental study, 4 years duration Comparison of structured care (SC) and usual care (UC) SC including organizational components: Multidisciplinary cooperation, clear task division, and cooperation between general practitioners, diabetes specialist nurse, and dietitians UC based on clinical guidelines performed by GPs, nurses, or assistants Questionnaires sent to healthcare professionals and patients in the SC and the UC group	No differences between SC and UC in yearly and three monthly checks More patients in the SC group received diabetes education by diabetes specialist nurses All practices in the SC used the diabetes registry GPs in the SC were significantly more satisfied than GPs in the UC group More patients in the SC group reported contact with GPs, nurses, assistant and dietitians, received adequate education about diet and foot care, and knew their blood glucose level One year after SC finished, the effects of structured care were still visible

Table 22.1 (continued)

Year, country, and reference	Objectives	Type of study and intervention	Results
2013 Denmark [62]	Follow-up of study referenced as [47]	Observational study 1381 patients aged ≥40 years and newly diagnosed with type 2 diabetes from national registries 19-year follow-up	Group differences in risk factors from the 6-year follow-up had leveled Lower rates of microalbuminuria and triglycerides in the intervention group Similar rates in all-cause mortality between the intervention and control group Prompting, feedback, clinical guidelines, continuing medical education, individualization of goal setting, and drug treatment among patients with newly diagnosed type 2 diabetes lowers the risk of complications
2013 United Kingdom [63]	Effectiveness of integrated, structured primary diabetes care in partnership with specialists to challenge the secondary care status quo and to shift resources within the health economy	Consistent messages tailored and delivered to primary and secondary care providers to persuade them about the need and benefits of change Two phases of implementation: establishment of community diabetes teams Changing the secondary care model, establishment of six "super-clinics": Pregnancy, renal dialysis, insulin pumps, acute type 1 diabetes, type 1 education, adolescents	Significant improvements of care; 85% of patients discharged from secondary care; estimated savings: £59,940.00 per year 108 patients receiving appropriate treatment in the "super-six" clinic 2996 patients received DESMOND education training 287 clinicians received training Consistently positive relationships with clinicians and staff Patient feedback overwhelmingly positive
2013 Australia [64]	Effectiveness of an integrated primary/specialist model for community care for complex type 2 diabetes management compared with outcomes for usual care at a tertiary care hospital for diabetes outpatients	Prospective open controlled trial in a primary and tertiary care setting 330 patients with type 2 diabetes ≥18 years allocated to community-based care by general practitioner with advanced skills and endocrinologist partnership or to usual care in hospital diabetes outpatient clinic	By comparison to the usual care group, patients in the intervention group showed a 0.8% decrease in A1c; 21% to 42% achieving an HbA1c target of >7.0%, significant improvements in blood pressure and total cholesterol, and significantly higher combined A1c, blood pressure and LDL cholesterol targets Community-based, integrated models of complex diabetes care delivered by general practitioners with advanced skills, produce clinical and process benefits compared with tertiary diabetes outpatient clinics
2015 United States [65]	Comparative effectiveness of in-clinic health coaching by medical assistants on diabetes and cardiovascular risk factor control versus usual care	Randomized controlled trial 441 patients from two primary care clinics Health coaching delivered by three medical assistants who received 40 hours of training and were embedded as part of the care team Patients randomized to usual care had access to any resources available at the clinics except for health coaching Primary outcome: Composite measure of HbA1c, systolic blood pressure and LDL cholesterol Secondary outcome: Meeting all three goals	Participants in the coaching arm were more likely to achieve goals for one or more uncontrolled conditions at baseline and more likely to achieve control of all conditions Almost twice of people in the health coaching group achieved the HbA1c goal and more likely to achieve LDL cholesterol goals Nonsignificant changes in systolic blood pressure Health coaching by medical assistants has the potential to alleviate nationwide deficiencies in diabetes control in an environment of deepening primary care clinician shortage

(continued)

Table 22.1 (continued)

Year, country, and reference	Objectives	Type of study and intervention	Results
2015 Australia [66]	Effectiveness of an integrated model of care for patients with complex type 2 diabetes on potentially preventable hospitalizations	Prospective controlled trial, 36 months duration multidisciplinary, community-based, integrated primary-secondary diabetes care compared to usual care at a hospital diabetes outpatient clinic 327 patients, 206 of them hospitalized	Compared with the usual care group, patients in the integrated model of care group were nearly half less likely to be hospitalized for a potentially preventable diabetes-related diagnosis after 24 months models reduce hospitalizations
2016 United States [67]	Association between patient-centered care (PCC), diabetes self-care, glycemic control, and quality of life (QOL)	Two adult primary care clinics 615 patients	PCC was significantly associated with QOL, medication adherence, general diet, specific diet, blood sugar testing, and foot care, but not with glycemic control Increasing patient-centered care is required for changes in outcomes occur
2017 United Kingdom [68]	Comparative effectiveness of enhanced diabetes primary care with more expensive integrated specialist-community diabetes services	Eight primary care practices and eight matching neighboring practices Enhanced practices had primary care physicians and nurses with an interest in diabetes who attended monthly diabetes education meetings and provided care plans and audits Control practices provided integrated primary-specialist care services	No significant differences were noted between enhanced and primary specialist services Enhanced primary diabetes care has similar outcomes to that provided by more expensive primary-specialist care
2017 Brazil [69]	Effectiveness of a structured intervention to improve type 2 diabetes management in primary care in a defined region	Comparative observational study 230,448 patients, 124,779 in the intervention group 105,669 in the control group 61 family strategy team professionals (FHS) from 2 cities 29 in the intervention group 32 in the control group One awareness raising workshop with heads of municipal health departments of the selected cities, with extensive participation of FHS health professionals Local management teams, reorganization, and local action plans to improve diabetes care Three training sessions for FHS professionals	Significant but negative differences in staffing the intervention group, including physicians and nurses By comparison with the intervention group, control group had better outcomes including multidisciplinary management, adherence to treatment, diagnostic tests, and educational activities The intervention had no detectable impact despite an enormous investment in money and manpower
2019 Denmark [70]	Comparative assessment of type 2 diabetes management shared between a specialized outpatient clinic and primary health care	Randomized, controlled, noninferiority study 140 patients with type 2 diabetes assigned to quarterly checkups by general practitioners (GPs) for the shared care group or to be treated by endocrinologists for the control group	Twelve months afterward, HbA1c increased 0.2% in the shared care group and 0.1% in the control group. Noninferiority was confirmed in the per protocol and intention to treat analysis
2019 United States [71]	Effectiveness of an interdisciplinary diabetes team model to improve glucose control in a primary care rural setting	An interdisciplinary diabetes team was established in a family rural medicine clinic Patients were referred if their HbA1c was ≥9.0% for initial consultation and follow-up visits	Ninety-four patients attended a baseline and at least one follow-up visit within 6 months. Significant reductions in HbA1c from 10.25% to 8.7% between baseline and follow-up visits were observed; 86% of patients had lower HbA1c levels at follow-up, and in 33%, it was <8.0%

Outpatient Management of Type 1 Diabetes

Traditional models for type 1 diabetes are organized around specialists in pediatric diabetes centers of excellence involving multidisciplinary team to deal with education, nutrition, and psychosocial adjustment [72–74]. A limited number of patients with type 1 diabetes are treated by primary physicians, but even in developed countries, availability and geographical distribution of specialists are real obstacles to refer all these patients to diabetologists [73, 74]. Even in the United States, it was estimated that in 2014, the shortage of adult and pediatric endocrinologists was of 1500 and 100, respectively, and that the gap for adult endocrinologists would continue to increase [75–78]. Models of primary care for type 1 diabetes are scarce, but innovative strategies have been conceived and implemented. Based on experiences collected as one of the participating centers in the DCCT, in 1988, the International Diabetes Center organized a team comprising three family physicians, four endocrinologists, a clinical epidemiologist, three nurse specialists, and a dietitian and developed Staged Diabetes Management (SDM), a systematic approach to support clinical decision-making including clinical pathways or DecisionPaths to start, adjust, maintain, or change therapies [72, 79]. The experience with SDM in the United States demonstrated its feasibility, its capacity to standardize clinical practice, reduce clinical inertia, and establish criteria for referral [79]. International dissemination of Staged Diabetes Management has confirmed its feasibility and effectiveness [44, 54, 59].

Comorbidity and Multi-morbidity in Diabetes Management

Treating a chronic disease like diabetes is often complicated by the coexistence with multiple medical conditions and by social and psychological deterrents. Currently, the most common chronic condition among adults is multi-morbidity [80, 81], in the words of Kate Lorig, "the Disease of the 21st Century" [82]. The contribution of multi-morbidity to the global burden of disease is already huge, but projections are of great concern: it is estimated that during the last 15 years of life, one-half of the newborns in industrialized countries will suffer multi-morbidity and its consequences, including poor quality of life, psychological distress, worsening functional capacity, longer hospital stays, higher costs of care, and higher mortality [83–88]. MM also affects processes of care resulting in complex self-care needs; multiple organizational problems; polypharmacy; increased use of emergency facilities; difficulties to apply clinical guidelines; fragmented, costly, and ineffective care; and higher mortality rates [83–92]. Multi-morbidity is important for diabetes management because besides its long-time recognized association with metabolic and cardiovascular risk factors, the frequency of non-diabetes-related (or non-apparently related) comorbidities is high and frequently influential in diabetes management. Negative outcomes associated with multi-morbidity partly result from the fact that healthcare delivery traditionally has been conceived and designed for patients with "isolated" diseases [83]. Fortin and colleagues state that "clinical practice is still based on a single disease paradigm which is not appropriate for patients with complex and overlapping health problems [84]". To make matters worse, most clinical trials exclude patients with comorbidities, limiting generalization of research results [92]. Diabetes management clearly applies to these statements: until recently, clinical guidelines failed to recognize the importance of comorbidity, and it has been demonstrated that this is a limiting factor to their implementation [83]. Research about the epidemiology of multi-morbidity, its consequences, and its effects on the process of care is still very limited [92–96].

Multi-morbidity (MM) was originally defined by Feinstein in 1970 as "coexistence of two or more diseases, pathological conditions or clinical entities in the same patient" [97], while comorbidity (CM) is defined as the presence of one index disease and at least one another chronic condition in the same person [98]. Due to the growing ambiguity around the use of both terms, van den Akker and colleagues suggested that CM be defined according to Feinstein's original definition and MM be defined as "the co-occurrence of multiple chronic or acute diseases and medical conditions," and in 2010 Boyd and Fortin provided a simpler definition of MM as "the coexistence of two or more chronic conditions, where one is not necessarily more central than the others" [99].

MM and CM have become great challenges and additional pressures on healthcare systems. They represent an additional burden on the acute care model which impedes in many cases, even recognizing the main complaint in a hurried visit. Healthcare interventions have successfully delayed death by managing (not curing) diseases but have also led to a marked increase in the coexistence of separate diseases in individuals [100]. In less than three decades, the frequency of chronic diseases and associated patterns of comorbidity and multi-morbidity has escalated for several reasons: (1) lowered diagnostic thresholds, (2) new diagnoses, and (3) true increases of some diseases, such as diabetes [100, 101].

Comorbidity and Multi-morbidity in Diabetes

Comorbidity and multi-morbidity are extremely frequent among patients with diabetes; its association with cardiovascular risk factors has been recognized for a long time, but coexisting conditions in other categories are also frequent and influential in diabetes care and outcomes. From

this perspective, Piette and Kerr proposed a framework to consider ways by which associated chronic conditions could influence diabetes medical care, self-management, and outcomes [102]. They classified comorbidities in three groups: (1) clinical dominant conditions, (2) concordant versus discordant chronic conditions, and (3) symptomatic versus asymptomatic chronic conditions, and recognized the preeminence of diseases like cancer, end-stage renal failure or severe cognitive impairment in the realities of diabetes care and life expectancy. Comorbidities in the second group are common and compete for time in the medical visit, for economic resources and support from patients and their families; some of them are inextricably related to the outcomes of diabetes care (hypertension, dyslipidemia), and others are related to mental health (depression, stress) or to recently explained pathogenic mechanisms (diabetic cheiroarthropathy). The third group includes chronic conditions which should be managed regardless of symptoms, worsening, or recurrence [109]. Most reports about diabetes and chronic disease are about associations with single medical disorders or clusters of chronic conditions, in denial of the unifying role of diabetes in the pathogenesis of apparently disparate disorders in the cardiovascular, musculoskeletal, or digestive systems. Table 22.2 depicts reports about comorbidity in patients with diabetes:

Linking Multi-morbidity in Diabetes

The results of studies described in Table 22.2 confirm the increasing prevalence of comorbidity and multi-morbidity in persons with diabetes and its negative effect on quality of care, quality of life, and direct costs. The prevalence more than doubles the observed rates in people without diabetes, partly explained by the long-time recognized aggregation of cardiovascular risk factors. The concept of multi-morbidity started from a unidimensional approach, the simple counting of co-occurring diseases in which patients are usually managed for each individual disease according to specific guidelines, and by different physicians [119, 120]. The logical limitations of this approach have encouraged a shift to integrated approaches to meet the needs of individual patients [120]. The current view and classification of human diseases dates to the late nineteenth century and derived from the observational correlation between pathological analysis and clinical syndromes [121]. Over the years, attention to the interactions of multiple, apparently unrelated diseases occurring at different levels led to a vertical dimension which attempts to clarify the complex interactions of multi-morbidity at the cellular, organizational, community, and even the emotional levels [122]. Aron addressed the additional burden imposed by multi-morbidity on diabetes self-management, the conflicts, and potential risks of glycemic control [119]. A new, holistic view suggests that common linked pathophysiological pathways underlie the development of diseases in a non-organ-specific manner and that multiple diseases within one person, regardless of symptoms or organ-system, are not necessarily caused by independent mechanisms [120]. Considering the highly internal organization of the cell, it would be possible to improve the one-gene-one-disease approach by developing a conceptual framework to link all genetic disorders with the complete list of disease genes, resulting in a global view of the "diseasome," the combined set of all known disease/gene associations [123]. In the "human disease network," nodes represent diseases, and two diseases are connected if they share at least one gene in which mutations are associated with both diseases [122]. Coexistence of intricate molecular links between subcellular components and disease genes raises the possibility that diseases may not be as independent of each other as physicians traditionally think and that diseases form networks in which two of them are connected if they share at least one gene [122]. Diabetes management at the one-gene-one disease level ignores its complexity, clearly illustrated by the aggregation of concordant and discordant conditions. From this perspective, clinicians should move forward and start thinking in multiple dimensions! [119].

Comorbidity in Clinical Practice

Several instruments have been devised to measure comorbidity [124], but the most widely used at the outpatient level is the Charlson Co-morbidity Index (CCI) [125]. Developed by Mary E. Charlson and colleagues, the CCI assigns weights from 1 to 10 for a variety of diseases, including diabetes without organ damage [126]. Summing the weights of each condition, the relative 1-year mortality risk is calculated: six diseases have weights of 2, one disease has a weight of 3, and two diseases have weights of 6; scores range from 0 to 10, although higher scores are possible for severely ill patients [126]. The CCI has been used to estimate the prognosis of comorbidities in a variety of disciplines, from dermatology to oncology, and its power to predict morbidity, mortality, costs, and hospitalizations has been validated and compared with other measures [127]. Its use continues to extend, and it has become available in several versions of online calculators.

Comorbidity is usually managed by different specialists ("as many as necessary"), using independent clinical guidelines. This approach is ineffective and conflicting, increases the demand of professional services and costs, and may even pose risks for the patients. Current disease-oriented guidelines do not account the interactions between different diseases and are designed to manage single chronic conditions [128]. Innovative approaches have been proposed to address the challenge of comorbidity, such as the Adriane principles, a tool to support decision-making during consultations in primary care that involve patients [129, 130]. The Adriane principles were designed to foster an innovative concept in

Table 22.2 Comorbidity in patients with diabetes

Year, author, and reference	Country	Patients	Prevalence of MM and comments
Kerr et al. (2007) [103]	United States	1901 diabetes patients responding to a survey	40% of patients had at least one microvascular comorbidity, 79% had at least one macrovascular comorbidity, 61% had at least one nondiabetes comorbidity including arthritis (55%), cancer (14%), lung disease (10%) Patients with greater number of comorbidities placed lower priority to diabetes and had worse diabetes self-management scores Type and severity of comorbid conditions, beyond the comorbidity count, influence diabetes self-management Patients with comorbidities need additional support to accomplish self-management activities
Ose et al. (2009) [104]	Germany	3546 patients with type 2 diabetes	The number of comorbidities and the interaction between management and comorbidities have a significant impact on quality of life Structured diabetes management may help to counteract the negative effect of comorbidity
Zhang et al. (2010) [105]	Australia	17,095 patients with diabetes ≥65 years	80% of patients had four or more comorbid conditions Only 1% had no comorbidities 18.7% were receiving medications for chronic obstructive pulmonary disease or asthma 17.5% were receiving nonsteroidal anti-inflammatory drugs 7.1% had cancer 4.4% were receiving medications for dementia Patients with comorbidity have low utilization of preventive diabetes services Competing health demands and patients' preferences are very influential in diabetes care
Wermeling et al. (2012) [106]	Netherlands	2086 well-controlled patients with type 2 diabetes, including A1c, systolic blood pressure, and total cholesterol	Compared to patients without comorbidities, patients with type 2 diabetes, and comorbidities had much lower health status despite good diabetes control Physical limitations and functional impairment are decisive Physicians have to take into account patients' health status and integrate the impact of comorbidities into diabetes care

(continued)

Table 22.2 (continued)

Year, author, and reference	Country	Patients	Prevalence of MM and comments
Luijks et al. (2012) [107]	Netherlands	Prospective observational study 712 adults with newly diagnosed type 2 diabetes during a 17.3-year observational period from a practice-based research network	Prevalence of "any type" of comorbidity: 84.6% 70.6% had one or more discordant comorbid disorders, mostly musculoskeletal and mental, chronic functional somatic symptoms, or deafness 27.2% had three or more comorbid diseases At the date of diabetes diagnosis, patients had between 1.5 and 2.1 comorbidity clusters Diabetes management in general practice is complex in terms of chronic comorbidity "Straightforward" patients without comorbidities are extremely rare" Diabetes management demands management of comorbidities, including discordant diseases Validity of clinical guidelines is questionable if they do not consider comorbidity A patient-centered approach can be of added value
Pentakota et al. (2012) [108]	United States	42,826 patients with new-onset diabetes	Prevalence of comorbidity: 80% Prevalence of discordant illnesses: 30.1% Prevalence of both concordant and discordant illnesses: 25.5% Prevalence of concordant illness: 13% Prevalence of a dominant illness different to diabetes: 12% Comorbidity from concordant illnesses is associated with increased visit frequency and higher likelihood to receive recommended diabetes care Patients with discordant illnesses received less diabetes care and patients with dominant illnesses received markedly lower diabetes care
Teljeur et al. (2013) [109]	Ireland	424 patients with type 2 diabetes treated in general practice	Prevalence of comorbidity: 90% 25% of the patients had ≥4 additional chronic conditions, the most common: Hypertension: 66% Heart disease: 25% Arthritis: 16% Comorbidity significantly increased the number of medical visits and polypharmacy The variety of conditions emphasizes the complexity of diabetes management and the importance of maintaining a generalist and multidisciplinary approach
Alonso-Morán et al. (2015) [110]	Spain	126,889 patients with type 2 diabetes	87.6% of men and 92% of women with type 2 diabetes had at least another chronic condition 1.7% of men and 1.9% of women with type 2 diabetes had 10 or more chronic conditions; by comparison, 54.2% of men and 57% of women without diabetes had at least another chronic condition Ten morbidity clusters were identified, the most common related to cardiovascular risk factors and heart disease Patients with diabetes are at higher risk of peripheral vascular disease, heart failure, hypertension, and chronic renal disease

Table 22.2 (continued)

Year, author, and reference	Country	Patients	Prevalence of MM and comments
Ricci-Cabello et al. (2015) [111]	England	Cross-sectional study of 54,220,050 patients from 7884 family practices	Prevalence of diabetes concordant conditions: Hypertension: 13.8% Obesity: 11.25% Chronic kidney disease: 4.16% Coronary heart disease: 3.34% Stroke and TIA: 1.66% Atrial fibrillation: 1.45% Heart failure: 0.71% Prevalence of diabetes-discordant conditions: Asthma: 5.95% Depression: 5.78% Hypothyroidism: 3.17% Cancer: 1.87% Chronic obstructive pulmonary disease: 1.79% Severe mental disorders: 0.87% Epilepsy: 0.78% Dementia: 0.55% Concordant conditions were positively associated with quality of diabetes care Epilepsy and mental health disorders were negatively associated with quality of diabetes care
Adriaanse et al. (2016) [112]	Netherlands	Cross-sectional study of 1676 patients with type 2 diabetes Quality of life was measured and comorbidities were recorded from self-reports	21.5% of patients reported no comorbidities Diabetic patients with comorbidities showed lower scores in quality of life than patients without diabetes Comorbidities reducing most significantly quality of life included retinopathy, heart disease, peripheral artery disease, lung disease, incontinence, back, neck and shoulder disorders, osteoarthritis, and rheumatoid arthritis
Sancho-Mestre et al. (2016) [113]	Spain	491,854 patients with diabetes identified and selected through clinical codes	70% of patients suffered from more than two comorbidities, the most common: Hypertension: 68.4% Dyslipidemia: 53.3% Mental disorders: 25.0% Osteoarticular disease: 24.5% Cardiovascular disease: 14.4% Pharmaceutical expenditures increased according to the number of comorbidities
Bralic Lang et al. (2017) [114]	Croatia	10,264 patients from 449 primary care practices	Prevalence of comorbidities: 77.7%; the most common: Cardiovascular: 69.7% Endocrine and metabolic: 30.1% Musculoskeletal: 14.0% As the number of comorbidities increase, patients were less likely to achieve glycemic control Despite limited time, general physicians are able to deliver proper treatment of patients with type 2 diabetes and comorbidities Comorbidity increases clinical inertia and treatment fragmentation by physicians, institutions, and therapies

(continued)

Table 22.2 (continued)

Year, author, and reference	Country	Patients	Prevalence of MM and comments
Petrosyan et al. (2017) [115]	Canada	861,354 adults with diabetes Compliance with three quality measures according with type of comorbidity	Prevalence of comorbidity: 86% Diabetes-concordant conditions: 20.7% Diabetes discordant: 15.6% Patients with diabetes concordant and diabetes discordant conditions: 49.8% Receipt of all recommended monitoring tests in diabetes is higher in patients with diabetes concordant and discordant conditions (30.2%) and lower in patients with diabetes discordant conditions (19.6%) Hospitalization for diabetes complications is lower in patients with concordant conditions Meeting goals for HbA1c does not prevent hospitalizations for diabetes, especially in patients with comorbidities Other factors, including self-monitoring of blood glucose, glycemic control, lifestyle changes, patient education, and drug therapy are more important
Pouplier et al. (2018) [116]	Objectives: 1. Quantify development and composition of multi-morbidity (MM) following the diagnosis of type 2 diabetes 2. Effectiveness of structured personal diabetes care between patients with and without MM	Randomized controlled trial: 19 years follow-up of 1381 patients with newly diagnosed type 2 diabetes receiving structured personal diabetes care or routine diabetes care	MM increased from 31.6% at diagnosis to 80.4% at 16 years Cardiovascular and gastrointestinal diseases decreased; musculoskeletal, eye and neurological diseases increased
An et al. (2019) [117]	Association between different types of comorbidities and quality of diabetes care, quality of life, and total healthcare expenditures	Retrospective observational study from a sample of 8292 patients with diabetes from a medical expenditure survey Twenty chronic conditions identified and classified as (1) diabetes only, (2) diabetes plus concordant comorbidities, (3) diabetes plus non-concordant comorbidities	Prevalence by categories: Diabetes only: 11.4% Concordant comorbidities: 40.5% Discordant comorbidities: 48.1% Patients with diabetes and comorbidities received better quality of diabetes care Patients with discordant comorbidities had lower quality of life and higher health care expenditures
Pati et al. (2020) [118]	Impact of comorbidities on quality of life of receiving primary care	Cross-sectional study: 942 patients with type 2 diabetes assessed with a questionnaire for measuring comorbidities, physical and mental health scores, sociodemographic and clinical variables	Comorbidity was statistically associated with lower scores of physical and mental health Lower quality of life increased with the number of comorbidities Clinical relevant scores occurred with peptic disease, chronic lung disease, visual impairment, depression and stroke, duration of diabetes, insulin use, and obesity

medical decision-making for patients with multi-morbidity in primary care by establishing realistic goals at the center, and three core principles: (1) individualized management, (2) prioritization of patients' preferences, and (3) interactive assessment [129, 130].

Multi-morbidity in Diabetes Management

Comorbidity or multi-morbidity has negative effects on mental status and quality of life and increases the frequency of medical visits and the risk of death [87, 131]. Integrated, simplified care of comorbidities involving physical diseases and mental disorders can decrease disabilities and is associated with significant reductions in total healthcare costs and hospital costs [89, 94]. The challenge to deliver patient-centered care for people with comorbidities is to provide the right care for the right person at the right time, but current medical structures do not support multidimensional care and encourage treating only disease-specific outcomes [132]. The number and type of comorbid diseases have multiple consequences in patients with diabetes, create competing demands, and promote clinical inertia [133, 134], impairs controlling diabetes and cardiovascular risk factors [135,

136], and increases use and costs of antidiabetics and all other classes of medications [137]. For patients with diabetes, dominant comorbidities including end-stage diseases, severely symptomatic conditions, and acute health problems determine prognosis and dictate everyday experiences [138]. Shared decision-making and comorbidity hierarchies are critical to guiding treatment decisions in patients with diabetes [138]. Diabetes guidelines typically focus on decreasing microvascular and cardiovascular complications in disregard of the burden of comorbidity [138]. The current narrow focus on single diseases should be replaced with a holistic view and approach to established patterns of comorbidity and multi-morbidity [139, 140]. Only a radical rethinking of health systems will facilitate the transition and challenges multi-morbidity and its associated disability [141].

Diabetes and the Chronic Care Model

Well-trained, hard-working clinicians frequently unable to deliver effective services or achieve diabetes goals [142]. Usual medical care often fails to meet the needs of patients with chronic diseases; meeting their complex needs is the single greatest challenge facing organized medical practice, usual care is still not doing the job, and the medical system is perfectly designed to achieve the mediocre results it achieves [142–144]. Many patients with diabetes have no access to medical care or receive inadequate treatment [145]. New paradigms have been proposed for improving care for patients with chronic diseases in the face of the ineffectiveness of usual care, and the evidence about the benefits of innovations in ambulatory care has encouraged new paradigms. Based on clinical experience, literature reviews, and suggestions of an advisory panel, Wagner and colleagues developed a model to improve chronic illness care by incorporating successful interventions [146]. The Chronic Care Model (CCM) is based on the reality that in chronic diseases, the outcomes are largely dependent on the efforts, resources, and support of patients and their families [146]. Successful treatment requires that patients are well informed about their disease, the place where they can receive treatment, and to have greater control over their treatment [147]. The CCM is not a quick and easy fix or an abstract theory; it is a multidimensional solution to a complex problem, a concrete guide to improve clinical practice [145]. Care for chronic noncommunicable diseases (NCDs) is a global problem; the CCM is a tool to deliver integrated management for NCDs in primary care and a practical guidance for healthcare program managers, policy-makers, and stakeholders to plan and deliver high-quality services for people with NCDs [148].

The CCM assumes that medical care is centered in the interaction of patients and practice teams, with self-management support from the community and organization of health care inside and outside the health system [149]. By comparison to usual care, in which isolated physicians give orders to patients, chronic disease management involves collaboration with clinicians from diverse disciplines (nurse case managers, physicians, pharmacists, social workers, dietitians, lay health workers) who communicate regularly and participate in the care of a defined group of patients [149]. Interventions that improve care and outcomes fall into four categories: changes to the way care is delivered (practice redesign), changes to patient education and support (patient education), interventions to educate or remind providers (expert system), and changes to information systems (information) [142]. The "six pillars of the chronic care edifice" include (1) community resources and policies, (2) healthcare organizations, (3) self-management support, (4) delivery systems design, (5) decision support, and (6) clinical information systems [145, 150, 151]. Incorporating most or all its elements is associated with improved quality of care and outcomes in chronic disease management [152]. Interventions in the four categories improved care across different chronic conditions and resulted in the largest improvements in care and outcomes [142].

The CCM in Diabetes

In many ways, diabetes care is the prototype for the CCM and became an emblematic clinical scenario to assess its effectiveness; accumulating evidence shows that the CCM provides a framework for optimal diabetes care [152]. Table 22.3 summarizes two decades of interventions implementing the CCM for diabetes management since 2001:

- Diabetes represents an ideal clinical setting to implement the CCM. After two decades of being conceived however, the number of studies and, most importantly, the number of health organizations and national health systems who have implemented the CCM is still scarce. Beyond endorsement from international agencies [148] and with remarkable exceptions [162], most of the studies and interventions to implement the CCM have occurred in developed countries; adaptations to preexisting models are the rule, instead of studies devoted to implement the CCM "as it is" [164]. Most of the studies continue to appear in previous systematic reviews, not only because of their importance but also because of scarcity of new trials [165, 166]. Available studies show limitations, including non-blinding of participants, brief follow-up, the absence of self-report measures for behavior change, small sample size, inadequate training of health professionals, and the absence of registries and electronic medical records [166]. Despite these challenges, 24 years after publication of the description of the Chronic Care Model, a large amount of experience using the CCM has accumulated worldwide. More evidence about its effectiveness in diabetes management is essential.

Table 22.3 The Chronic Care Model (CCM) in diabetes management

Year, country, and reference	Design and intervention	Results	Comments
2001 United States [153]	Randomized controlled trial 57 primary care practices serving ≈500,000 people Patients with diabetes ≥30 years attending chronic care clinics at 3–6-month intervals. Components of the CCM: Baseline assessment Individual visits with primary care physicians, nurses, clinical pharmacists, one group peer support session	Patients receiving the intervention were more likely to receive preventive procedures, foot and retinal examinations, and medication reviews, without significant differences Significant higher participation rates in diabetes education Nonsignificant differences on physical function, depression measures, days confined in bed, and patient satisfaction Mean A1c levels equally high in both groups, cholesterol levels equally lower Chronic care clinic patients visited primary care more frequently; the increase was associated with significant reductions in specialty, emergency room visits, and hospital admissions	Redesign of care including delegation of roles within the practice team, involvement of other disciplines, organization of visits and follow-up and integration of psychoeducational interventions is important for success
2006 United States [154–156]	Multilevel, cluster design, randomized controlled trial 19 hospitals 166 primary care clinics 1400 academic physicians 90,000 patients with diabetes Stepped implementation of the six elements of the CCM Delivery of diabetes self-management (DSMT) training	The number of CCM recognized programs grew from 3 to 21 over 4 years Significant differences in HbA1c among patients receiving DSMT in hospital programs versus primary care 2–3 greater proportion of patients received SMDT at primary care offices versus patients referred to hospital-based programs	The CCM is an effective framework to support DSMT With reliable clinical information systems, educators can demonstrate the benefits of DSMT on HbA1c levels Improvements in program and patient outcomes can be sustained, financially self-supporting
2007 United States [157]	Controlled pre- and post-intervention study, 1-year duration 1170 patients with type 2 diabetes, 613 assigned to chronic care 557 assigned to usual care	Patients in both groups had improvements in HbA1c, blood pressure, and lipoprotein levels Participants in the intervention group had a 2.1% greater reduction in cardiovascular risk	Collaborative interventions using the CCM lower cardiovascular risk factors in patients with diabetes
2007 United States [158]	Observational study 30 small, independent primary care practices 90 clinicians, including 60 physicians, 17 nurses, 13 assistants who completed a questionnaire assessing the use of the CCM 886 patients with diabetes	Use of the CCM was significantly associated with lower HbA1c levels and ratios of total cholesterol to high-density lipoproteins Every unit increase in the use of the CCM was associated with a 30% A1c reduction and a 0.17% reduction in the lipid ratio	Clinicians in small independent primary care can incorporate elements of the CCM in their practice, with higher levels of process and intermediate outcomes of diabetes care
2009, 2010 Belgium [159, 160]	Four-year evaluation of a project based on the CCM Implementation based on the ACIC survey Implementation: First stage: 2300 patients with type 2 diabetes Follow-up: 4174 patients	Overall ACIC scores improved from 1.45 at baseline to 5.5 at the end of the study Significant improvements in HbA1c and total cholesterol in the intervention group Insufficient assessment of long-term complications Crucial steps for strengthening primary care: Local steering group, appointment of program managers, willingness of well trained and motivated care providers Barriers include complexity of the intervention, lack of quality data, inadequate information technology, lack of commitment, unsustainable funding	Adapting the CCM in primary diabetes care has opportunities and bottlenecks Further improvements are required to deliver the components of the CCM Albeit remarkable improvements were achieved, primary care providers lack opportunities and resources to take full responsibility for chronic care

Table 22.3 (continued)

Year, country, and reference	Design and intervention	Results	Comments
2010 United States [161]	Intervention trial 25 practices, 4 physicians per practice Implementation of the CCM measured through staff and clinical management surveys, chart audits and patient questionnaires	Low levels of implementation Sites with higher levels of CCM implementation showed improvements in diabetes assessment and treatment Physical activity counseling for persons with overweight and obesity was associated with CCM implementation, except for people with diabetes	Modest levels of CCM implementation Unsupported primary care is associated with improvements in diabetes care and higher rates of behavioral counseling
2015 Philippines [162]	Observational study Two primary healthcare units in semirural and rural municipalities Adaptation and implementation of the CCM Assessment of chronic illness care and glycemic control	Significant improvements in HbA1c, glycemic control, and chronic care scores	In resource-limited settings, the CCM improves the quality of primary diabetes care
2017 Italy [163]	Population-based study 8486 patients exposed to the CCM versus 8486 nonexposed patients Four-year duration	Significant improvements for adherence to clinical guidelines, lower risk of cardiovascular complications, protective effects against neurological, cardio-cerebrovascular complications and mortality	Implementation of the CCM improved diabetes management and reduced cardiovascular outcomes

Diabetes as a Complex Disease

Zimmerman, Lindberg, and Plsek described three kinds of problems in the world: simple, complicated, and complex [167]. Simple problems are clearly defined, with straightforward solutions. Complicated problems don't have straightforward solutions but can be dissected into groups of simple problems. Complex problems have multiple components, commonly not initially perceived and appear during the process of solution. To address complex problems, expertise is important but not sufficient, and uncertainty and risk are trademarks. Diabetes management is a complex task. Complexities of diabetic control were recognized five decades ago by Franklin Williams and colleagues, who described the degree in which a variety of continuing intervening factors, including (1) biological, (2) psychological, (3) appropriateness (and timeliness referring to clinical inertia) of medical recommendations, (4) adequacy of diabetes education (from a pedagogic to an andragogic approach in adults), (5) patient's resources (cognitive, socioeconomic, motivation, health literacy), and (6) family and social support, converge to achieve the lifetime challenge of day-to-day control [168]. Despite these arguments, reductionist approaches abound and prevail in diabetes management. Countless efforts have failed and continue to fail from denial of this reality. Recognition of complexities of diabetes care starts by identifying the three components of successful diabetes management: (1) patient activation, (2) self-care, and (3) support. Each one is essential to achieve the desired outcomes; all of them are directly related to the crucial role and responsibility of people with diabetes and their families. Self-care and support are associated with the capacity to deliver multidisciplinary, patient-centered care, including diabetes self-care education and support. The absence of any one of these components leads to clinical failure, waste of economic resources, and overall dissatisfaction from patients, their families, payers, and providers.

Conclusions

> "Establishing the best evidence is not the same as implementing the best practice, though the former does provide a basis for the latter"
> Philip Davies [169]

Randomized controlled trials, meta-analysis, and systematic reviews have confirmed that unstructured community care is associated with poorer follow-up, worse glycemic control, and greater mortality [166]. This is the case of health systems reluctant and resistant to change of the acute care approach in diabetes management like Mexico where three decades of ill-devised, unstructured, short-range, and low resource efforts have not been able to improve clinical outcomes or to reduce diabetes morbidity and mortality [170, 171]. By comparison, worldwide experiences accumulated in almost four decades confirmed the effectiveness of primary diabetes care to reduce risk factors, improve the process of care, decrease referrals to specialists, and direct costs when complex, multifaceted interventions and organizational interventions that facilitate structured and regular review of patients are established, in addition to patient education and with support [19, 34–70, 172, 173]. Essential components of structured diabetes management include (1)

targeting patients at high risk, intensive reducing A1c levels ≥9.0%, blood pressure ≥ 160/95 mmHg, and foot care in patients at high risk of foot ulcers [56, 174]; (2) establishing diabetes registries for data collection, reporting, support, and quality improvement [175–179]; (3) local physician champions with specific interest in diabetes and chronic care management and responsible to coordinate the implementation of the patient-centered medical home [56, 179]; (4) team management involving primary care providers, nurse practitioners, dietitians, and "physician extenders" [179–181]; and (5) health coaching to make sure that patients understand the care plan involving "knowing their numbers," shared decision-making, promoting behavior change, and medication adherence [181].

Controlled clinical trials have demonstrated that achieving the goals of metabolic control by lowering glucose, blood pressure, and LDL cholesterol reduces the risk of microvascular and macrovascular diabetes complications [182]. Nevertheless, most diabetic patients do not meet these recommended goals; prevailing and persistent structure and process deficiencies in primary care impede the achievement of outcomes. Studies of the level of diabetes care provided "in the real world" and especially in primary care continue to show that professional performance is suboptimal and conflicting with recommendations [145, 183]. Challenges in diabetes translation, starting with the urgency to change healthcare systems, were described by Anderson 30 years ago, but a large proportion of persons with diabetes worldwide continue to be treated "as usual" [184]. Establishing effective, sustainable, long-term outpatient diabetes management is one of the greatest challenges in this era.

Multiple Choice Questions

1. Initial experience of hospital diabetes clinics in Europe showed that:
   (a) It was absolutely feasible to treat all patients with diabetes.
   (b) Every patient could receive treatment from highly trained specialists.
   (c) Nurses and dietitians were not required.
   (d) Physicians were the most important elements of success.
   (e) **Clinics became overwhelmed, resulting in long waiting times and dissatisfaction.**
2. Successful clinics are the ones:
   (a) With the most qualified medical specialists
   (b) **The ones who had the vision and were able to offer comprehensive services**
   (c) Charging the highest fees for their services
   (d) In which patients could be admitted to a hospital
   (e) Having access to the newest medications
3. Diabetes management from a paternalistic approach:
   (a) Is essential to make patients follow physicians' orders
   (b) Has been shown to reduce the risk of acute complications
   (c) Reduces the risk of chronic complications
   (d) Has received high levels of satisfaction from patients and their families
   (e) **Has never been assessed and is associated with acute and late complications**
4. Planning of diabetes services:
   (a) **Needs to be broader beyond those available in most centers**
   (b) Requires procuring for new medications.
   (c) Must be based on the expertise of specialists.
   (d) Occurs exclusively at the medical office.
   (e) Is not important; patients may attend whenever they want.
5. Implementation of a model based on the DCCT in clinical practice requires all the following except:
   (a) Allocation and effective use of resources
   (b) Standards of care and quality assurance.
   (c) Training and continuing education.
   (d) Research and evaluation.
   (e) **Recognition that patients are unable to self-manage**.
6. Outpatient diabetes management:
   (a) Is feasible, acceptable, and effective
   (b) Produces significant improvements in A1c
   (c) Does not increase the frequency of hypoglycemia
   (d) Is not inferior to management in hospital clinics
   (e) **All of the above**
7. Comorbidity:
   (a) Should be treated by different specialists
   (b) Is very uncommon
   (c) Has no impact on diabetes management
   (d) **Is increasingly frequent, "the disease of the 20th Century"**
   (e) Are never be more important than diabetes
8. Compared with people without diabetes, the prevalence of comorbidity in patients with diabetes:
   (a) Is very rare
   (b) Is lower
   (c) Is equal
   (d) Is slightly higher
   (e) **Is more than double**
9. The Chronic Care Model:
   (a) **Recognizes that outcomes are largely dependent on patients and their families**
   (b) Depends on the availability of all the necessary medications
   (c) Recognizes the preeminence of physicians in all the decisions of management
   (d) Involves fragmentation of services

(e) Is important but very expensive and complicated

10. Diabetes management:
    (a) Is simple and straightforward
    (b) Is complex but outcomes are certain
    (c) **Is complex and outcomes are uncertain**
    (d) Depends exclusively on physicians' expertise
    (e) Is independent of patients' resources

The Unwarranted Variation in Health Care and Its Consequences

In 1938, J. Alison Glover reported a remarkable finding: high variations in the rates of tonsillectomy in small areas of Britain in which the probability of undergoing the operation was 20 times higher in children living 7 miles apart [1]. Despite the amount of similar evidence collected for almost four decades, when John Wennberg published his first article on unwarranted variations in the delivery of health care in 1973, he was largely ignored [2]. Over the next four decades, Wennberg and his colleagues collected compelling research against the traditional view of quality of health care as "the best in the world" at the expense of high variability in costs. They showed that a large part of the medical services delivered in the United States and other countries was not only unnecessary, it also inflicted a large burden in costs and was potentially harmful [3]. Following these observations, in 1967, Wennberg and Gittelsohn developed a database to identify and compare the underuse of care among neighboring hospital service areas assuming that lack of access and undertreatment were the most important problems. Surprisingly, they found the opposite: large unjustified variations in the delivery of services among neighboring communities. Instead of under-service and undertreatment, large variations in the availability of resources and using services in neighboring communities without scientific basis were the rule [4, 5]. Wennberg came to the conclusion that medicine had wrapped itself in a mantle of science, but much of what doctors were doing was based more on hunches than good research [2]. These landmark studies were not warmly received: the first two reports had to be published in Science and Scientific American [6, 7], because journals with wide clinical readerships rejected them arguing that patient demand was the only explanation for variations in healthcare delivery, and those studies would be of no interest to the readers [5]. Despite the initial and persistent resistance to accept their existence, similar variations in hospital admissions, length of stay, and specific surgical procedures started to appear in other regions in the United States [8, 9]. Wennberg's studies led to healthcare reforms at the federal and state levels in the United States, but in most places in the world, these proposals are still unacceptable [2]. Despite continuing advances in medical science, regional variations in surgery have not decreased, rates of common surgical procedures remained stable, and it is very likely that comparable variations could be demonstrated for diagnostic and medical procedures [10–14]. Clinical inertia, personal beliefs, and economic interests are still relevant barriers to standardize medical practice. Instead of applying "evidence-based," "eminence-based medicine" prevails and rules. A patient's odds of undergoing surgical, diagnostic, and therapeutic procedures is more related to where he or she lives than on clinical decisions. "What you get depends on where you live and who you see [15]."

Substantial variations in diagnostic, medical, and surgical procedures are associated with (1) differences in health systems, (2) practice styles of physicians, and (3) characteristics and preferences of patients [16]. Beyond structural differences and recognizing the role of patients to pursuit and select health care, physicians' beliefs about the effectiveness of clinical interventions and their personal interpretation to what constitutes evidence are the main contributing factor. Patients in high-intensity areas, with high availability of services, do not experience better health outcomes [17]. The use of clinical practice guidelines (CPG) to apply scientific evidence has become increasingly important to address unexplained variations as an effort to standardize clinical practice and to improve the quality of health care.

The Ascent of Clinical Practice Guidelines

One of the most important factors influencing physicians is the use of clinical policies [18]. In 1989, Robert Brook announced the emergence of the movement leading to practice guidelines based on (1) documented high rates of unexplained variations, inappropriate care, adverse events, and medical errors; (2) escalating financial pressures and cost-containment; (3) the accelerated introduction of technology; and (4) unprecedented questioning and scrutiny of medical care [19–21]. All these issues demanded collecting clinical evidence about efficiency, cost-effectiveness, and the impact of medical interventions on quality of life [21]. Attention shifted to the development of methods with the ability to provide valid and reliable guidelines about the best interventions "for the real world," based on high standards of quality, understandable and practical evidence-based information, not simply anecdotal, consensus-based, opinionated, nihilistic, or with limited scope [22, 23].

Articles about guidelines started to appear in the 1960s, and the title "clinical guidelines" was mentioned since the 1970s, but 1990 became the landmark. Brooke was accurate in his prediction: the vision and efforts of a distinguished group of leaders, including David Eddy, Stephen H. Woolf, Scott Weingarten, Marilyn Field, and Kathleen Lohr in the United States; Richard Grol in the Netherlands; Jeremy Grimshaw, Ian Russell, and Martin Eccles in the United Kingdom; and the pioneering work of the Agency for Health Care Policy and Research (AHCPR), the Institute of Medicine (IOM), the American College of Physicians, the Veterans Health Administration in the United States, the National Institute of Clinical Excellence in England (NICE UK), and the Guidelines International Network (G-I-N) led to an explosion in the development of CPGs and created a worldwide discussion about their methodology, implementa-

tion, impact, and quality of health care [24–31]. They understood the required roles to improve organizations to attain its professional goals: to advance – from the craft stage in which skills are passed from practitioner to apprentice to a stage where experience is collected and systematized to establish principles of integrated structure of thought [24].

Critical pathways were first used in industry; the critical path method was developed in the 1950s to coordinate multiple contractors to identify the sequence and critical path that would drive the timeline of a project and started to be applied to health care in the 1970s to define the optimal sequencing and timing of interventions by physicians, nurses, and other staff for diagnostic or clinical procedures [25]. Critical pathways are devoted to (1) improve the health status of large amounts of individuals; (2) reduce unwarranted variations in patient care; (3) minimize delays and resource utilization; (4) enhance communication; (5) decrease costs; (6) reduce variations in outcomes; and (7) maximize the quality of health care [25, 26].

Defining Clinical Guidelines

Different definitions of CPG have been proposed. According to the AHCPR, CPG are "systematically developed statements developed to assist practitioners' and patients, decisions about health care to be provided for specific clinical circumstances [29]," the IOM defines CPG as "all the information relevant to approach the diagnostic and therapeutic management of a clinical problem [30]," and Margolis defined them as "all the relevant information to approach the diagnostic and therapeutic management of a clinical problem, logically driven by a clinical algorithm [32]. CPG evolved from pathways to direct the diagnosis or management of symptoms or signs to graphical descriptions of quality improvement. Their primary goals are (1) to improve the quality of care, enforcing professionalism, accountability, and efficiency as part of professional activities (2) to support systems in decision-making for clinicians and patients [33].

Rationale and Evolution

Clinical practice guidelines (CPG) became the preferred methods to influence medical decisions and to develop practice policies beyond the traditional approach in which practice policies evolved through collection of "standard and accepted" practices, which were not to be changed [34, 35]. The traditional approach had several issues, including (1) obligatory compliance with policies and norms and the expectative that people must perform them without deviation. In this approach, the former defines the latter and creates two problems: (1) it is not anchored on reality because policies are not explicitly described or analyzed; and (2) the outcomes are subjective [34]. Eddy proposed substituting global subjective judgment for an evidence-based approach, in which clinical decisions were supported by evidence. The steps that he described to design practice policies are still paradigms [34–39]:

1. Formulate the problem to be assessed by the guideline.
2. Identify and interpret the evidence.
3. Synthesize the evidence including magnitude of benefits and harms.
4. Direct comparison of benefits and risks.
5. Estimate costs.
6. Compare health outcomes and costs.
7. Setting priorities.
8. Design a practice policy.

CPG have to be flexible because outcomes must be assessed by heterogeneous audiences including providers, payers, and users [39]. The Clinical Practice Guideline movement consolidated through the common interest of leaders and institutions from the United States and Europe. Multiple approaches were published over one decade until the 28th Bethesda Conference analyzed their association with quality of care, development, and implementation [40–45].

Development of CPG

Clinicians need simple, patient-specific, user-friendly guidelines which include three basic components: (1) description of decisions to be made and their possible consequences; (2) collection of valid evidence to make informed decisions at key decision points; and (3) presentation of evidence and recommendations in a concise, accessible format [46]. The process starts with the pathway of CPG development [47] and the need to abandon the consensus approach, a method of subjective judgment in which participants "simply decide what to recommend" and privileges the biases of traditional, empirical, medical practice [48]. The consensus approach, evolved from collective personal experiences which are sanctioned by selected, frequently biased, groups of experts, without explicit criteria to select the evidence supporting specific recommendations, is open to misuse and reluctant to meet quality standards [21, 48–52]. Components of high-quality guidelines are summarized in Table 23.1 [31, 46–72]:

Challenges of Implementation

Despite the resources and expertise devoted in their development, serious deficiencies persist in the adoption of CPG

Table 23.1 Stages in the Development of Clinical Practice Guidelines [24, 30, 31, 46–72]

Stage	Description
1	Composition of guideline development group Identifying and refining the subject inviting clinicians, experts on the topic, patients, potential users, or evaluators Define the topic in precise terms including condition or disease, interventions, patient population, evidence, and outcomes
2	Cost analysis and hidden costs involved in implementation. Health interventions are not free, people are not infinitely rich, and budgets are limited. Costs of alternative preventive, diagnostic, and management strategies for each clinical situation
3	Target audience and clinical setting, objectives, and scope
4	Groups or individuals responsible to develop and implement the guideline
5	Establishing a panel of 10–20 members balancing scientific, practical and political concerns, including primary care professionals with specific interest, health authorities, medical specialists with expertise in the guideline topic, one epidemiologist, one health economist
6	Conflicts of interest: Disclosure of financial and nonfinancial conflicts of interest for members of the guideline development group
7	Decision-making process: The method to develop the guideline: (a) Informal consensus conference or working party (b) Formal consensus: Expert panel in compliance with appropriateness ratings (c) Evidence-based: Linked to the quality of scientific evidence (d) Explicit method based on the evidence-based approach (e) Synthetic method: Preparing a draft by one specialist and one general practitioner, review by the editorial panel, circulation for comments by local doctors to create a refined version for printing and implementation
8	The causal pathway of the guideline: An explicit method describing the use of evidence to establish effectiveness, outcomes, and adverse consequences of interventions
9	Defining questions to be answered to reach recommendations, types of evidence, and relevant information for analysis
10	Literature retrieval and review; using systematic review methods to identify and evaluate evidence related to the guideline topic
11	Trade-offs to balance benefits and harms of recommendations
12	Wording recommendations: Clarity and precision, use of direct, specific terms, clear and concise statements, in active voice Avoid using vague, nonspecific words and passive voice
13	Rating of evidence and recommendations based on established hierarchies by the Canadian Task Force of the Periodic Health Examination (CTF-PHE), the United States Agency for Health Care Policy and Research (AHCPR), or the United States Preventive Services Task Force (USPSTF)
14	Disclosure of uncertainties in recommendations and algorithms including lack of scientific evidence, expert opinion, special clinical circumstances
15	Addressing physicians' confidence in the correctness of guidelines, tailoring, or customization
16	A clear strategy of implementation including population to be benefited, reminders for physicians and patients, quality improvement strategies to reduce clinical and managerial discordances
17	Dissemination and learning, ascertainment that the guideline reaches the users who will learn from it and practice accordingly
18	Peer review and stakeholder consultation: Internal and external evaluation by experts, professional societies, government organizations, consumers, health management organizations, insurers, clinicians. Monitoring of intermediate and long-term clinical outcomes
19	Effects on quality of health: Number of patients receiving process measures, achieving outcome measures, cost-effectiveness, patient satisfaction
20	Regular review and updating or expiration
21	Feasibility and sustainability: Long-term likelihood to operate "in the real world"
22	Strategies to enhance implementation, identification of barriers; anticipative solutions, formats, and channels for dissemination, adaptation of educational resources
23	Financial support and sponsoring organization

resulting from perceived conflicts with clinical freedom; divisive, individualistic personalities; poor planning; lack of resources; and the absence of strategies to change practitioners and patients' behavior [22, 71–80]. Guidelines do not implement by themselves (or by decree!) [73]. Publishing a guideline is not enough to produce sustained changes in clinical management [81]. Weingarten stated that "a well-intentioned society puts together a wonderful guideline…they publish it in a journal, and that's where it ends [82]." Implementation requires time, enthusiasm, and resources. There is no single effective way to ensure their use in practice, dissemination, and implementation requires multifaceted interventions [81].

Low rates of adoption of internationally praised guidelines for chronic diseases like diabetes exemplify the complexities of implementation. Profiling (identifying the right person willing to implement a clinical guideline) and detailing (training, support, and follow-up) are still essential. In 1992, Grol described a series of views to change behavior [73]:

- Awareness about their existence, interest, and commitment
- Understanding its purpose and contents, recognizing personal gaps or deficiencies, and the need to change and improve
- A positive attitude; confidence in performance and success
- Initial and sustained implementation "in the real world," identification and addressing barriers and obstacles [73]

Table 23.2 Approaches to changing clinical practice

Approach	Theories	Focus	Strategy and interventions
Internal processes	Adult learning	Intrinsic professional motivation	Local consensus Interactive learning in small groups Problem-based learning
Epidemiologic	Cognitive	Information seeking, decision-making	Evidence-based guideline development Disseminating research findings through courses, mailing, journals
Marketing	Health promotion, innovation, social marketing	Adapt to the needs of target audience	Needs assessment adapt change proposals to local needs Stepwise approach Dissemination through diverse channels (mass media, personal)
Behavioral	Learning	Control by external stimuli	Audit and feedback Reminders, monitoring Economic incentives, sanctions
Social interaction	Social learning and innovation, based on social influence/power	Influence of significant peers/role models	Peer review in local networks Outreach visits, individual instruction Opinion leaders Key people in social networks Patient-mediated interventions
Organizational	Management and system	Structural and organizational conditions to improve care	Reengineering the process of care Total quality management/continuous quality improvement Team building Enhancing leadership Change structures, tasks
Coercive	Economic power and learning	Control and pressure, external motivation	Regulations, laws Budgeting, contracting Licensing, accreditation Complaints/legal procedures

Adapted from Grol [90]

An extensive review about implementation of CPG in pulmonary medicine addressed the complexities of physician's behavior and the influence of background, ethics, beliefs, and exposure to countless formal and informal guidelines as part of professional training [81–92]. One of these articles stated that (1) education in small doses is ineffective, because it pales in comparison with previous years or decades of physician education; (2) traditional methods of passive dissemination are unsuccessful to effect behavior change; (3) multiple strategies are more effective than isolated interventions; (4) implementation "by decree" doesn't work; (5) reminders have shown to be effective; and (6) disregard of situational and environmental factors, structure, and process deficiencies in health care and the delusion that guidelines by themselves "will improve the situation" are very frequent [84].

Grol and colleagues published a classical report about professional barriers to implement CPG in which they described approaches to change physician behavior (Table 23.2) [93]:

In their conclusions, they stated that "when people are planning changes, they often adopt a naïve and opportunistic attitude…a strategy is usually chosen quickly and often does not produce the expected results…our understanding of the crucial processes determining whether change will be achieved is still limited [93]."

CPG and Implementation Science

Despite the limited impact and the waste of time and resources of national standards, norms, regulations, and traditional methods of continuing medical education, consensus conferences, these faulty strategies are still preferred and supported [94]. Development, implementation, and evaluation of national CPG are complex tasks. Local adaptation and effective implementation are keys to success [95]. Gagliardi and colleagues developed and implemented a format that would influence the use of CPG and examine their contents and dissemination [96]. They found that encouraging their use involves:

1. Easy access
2. Authorship familiarity and trustworthy
3. Short and concise recommendations

4. Additional tools such as checklists, standard orders, summaries, algorithms, diagrams, color-coded tabs, pocket cards
5. Printed and electronic formats
6. Strong supporting evidence
7. Flexibility of recommendations to the local context
8. Suitability to patient's needs and preferences; auxiliary documents for patients such as leaflets
9. Clinical vignettes describing patient needs and preferences
10. Explicit resource implications
11. Tools to collect evaluative data [96]

In 2013, Grol and colleagues published a review about the effects of implementation on quality of health care [97]. In the basic principles of their landmark book, they stated that changes in organization of institutions or practices are very important, but improvement of agents of change, including doctors and health professionals, is essential to improve the quality of health care [97]. In 2017, the American College of Cardiology and the American Heart Association reviewed the evidence from the published implementation science literature to identify enhancing the adoption and implementation of clinical practice guidelines and established three categories to characterize the effectiveness of interventions [98]:

1. Generally effective for which more than two thirds of reviewed studies had positive intervention results.
2. Mixed effectiveness, in which one third to two thirds of studies showed positive effects.
3. Generally ineffective, of which less than one third of reviewed studies showed positive effects.

The overall effectiveness of four types of interventions included in 55 systematic reviews and overviews analyzed in the study was as follows [98]:

- Educational outreach visits: generally effective for both process of care and clinical effectiveness.
- Audit and feedback: generally effective for both process of care and clinical effectiveness.
- Reminders: mixed effectiveness for process of care and general ineffectiveness for clinical outcomes.
- Provider incentives: mixed effectiveness for both.
- Modified from [98].

The authors conclude that guideline implementation interventions are effective for both process of care and clinical outcomes, albeit limitations persist about their effectiveness at reducing costs [98]. Additional research and evidence about implementation in the real world are essential.

Crossing the Professional Abyss

Despite the enthusiasm behind the creation of countless CPG, a large level of unwarranted variation in clinical practice persists even when guidelines based on reputable evidence are available [99]. CPG frequently do not affect clinical practice or health outcomes. A national survey of a random sample of members of the American College of Physicians showed that although physicians recognized their potential benefits, many were concerned about their possible effects on clinical autonomy, healthcare costs, and satisfaction with clinical practice [100]. Many physicians argue that CPG are being used for cost containment, instead, to improve the quality of care [95, 101]. The potential inability of guidelines to be translated to clinical practice undermines their role as strategies for quality improvement, cost containment, and health system reform [101].

Multiple studies have confirmed the lack of adherence to CPG by physicians and their failure to change clinical practice [102]. Frolkis and colleagues showed that physicians are poorly compliant with CPG for cholesterol control even in patients at high risk of coronary heart disease [103]. Only 50% of the time they requested LDL cholesterol measurements, and screening for additional cardiovascular risk factors (hypertension, smoking, diabetes) was suboptimal, and many patients remained untreated [103]. In a similar recent report, Arnold et al. described the use of evidence-based therapies for secondary prevention in a large US cohort of patients with prior myocardial infarction and high levels of LDL cholesterol who were treated by cardiologists (46%), primary care physicians (45%), and other specialists (9%) [104]. Among 1546 patients, the authors identified "a number of concerning gaps in secondary prevention," and prescription rates are high at discharge, but the intensity of preventative therapies tended to wane over time because of a combination of clinical decisions and patient nonpersistence [104]. Choudry and associates showed an inverse relationship between the number of years in clinical practice and quality of care: more experience is not associated with better clinical outcomes [105]. Implementation is low, professional compliance is inadequate, and long-term follow-up is limited [106–109]. Despite these shortcomings, decisive, clear-cut guidance about the successful implementation of CPGs is "surprisingly little," and the knowledge gap regarding the effectiveness of CPGs on patient outcomes is substantial [110]. If patients will benefit from the results of clinical trials, the existing gap (or abyss) between evidence and clinical practice must be reduced. Unfortunately, multiple weaknesses occur at this stage [109]. Medical factors or barriers reducing adoption or compliance with CPG include [111–114]:

1. Disregard by physicians and health professionals expected to implement them, lack of familiarity or awareness
2. The conservative nature of physicians, including the innovation itself, communication channels, length of time, and characteristics of members of the social environment
3. Individualistic physician judgment resulting in:
   (a) Lack of agreement with specific guidelines
   (b) Lack of agreement with guidelines in general
   (c) Lack of outcome expectancy
   (d) Lack of self-efficacy
   (e) Lack of motivation, clinical inertia
4. Autonomous groups reluctant to introduce innovations or improvements
5. Wandering teams, loss or absence of leadership
6. Overemphasis on the guideline and failure to consider implementation
7. Deficiencies in implementation, poor planning, or communication
8. Deficiencies of healthcare systems
9. Fragmented information, fragmented groups, or institutions
10. Lack of time, poor allocation of resources, lack of resources
11. Patient factors
    (a) Changes in clinical status
    (b) Patient preferences
12. Plain refusal, "loose cannons"
13. Undetermined reasons

Adoption of CPGs depends on (1) awareness and knowledge about their existence; (2) agreement and self-efficacy; (3) complexities in structure and process; (4) frequency of reminders; (5) self-reported effect in personal versus actual performance and outcomes, measurable improvements in quality of health care; (6) incentives; and (7) removal of disincentives [100, 115–118]. To succeed, physicians, health professionals, and institutions must participate actively in the development of guidelines and commit to their use, and patients should be aware and willing to follow their recommendations [117]. Their main potential benefit is their capacity to improve the outcomes of medical care through intermediate steps of changing knowledge, attitudes, and behavior. Adherence to CPG involves a dynamic process influenced by multiple contextual factors, including barriers and facilitators previously discussed [117].

The development of CPG has become crucial. They are familiar components of clinical practice, but they also have potential benefits and harms [118, 119]. Rigorously developed, evidence-based guidelines minimize potential harms and improve the quality of health care [119]. The worldwide interest is based on a series of challenges to healthcare systems: (1) increasing demand and costs of technologies and treatment; (2) lack of applicability to address relevant issues of clinical practice included comorbidities, safety, and risk management; multidisciplinary collaboration; effect on costs or compliance; and patient self-care; (3) persistence of unwarranted variations in clinical practice; (4) clinical inertia, the fact that even when evidence is available, final recommendations often reflect personal opinions, local culture, or vested interests of developers or sponsors; and (5) the intrinsic desire to offer the best possible care [119, 120]. Expectations on their impact depend on the variety of people involved in their implementation including clinicians, patients, payers, administrators, and politicians, but their main goal is still to improve the quality of care [121]. Their main potential risk is to be inaccurate or erroneous, with resulting harms to patients and everyone [119]. CPG are criticized when they become "cookbook recipes" in disregard of the variability of clinical situations [119, 122, 123]. In addition of their use to assess clinical effectiveness, CPG also have ethical consequences: either as instruments to direct medical ethics or because their coercive enforcement for other reasons than the patients' benefit [124, 125]. Beyond their increase, CPG have not eclipsed traditional paradigms based on individual expertise [126, 127]. Guidelines are important to improve patient care, but innovations are essential to make them relevant and effective [126]. "Without these changes, they will be seen as expensive but unhelpful and ineffective toys for a happy few [120]."

Evidence-Based Medicine and CPG

> "Evidence from modern research has a lot to say about the management of diabetes mellitus"
> R. Brian Haynes and Hertzel C. Gerstein [127]

Changing Approaches of Diabetes Guidelines

Two pathways converged in the ascent of CPG for diabetes management: the surge of CPG in the 1980s and the collection of evidence with the mega-trials on secondary prevention. In 1989, the American Diabetes Association (ADA) published the first version of its "Standards of Medical Care for Patients with Diabetes Mellitus" which over three decades has become the most highly referenced [128]. The first edition of the ADA's standards included basic medical care for the initial visit, continuing care, intercurrent illness, special considerations for hyperglycemic crises, hypoglycemia, pregnancy, hypertension, chronic complications and foot care, and a brief comment for children and adolescents [128]. Management in pregnancy and in the elderly was not included [128]. Three years later, the Expert Committee of

the Canadian Diabetes Advisory Board published its clinical practice guidelines for the treatment of diabetes which were more extensive, included definition and classification, and a list of patient-centered goals of care [129]. Besides glycemic targets, the 1992 Canadian diabetes guidelines established the following goals: (1) alleviation of symptoms, (2) prevention and treatment of acute and long-term complications, (3) promoting self-care, (4) treating accompanying disorders, (5) quality of life improvement, and (6) reducing morbidity and mortality associated with diabetes [129]. The Canadian guideline emphasized the responsibilities of primary care physicians to diagnose and help patients to attain goals, educate, and motivate them and coordinate care and referrals [129]. It included explanations about diagnosis and management in adults, children, and adolescents; the elderly; native Canadians; and pregnancy become the first guideline presenting a comprehensive, patient-centered approach to diabetes care [129].

Evidence-Based Medicine and Diabetes Guidelines

The first version of a grading system for clinical recommendations appeared in the first report of the Canadian Task Force (CTF) on the Periodic Health Examination in 1979 [130]. Starting in 2002, the American Diabetes Association Standards of Medical Care included a grading system modeled "after existing methods" which were not described in the text [131]. Within its natural chronological evolution, the Canadian Task Force grading system became a benchmark to establish three major categories of evidence to assess the effectiveness of interventions [129]:

- I or A: Evidence obtained from randomized controlled trials
- II or B: Evidence obtained from cohort studies
- III or D: Opinions of respected authorities, clinical experiences, descriptive studies or expert consensus

In which I, II, and III refer to the CTF, ABD represents the ADA grading systems. The ADA included a C level for evidence obtained from poorly controlled or uncontrolled studies [131].

Evolution of Diabetes Guidelines

After three decades, diabetes guidelines expanded their scope and aligned in methodology. Management of hyperglycemia continued to be a priority, as reflected in the highly referenced algorithm published by the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) [132]. The ADA/EASD algorithm established a "general" glycemic goal below 7.0% based on the results of benchmark controlled clinical trials, like the Diabetes Control and Complications Trial (DCCT), the Stockholm Diabetes Intervention Study, the UK Prospective Diabetes Study (UKPDS), and the Kumamoto Study, which demonstrated that decreasing glycemia effectively reduced microvascular and neuropathic complications [133]. The ADA/EASD algorithm included a brief discussion about lifestyle interventions and a detailed review of the antidiabetic drugs available in the United States, Canada, and Europe, one algorithm to initiate and adjust insulin regimens, and another "for metabolic management" with focus on pharmacologic alternatives to achieve A1c goals [133]. The 2009 version of the ADA/EASD algorithm and recent guidelines from other countries maintain glycemic control as the main goal. Table 23.3 presents glycemic targets for adults with type 2 diabetes from several highly referenced institutions [134–140]:

Patient-Centeredness and CPG

In 2012, the ADA and the EASD updated their position statement to recognize that glycemic control needs to be pursued within a multifactorial reduction framework and that aggressive management of cardiovascular risk factors would have more benefits [141]. Based on the results of the Action to Control Cardiovascular Risk in Diabetes (ACCORD) [142], the Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified-Release Controlled Evaluation (ADVANCE) [143], and the Veterans Affairs Diabetes Trial (VADT) [144] showing that not everyone benefits from aggressive glucose management, the 2012 ADA/EASD position statement stressed the importance of individualizing treatment targets [141]. Glycemic targets could be more stringent in newly diagnosed, highly motivated, resourceful adherent patients with excellent self-care capabilities, low risk of hypoglycemia, long life expectancy, absence of comorbidities, and vascular complications, while less stringent efforts should be applied to less motivated, non-adherent patients with poor self-care capabilities, high risk of hypoglycemia, long-standing disease, short life expectancy, severe comorbidities and vascular complications, and limited resources [141]. Clinical decisions should also address patients' values and desires [141]. In the following year, the ADA convened an expert forum to discuss the concept of personalized medicine in the wake of the 2012 ADA/EASD position statement [145]. The authors recognized that patients' preferences, life expectancy, disease duration, comorbidities, socioeconomic status, and cognitive abilities play a role in the selection of therapeutic

Table 23.3 Targets for glycemic control for adults with type 2 diabetes

Year	Organization and reference	HbA1c	Fasting or preprandial blood glucose	Postprandial blood glucose
2017	International Diabetes Federation [129]	<7.0%: A target between 7.5% and 8.0% may be appropriate Patients using multiple medications, with reduced life expectancy, cognitive impairment, chronic kidney disease, severe cardiovascular disease or multiple comorbidities: Values above 8.0% are unacceptable		
2018	American College of Physicians: Clinical Guidelines Committee [130]	1. Personalize goals for glycemic control based on benefits and harms of pharmacotherapy, patients' preferences, general health, life expectancy, treatment burden, and costs of care (a) Aim to achieve an A1c level between 7.0% and 8.0% in most patients (b) Consider de-intensifying pharmacologic therapy in patients achieving A1c levels <6.5% Minimize symptoms of hyperglycemia, avoid targeting an A1c level in patients with reduced life expectancy, living in nursing homes, or with severe chronic conditions	NA	NA
2018	Diabetes Canada [131]	<6.5%: To reduce the risk of chronic kidney disease and retinopathy if at low risk of hypoglycemia ≤*7.0%*: *Most adults with type 1 or type 2 diabetes* 7.1–8.5%: *Functionally dependent: 7.1–8.0%* Recurrent severe hypoglycemia and/or hypoglycemia unawareness: *7.1–8.5%* Limited life expectancy: *7.1–8.5%* Frail elderly and/or with dementia: *7.1–8.5%* *Avoid higher HbA1c to reduce the risk of symptomatic hyperglycemia and acute and chronic complications*	70–126 mg/dL	90–180 mg/dL
2020	National Institute of Clinical Excellence NICE UK [132]	Adults managed by lifestyle and diet or lifestyle and diet combined with a single drug not associated with hypoglycemia: 6.5% Adults on a drug associated with hypoglycemia: 7.0% Consider relaxing the HbA1c target on an individual basis Particular consideration for the elderly and frail with reduced life expectancy, and for people at high risk of the consequences of hypoglycemia including: Risk of falls Impaired awareness of hypoglycemia Operators of machinery Significant comorbidities Encourage patients who achieve lower HbA1c levels without experiencing hypoglycemia to maintain them	NA	NA
2020	American Association of Clinical Endocrinology [133]	Patients without concurrent serious illness and low hypoglycemic risk: ≤6.5% Patients with concurrent serious illness and at risk for hypoglycemia: >6.5%		
2020	Joslin Diabetes Center [134]	For most patients to reduce the risk of long-term complications of diabetes: <7.0% Alternative goals may be set based upon the presence or absence of microvascular and/or cardiovascular complications, hypoglycemic unawareness, cognitive status, and life expectancy For patients with long-standing type 2 diabetes, preexisting cardiovascular disease or high coronary artery risk, revisit goals to avoid adverse consequences including hypoglycemia	80–130 mg/dL	<180 mg/dL
2021	American Diabetes Association [135]	Patients without concurrent serious illness and at low hypoglycemic risk: ≤6.5% Patients with concurrent serious illness and at risk for hypoglycemia: >6.5% Pregnant women without significant hypoglycemia: <7.0% If using ambulatory glucose profile: Time in range: >70% Time below range: <4% Less stringent goals <8% for patients with limited life expectancy or if harms of treatment are greater than benefits	<130 mg/dL	<180 mg/dL

options and targets and concluded that "one size does not fit all" and patient-centered care and standardized algorithmic management are conflicting approaches but that they can be made more compatible by recognizing instances in which personalized HbA1c targets and clinical circumstances requiring co-management by primary care and specialty clinicians are warranted [145]. From this approach, HbA1c targets range from <7.0% in healthy, motivated, and resourceful patients to 7.5–8.5% in patients with social and educational issues, comorbidities, and complications [145]. Trends to recognize the preeminence of persons with diabetes in the outcomes started changing a paradigm that until recently was focused on glycemic targets and selecting the right medication regardless of costs that even the best candidates from the clinical standpoint are unable to pursue or cannot afford.

The Evidence Behind Diabetes Guidelines

During the last three decades, the importance to address all the components of CPG, including validity, reliability, reproducibility, clinical applicability, clarity, multidisciplinary process, review, and documentation, has been emphasized [146]. Guidelines had to adhere to increasingly tougher standards of transparency and objectivity and to adopt consistent formats to make them accessible for clinicians and patients [147]. These requirements are essential to guarantee that they are trustworthy because they set the standard for medical practice, influencing clinical decisions about patients, practice measures, coverage, and reimbursement [148]. Two pathways converged to establish the reliability of CPG: the AGREE II instrument [149, 150] and the Institute of Medicine standards for trustworthiness of clinical practice guidelines [30]. As in other clinical disciplines, diabetes guidelines have been carefully reviewed and appraised [188, 191, 192]. Reviews by Mülhauser and Meyer [146] and Vigersky [151] showed that:

1. Diabetes guidelines have lower scores compared with guidelines about other chronic diseases.
2. Diabetes guidelines show substantial variations in methodological quality.
3. The role of evidence versus expert opinion remains obscure in most diabetes guidelines.
4. Multiple algorithm complexities including (a) lack of evidence about selected HbA1c cutoff points, (b) lack of evidence about the effectiveness of starting triple therapy in disregard of the risk of drug interactions, (c) underestimation of the effectiveness of lifestyle interventions, (d) rapid obsolescence, and (e) disregard of out-of-pocket costs and the near equivalent effectiveness of most classes of therapeutic agents.
5. Absence of peer review. According to the ADA, "once written by the panel, a consensus statement is not subject to subsequent review and does not represent the official Association opinion."
6. The most reputed diabetes guidelines fell short of the idea in key respects including grading of evidence, complexity of algorithms, stratification of patients, disregard of costs, inflexible glucose targets, absence of peer review, and conflicts of interest.

Quality of Evidence of Diabetes Guidelines

In 2015, the ADA stated that 51% of the recommendations supporting their standards of medical care were based on higher-level evidence, and nearly half of recommendations were still of lower level [152]. Two recent systematic reviews confirm this statement [153, 154]. Bouchonville and colleagues reviewed all clinical trials with hard cardiovascular (CVD) endpoints cited in the 2016 ADA guidelines and additional studies to analyze CVD endpoints that were omitted in the ADA guidelines [153]. Analysis of 42 studies showed limitations to interpret the available evidence about the impact of glycemic control on CVD and mortality [153]. The authors state (1) that it is difficult to ascertain to what extent the reported benefits of glycemic control might be attributable to specific lowering agents or to additional reductions in blood pressure and body composition; (2) observation time of many of these studies is insufficient to draw conclusions about CVD events and mortality; and (3) current multifaceted standards for CVD reduction introduce confounding to control groups when endpoints are affected by other factors independent of glycemic control [153]. In their recommendations, the authors state that "while treatment of individual risk factors in isolation is not associated with proven benefits…treatment of multiple risk factors improves CVD outcomes in people with diabetes [153]". Kruse and Vassar performed a systematic review to analyze their Fragility Index (FI) and the Fragility Quotient (FQ) of all the randomized controlled trials referenced in the 2017 ADA Standards of Medical Care [154]. The results of 35 out of 172 analyzed studies showed low risks of bias, overall low robustness, and modest FI and FQ levels; this means that only 16 events were required to reverse the significance of a given result [154]. Loss of follow-up is also important: lost participants may have provided enough data to sway the statistical signifi-

cance of the trials, rendering the result nonsignificant [154]. Their conclusion is compelling: simply collecting the data on participants who were lost to follow-up could alter not only the results of the study but ultimately *the recommendations guiding treatment* [154]. "If we truly aspire to bring evidence based rather than authority-based medicine to clinical decisions, CPG must be the product of explicit, rigorous, scientific processes; few are" [155]. Most recommendations intended to optimize diabetes care are still developed by consensus-based panels that move us back toward authority-based medicine [155].

Conflict of Interest, Magnitude, and Consequences

Of all these issues, probably conflict of interest is the most common. In a review of disclosures, 100% percent of members of the AACE guideline group had conflicts of interest in 2011, compared with 83% in 2010. A similar review showed that 100% of the ADA/EASD had conflicts of interest in 2011 compared with 83% in the previous year [156]. To address this situation, Bennett and colleagues published a systematic review to assess whether guidelines about oral antidiabetics are consistent with current evidence and if consistency of guidelines depends on the quality of guideline development [156]. Two reviewers screened citations to identify English-language guidelines on oral medications for type 2 diabetes in the United States, Canada, and the United Kingdom [156]. The authors assessed if diabetes guidelines addressed and agreed with seven evidence-based conclusions and independently rated their quality using the AGREE instrument (Box 23.1) [157]. The results showed that: (1) 11 out of 1118 guidelines met the inclusion criteria; (2) only 3 were peer reviewed, (3) most of them made recommendations based on combinations of expert opinion and literature review; (4) the rigor of development using AGREE summary scores ranged from 0% to 100%; (5) the risk of bias using the AGREE independence domain items showed summary scores ranging from 8.3% to 100.0%; (6) 6 of the 11 guidelines reported conflicts of interest among guideline development members; and (7) guidelines with lower editorial independence scores had also lower rigor of development scores, whereas those with higher quality scores scored higher in both domains [156]. Brems et al. conducted a retrospective review of conflict of interest (COI) policies from organizations that published five or more CPGs between January 2018 and December 2019, and they found that 67% violated the COI standard [157]. Conflict of interest jeopardizes the validity of CPG and is still highly prevalent [157].

Box 23.1 Items of the AGREE II Instrument

Domain	Item or question
Scope and purpose	1. The objectives of the guideline are specifically described 2. Health questions specifically described 3. The population to whom the guideline is meant to be applied is specifically described
Stakeholder involvement	4. The guideline development group includes persons from all the relevant professional groups 5. Views and preferences of target population have been pursued 6. Target users of the guideline are clearly defined
Rigor of development	7. Evidence obtained by systematic methods 8. Criteria for selecting evidence clearly described 9. Strength and limitations of evidence clearly described 10. Methods for formulating recommendations clearly described 11. Health benefits, side effects, and risks considered in the recommendations 12. Explicit link between recommendations and supporting evidence 13. External peer review before publication 14. Updating procedure
Clarity of presentation	15. Specific, nonambiguous recommendations 16. Management options clearly described 17. Key recommendations easily identifiable
Applicability	18. Facilitators and barriers to implementation 19. Advice and/or tools to put into practice the recommendations 20. Potential resource implications 21. Monitoring or auditing criteria
Editorial independence	22. The guideline is not influenced by the views of the funding source 23. Competing interests of guideline group members recorded and addressed
Guideline assessment	24. Overall quality rating 25. I would recommend it

Modified from [158]

The Quest for Quality in Diabetes Guidelines

The AGREE Instrument has become the gold standard to appraise the quality of clinical practice guidelines for many disciplines, including type 2 diabetes [158]. Anwer and colleagues assessed the quality of type 2 diabetes guidelines using the AGREE II Instrument [159]. The final analysis included seven guidelines and showed that the two domains with highest scores were (1) scope and purpose and (4) clarity of presentation. Dominion 3, rigor of development, scored high in three guidelines, and dominion 3, applicability (implementation), scored high in three guidelines, and six guidelines declared editorial independence. Overall, one

guideline was recommended without changes, and six were recommended as long as they were modified according to the healthcare context in which they would be implemented [159]. The study confirmed the need of clinicians to recognize high-quality, trustworthy diabetes guidelines among the huge amount of available guidelines and the importance of the AGREE II Instrument in their design [159]. To support these claims, Ng and Verma assessed the quality of diabetes CPGs, and they found that the scaled domain percentages from highest to lowest were clarity of presentation (81.2%), scope and purpose (77.1%), stakeholder involvement (52.8%), applicability (42.9%), rigor of development (41.5%), and editorial independence (35.1%) [160]. The methodological quality of diabetes guidelines continues to be disappointingly low and needs to be improved for the benefit of all clinicians, stakeholders, and patients [161]. At the global level, these shortcomings have also been documented. The evaluation of quality of 17 diabetes GPGs from Europe, Canada, the United States, Australia, and Latin America by Barcelo et al. showed that ten guidelines scored ≥70% according to the AGREE II instrument, and seven guidelines scored ≥80%, with a wide range from 21% for the guideline authored by Nicaragua's Ministry of Health to 100% for the guideline developed by the National Institute of Clinical Excellence in the United Kingdom [162]. Further improvements are required in the development of CPGs to improve their effect on quality of diabetes care [162].

Diabetes Guidelines and the Real World

High-quality diabetes guidelines and evidence-based medicine are not a guarantee to improve clinical practice. Adherence rates to diabetes guidelines and clinical inertia among physicians continue to be very low 20 years after it was addressed by El-Kebbi and colleagues [163]. Less than 50% of patients treated by general physicians receive eye examinations, electrocardiograms, HbA1c measurements, and microalbuminuria screenings [164]. Wide gaps in the awareness about their existence, acceptance, and adherence prevail, resulting in wide variations of care, not just from region to region, but between primary and secondary care, even in the same region [165]. Variation in the use of CPGs diabetes ranges from 86 to 90% in Australia and Greece to 10–17% in Nigeria and Mexico [166–169].

Despite positive attitudes toward guidelines, their use is limited; only one third of clinicians report using them often or very often [170, 171]. Disconnection between primary care physicians' perceptions about the use of diabetes guidelines has extensive negative effects on clinical practice and referrals to diabetes self-care education programs [171]. Even at teaching hospitals, treatment targets for HbA1c, blood pressure, and LDL cholesterol are frequently not met [172]. Noncompliance with CPGs is as high as 70% and occurs across disciplines and countries [173]. Even in countries with longstanding traditions in the design and implementation of clinical guidelines like the Netherlands, 35% of primary care physicians reported difficulties in changing personal routines and 6% admitted to being resistant adhering with clinical guidelines [174]. Arguments to explain physician noncompliance with CPG include lack of awareness, complexity, disagreement with contents, overconfidence, time pressures, difficulties to change clinical practice, and fragmentation of care [174]. On the other hand, adherence to diabetes guidelines by patients is very low [175, 176]. Patients and their familiar circumstance are decisive for the success of GPGs but paradoxically they are usually unaware about their existence. Shared decision-making and mutual agreement is the desired endpoints of CPGs implementation [110]. It occurs when patients and their healthcare providers make joint decisions about healthcare interventions based on the best evidence and supported by preferences, values, clinical judgment, and local context [110]. To increase the effectiveness of diabetes guidelines, patients' values and beliefs should not be underestimated [177].

Strategies to implement and improve adherence to diabetes guidelines involve multifaceted interventions directed to practitioners, health professionals, and patients such as audit, feedback, training, and problem-based learning [178–180]. In combination, these interventions have shown significant improvements in adherence to diabetes guidelines and the process of diabetes care. Advances in the implementation of diabetes guidelines have been achieved mainly in Australia, the United States, and Europe [166, 167, 181]. Challenges persist in most other regions largely due to deficiencies in health systems which negatively impact adherence and implementation [182]. Hashmi and Khan described and classified factors affecting the implementation and adherence to diabetes guidelines including (a) factors related to the intrinsic attributes of the guidelines (validity, reliability, applicability) and the process of implementation (dissemination to stakeholders), (b) physician-related factors (attitude, motivation, training, incentives, coordination, goal setting), (c) patient-related factors (disease-related comorbidities, health beliefs, anxiety, depression, diabetes distress, relationship with providers and medical systems, economic constraints, refusal), and (d) health system factors (infrastructure, financial resources, policies, organization setup) [182].

In support of this statement, Owalabi et al. carried out a systematic review to compare type 2 diabetes guidelines in low- and middle-resource countries (LMIC) versus high-income countries (HIC), and they found that most LMIC guidelines were inadequate in terms of applicability, clarity, and dissemination plan, as well as socioeconomic and ethical context [183]. LMIC guidelines are mainly targeted to health professionals, and only the minority includes patients (7%), payers (11%), and policy-makers (18%)

[183]. Most guidelines from LMIC comply with less than half of the IOM standards [183]. Beyond their usefulness as reminders to prescribe medications, diabetes clinical guidelines will have to change their approach to improve outcomes.

Beyond Glycemic Targets and the Role of Patients

Diabetes outpatient management is complex and goes beyond glycemic targets. The analysis of the Steno-2 study confirmed that intensified multifactorial intervention is more effective to slow progression of retinopathy, nephropathy, and neuropathy; macro- and microvascular events; and cardiovascular and overall mortality; increases median life length over 22 years follow-up; and is more cost-effective than conventional treatment in terms of life-years gained and health benefits [184–189]. Resources for self-monitoring of blood glucose and communication technologies for patient coaching and support are valuable tools to intensify and adjust diabetes management. By comparison, type 2 diabetes management algorithms establish rational sequences for introducing, adjusting, or intensifying pharmacologic alternatives, reinforcing the need to wait and contributing to clinical inertia [190]. One key barrier to treatment intensification is lack of communication between patients and physicians that would allow patients to understand the consequences of diagnosis and engage in treatment [182, 191]. Despite the recognized role of patients in the outcomes, their involvement in guidelines is poor; information about lifestyle changes; and diabetes education and nutrition counseling are scarce or absent in type 2 diabetes guidelines [192, 193]. The third standard of the Institutes of Health emphasizes that guideline development groups should include populations impacted by the guideline and states that "patient and public involvement should be facilitated by including a current or former patient and a patient advocate or patient/consumer organization representative on the guideline development group [191]".

The Role of Comorbidities

The ascent of comorbidities in persons with diabetes is increasingly frequent, and feasible strategies have to be implemented. Some, like cancer or heart failure, are clearly dominant and influential over every aspect of diabetes care and life expectancy [194]. The importance of comorbidities has been recognized and recently discussed in diabetes guidelines [195]. Until recently, diabetes guidelines have targeted the disease in isolation. Single-disease CPGs are not designed to consider patients with multiple chronic conditions or multi-morbidity, and the alternative of applying multiple CPGs to a single patient is time-consuming, costly, and disruptive [196]. In caring for people with comorbidities, it would be more helpful to develop guidelines that summarized and cross-reference all the possible recommendations to a particular patient beyond and in addition to medications [195, 197]. To address these challenges, precision medicine is an innovative, appealing approach [197, 198]. With precision medicine, doctors and health professionals adopt more accurate treatment and prevention strategies and consider individual differences instead of the one-size-fits-all approach [197]. Precision health care involves patient care preferences, patient-oriented care, evidence-based care and self-management, and the building blocks of diabetes success [197].

Comorbidities will become more frequent as the population ages and survival from acute disease improves [195]. Developing diabetes guidelines has become increasingly challenging: treatment algorithms need to be personalized and comprehensive at the same time; the traditional glucose-centered approach is disconnected with the realities and demands of clinical practice [199]. Although seemingly impossible, new approaches have shown that it is feasible to create personalized, down-to-earth CPG for type 2 diabetes [200]. The CPG Committee of the American College of Physicians (ACP) and the US Department of Defense recently presented two innovative approaches: instead of glycemic targets, the first statement of the ACP guidance recommends that "clinicians should personalize goals for glycemic control on the basis of a discussion of benefits and harms of pharmacotherapy, patients' preferences, patients' general health and life expectancy, treatment burden and costs of care" [201]. Addressing these usually "invisible" factors is decisive to at least explore the possibility that patients will accept and adhere to clinical recommendations. The clinical guideline of the US Department of Veterans provides a detailed algorithm in which before deciding the first pharmacologic alternative, glycemic control should take into consideration the patient's age, reproductive status, comorbidities (including an extensive list of the most important), adverse effects and contraindications of medications, history of severe hyper or hypoglycemia, social determinants of health, and providing diabetes education "that patients understand" [201]. Moving forward, the consensus report for Management of Hyperglycemia of the American Diabetes Association and the European Association for the Study of Diabetes provides a patient-centered decision cycle involving (1) assessing patient characteristics, (2) specific factors that impact choice of treatment, (3) shared decision-making to create a management plan, (4) agree on management plan, (5) implementing the management plan, (6) ongoing monitoring and support, and (7) review and agree on the management plan with patients [132].

Conclusions

Traditional ABCs of management (A1c, blood pressure, cholesterol) should also include additional essential elements of care: (D) diabetes education, (E) eye examinations, (F) foot examination, (G) glucose monitoring, (H) health maintenance, and (I) indications for special care [202]. Traditional diabetes guidelines stress that patients should receive health care from interdisciplinary teams including physicians, nurse practitioners, physician assistants, nurses, dietitians, exercise specialists, pharmacists, dentists, podiatrists, and mental health professionals, and patients must assume an active role in their care. Fulfilling these recommendations escapes the realities of everyday diabetes care, even in developed, more resourceful countries like Switzerland, where 32% of patients with type 1 diabetes and 44% achieve A1c levels below 7.0% and low levels of LDL cholesterol [203]. Implementing diabetes guidelines is still the big challenge, the gap, or the abyss to achieve their expected results in the real world; even high-quality CPGs have room for improvement in terms of implementation [204]. Continuing support for implementation of diabetes guidelines among primary care practitioners is essential to improve the perspectives and reduce the suffering of the increasingly large number of persons with diabetes. In conclusion, room for improvement for diabetes clinical guidelines is everywhere [205, 206].

Multiple Choice Questions

1. According to the American Diabetes Association guideline, the goal for HbA1c levels in patients with type 2 diabetes is:
   (a) <6.0%
   (b) <6.5%
   (c) **<7.0%**
   (d) <7.5%
   (e) <8.0%
2. According to the American Association of Clinical Endocrinologists guideline, the goal for blood pressure in patients with diabetes is:
   (a) ≤140/90 mmHg
   (b) <140/80 mmHg
   (c) <130/90 mmHg
   (d) **<130/80 mmHg**
   (e) <120/80 mmHg
3. According to the Joslin Guideline, the goal for LDL cholesterol in patients with type 2 diabetes and atherosclerotic cardiovascular disease is:
   (a) **<70 mg/dL**
   (b) <100 mg/dL
   (c) <130 mg/dL
   (d) <160 mg/dL
   (e) <200 mg/dL
4. One of the primary goals of clinical guidelines is:
   (a) To promote the use of new medications
   (b) To establish medical consensus
   (c) To increase medical knowledge
   (d) To create norms to be followed
   (e) **To improve the quality of health care**
5. In order to improve the quality of care, clinical guidelines pursue:
   (a) **Reducing the unjustified variation of medical care**
   (b) Guaranteeing obtaining the necessary resources
   (c) Treating all patients in tertiary care facilities
   (d) Total patients' compliance
   (e) Reinforcing the role of physicians in chronic care management
6. One major challenge of clinical guidelines is:
   (a) **Adoption and implementation**
   (b) Compliance of patients
   (c) Obtaining the required resources
   (d) All of the above
   (e) None of the above
7. Successful implementation of clinical guidelines is associated with all of the following, except:
   (a) Awareness about its existence
   (b) Understanding its purpose and contents
   (c) Recognition of personal gaps and deficiencies
   (d) **Publication in a leading medical journal**
   (e) Confidence in performance and success
8. Encouraging the use of clinical guidelines involves:
   (a) Easy access
   (b) Additional tools including checklists or algorithms
   (c) Strong supporting evidence
   (d) Flexibility of recommendations to the local context
   (e) **All of the above**
9. Medical factors or barriers reducing adoption of clinical guidelines include:
   (a) Disregard of physicians expected to implement them
   (b) The conservative nature of physicians
   (c) Autonomy and reluctance to innovate or improve
   (d) Absence of leadership
   (e) **All of the above**
10. Most diabetes guidelines:
    (a) Are high-quality, evidenced-based
    (b) Are high-quality, consensus-based
    (c) Are medium-quality, evidence-based
    (d) Are low-quality, evidence-based
    (e) **Are low-quality, consensus based**
