Measuring Diabetes Quality of Care: Clinical Outcomes, Cost-Effectiveness, and Patient Experience of Care

24

Patrick J. O'Connor, Katherine Diaz Vickery, and Todd P. Gilmer

Chapter Objectives

- To discuss advantages and challenges of measuring outpatient diabetes care quality.
- To identify and discuss key quality measures for outpatient diabetes care including single-domain and composite measures of glucose, blood pressure (BP), lipids, weight, tobacco use, and appropriate use of antithrombotic medications.
- To identify emerging opportunities and challenges related to assessment of patient experience of care, shared decision-making, and burden of treatment.
- To discuss factors that influence the cost-effectiveness of diabetes care and to discuss the cost-effectiveness of diabetes case management, clinical decision support, and shared decision-making strategies.

Concluding Remarks

- Providing simple and understandable measures of diabetes care quality to clinicians, patients, and the public may be associated with improved diabetes care quality in some settings.
- Clinicians and care systems often direct available resources to improve what is measured, so selecting a narrow set of diabetes quality measures that are directly and strongly linked to major clinical outcomes is desirable.
- Recent data indicate wide variation in care quality across clinicians after adjustment for patient factors. This information can be used to guide clinician-specific quality improvement and learning interventions.
- In settings with high-quality diabetes care, there is as much as 300% variation in costs. Thus, identifying maximally cost-effective treatment pathways is an area of needed clarity.
- Improving shared decision-making and patient experience of care and reducing treatment burden may improve treatment adherence, continuity of care, and clinical outcomes.

Box 24.1 Implementing a Diabetes Composite Quality of Care Measure

- Step I: Identify all adult patients with a diagnosis of diabetes and with two or more visits to the clinic in the last 12 months. This is the denominator.
- Step II: (a) Classify each patient in the denominator as meeting or not meeting each of these five clinical goals in the past 12 months. (b) If the patient is excluded (criteria for exclusion noted below), they get credit for that clinical goal. (c) If there is no BP measure, A1c test, documentation of use of antithrombotic or lipid lowering therapy, or documentation of tobacco use status within 12 months, they are classified as not meeting that clinical goal.
  - Most recent glycated hemoglobin (A1c) measure done within 12 months is <8%.
  - Most recent systolic BP measure within 12 months is <140 mmHg.

  - Patient is currently prescribed a moderate or high-dose statin or other lipid-lowering medication. (Exclude: LDL < 100 mg/dL, documented lipid-lowering medication intolerance; women of child-bearing potential.)
  - If the patient has diagnosed atherosclerotic cardiovascular disease, they are taking daily antithrombotic medication. (Exclude: those with no prior diagnosis of cardiovascular disease and those at high risk of gastrointestinal bleed.)
  - Chart documentation that the patient is currently a nonsmoker.
- Step III: The patent is counted in the numerator only if they meet all five clinical goals as specified.
- Step IV: Divide the numerator by the denominator and multiply by 100 to calculate the percentage of diabetes patients at the composite diabetes goal.
- Step V: This measure can be used (a) to compare quality of diabetes care across care systems, clinics, clinicians, or groups of patients, and (b) to inform patient or payer selection of preferred clinicians based on quality of care. Adjustment of results based on patient factors (such as age, race, sex, education, income, or insurance status) may be considered.

Introduction

It is widely recognized worldwide that the quality of care provided to those with diabetes mellitus is far from optimal. To guide quality improvement efforts in an efficient way, it is important to identify and target key aspects of diabetes care, track valid measures of care quality over time, and use these measures to direct improvement efforts and assess their results. Here we will discuss the strengths and weaknesses of current measures of diabetes care quality and comment on current challenges that face those engaged in this effort, including developers of quality measures, users of such measures to improve clinical care delivery, or users of such measures to monitor population health. For the sake of brevity, we will focus on outpatient care of adults with type 2 diabetes and limit our attention in this chapter to selected measures of clinical outcomes, cost of care, and patient care experience.

Measuring Clinical Quality of Care: Accountability Versus Improvement Measures

Data from the United States suggest that diabetes leads to about a 5 year loss of life expectancy and a 10 year loss of disability-free life expectancy [1, 2]. A key question for both clinicians and public health leaders is to identify effective prevention or treatment strategies that mitigate these losses both at the population level and for each individual patient.

The most effective way to mitigate the loss of life expectancy and disability-free life expectancy from diabetes is to prevent or delay the onset of type 2 diabetes. This is the topic of several chapters in this book. It is clear from large randomized trials such as the Diabetes Prevention Program and similar programs in Scandinavia and China that both lifestyle interventions and certain pharmacologic agents are somewhat effective in this regard [3, 4]. It is clear that primary prevention of type 2 diabetes should be a very high priority for both clinicians and public health policy makers, and studies to improve the effectiveness of both lifestyle and pharmacologic interventions to prevent diabetes are needed [5].

Once a patient develops type 2 diabetes, the question becomes how to prevent or delay downstream diabetes-related complications and mitigate the adverse impact that diabetes often has on length and quality of life. Microvascular complications such as retinopathy (that may lead to blindness), nephropathy (that may lead to dialysis or renal transplantation), and neuropathy (which may cause pain and lead to falls or amputations) affect a high proportion of adults with type 2 diabetes. The occurrence of these microvascular complications typically increases with the duration of diabetes and is often accelerated by tobacco use and by inadequate control of glucose and blood pressure. However, while trials of intensive glucose and blood pressure (BP) control have shown some benefit on delaying the onset and progression of these microvascular complications, there is little hard evidence to show an impact on reduced rates of the end-stage microvascular complications such as blindness, end-stage renal disease (ESRD), or amputation [6–8]. Moreover, lifetime occurrence of these three end-stage microvascular complications is much lower than is the lifetime risk of a fatal or nonfatal macrovascular complications of myocardial infarction or stroke in adults with type 2 diabetes [1, 2].

The occurrence of macrovascular complications of myocardial infarction and stroke in those with diabetes has been improving in the last 20 years but is still about twice as high as in those without diabetes. These major cardiovascular events account for the majority of excess deaths and excess costs attributable to type 2 diabetes [9, 10]. Thus, in measuring quality of diabetes care, control of multiple major risk factors that are the principal drivers of microvascular and especially macrovascular complications should be the focus of clinical and public health attention.

In recent years, a composite quality measure often used to assess care of adults with diabetes consists of the proportion of diabetes patients who simultaneously meet all five of these clinical measures: adequate BP control, glucose control, and tobacco control, plus appropriate use of lipid medications and antithrombotic medications. Many experts

support this "composite measure" of these five clinical domains, calculated as the proportion of diabetes patients seen at least twice in 12 months in a given care system who meet these five measures (based on most recent measure available within the 12-month period): nonsmoker, A1c < 8%, BP < 140/90 mmHg, on lipid medication if tolerated, and on antithrombotic medication such as asprin (which applies only to patients with atherosclerotic cardiovascular disease) [11]. Box 24.1 below describes how this composite measure can be computed and used.

When a diabetes composite measure was first introduced in 2003 in the United States, less than 5% of US adults with diabetes had all five components at the goals proposed in Box 24.1. The proportion of diabetes patients with all five components at these proposed goals rose to about 30% in the United States by 2015–2018 [12], with major variation from less than 5% to about over 50% across care delivery systems, clinics, individual clinicians, and subgroups of patients. Levels of risk factor control are significantly lower in younger adults versus older adults and lower for Blacks, Latinos, and Native Americans compared to non-Latino Whites. With the onset of the COVID-19 pandemic, there has been a decrease in the proportion of diabetes patients meeting these composite quality measure goals, mostly due to decreased A1c and BP measurement related to reduced access to care [13].

There are several factors to consider when comparing clinicians, clinics, or delivery systems performance using various diabetes or other clinical quality measures. First, if the goal is to incent clinicians to improve care, it may be important to adjust content and interpretation of quality measures based on (a) socioeconomic or clinical characteristics of patients, and (b) availability of technology such as A1c testing available at primary care facilities [14–16]. Otherwise, facilities with less access to technology and/or clinicians who take care of low income or less educated patients (who may have more difficulty getting to clinical goals for a variety of reasons) will be penalized by the quality measures. This issue is especially important if quality measures are publicly reported or if performance on the quality measures is linked to financial compensation [15]. The counter argument is that adjusting quality measure thresholds based on patient characteristics may lead to a double standard of care, with implicit acceptance of lower quality care for more challenging patient populations.

Another consideration related to use of a composite quality measures is whether to weight the components of the composite measure equally or unequally. Are they all equally important? The impact of BP control, lipid control, and tobacco control on life expectancy and major cardiovascular (CV) events in those with diabetes has historically been much greater than the impact of glucose control, unless glucose control is especially poor [17–20]. However, some research suggests that not only the most recent values, but also past values of A1c, BP, lipids, and tobacco use may impact subsequent health outcomes [21]. Moreover, the relative benefit of improving A1c, BP, lipid, or tobacco control varies across patients; in general, the further from goal a patient is on a given measure the greater the potential benefit after effective control is achieved.

These considerations would favor a weighted approach to quality measures, with the weight of each component of the composite measure proportional to the potential benefit of that component. Ideally, the weights should vary based on the clinical circumstances of an individual patient (in some patients, control of very high A1c may confer the most benefit). Technology to enable prioritization of treatment options for individual patients with and without diabetes has recently become available [22–25]. However, the use of individualized care quality measures, although logical and potentially useful, is complex to operationalize and therefore has not yet been widely used. As this science matures, it may be possible to measure diabetes quality at the patient level not only by achievement of threshold levels of A1c, BP, or lipid control but also by estimating change over time in a patient's CV risk, using equations such as the American College of Cardiology/American Heart Association (ACC/AHA) CV disease risk equations, the UKPDS Outcome Model 2 prediction equations, or a combination of these [26, 27].

Just as there is wide variation across clinicians, medical groups, and care delivery system in composite measures of diabetes care quality, so too there is wide variations in the five specific components of the composite measure. For example, some clinicians do a better job with BP control than with glucose control. There are few studies that investigate in detail this variation at the clinician level in patterns of risk factor control. Some of the variation is likely attributable to variation in patients' health literacy, numeracy, or overall educational or poverty level. Thus, when assessing variation in diabetes care quality across clinicians and delivery systems, some experts suggest that credibility requires that the analysis be adjusted for differences in patient characteristics.

Another factor linked to variation in quality of diabetes care is a long delay in clinician recognition or management of changing levels of glucose, BP, lipids, or other clinical parameters. Deterioration in glucose control, for example, may be due to progression of diabetes, nonadherence to medications, lapses in dietary practices, stress, occult infections, or other factors. When patients well-controlled on glucose, BP, or lipids deteriorate, clinicians who delay addressing the underlying reasons and adjust pharmacotherapy if needed in a timely way will, on average, have lower proportions of their diabetes patients at goal. Delayed adjustment in treatment, often referred to as "clinical inertia," is associated with poor clinician performance on key measures of diabetes quality of care and adverse clinical outcomes [28]. Quality measures that assess clinical inertia have been

proposed by some but are time consuming to measure and report and may not adequately consider patient-related financial, social, and psychological constraints that sometimes present barriers to optimal care [29–31].

There are hundreds of "evidence-based" components of diabetes care, but not all are of equal benefit to a given patient at a given point in time, and the strength of the supporting evidence from randomized trials varies widely. Thus, all evidence-based aspects of diabetes care are *not* suitable for selection as quality measures. It is best to focus attention on clinical domains that need improvement, have a major direct impact on important health outcomes, have affordable and available management strategies, and can be easily measured.

It is also important to keep in mind that once a clinical quality measure is adopted as a publicly reported accountability measure, clinicians and health care systems tend to narrowly focus on measuring and improving that aspect of care. This can lead to unintended consequences. For example, in the 1990s in the United States, the first publicly reported diabetes quality measure was retinopathy screening—because in the pre-electronic medical record era, it could be accurately and inexpensively measured from insurance claims data. Delivery systems devoted immense resources to improving eye exam rates, while largely ignoring poor glucose or BP control—clinical factors that cause retinopathy. That early quality measure may well have *increased* the prevalence of retinopathy by drawing attention away from glucose and BP control.

Thus, we propose a small core set of "accountability measures" that can be used to publicly report diabetes care quality, and a larger set of "improvement measures" that are not publicly reported, but that can be used privately by clinicians and care delivery organizations, as needed, to improve care by pinpointing specific barriers to higher quality diabetes care.

If a clinician, clinic, or care system is doing poorly on *accountability measures* such as those listed in Box 24.1, it may be helpful to deploy a set of more detailed *improvement measures* to identify care improvement opportunities related to glucose, BP, lipid, or other clinical goals. Improvement measures are designed to (a) identify *why* a particular clinician may have suboptimal accountability measures and (b) point to clinician-specific or clinic-specific "care improvement opportunities" that can reasonably be expected to improve quality of care. Prior work provides some empiric support for this approach [32, 33].

Clinicians with similar levels of performance on accountability measures may have substantially different patterns in associated improvement measures. This observed variation in patterns of care across clinicians is illustrated in Table 24.1 and suggests the potential usefulness of tailoring quality improvement and learning strategies to clinician-specific "care improvement opportunities." The definition of a "care improvement opportunity" for a specific clinician may be as simple as identifying performance on improvement measures relative to the median of their peer group's performance (Table 24.2). In settings where electronic health records or other sophisticated health information technology is available, collecting detailed clinical data on specific patterns of care at the clinician level is increasingly feasible.

When improvement measures are assessed, it is important to consider how best to share such information with clinicians, clinic leaders, or others. Several characteristics increase the effectiveness of feedback, such as timeliness, regularity over time, positive feedback alongside feedback on sub-optimal performance, feedback to a supervisor as well as the front-line clinician, providing feedback in both

Table 24.1 Examples of variation in percentages of PCC-specific care improvement opportunities (CIOs) in study-eligible patients from a larger algorithmically defined set. Columns represent the percentage of patients with each CIO within PCC percentiles, and a ratio of COIs in 90th to 10th percentile PCCs

CIO topic	CIO description	10th	25th	50th	75th	90th	Ratio
Thiazide diuretic under use	% of patients with uncontrolled BP and adequate renal function not on a thiazide	16.3	18.9	23.1	27.6	30.3	1.9
ACEI/ARB under use	% of patients with uncontrolled BP who are not on ACEI/ARB use	13.7	15.5	20.0	24.7	27.9	2.0
Use of 3 or more BP medications	% of patients with uncontrolled BP on three or more medications	1.0	1.9	3.0	4.3	6.0	6.1
Hypertension recognition	% of patients meeting BP criteria without a problem list diagnosis	9.6	12.6	16.0	19.4	23.9	2.5
Use of moderate or high intensity statins when indicated	% of patients meeting ACC/AHA criteria for statin use with ASCVD risk ≥10% on less than moderate intensity statin	12.6	16.3	23.7	32.3	42.9	3.4
Statin initiation when indicated	% of patients meeting ACC/AHA criteria for statin use but not on a statin	17.1	21.2	27.8	37.3	47.5	2.8
Antithrombotic underuse	% of patients meeting criteria for antithrombotic use, but not on an antithrombotic	7.5	9.5	13.0	18.2	22.3	3.0
Antithrombotic overuse	% of patients not meeting criteria for antithrombotic use, but on an antithrombotic	5.0	6.3	9.5	12.3	15.9	3.2
Screening for diabetes when indicated	% of patients meeting USPSTF criteria for diabetes screening without tests in 3 years	6.5	9.2	12.6	17.0	20.3	3.1

Abbreviations: *CIO* care improvement opportunity, *PCC* primary care clinician, *BP* blood pressure, *ACEI* angiotensin converting enzyme inhibitor, *ARB* angiotensin receptor blocker, *ACC/AHA* American College of Cardiology/American Heart Association, *ASCVD* atherosclerotic cardiovascular disease, *USPSTF* United States Preventive Service Task Force

Table 24.2 Prototype content of PPF feedback to PCC and their supervisor, updated every 2 months

Selected care improvement opportunity (CIO) from a set of 30	You're doing better than this % of PCP peers	Number of patients evaluated in past 2 months	% of your patients with opportunity to improve care	
			You now	Your goal[a]
Use thiazide diuretics	8	50	38%	23%
Initiate statin treatment when indicated	11	24	35%	28%
Refer smokers to cessation programs	23	14	24%	16%
Hypertension recognition	71	61	12%	☺ Great job!
Screening for diabetes when indicated	83	33	9%	☺ Great job!
Antithrombotic underuse	94	17	8%	☺ Great job!

[a] This is performance level of median PCC

verbal and written form, feedback that is actionable, and setting specific goals for improvement with repeat measurement to assess progress [34]. In a time of widespread clinician and health worker burnout, feedback must be provided as sensitively as possible.

Measuring Patient Experience of Care

Diabetes is a complex chronic disease, and clinicians are faced with the daunting challenge of dealing with a myriad of effects that diabetes may have on many dimensions of a patient's life. In addition to its direct biological, psychological, and financial impact on patients, diabetes also may significantly impact the family, friends, employers, and caregivers of those with the illness. The social and economic impact of diabetes on direct medical care costs, indirect costs, and workforce productivity is also substantial. A fundamental question related to measurement of diabetes quality of care is this: how wide a net do we want to cast? Can we hold the care delivery system accountable for the myriad impact of diabetes on a person's life? Should governments, employers, schools, or nursing homes be held accountable for accommodating the needs of those with diabetes?

There is increasing attention to integration of health care with behavioral health and social services for vulnerable persons or families, which would include many individuals or families affected by diabetes. Diabetes may be associated with increased work absenteeism or presenteeism, decreased income, high medication costs, high health-care costs, and decreases in physical, emotional, and social function. The strongest evidence exists for integration of psychological and diabetes care in models such as Collaborative Care [35]. In many communities, social services are available to provide necessary assistance with income, housing, food, safety, or health-care costs. However, integration of social services with primary health care services is often incomplete, and better access to and coordination of services is often needed [36, 37]. Although integration of health-care services and behavioral health and social services may be beneficial for many patients with diabetes, holding clinicians or clinics responsible for delivery of integrated services may not be well accepted by some clinicians and may not be feasible in some rural or under-resourced areas. Moreover, quality measures that assess integration and coordination of care are not yet fully developed and validated.

Quality measures that focus on *patient experience of care* are now being used in some care delivery systems. Important aspects of patient experience of care include a timely access to necessary health-care services, clear and comprehensible communication from clinicians, an active role in care decisions, and satisfaction with clinical care provided.

Collecting patient-reported information on experience of care, patient-centered care, or shared decision-making may require surveys, conversations, electronic communication, and analysis of verbal or questionnaire data. This can be quite time consuming and expensive. Although representative random sampling of patients may reduce the resources required for such measures, accuracy may be compromised if sampling is done in a biased way, if response rates are low, or if the sample size is insufficient to draw reliable conclusions.

Nonetheless, a number of survey instruments have been reasonably well validated to measure patients' experience of care, diabetes distress (Problem Areas in Diabetes/PAID), patient-centered care, shared decision-making, and self-efficacy (Diabetes Empowerment Scale/DES); some of these are available in validated Spanish versions [38–40].

Shared Decision-Making and Treatment Burden

Shared decision-making (SDM) can be informally defined as timely sharing of information between patients and clinicians that empowers patients to actively participate (if so desired) in selecting from a set of evidence-based treatment options, those that best reflect their values and personal preferences. Shared decision-making is an intrinsic and necessary part of primary care practice but is often neglected [41]. One study found that primary care clinicians provided basic information on newly prescribed medications—the name of the medication, frequency of dosing, duration of use,

intended benefits, and major side effects—only about 20% of the time [42]. This lack of basic information precludes shared decision-making and has been linked to low medication adherence and increased mortality in some studies [21]. The impact of shared decision-making on diabetes-related clinical outcomes is an area of active research [43].

Some thought leaders have recently proposed that treatment regimens be designed to minimize the burden of care imposed on the patient by their diabetes treatment [44]. This is a neglected but important aspect of care; the typical adult with diabetes takes seven to eight medications a day in the United States, and glucose monitoring, dietary considerations, and frequent office visits increase time and resources devoted to diabetes care [45, 46]. For example, treatment with insulin often imposes burdens related to blood glucose monitoring, disruption of daily routines, risks of hypoglycemia, and high out-of-pocket costs for insulin and associated supplies and equipment. Use of sophisticated insulin delivery systems and continuous glucose monitoring may confer clinical benefits for some patients, while adding different care requirements, concerns, and expense. Some data suggest that minimizing the burden of care may improve treatment adherence, timely follow-up care, and reduce patient stress [44, 47]. For these reasons, some experts suggest that measuring burden of care is justified and that development of creative strategies to minimize burden of care may improve care, adherence, and long-term clinical outcomes [48].

Shared decision-making may help reduce the burden of care [49] and can be used to develop individualized care goals and care plans for complex patients [50–52]. Note that quality measurement becomes more complicated if it must accommodate patient-specific clinical goals. One possible solution to this problem is to select clinical goals for quality measure that are more generalizable, such as an A1c goal of <8% rather than A1c<7%, to accommodate patient-specific variation in clinical goals [53, 54].

It is of particular concern that many clinicians (and patients) overestimate treatment benefits, often by an order of magnitude. For example, in the UKPDS, intensive glucose treatment for about 18 years led to an additional 90–180 days of quality-adjusted life [55]. In the ACCORD randomized trial, intensive glucose control significantly increased death rates by 18–20% compared to moderate glucose control [17, 56]. How many patients, with this information in mind, would opt for intensive glucose treatment using the medications available when those studies were conducted? Fortunately, newer classes of drugs such as GLP-1RA and SGLT2i appear to confer impressive clinical benefits on many diabetes patients who also have cardiovascular disease, chronic kidney disease, or congestive heart failure [57, 58].

These considerations underscore the complexity of shared decision-making and patient-centered care. That complexity has led to increased interest in use of web-based decision support algorithms and risk equations that can be used to accurately estimate and compare the potential benefits of various evidence-based treatment options for a specific patient [59]. Observing and understanding the treatment preferences of well-informed patients can, in turn, improve our understanding of what factors influence treatment preferences and lead to improved approaches to shared decision-making [22, 23, 25, 60].

Measuring Affordability and Cost-Effectiveness of Diabetes Care

Several studies document that health-care costs of those with diabetes are more than double the health-care costs of age- and sex-matched patients without diabetes [9]. Higher costs are driven by several factors, including pharmaceutical and equipment costs, more outpatient visits, and more frequent and longer hospitalizations across a wide range of admission diagnoses [61]. From the clinical point of view, the major driver of excess, potentially avoidable costs is major cardiovascular events, including admissions for congestive heart failure, myocardial infarction, stroke, peripheral arterial disease, and revascularization procedures.

Although cost of care is generally higher for those with diabetes, studies indicate that there is a wide variation in costs of care not only across patients but also across care delivery systems for similar patients. This has led many experts to speculate that more attention should be devoted to identifying optimal "care pathways" that combine clinical success with low costs. For example, suppose a patient requires two glucose-lowering agents to achieve their evidence-based glucose goal, the cost to the care delivery system (insurer or government) for various combinations of effective glucose-lowering medications may vary as much as 50-fold with generic metformin and sulfonylureas being least expensive, and SGLT2i and GLP-1RA being most expensive drug classes. Likewise, out-of-pocket cost to the patient may vary widely by care system and insurance arrangements [62].

Insulin acquisition costs are another example of variability in cost to the delivery system, and in some cases to patients. Recent analysis indicates up to tenfold variation in insulin costs in the United States based on the type of insulin (human vs. analog) and delivery system (vial versus cartridges). Thus, judicious use of analog insulins, perhaps reserving them for patients at high risk of serious hypoglycemia, could be a policy that substantially lowers costs [63–65].

The analysis of cost-effectiveness in diabetes care is even more complicated. The threshold of costs per quality-adjusted life year (QALY) that purchasers are willing to pay

varies substantially by country, by payer, and by year. The cost of complications such as an amputation or myocardial infarction also varies greatly across nations and across delivery systems within nations. Moreover, pharmaceutical corporations may agree to very different acquisition costs for a given medication in different countries, and within some countries, in different delivery systems. All these factors complicate efforts to accurately estimate cost-effectiveness of diabetes care across time, nations, and delivery systems.

Despite challenges, it is instructive for delivery systems to estimate cost per QALY gained, for various treatment pathways (human vs. analog insulin, vials vs. pen insulin delivery systems, use vs. nonuse of continuous glucose monitoring in stable type 2 diabetes, expensive vs. less expensive non-insulin glucose-lowering drugs, various lipid lowering treatment strategies, various visit intervals, in-person vs. virtual clinical encounters). Doing so and using these data to identify optimal treatment pathways for various groups of diabetes patients, and to aggressively negotiate drug acquisition costs with suppliers, may well reduce the cost and improve the cost-effectiveness of diabetes care in some clinically defined groups of patients.

The recent demonstration that selected GLP-1 receptor agonists (GLP-1RA) and SGLT2 inhibitors may significantly reduce major CV events and CV mortality and preserve renal function, which will complicate efforts to assess optimal treatment pathways from the cost and cost-effectiveness point of view. The cost-effectiveness of these new medication classes will be driven both by their clinical benefits and by their variable but generally high acquisition costs. Also, important to consider are cost-sharing arrangements with patients, whose ability to afford substantial out-of-pocket costs typically varies widely by income.

At the population level, a certain fraction of diabetes patients will require intensive interventions to achieve and maintain glucose, BP, and lipid care goals. Intensive interventions that can be deployed in a targeted way across a population of diabetes patients and can range from intensive, individual level interventions such as nurse case management combined with peer-led, collaborative diabetes education and self-management training to web-based clinical decision support delivered through the electronic health record at primary care encounters. Diabetes care management including diabetes self-management education and peer support is more expensive at the individual level but has been shown to produce more significant improvements in clinical risk factors including A1c [66–68]. Clinical decision support requires a substantial initial investment, but that can be spread over a large population resulting in low individual level costs, although with smaller clinical effects. These two intervention strategies have been shown to be similarly cost-effective and can be used in a coordinated, complementary way [69].

Finally, it is important to note that the cost-effectiveness of type 2 diabetes prevention has been thoroughly studied and in most scenarios is either cost saving or highly cost-effective, whether accomplished via lifestyle change programs or by using medications such as metformin [70]. Very few things in health care are cost saving, so investments in type 2 diabetes prevention programs is increasingly recognized as a good investment by various private and public care delivery systems [71].

Summary

Systematic measurement of diabetes care quality can identify important gaps in clinical care, map variation in quality of care across clinicians and delivery systems, and provide useful information to guide care improvement efforts. A wide range of diabetes quality measures are available. Selection of a parsimonious set of *accountability measures* that are causally related to key clinical outcomes is a top priority. A larger set of optional *improvement measures* can be used to map care improvement opportunities that, if addressed, will improve accountability measures. Measures that assess patient experience of care, shared decision-making, and cost of care may also be considered. However, resources needed for quality measures can be considerable and may reduce resources available for direct patient care. Measures that can be extracted from electronic clinical databases are generally much less expensive than measures that require patient-reported data. Ongoing efforts are needed to optimize diabetes quality measures and develop new measures of patient-centered care, efficient use of resources, and patient-reported outcomes and to identify effective strategies for primary prevention of type 2 diabetes.

Multiple Choice Questions

1. Clinical measures that are causally related to major microvascular and macrovascular diabetes complications are often selected for clinical quality of care measures. Such clinical measures might include all the following except:
   (a) Antithrombotic use
   (b) Cholesterol control
   (c) Blood pressure control
   (d) **Annual diabetes patient education**
   (e) Glucose control
   (f) Nonuse of tobacco

   Comment: Diabetes patient education is extremely important, but in randomized trials it has only a marginal impact on glucose, BP, lipid, or tobacco control and is not casually related to lower rates of major diabetes complications. Thus, the other aspects of care listed here are more suitable for diabetes quality of care measures.

2. Regarding the cost-effectiveness of electronic health record (EHR)-linked clinical decision support and diabetes case management, which of the following statements is false:
   (a) Case management is much more expensive on a per-patient basis,
   (b) Over the long run, clinical decision support may be cost-saving.
   (c) They are about equally cost-effective.
   (d) **Most patients resist active case management as an invasion of privacy.**
   (e) Clinical decision support has high initial implementation costs.

   Comment: In large studies of diabetes case management, about 2/3 of high-risk diabetes patients engage in the case management process.
3. Reasons to measure diabetes care quality at the clinician level include all the following except:
   (a) There is significant variation in patterns of care at the clinician level.
   (b) **It is often difficult to link individual patients to a single responsible clinician.**
   (c) Many clinicians like to know how they are doing compared to their peers.
   (d) Such information can guide clinician-specific learning interventions.
   (e) Electronic data make this easier to do than in the past.

   Comment: Well over 90% of patients can be linked to a usual primary care clinician in most health care systems, based on frequency of visits with various clinicians and/or patient designation of a usual primary care clinician in electronic health record systems.
4. Which one of the following statements about the relationship of outpatient cost of diabetes care to outpatient quality of diabetes care is false:
   (a) Quality of care is not related to cost of care at the clinic level.
   (b) **High-quality care costs more.**
   (c) Low-quality care can be as expensive as high-quality care.
   (d) Cost of care is important both to the patient and to the care delivery system.
   (e) Costs of care vary widely across patients with diabetes.

   Comment: There is abundant evidence that there is not a strong association of outpatient costs of diabetes care with quality of outpatient diabetes care.

Introduction

Type 2 diabetes (T2D) affects 9.4 million adults aged 20 years and over in Mexico, equivalent to 11.3% of the total adult population, and is the second leading cause of death, contributing with 9% of the total deaths that occur in the country—100,000 per year [1, 2].

Public and private institutions and providers make up the Mexican health system and develop mostly independently health programs and innovations to address health problems and particularly diabetes. The Mexican Institute of Social Security (IMSS, its acronym in Spanish)—the largest public institution in the country—covers 31.5 million adults over 20 years—38% of the country's total—through mandatory coverage of formal private sector employees and their families. IMSS employs 17,561 general practitioner and 90,587 nurses in primary care nationwide [3]. In 2002, IMSS established PrevenIMSS, a program to address diabetes and other chronic diseases supported on screening modules in primary care clinics staffed by nurses and referring presumptively diagnosed cases to family doctors for confirmation.

From 2008, IMSS aimed to address a growing diabetes epidemic through a vertical program—DiabetIMSS—supported on specialized diabetes primary care modules staffed by a family physician, a nurse, a nutritionist, and a social worker [4]. In spite of some success in improving metabolic control, DiabetIMSS scaling up was interrupted in 2012 due to human resource and financial constraints and reached only 8% of primary care clinics and 3% of people living with diabetes [5, 6]. IMSS also went on to implement a Diabetes Clinical Practice Guideline (DCPG) in collaboration with the Ministry of Health, aiming to improve quality of care by family medicine physicians [7]. The scaling up of this guideline was also limited due to constraints in the adaptation of the guideline to local conditions and a lack of leadership at the national level by the Ministry of Health [8].

From 2017, IMSS aimed to strengthen the quality of care for the most prevalent chronic diseases, abandoning vertical efforts and relying on institutional leadership at the national level inspired in the internationally recognized Chronic Care Model (CCM) aim of improving quality, increasing coverage, and reducing cost. This was done through piloting the Chronic Disease Preventive Model (CDPM) and developing Integral Care Protocols (ICP).

CDPM is currently in a pilot phase in the state of Nuevo León and includes four strategies: risk stratification, targeting actions to specific risk groups, monitoring people in the continuum of care, and health process and impact evaluation [9, 10]. People who do not achieve metabolic control of diabetes—estimated at 30% of the total—are referred to Outpatient Metabolic Control Units (OMCU) [11]. The CDPM includes intensive diabetes education, interdisciplin-

ary care teams, and intensification of insulin therapy and of HbA1c monitoring; all of them are key aspects to achieve effective coverage. The diabetes education model adopted by the CDPM was based on best international evidence testing various alternatives through a small-scale randomized trial [12]. Interdisciplinary care is based on previous experience demonstrating the need both to avoid specialized diabetes primary care modules and to integrate interdisciplinary care within existing resources [6] as supported by international best practices [13]. DCPM also includes an information and patient recall platform that could impact on greater screening of at-risk persons, as well as follow-up for diagnosis.

The high prevalence of diabetes, particularly in the age group of 60–79 years of age, clearly justifies integrating diabetes care within general practice. Intensification of insulin therapy is in agreement with observed high levels of diabetes complications within IMSS population and low insulin use according to international best practices. In addition, a focus on universalizing HbA1c monitoring is also congruent with best international practices [14, 15].

While CDPM innovations are highly justified, IMSS faces diverse challenges to innovation in its internal institutional context characterized by centralization and bureaucratic controls, in the external context relating the institution to its governing institutions, its financing and to the expectations of its beneficiaries, and in the processes through which innovations are developed.

This chapter presents a comprehensive overview of the CDPM implementation challenges through exploring the main coverage bottlenecks facing detection, diagnosis, and diabetes care and exploring the facilitators and barriers to the implementation of care innovations in its internal and external contexts and in its implementation process. Implementation challenges focus on four CDPM innovations: intensive education, interdisciplinary teams, intensification of insulin therapy, and HbA1c monitoring in primary care.

Data was obtained through a mixed-method approach including the review of program and research and innovation development documents; the analysis of the National Health and Nutrition Survey (ENSANUT in Spanish) of 2018 [16]; and interviews with 13 family physicians, diabetes specialists, innovation leaders and with 13 persons living with diabetes. ENSANUT was processed to identify measures of coverage and quality of care offered by IMSS in the detection, diagnosis, and treatment of diabetes. Interviews with IMSS personnel aimed to explore qualitatively the range of perceptions regarding the internal context, while interviews with persons living with diabetes aimed to assess the external context, complemented with documentary research regarding the support to innovation provided by IMSS governors. Financial constraints to diabetes care innovation were assessed through a costing exercise to assess the requirements for each of the four CDPM innovation areas within diverse scenarios of population coverage and depth of vertical scaling-up of innovations for 2030. The costing exercise enabled an assessment of the budgetary impact expected by IMSS. The detailed methods and results obtained can be consulted in published book and journal article [17, 18].

Diabetes Care Coverage Bottlenecks

IMSS provided early diabetes detection tests at least once every 3 years, according to institutional norms, to only 49% of its adult beneficiaries aged 20 years or more in 2018 [19] (Fig. 25.1, Table 25.1). Data for previous years suggest that only a fraction of beneficiaries that receive a presumptive diagnosis go on to demand confirmation through primary care consultations and lab tests, with only 26% of the total in 2014. According to national IMSS planners, the main problems limiting early detection and confirmation are that beneficiaries are not targeted according to risks such as age, weight, and family history with diabetes, and that there is poor follow-up of persons with a presumptive diagnosis [20].

The total IMSS beneficiary population aged 20 or more years living with diabetes in 2018 according to ENSANUT 2018—diagnosed or undiagnosed—was 4.13 million for a prevalence of 13.1% of adults (Table 25.1), of whom 3.87 million self-reported their condition based on previous diagnosis, and 0.26 million were discovered through testing as part of the survey. However, the burden of diabetes among IMSS beneficiaries reported by IMSS based on clinical records is higher, which amounts to 5.4 million persons for 2020. Diabetes prevalence is larger among females, with 14.9% as against 11.0% for males while the burden of diabetes is higher in the age group of 60–79 years, reaching 30.3%. According to ENSANUT, 9.1% of beneficiaries with confirmed diabetes seek care outside the institute (Fig. 25.1). However, IMSS reports a much larger treatment gap of 43% based on their own estimates of total beneficiaries living with diabetes. Beneficiaries receive at least four medical consultation per year within or outside the institute in 77.4% of cases, with a somewhat higher percentage among beneficiaries treated by IMSS, of 79.9%. The majority of beneficiaries—89.2%—receive some form of medication while 23.2% are treated with insulin. According to IMSS diabetes program officers, insulin therapy should cover 40% of the population treated; thus, current attainment is 58.0% of target.

HbA1c tests are performed only to a small proportion of persons living with diabetes, with 15% receiving two or more tests. Control of diabetes through exercise and/or diet was reported by 11.1% of IMSS beneficiaries. Beneficiaries receive good quality care in only 37.0% of cases as measured by access to a set of ten key indicators, while IMSS reports

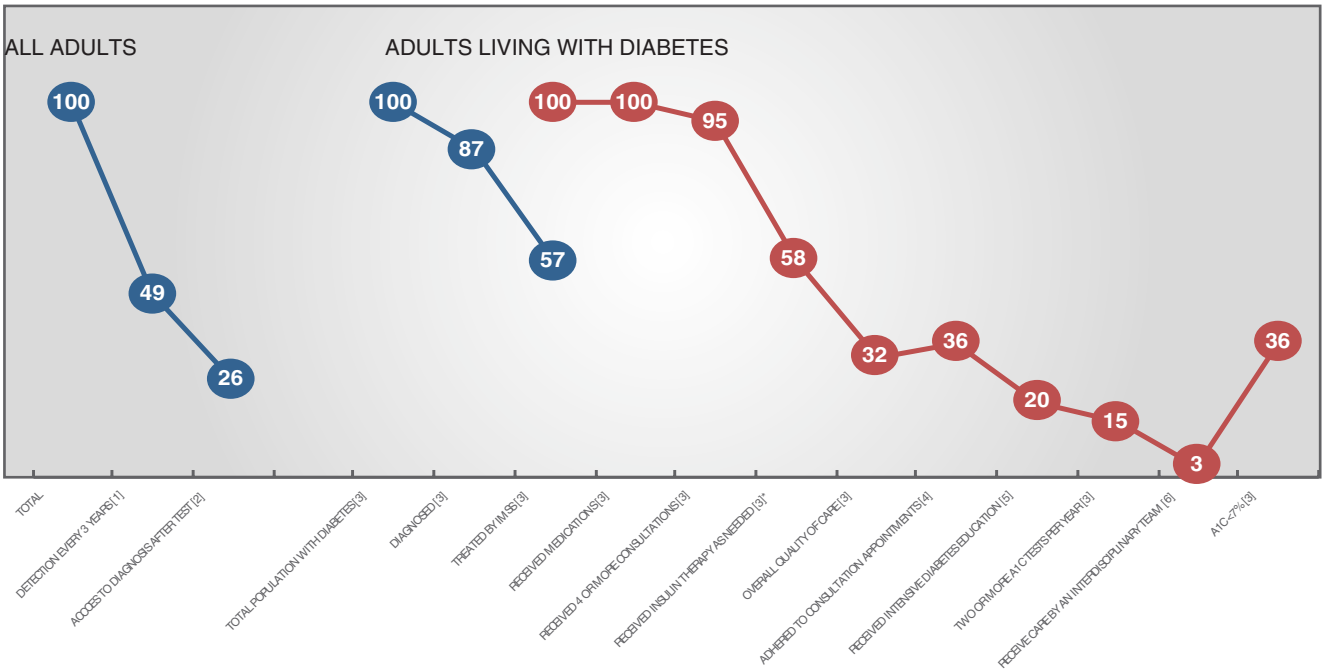

Fig. 25.1 Coverage bottlenecks for diabetes detection and control among IMSS beneficiaries. ENSANUT 2018. Data dates, notes and sources: 1: 2018, IMSS [19]. 2: 2014, Sánchez O [20]. 3: 2018, INSP [16]. 4: 2016, Cerón [21]. 5: 2019, Interview, Family Medicine Division coordinator based on patients accessing DiabetIMSS. 6: 2017, for IMSS beneficiaries having access to interdisciplinary teams in DiabetIMSS [5]. *The 32% of insulin coverage corresponds to the coverage as reported in Table 1 of 23.1% of the total beneficiaries living with diabetes against the coverage target of 40% of the total set by CDPM. Thus, 23.2%/40% = 58%

that full adherence by patients to scheduled diabetes consultations is at 32% [21]. Diabetes education under diverse models and intensities is received by only 20% of persons living with diabetes [12] and interdisciplinary diabetes care is received by only 3% of beneficiaries, of those treated by the DiabetIMSS program.

The percentage of IMSS beneficiaries with diabetes under control as measured by the test of HbA1c below 7% is 38.1%, while up to 26.1% of beneficiaries live with highly uncontrolled diabetes as measured by HbA1c levels above

9%. The percentage of IMSS beneficiaries with levels of HbA1c < 7% is below that observed in other countries, for example in the USA, where 64% of the population is reported with HbA1c < 7% [22]. HbA1c levels across the IMSS beneficiary population thus suggest opportunities to improve glycemic control.

The most critical bottlenecks can be identified based not so much on the lowest values observed for each indicator but on the sharpest drop along the value chain of indicators. These are early detection of diabetes every 3 years and overall quality of care for persons with confirmed diabetes. While current data for the former is limited given its focus on all adults rather than those at highest risk, the drop goes from a need of 100% to 49% of coverage. In quality of care, the drop goes from 80% of persons accessing an adequate number of yearly consultations to only 37% receiving appropriate quality of care. Critical indicators as assessed according to coverage are intensive diabetes education and receiving a minimum of two HbA1c tests per year, and particularly accessing interdisciplinary care, with only 3% of coverage.

Internal Facilitators and Barriers to Innovation

IMSS is structured by levels of operational, tactical and strategic responsibility with the potential to identify problems, identify alternatives for innovation, as well as to plan responses. IMSS operates with a high degree of centralization where innovation at the local level depends on the initiatives and orders issued at the national level. According to our interviews, physicians experience centralization as limiting their capacity for decision-making for clinical care improvement.

The education of people living with diabetes tends to be vertical, reproducing centralization in management and hindering empowerment. Centralization makes it difficult for staff to coordinate with different disciplinary profiles, while mechanisms to generate professional coalitions are difficult to establish or operate. Family physicians perceived the feasibility of improving diabetes education through allocating more time for consultations, training all professional profiles to work in teams, and through increasing the awareness on the need of patient education on the part of decision-makers higher up in the hierarchy.

Training of health workers through continuous and intensive approaches is a critical aspect in the process of scaling-up innovation. IMSS operates a national health worker education and training program supported on hospital traineeships and most importantly on-line, automated short courses. For 2018 a total of 66 courses were offered, of which only three focused on diabetes care yet none had been aligned to CDPM's needs, particularly toward interdisciplinary care. Continuing education coverage across all on-line training courses and traineeships reached only 3.5% of the total IMSS health workforce in 2018. Of this total, 1.5% participated in traineeships and 2.0% in on-line courses. Training across health worker profiles varied, with 8.8% of the medical personnel having been trained, as against 2.2% of the Nursing personnel and 0.7% of other health personnel, including Social Work and Nutrition. At the current pace, it would take IMSS 11 years to train 100% of physicians in any of the currently provided health areas, 44 years in the case of Nursing and 151 years for other health personnel. Given that only 3 out of 66 courses were focused on diabetes care, training times would take 20 times longer to ensure all personnel are trained in diabetes and are thus able to participate in interdisciplinary, fully integrated diabetes care.

In spite of the paucity of training, the physicians and innovation leaders interviewed had a clear sense of urgency of the need to address major changes to ensure quality diabetes care. The levels of uncontrolled diabetes are clearly viewed as an unacceptable problem, threatening the financial collapse of IMSS. In particular, family physicians perceive as unacceptable the restrictions they live with respect to the routine use of HbA1c and the intensification of insulin therapy. They considered that the availability of the HbA1c and the training to use insulin therapy could allow them to improve the quality of care, thus reducing patient referrals and consequent delays to internists in secondary care.

However, innovation at IMSS is incompatible with the daily pressures faced by family physicians. The HbA1c test was perceived by physicians to be hampered by current standards, by the demand to speed up consultations, and particularly by the supply shortages, provoked by the perceptions, on the part of administrative personnel, of wasteful application in the absence of precise norms. In spite of higher purchases of HbA1c tests at the time of the interviews to ensure their widespread availability in primary care, physicians that were interviewed still lacked knowledge regarding its availability or the norms regulating its application. Intensive diabetes education also faces incompatibility within the institutional context, particularly with regards to family physician's productivity.

Performance incentives are recognized at the strategic level as important tools toward the attainment of quality-of-care goals. However, informants were frustrated by failures in attempts to implement them in the recent past. Performance management is limited to the occasional clinical record review while family physicians perceived that professional training provides weak incentives toward innovation, being limited to providing a certification of points per completed course. They considered that it is important to increase staff motivation by systematizing access and promotion of patient education, offering performance incentives and improving support at the strategic level.

Communication of CDPM innovation objectives and goals was perceived as weak, much as it had been in the past with the DiabetIMSS program and with the implementation of clinical guidelines. CDPM progress is being reviewed at the national level based on occasional presentations to top level authorities and leaders such as at the National Academy of Medicine, without strategies clearly in place to encourage primary care staff toward innovation. Although family physicians show willingness to learn, they perceived themselves as undervalued and poorly informed about innovations. Family physicians were insistent on the time constraints they face in their daily routines, which act as barriers to learning and impact on their capacity to put in place reflective processes.

Delays in scaling up of innovation and interruption of past innovations—in the case of DiabetIMSS—were perceived by physicians as a consequence of decision-making by officials who are insensitive to health team needs and who lack a long-term vision. While IMSS is attempting to strengthen CDPM innovation implementation through designated leaders, part-time coaches, and full-time process managers at each primary care unit, interviews and documentary evidence suggest that these resources aim to enforce discipline among health personnel rather than to promote problem solving.

IMSS shows strengths for innovation planning, particularly for the design and piloting of innovations at the national level. However, the institution's overly large size, verticality, excessive bureaucratic control, and limitation of autonomy at the local level act as significant barriers restraining staff motivation, coordination, and alignment of interests along the innovation value chain.

The most salient barriers perceived by family physicians are related to organizational factors at the strategic level. Current functional differentiation results in a pyramidal hierarchy that marks a distance between top-level staff and family physicians. While staff in planning functions at the strategic level are optimistic, family physicians expressed little enthusiasm and confidence in the capacity of upper management to bring about change.

The main barriers expressed by interviewees related to the internal context to CDPM implementation are weak communication, weak feedback strategies, and absence of performance-related incentives. Studies in other health systems have demonstrated the need for efforts to motivate staff toward the attainment of organizational objectives, something that the size and vertical nature of IMSS undoubtedly requires for success [23].

IMSS has demonstrated capacity to design and test diabetes innovations in the past, and the CDPM follows in this trend [12, 24–27]. However, innovation efforts are mostly spearheaded and organized by upper management without the participation of sector-wide actors and strategies of national and international research and innovation institutions. Such collaboration has the opportunity to introduce more rigorous development and evaluation methods.

Implementation Process Facilitators and Barriers

Research is critical for innovation given its capacity to assess with objectivity the efficacy and effectiveness of care improvements in their capacity to increase coverage and quality while controlling costs. The importance of research is attested by the international literature in the intervention areas pertinent to CDPM, where our search identified 23 research articles in the last 10 years in journals indexed in PubMed testing innovations with interdisciplinary teams, people education, intensification of insulin therapy, and use of HbA1c as a gold standard for diagnosis. Most of these articles reported on randomized controlled trials involving large populations at national level. Importantly, IMSS research teams published two articles, both focusing on testing innovations in education.

An article by Gamiochipi et al. compared the effectiveness of two models of education: shared decision-making between the doctor and the person and strengthening of disease self-management.[1] While the methodology was quasi-experimental, the study did not allocate individuals to each treatment protocol in a randomized manner, while only local samples of 200 people that did not address cultural or regional variability were involved in a 6-month follow-up. The research found that self-management had a greater impact on diabetes control than shared decision-making, leading to its adoption for the intensive education component of CDPM. The second study by Pineda and collaborators tested multimedia information modules in family medicine units. This research found modest results in disease control and was not adopted in the design of the CDPM.[2]

The two published research projects undertaken by IMSS to support innovation are the product of a fairly strong research infrastructure available to the institute through its national level health research coordination. However, research focuses on small-scale testing of innovations and does not take advantage of the large size and high centralization of the institution.

[1]Gamiochipi, Mireya, Miguel Cruz, Jesús Kumate, y Niels H. Wacher. "Effect of an intensive metabolic control lifestyle intervention in type-2 diabetes patients." Patient Education and Counseling 99, núm. 7 (2016): 1184–89. https://doi.org/10.1016/j.pec.2016.01.017.

"Multimedia education to support management of type 2 diabetes patients. A quasi-experimental study." Surgery and Surgeons (English Edition) 86, núm. 5 (2018): 404–11.

The CDPM includes in its design the undertaking of periodic evaluations to assess progress, identify areas for improvement, and monitor the quality of implementation. Program staff carried out a CDPM pilot to assess its impact 1 year after its implementation, using a before and after design. Even though with design limitations, the exercise showed positive results, especially regarding intensification of insulin therapy following training.

IMSS is strengthening planning of the CDPM to address the risk of scale-up interruption due to lack of resources. To establish interdisciplinary care protocols, emphasis is being given to the redefinition of professional roles rather than to new contracting. Professional training is now mandatory according to resource profiles and needs, while the above-mentioned management strategies are intended to modify professional behavior. Planning through plan-do-study-act (PDSA) cycles is driving target definition for HbA1c coverage, intensification of insulin therapy, and diabetes control. Leaders with management expertise and experience in the implementation of the CDPM are being formed to support the PDSA-based planning, as with the case of coaches mentioned above. The intensive education strategy of CDPM was developed, as mentioned above, through testing alternative models following a randomized trial published in a peer-reviewed journal and then adapted for implementation by interdisciplinary teams [12]. Loss of fidelity of these interventions during scale-up is being addressed through a supervision strategy.

The CDPM planning process has clear facilitators including process reengineering, clinical protocols, role redefinition, and an incremental approach to implementation based on the PDSA cycles already mentioned, all directed to maximize performance and reduce the need for additional resources. Another facilitator is the allocation to innovation of full-time senior managers and leaders with extensive experience and designation of innovation champions.

Facilitators and Barriers in the External Context of Innovation

The scaling-up of innovation requires support and the capacity to overcome barriers in the external institutional context, which, in the case of IMSS, includes inputs from the governing employee and employer unions through the technical council and from the user base. The IMSS Technical Council, the highest level institutional governing body, is focused above all on the general administration of the institute, with very little participation in decision-making to promote innovation toward the control of chronic diseases. Thus, between 2000 and 2019, the technical council supported only four agreement toward innovation in diabetes. The most important authorized in 2014 financing for USD 30 million for a multiannual pilot to outsource primary diabetes care with private providers. However, the initiative was canceled without reaching the award due protests by the IMSS health worker trade union. While part of this funding was reallocated to pilot the CDPM through the fully in-house initiative already described, the technical council did not participate in this reallocation, thus limiting the support this body could have given to scaling-up of this important initiative.

The perspectives regarding quality of care and trust held by IMSS beneficiaries living with diabetes present more barriers than facilitators to care innovation toward the CCM. In this model, people and health professionals would have to form symmetrical relationships characterized by mutual trust and effective control on the part of people over their care processes. The current situation, however, is characterized by the verticality of care, a distrust on the part of people toward the care processes and by their discontinuity given the participation of multiple, uncoordinated service providers within and outside IMSS (Fig. 25.2).

Beneficiaries expect IMSS to be a provider of medications rather than to be a partner in the provision of comprehensive care. This perspective suggests a "pharmacologization" of routine medical care. Our qualitative study suggests than younger beneficiaries living with diabetes do not perceive losing the right to medical care with the IMSS as a major problem, as they can find options for the supply of medicines at low cost through private sector physicians working in consulting rooms adjacent to pharmacies and subsidized through the sale of medications. Other alternatives to obtain low-cost medicines include demanding services from the Ministry of Health consulting rooms available for the uninsured or, in some cases, affiliating as a dependent of a family member with access to IMSS. However, older adults—especially those who require insulin or other medications related to diabetes complications—perceive as highly important retaining care by IMSS since they face multiple barriers to acquire the medications they need.

Another important element that must be transformed to achieve the empowerment of IMSS beneficiaries is the perception that medical services are a concession of the state and employers and not a right by virtue of their contribution. In this way, the loss of access to IMSS due to losing a contract with a formal employer, drug supply shortages, and dissatisfaction with services are accepted in many cases. Awareness of their health rights could facilitate the empowerment of people living with diabetes to self-manage their care and to demand innovation.

Costs of Scaling-Up Innovations and Budgetary Impact

For a successful implementation and scaling-up of the CDPM and CCM, IMSS should invest in promoting beneficiary empowerment, establish interdisciplinary care teams, intensify insulin therapy, extend HbA1c monitoring, and strengthen management teams. Table 25.2 presents specific indicators to be attained within each of these five areas, identifying the current coverage and proposing implementation goals for 2030 along two scenarios: medium and high. These indicators were validated by the IMSS national diabetes management team.

Besides scaling-up innovations to the desired level (vertical coverage), IMSS should also consider expanding diabetes care coverage to reduce the number of persons living with diabetes that are not treated by the institution (horizontal coverage). Based on IMSS own figures, as noted above, the total population with diabetes is of 5.4 million, while those covered are 3.1 million for a coverage gap of 43%. Given population growth and diabetes epidemic trends, we estimated a total diabetes population of seven million for 2030. Considering the current IMSS diabetes coverage expansion rates, we expect up to 4.3 million people to be covered for 2030, still leaving a gap of 39%. Innovations should, therefore, be scaled-up not only to attain this coverage rate but also to reduce the coverage gap. We proposed reducing this gap in two scenarios for 2030: a modest reduction of 30%, which represents the treatment of an additional 0.8 million people, and an ambitious reduction of 70%, which would lead to the coverage of a total 6.2 million people.

The human resources needed to scale-up diabetes care innovations for 2030 ranges from a 3.4% increase in the total number of family physicians in a scenario of no increment in the horizontal dimension and a medium vertical coverage to 16.2% increment in the scenarios of ambitious reduction the horizontal dimension gap and high vertical coverage (Table 25.3). Indeed, given current low levels of staffing in these professional disciplines and the demands of CDPM, increments would be required at between 426% and 956% for clinical psychology in the two extreme scenarios and of 2399% and 5017% for nutriology.

The expected increments for family medicine and nursing assume maintaining today’s observed density per 1000 pop-

Table 25.2 Innovation area and indicator to scale-up the CDPM, with medium- and high-level attainment goals for 2030

Innovation	Indicator	Situation in 2019	2030 goal	
			Medium	High
Education with an intensive model for people with T2D	1. People graduated from courses	3%	50%	70%
Interdisciplinary work teams	2. Professionals who participate in care teams and who are trained	0%	100%	100%
	3. People served by teams	3%	50%	70%
Insulinization	4. People who use insulin	16%	28%	40%
	- NPH	12%	20%	25%

Table 25.3 Percentage increase in professional profiles to provide team care according to the CDPM required by two innovation scenarios*

Coverage gap reduction (horizontal)	Innovation scale-up (vertical)	Family medicine	Nursing	Social work	Clinical psychology	Nutriology
Current trend	Medium	3.4	0.5	-0.7	426	2399
	High	4.8	0.7	-1.0	637	3439
30%	Medium	6.8	0.6	3.4	524	2882
	High	9.3	0.8	4.7	774	4115
70%	Medium	12.1	0.7	10.2	654	3526
	High	16.2	1.0	13.6	956	5017

Increases for Family Medicine and Nursing assume maintaining current observed densities per 1000 beneficiaries among the general population
Source: Author data

ulation, which may be insufficient. Indeed, keeping the same density would imply that family physicians would have to increase their dedication to diabetes care, from 12.9% of their total contracted time up to 26%, depending on the coverage scenario (Table 25.4). While increases in nursing dedication for diabetes care would be more modest—between 2% and 4% of their total time—dedication by social work, clinical psychology, and nutrition would be between 22.4% in the case of the former and up to 100% for the latter two. Such expected increments in any scenario except doing nothing are unsustainable and point to the need to develop new professional profiles—particularly for psychology and nutrition, as well as task shifting and automation across professionals and technical personnel for all disciplines.

The costs of human resources for both patient care and management as well as those for training, beneficiary education, technology platforms, insulin, and HbA1, were calculated for the various scenarios (Table 25.5). Costs of

[a] Costs are adjusted to present value considering a discount of 3% per year

[b] Refers to differences between total and status quo costs considering only the costs of additional human resources required to increase the goals while maintaining the population density observed in 2019. Hence, additional costs do not match the total costs less the status quo costs

[c] Correspond to the difference between total costs in each scenario with respect to the costs of the status quo and current trend in coverage gap closure (shaded, $1695)

expanding low-cost oral medications in the horizontal dimension were not considered for simplicity, while it was assumed that physician and nursing densities would be kept at today's levels with the corresponding increments in the proportion of time spent to diabetes care. The costs of improving governance and attaining beneficiary empowerment and satisfaction were not included and should be considered for a more accurate estimation of the needs of implementing the CDMP.

The total additional costs estimated range from $1695 million pesos, in the scenario of current horizontal expansion and medium vertical scale-up, to $10,549 million pesos for the scenario of 70% of reduction in the horizontal gap and high level of vertical expansion of innovations. The incremental cost in each scenario with respect to the status quo (current trend in horizontal expansion without innovation) differ importantly. Scaling-up innovations to the high-coverage scenario for 2030 would require a 306% increase in diabetes care costs. However, expanding innovations while also closing the coverage gap by 70% would require incrementing costs by 335%—only 39% more than following the coverage increment in the status quo. Therefore, if such a large investment is approved, IMSS should consider improving the quality of diabetes care along with increasing horizontal coverage, considering the reductions in potential diabetes complications. If the cost increments are compared across the scenarios including high innovation goals and varying horizontal coverage—from the reduction of the coverage gap expected following current trends to a 70% reduction—then cost increases up to 53%. With this level of cost increment, both vertical and horizontal expansion goals should be targeted.

The total costs vary considerably across specific CDPM innovations, as shown in Table 25.6 for costs within the sce-

Table 25.6 Costs of innovations in care for people who will live with diabetes in the high coverage and quality scenario by 2030, covering 5.1 million people. Millions of pesos in 2019

innovation	Cost in 2019	Coverage goal	Total cost in 2030	
			$	%
1. People with T2D who participate in intensive education courses	$36	70%	$1188	10%
2.- People with T2D treated by a multidisciplinary team	$113	70%	$3758	31%
3.- DT2 training courses that include interdisciplinary work practices	$0	70%	$72	1%
4.- People with diabetes on insulin treatment	$2481	40%	$5013	41%
Monitoring with HbA1c				
5.- People with T2D who received 2 tests per year	$149	100%	$1438	12%
6.- Rapid tests as% of the total	$0	30%	$337	3%
7.- UMF with management teams	$0	100%	$107	1%
8.- Health teams with incentives to perform in T2D	$0	30%	$197	2%
9.- People with T2D registered in monitoring platforms	$0	70%	$135	1%
Total	$2778		$12244	100%

nario of closure at 70% of the coverage gap and a high level of innovation implementation. Considering total costs, intensification of insulin therapy would consume 41% of total costs, followed by the establishment of interdisciplinary teams, with 31% of total costs. Importantly, training courses, monitoring platforms, management teams, and rapid tests would absorb between 1% and 3% in each case. This analysis suggests the importance of investing in pharmaceutical industry and in human resource development, while taking advantage of the relatively small but highly productive investments in the other innovation areas.

The impact that diabetes innovation costs would have on the IMSS budget can now be considered, including its benefit in reducing diabetes-related complications and their associated costs. Projecting the current levels of diabetes care, the trends in reducing beneficiary coverage gaps, and the expenditure on diabetes care reported by IMSS [28], the total 2030 spending on diabetes is expected to sum up to 14.3% of the sickness and maternity insurance (SEM) budget (Fig. 25.3). In the scenario of reducing 70% of the coverage gap without implementing innovations, diabetes care spending would represent 20.6% of the total SEM budget. However, if innovations are scaled-up at the same time to a high level, spending would only increase by 3.9%, to reach 22.8% of total SEM budget. The majority of the financial effort would thus be directed to reducing the coverage gap. Including innovations to increase quality of care, reduce morbidity and mortality, and offset hospitalization costs related to complications should be considered in order to provide better care for IMSS beneficiaries.

Diabetes-related complications are expected to represent 5.4% of SEM budget for 2030 under current trends. In the scenario of increasing only coverage without innovations, the SEM budget share expected to care for diabetes-related complications would increase to 7.8%. However, with innovations this is expected to be reduced to 6.0%.

Investing in diabetes care coverage and innovation should be considered taking into account the expected impact on quality-adjusted life years (QALYS), and hence in productivity for a population such as is the case in Mexico with a high diabetes prevalence among younger-aged persons in the labor market. Indeed, simulation of QALYS led us to expect a significant increase, from 24.54 million years among persons living with diabetes in the status quo scenario, to 32.26 million in the scenario with greatest coverage gap closure and highest innovation implementation.

Discussion

Being the largest and public health institution in Mexico, IMSS exemplifies well the opportunities as well as the challenges to adopt and scale-up diabetes care innovations toward the Chronic Care Model in a middle-income country with a complex set of autonomous public institutions as well as a large private sector.

IMSS faces a major diabetes epidemic affecting the country as a whole and clearly overwhelming the institution, with up to 43% of its beneficiaries seeking care with private or other public providers, with at least 23% of them failing to obtain a minimum number of consultations and 64% failing to receive quality care. While diabetes affects women and younger age groups disproportionately, IMSS does not have a clear strategy to address this situation and has been unable to implement risk targeting. The most acute diabetes care bottlenecks are related to improving early diagnosis and quality of care, particularly ensuring integral care supported by multidisciplinary professional teams.

Innovation should balance the dual challenge of increasing horizontal diabetes care coverage for persons not currently accessing care and vertical scale-up of quality care innovations to improve effectiveness. We found that the costs of scaling-up insulin treatment and establishing interdisciplinary teams are by far the greatest in the set of innovations to implement the Chronic Care Model for diabetes. Scaling-up innovations would imply trebling current expenditure allocated to quality improvements, while reducing horizontal access barriers significantly would imply only increasing what is currently provided to enhance quality by only 43%. Considering just the cost of innovations, it would therefore seem that improving horizontal coverage by itself would be more cost-effective than improving quality of care with the current coverage restrictions. However, when the budgetary impact of innovations is considered in the context of total diabetes care costs, it is clear that the greatest financial impact would be borne by treating a greater number of persons living with diabetes at current standards of care. These trade-offs have to be addressed through a national policy that ensures cross-institutional coverage regardless of affiliation while placing incentives on scaling-up quality of care innovation.

IMSS physicians and leaders are keenly aware of the threats that diabetes poses to the institution and are motivated toward innovation through vertically driven programs and a willingness for training. Yet a high degree of centralization; absence of performance incentives; and high workload, time constraints, and training limitations inhibit performance and hamper innovation.

Innovation also faces barriers in the external context as evidenced by the governance of the response to chronic diseases increasingly affecting the country, the expectations held by beneficiaries living with diabetes, and difficulty to address the budgetary impact of diabetes. The current governance of IMSS depends on a narrow set of actors from industry and labor that fail to represent the vast majority of beneficiaries and are focused on administrative decisions aiming to reconcile narrow political interests rather than focusing on the beneficiary's right to health [29].

The range of expectations held by beneficiaries regarding the institutional response focus on the procurement of medicines and on the passive acceptance of institutional limitations, perceptions that are supported on the ready availability of alternative sources of care and on a focus by IMSS itself on addressing supply of consultations and oral medications rather than on promoting beneficiary empowerment.

The current budgetary impact of diabetes care is around 14% of the sickness and maternity insurance and needs to be taken up to 22% if access and quality of care is to be significantly improved. Yet IMSS financing is characterized by funding shortages given it depends on contributions by employers, employees and the government which are tied to affiliation, itself stagnant in the context of a slow-growing formal private sector.

Recommendations

Given that the most costly and challenging diabetes care interventions are those related to human resources and insulin, reforms should be developed with universities, professional associations, and trade unions as well as with the pharmaceutical industry to ensure breakthroughs in new professional and technical profiles and more efficient pharmaceutical production and distribution. These strategies should be firmly supported on digital innovation capable of drastically reducing treatment costs while improving adherence, quality monitoring, and evaluation. Reforms should focus on efficiency, quality, and equity through a national diabetes care policy capable of empowering persons living with the disease regardless of institutional affiliation and providing cross-institutional technical support and monitoring platforms. Such a policy should also integrate financing through a national diabetes care fund to provide performance incentives and ensure continuity of quality care for persons cycling through the formal and informal economy. Public private collaboration should also be supported through legal and normative changes to enable competition and promote collaboration. Other countries have already experimented successfully with such national disease-oriented policies, with Germany as a case in point given that its social insurance institutions were the basis on which IMSS was established in Mexico [30].

Clinical Inertia and Diabetes Outcomes

26

Joel Rodriguez-Saldana

Introduction

Health care delivery or medications are not the only possible influences on diabetes control [1, 2]. Patients and physicians' factors and the organization and process of health care interact by need and determine the outcomes. Clinical inertia and patient adherence are two main deterrents of the effectiveness in patient-provider encounters. Awareness, prevention, and tailored interventions to reduce their impact are essential to achieve the goals and improve the quality of diabetes management.

Clinical Inertia

Resistance to accept and implement effective innovations has always been characteristic of every human endeavor, and the history of medicine provides many illustrative examples of evidence-based interventions that had to wait years or even decades before acceptance by practitioners. A major challenge of health care is to increase the uptake of evidence-based medicine in "the real world," that is, knowledge translation, "the process of taking evidence from research and applying it in clinical practice" [3]. The history of medicine is plagued by multiple examples about the difficulties and delays to introduce evidence into this "real world" [3]. Despite the development of new medications, a significant proportion of people with type 1 and type 2 diabetes fail to achieve glycemic goals [4]. One of the main goals of clinical practice guidelines (CPG) is to accelerate the introduction of medical innovations, but implementation and compliance by physicians is still limited and challenged. Clinical inertia is one of the main causes.

Definitions and Evolution

Clinical inertia as an entity was recently described, albeit examples of noncompliance with clinical guidelines or failure to intensify medical treatment have been recognized many years ago. In 1998, for example, Frolkis and colleagues published the results of a chart review of 225 patients admitted to a coronary care unit, in which they showed that despite the wide availability of guidelines for the detection, evaluation and treatment of hyperlipidemia, and the results of major clinical trials of primary and secondary prevention of coronary heart disease, physicians were poorly compliant, even in patients at high risk [5]. Implementation of clinical guidelines and putting evidence-based medicine at work is still far from accomplished [5–8].

Origins and Definition

The term "clinical inertia" was coined by Curtis Cook and colleagues in 1999 to describe the effectiveness of a structured program to improve glycemic control and the importance of self-examination of performance to overcome clinical inertia in 698 African–American patients with type 2 diabetes from Atlanta [9]. Recognizing its importance, the authors of this study established and measured a quality improvement program with increased emphasis on intensification of therapy, along with perceived barriers to advance treatment [9]. Two years later, they authored the landmark review about clinical inertia, which they defined as "the inability of physicians to achieve the goals of treatment after repeated visits," "the recognition of the problem but failure to act," or more specifically as the "failure of health care pro-

viders to initiate or intensify therapy when indicated" [10]. Recent definitions describe clinical inertia as "an office visit at which no therapeutic move was made to achieve the goals of treatment" [11] or as "failure to treat to target or prescribing that is not concordant with clinical guidelines" [11], with the additional claim that clinical inertia could be "a clinical safeguard for the drug intensive style of medicine fueled by current medical literature and pharmaceutical companies, in the best benefit of patients to adopt less aggressive and also less risky and costly approaches" [12]. Finally, Fraenkel and colleagues defined clinical inertia as "the preference to maintain the status quo, a barrier to implement treat to target protocols in patients with chronic diseases" [13].

The influence of clinical inertia on the negative results of patient management has been documented worldwide in the treatment of a variety of diseases and disciplines, starting with diabetes and including hypertension [14–19], dyslipidemia [20, 21], depression [22], osteoporosis [23], hepatic encephalopathy [24], geriatrics [25, 26], kidney transplantation [27], valvular heart disease [28], dentistry [29], osteoarthritis [30], and chronic obstructive pulmonary disease [31].

The Impact of Clinical Inertia in Diabetes Management

Clinical inertia was originally described in diabetes outpatient management, but it has also been reported in hospitalized patients. Table 26.1 presents a summary of studies published from 1999 to 2021 by a Pubmed search under the terms "Clinical Inertia and Diabetes" and "Failure to Intensify Diabetes Therapy" [9, 32–74].

Table 26.1 Studies about clinical inertia and diabetes

Year	Country and reference	Patients	Type of study or intervention	Results
1999	USA [9]	698 African–American patients with type 2 diabetes	Observational study: self-report of patients with intensified therapy; barriers to advance treatment	Average reduction in HbA1c of 1.4%; progressive improvement in the percentage of patients achieving HbA1c targets; 57% at goal in 5 years
2000	USA [32]	4523 patients with HbA1c results, 2892 with at least one follow-up test	Assessment of diabetes care using pharmacy and laboratory data from nine medical groups to determine dispensing patterns and changes of therapy based on HbA1c results	Despite having HbA1c levels above 8.0%, most patients had no changes in therapy. Inadequate follow-up was documented in more than 60% of patients. The effect of changes in therapy on subsequent HbA1c results could not be assessed.
2003	USA [33]	570 patients with type 2 diabetes receiving metformin in addition to sulfonylureas	Retrospective observational study Pace and patterns of therapeutic failure and clinical responses	HbA1c levels inexorably rise before clinicians react: patients spent months at HbA1c levels above 8.0%, and glucose lowering actions were only established when HbA1c levels were 9.0% or higher. Hyperglycemic peaks preceded changes in therapy.
2004	USA [34]	7208 complete courses of non-pharmacologic or oral antidiabetics	Retrospective observational study Cumulative glycemic burden: months at HbA1c levels above 8.0% or below 7.0%	The average patient accumulated nearly 5 years of excess glycemic burden above 8.0% from diagnosis until starting insulin and 10 years of excess glycemic burden above 7.0%.
2004	USA [35]	598 adults with type 2 diabetes receiving primary care in an academic medical center	Prospective observational study Failure to achieve treatment goals for HbA1c, systolic blood pressure (SBP) or low density cholesterol (LDL) after 1 year	Delays and low rates of intensification for every treatment goal: 51% of patients with high HbA1c, 30% of patients with high SBP and 30% of patients with high LDL had increases in regimes. A decline in the proportion of patients above the LDL after 1 year, not for HbA1c or blood pressure
2005	USA [36]	1765 adult patients with type 1 or type 2 diabetes from 27 primary care and 17 diabetes or endocrinology clinics	Retrospective observational study Measurement and control of HbA1c, blood pressure, cholesterol and corresponding medical regimen changes	High annual testing rates for HbA1c, blood pressure, and total cholesterol (97.7%, 96.6%, and 87.6%, respectively) Patients at goal for HbA1c: 34.0%, for blood pressure: 33.0%, for lipoproteins: 65.1%, for total cholesterol: 46.1%, for LDL cholesterol Only 10% of the patients met the recommended goals for all three risk factors. Lack of intensification was equal for patients with type 1 and type 2 diabetes.

Table 26.1 (continued)

Year	Country and reference	Patients	Type of study or intervention	Results
2005	Canada [37]	591 patients receiving specialist care and 1911 receiving primary care	Retrospective observational study Differences in clinical inertia between specialists and primary care physicians	45.1% of patients receiving specialist care versus 37.4% of patients receiving primary care had drug intensifications ($P = 0.009$), attributed to more frequent use of insulin among specialists High prevalence of clinical inertia in both groups
2005	USA [38]	23,291 patients with diabetes from 13 Department of Veterans Affairs hospitals	Retrospective observational study Developing a valid quality measure to identify clinical inertia and its consequences on glycemic control	Despite 39% of patients having an initial HbA1c level above 8.0%, increases of antidiabetic medications occurred at only 9.8% of visits. Patients receiving more intensive therapy had greater improvements in control.
2005	USA [39]	438 African American patients in primary care and 2157 patients from a specialty clinic by endocrinologists	Longitudinal observational study	Average A1c in the medical clinic: 8.6%, in the diabetes clinic: 7.7% ($P < 0.0001$) Lower number of drugs and rates of intensification occurred in the medical clinic, but intensification at both sites was associated with improvements in A1c. Patients from the medical clinic had worse glycemic control, were less likely to use insulin and to have their therapy intensified if glucose levels were above target.
2006	Australia [40]	531 patients with type 2 diabetes from an urban clinic	Longitudinal observational study Baseline assessment and 5 annual follow-up visits Assess effectiveness of management of type 2 diabetes	Low rates of intensification: after 8.1 years follow-up, 18% of patients progressed from diet to oral antidiabetics (OAD) 9% progressed from OAD to insulin Median HbA1c levels to start OAD or insulin were 7.7% and 9.4%.
2006	USA [41]	345 internal medicine residents receiving computerized reminders about patient-specific recommendations; feedback on performance	Behaviors when glucose was above 150 mg/dL were classified as "did nothing," "did anything," or "did enough" to describe clinical inertia or two levels of intensification	At baseline, residents "did nothing" in 65% of the visits, and "did anything" or "did enough" in 35% of visits After 3 years, 52% "did anything" and 30% "did enough" Active interventions were followed by significant increases in trends to intensify therapy during visits. Health care behavior improved more in the feedback intervention groups than in control groups. Greatest improvements in the first year, decreased afterwards.
2006	USA [42]	Random sample of 5% of 1812 hospital records with a discharge diagnosis of hyperglycemia	Observational study magnitude of clinical inertia in hospital management of diabetes	Despite a diagnosis of diabetes in 96% of patients at admission, daily notes mentioned diabetes in 62% of cases and 60% of discharge notes; only 20% of discharges included diabetes follow-up 86% of patients had bedside glucose measurements, but only 52% had documented assessment of glucose severity. Despite a high frequency of hyperglycemia (71%), only 34% of patients had changes in therapy

(continued)

Table 26.1 (continued)

Year	Country and reference	Patients	Type of study or intervention	Results
2006	USA [43]	253,238 patients with hypertension, dyslipidemia, and diabetes	Retrospective observational study	64% of patients experienced modifications for poorly controlled systolic blood pressure, 71% for poorly controlled diastolic blood pressure, 56% for poorly controlled LDL cholesterol, and 66% for poorly controlled A1c. Intensification included increases in the number of drug classes and increased dosage 3–4% of patients with high A1c values achieved control without changes in therapy, Patients' preferences and adherence were not measured,
2007	USA [44]	2065 patients with type 2 diabetes newly started on antidiabetics and followed 3 or more years	Prospective observational study Initial medication adherence and regimen intensification	Baseline medication adherence: 79.8 ± 19.3% By comparison to patients in the highest quartile of adherence, patients in the lowest quartile were significantly less likely to have increases in regime within 1 year of their first elevated A1c. Patients in the highest adherence quartile had 53% greatest odd of medication intensification.
2007	USA [45]	Patients with type 2 diabetes and 211 primary care visits	Cross-sectional observational study Competing demands to changes in antidiabetic medications Intervals of return appointments in patients with high HbA1c levels	Each additional patient concern was associated with a 49% reduction in the likelihood of change in medication, independent of the length of the visit and the most recent level of HbA1c. For each additional increase in HbA1c, the time to the next scheduled appointment decreased 8.6 days. The concept of clinical inertia is limited and does not fully characterize the complexity of primary care encounters.
2008	USA [46]	254 patients with type 2 diabetes	Prospective observational study Visit-based factors associated with intensification of antihypertensive medications in adults with diabetes	Primary care providers intensified antihypertensive treatment in only 13% of visits in which blood pressure was high Higher systolic and diastolic blood pressures were important predictors of intensification. Factors associated with failure to intensify treatment: capillary glucose >150 mg/dL, coronary heart disease, or comanagement by a cardiologist
2008	USA [47]	105 patients with diabetes hospitalized for cardiothoracic surgery	Retrospective observational study Barriers preventing appropriate glycemic control in an academic center	Only six patients (5.7%) had adequate glucose control, 99 (94.3%) required intervention. 30 barriers to achieve glycemic control identified, including "therapeutic reluctance," inappropriate titration of medication, lack of basal insulin, lack of weekend staff trained in diabetes management, use of sliding scale, prescription of inappropriate medications, knowledge deficits of the staff for weekends, and omission to restart outpatient diabetes medications
2009	USA [48]	1718 patients discharged from 37 academic medical centers	Retrospective observational study Contemporary management of hyperglycemia	Wide variations in hospital performance of recommended hospital diabetes care, including A1c and glucose measurement Median glucose significantly lower for patients in intensive care units compared to other areas On the third day of admission, only 25% of patients had 6:00 AM glucose. ≤110 mg/dL 50% of patients had ≥1 glucose measurement ≥180 mg/dL on days 2 and 3 severe hypoglycemia occurred in 2.8% of all patient days

Table 26.1 (continued)

Year	Country and reference	Patients	Type of study or intervention	Results
2009	Netherlands [49]	1283 patients from 30 general practices	Randomized controlled trial on the implementation of a locally adapted diabetes guideline	Percentage of patients with poor diabetes or lipid control who did not receive treatment intensification in the intervention and control group: 90% and 45%, respectively. Clinical inertia was higher in patients above target in blood pressure (72.7% vs. 63.3%). Clinical inertia was less common when nurses participated in the management. In both study groups, cholesterol decreased significantly more in patients receiving treatment intensification.
2010	Canada [50]	379 type 2 patients treated with insulin with and without oral antidiabetics	Survey of 109 family physicians including HbA1c target levels and perceived barriers to insulin initiation and intensification	Mean time from diagnosis of diabetes to insulin initiation: 9.2 years Mean HbA1c values before insulin initiation at visit 1: 9.5%, 8.1% at visit 2 and 7.9% at visit 3 20% of patients at visit three continued with HbA1c above 9.0%
2011	USA [51]	10,743 patients with newly diagnosed type 2 diabetes from an electronic medical record database	Retrospective observational study	Older patients had higher baseline HbA1c values. 59% of younger patients at 2 year follow-up received oral antidiabetics (OAD) compared with 44% in older patients. Median time between diagnosis and start treatment with OAD for younger patients: 350 days; more than 2 years for older patients
2012	France [52]	17,493 patients with type 2 diabetes receiving oral antidiabetics	Retrospective observational study Current procedures to intensify hypoglycemic treatment in general practice according with clinical guidelines	18% of patients required treatment intensification Treatment intensification after second HbA1c: immediately in 39% of patients, within 6 months in 13%, within 6 months in 39% and within 1 year in 59% Treatment intensification was less likely in older patients, and more likely at higher HbA1c levels.
2012	USA [53]	1359 patients from a veterans affairs hospital	Retrospective observational study Effect of hospital admission on the medical treatment of poorly controlled diabetes	Of 2015 admissions, 454 had some change in diabetes medications at discharge (22.4%). Higher preadmission HbA1c levels, higher mean glucose at admission, inpatient hypoglycemia, and use of insulin were associated with greater odds of change in therapy. Clinical inertia occurred in 656 admissions (32%), with no change of therapy, no documentation of HbA1c 2 months after discharge, and no follow-up appointment within 1 month of discharge.
2012	USA [54]	770 patients with type 2 diabetes	Survey of 508 primary care physicians by internet Relevant clinical information and reasons about absence of treatment in older patients	Reasons to omit pharmacologic treatment: use of diet and exercise (57.5%), mild hyperglycemia (23.8%), patient's concerns (13.4%), specific concerns about antidiabetics (3.0%), and comorbidities and polypharmacy (2.3%)
2012	USA [55]	83 primary care physicians	Cross-sectional study Structured interviews Providers perceptions about the importance to initiate insulin therapy, factors and barriers affecting this decision	80% of PCPs endorsed glycemic targets. 54% individualized targets based on age, life expectancy, comorbidities, self-management capacity, and willingness 64% reported that patients were resistant to new oral or insulin therapies because of fears about them 80% cited patients' nonadherence would dissuade them from initiating insulin 64% cited patients' resistance as a barrier to initiate insulin 43% cited problems of patient self-management

(continued)

Table 26.1 (continued)

Year	Country and reference	Patients	Type of study or intervention	Results
2013	Spain [56]	2783 patients with type 2 diabetes from primary care centers	Cross-sectional observational study	35.8% of patients had HbA1c levels above 7.0% Intensification of therapy occurred in 66.8%, including increase in dose (40.5%), addition of oral antidiabetics (45.8%), and addition of insulin (3.7%). Clinical inertia was established in 33.2% of patients and diminished along with complexity of therapy and with HbA1c increase. Clinical inertia decreased 47% for each unit of increase in HbA1c
2013	UK [57]	81,573 patients with type 2 diabetes from a national database	Retrospective observational study Time to treatment intensification in patients receiving one, two or three oral antidiabetics (OADs) and associated levels of glycemic control	Median time from HbA1c above goals (≥7.0, ≥7.5, or ≥8.0%) to intensification with an additional OAD: 2.9, 1.9, or 1.6 years, respectively, for patients taking one OAD, and >7.2, >7.2 and >6.9 years for those taking one, two, or, three OADs Mean HbA1c at intensification with another OAD or insulin for patients taking one, two, or three OADs: 8.7, 9.1 and 9.7% Probability of intensification in patients with poor glycemic control taking one, two, or three OADs at the end of follow-up with another OAD: 21.1–43.6%; with insulin: 5.1–12.0%
2014	UK, Spain, Brazil, India, Japan, USA [58]	652 patients with type 2 diabetes and 337 physicians	Cross-sectional study; 20-min online survey Opinions related to clinical inertia from patients and physicians' perspectives Perceptions and expectations about diagnosis, treatment, diabetes complications and therapeutic escalation	Important discrepancies in terms of patient and physician perceptions Physicians have low expectations for their patients. Patients have. at best, a rudimentary understanding of the risks of complications and the importance of control. Only 25% were reported to be worried about developing diabetes complications; the rest were either not concerned or thought the risk was remote. A small proportion believe that lifestyle changes are important; only 37% acknowledge that this is a treatment modality. The majority do not intend to adhere to treatment. Impairments in communication are at the heart of clinical inertia.
2014	Bahrain [59]	334 patients from a diabetes outpatient clinic	Retrospective observational study Association between clinical inertia with simpler interventions and outcomes	Greater treatment intensification for high HbA1c than for high blood pressure or LDL Clinical inertia for hyperglycemia: 29%, hypertension: 68%, high LDL: 80% Omission to increase oral antidiabetics or insulin occurred in 29% of medical visits Omission to increase antihypertensives occurred in 67.5% of medical visits Omission to increase lipid lowering therapy occurred in 79.7% of medical visits Clinical inertia is greater for blood pressure and lipid control than for hyperglycemia

Table 26.1 (continued)

Year	Country and reference	Patients	Type of study or intervention	Results
2014	Spain [60]	2971 patients with type 2 diabetes, 1416 controlled (A1c <7.0%) and 1555 not controlled (A1c ≥7.0%)	Retrospective, cross-sectional observational study	Prevalence of partial clinical inertia (PCI) in some medical visits was 52.5%. Prevalence of total clinical inertia (TCI), absence of intensification of therapy in all visits despite A1c ≥7.0% was 12.8% PCI was lower in patients controlled and associated with sedentary lifestyle, hypertension, and a higher prevalence of vascular complications,
2015	UK [61]	20 healthcare providers in general practice	Interviews with 20 providers, 19 physicians, and 1 nurse Ten providers worked in general practices with high scores for quality and outcomes framework (QOF) targets 10 providers from lower scoring practices	Most of the people interviewed were unaware of the term "clinical inertia" or unclear about its meaning. Interviewees from both lower and higher scoring practices were willing to acknowledge limitations in achievements related to glycemic control and a degree of responsibility. Participants had inaccurate perceptions about levels of achievement in their primary care centers and sought to lessen their own accountability by highlighting patient and system barriers. Addressing clinical inertia was not seen straightforward, as result of a complex and cumulative pattern of barriers at the provider, patient, and system level
2015	Croatia [62]	10,275 patients with diabetes	National, cross-sectional, observational study Rate of clinical inertia to treat diabetes in primary care; association of patient, physician, and health setting factors	Clinical inertia occurred in 57.7% of clinical encounters. Mean clinical inertia by practitioner was 55.6%; 9% were clinically inert with all patients. Clinical inertia was associated with increases in HbA1c. Patient and physician characteristics associated with clinical inertia: fasting blood glucose, hypertension, high triglycerides, unhealthy dietary habits, chronic comorbidities, number of patients under care, number of daily medical visits, and initiation of oral antidiabetics HbA1c levels had the highest association with clinical inertia; patients with worse glycemic control were more likely to experience it.
2015	USA [63]	75,000 patients with type 2 diabetes from a managed care claims database (IMPACT©)	Prevalence and predictors of clinical inertia based on personalized goals Three HbA1c targets to identify patients above targets during the index period; clinical inertia was defined as no intensification of treatment during the response period	Regardless of HbA1c target, 70% of the patients experienced clinical inertia over 6 months and remained above 50% up to 3.5 years later. Time to intensification by addition of an oral antidiabetic, insulin or a GLP-1 receptor agonist ranged from 50.5 to 59.0 days at 6 months and from 702 to 738 days at follow-up. During the first 6 months, 20% of patients were prescribed an oral antidiabetic, 5.3% received insulin, and 2.0 a GLP-1 analog predictors of intensification: point of service insurance, mental illness, a visit to an endocrinologist, or higher HbA1c level. Intensification was less likely in older patients, patients taking more than one antidiabetic during 6 months, or recent HbA1c measurement above target.

(continued)

Table 26.1 (continued)

Year	Country and reference	Patients	Type of study or intervention	Results
2016	UK [64]	11,696 patients with type 2 diabetes from a clinical practice research database	Retrospective observational study Prevalence of clinical inertia in patients treated with basal insulin	Basal insulin was started in all patients at a mean ± SD HbA1c of 9.7 ± 2.0% 80.3% of patients were receiving ≥2 oral antidiabetics at the start of insulin. 36.5% had intensification of treatment Median time to intensification: 3.7 years Delay to intensify was associated with increasing age, duration of diabetes, use of oral antidiabetics, and Charlson comorbidity index score. 32.1% of patients with HbA1c ≥7.5% suspended basal insulin
2016	Finland [65]	1075 adult patients with type 1 diabetes from a regional electronic patient database and medical records	Retrospective observational study To investigate if the targets established in the guidelines for patients with type 1 diabetes are achieved in medical practice	Despite one of the highest worldwide prevalence of type 1 diabetes (0.8%), only 19% of patients reached a HbA1c target of <7.0% and 45% had LDL levels below 100 mg/dL Overall, 13–16% of patients younger than 60 and 26% of patients older than 60 years achieved targets of glycemic control.
2016	Thailand [66]	98 patients with type 2 diabetes and mean HbA1c 10.3%	Retrospective observational study Effects of clinical inertia on glycemic control and diabetes related complications	Prevalence of clinical inertia: 68.4% Mean decrease of HbA1c at 6 months: Clinical inertia group: 0.82 ± 1.5% Non-inertia group: 3.02 ± 1.8% After 4 years: 1.46 ± 1.85% and 3.04 ± 1.76% Clinical inertia was associated with a shorter median time to progression and a higher incidence of diabetic retinopathy Adjusted incidence rate ratio of diabetic retinopathy in the clinical inertia group: 4.92
2017	Belgium [67]	578 insulin-naive patients with type 2 diabetes	Retrospective cohort study, 8-year analysis, 1.2 years follow-up Clinical inertia defined as equivalent to prolonged inaction (PI): no change in treatment with an A1c level > 7.0% for a 12-month minimum	Prevalence of clinical inertia or PI: 59% Associated factors: Moderate to severe chronic kidney disease (CKD) Less-frequent A1c measurement Lower A1c levels Less additional medications Physicians lag behind clinical guidelines: the "real trigger" for action is not an A1c level of 7.0%, intensification occurs above 7.0% or even at 8.0% Except for CKD, severe comorbidity does not impede adjustment in hypoglycemic treatment. Intensive follow-up at the process level is associated with intensive treatment adjustments.
2018	France [68]	6045 patients ≥18 years with type 2 diabetes either simultaneously or sequentially treated with two OADs, GLP-1 receptor agonists or basal insulin	Retrospective analysis of a database of commercial claims Clinical and economic outcomes in patients with uncontrolled type 2 diabetes initiating two OADs, GLP-1 agonists or basal insulin 1-year follow-up	Despite A1c lowering following treatment initiation, many patients do not achieve A1c goals, suggesting a need for earlier or more intensive treatment. The percentage of patients with A1c >7.0% 4 years after initiation of a new class of antihyperglycemic medication ranged from 48% with OADs to 74% in patients initiating basal insulin. Baseline A1c was highest in patients receiving basal-insulin as second drug (10.1%) At the last follow-up measurement, 47.5% of patients initiating OADs, 41.1% of patients initiating GLP-1 agonists, and 32-0.6% of patients initiating basal insulin had A1c levels <7.0%.

Table 26.1 (continued)

Year	Country and reference	Patients	Type of study or intervention	Results
2018	USA [69]	6597 patients with type 2 diabetes who started basal insulin following OADs and had at least one valid HbA1c result 90 days before and 720 days basal insulin initiation	Retrospective analysis of a database of commercial claims Probability of achieving glycemic control over 24 months after baseline insulin initiation in patients with type 2 diabetes	Average HbA1c at basal insulin initiation: 9.1%, 1.5% decrease in the first 6 months after, with no further reduction Rapid decrease in the probability of reaching glycemic control in the first year and remained low in the second year 38% of patients reached HbA1c <7.0% in the first year, 8.0% in the second year
2018	USA [70]	7389 patients with type 2 diabetes and an A1c value ≥7.0% despite a stable regimen of two OADs for at least 6 months	Retrospective analysis of an electronic health record system	62.9% of patients had no evidence of treatment intensification, including 71.7% of patients with A1c 7.0–7.9%, 53.3% of patients with A1c 8.8.9% and 44.4% of patients with A1c ≥9.0% Physicians do not respond quickly enough to poor glycemic control, even in patients with A1c levels far exceeding typical treatment targets
2018	Germany [71]	4576 patients with type 2 diabetes not achieving glycemic control (HbA1c >7.0%) with dipeptidyl peptidase-4 inhibitors (DPP-4i) and sodium/glucose cotransporter 2 inhibitors (SGLT-2i)	Retrospective observational study	Mean time on poor glycemic control until most recent visit was: 12.6 months with HbA1c >7.0% 9.9 month with HbA1c >7.5% 8.4 months with HbA1c >8.0% Even with the use of new oral antidiabetics, a substantial proportion of patients do not achieve glycemic control
2019	United States [72]	7389 patients with type 2 diabetes and an A1c value ≥7.0% despite a stable regimen of two OADs for at least 6 months	Follow-up retrospective analysis of an electronic health record system*	Probability of achieving an HbA1c goal of 7.0% At a baseline level of 7.0–7.9% with addition of: Oral antidiabetics: 57.3% GLP-1 agonists: 56.7% At a baseline level of 8.0–8.9% with the addition of: Oral antidiabetics: 31.9% Insulin: 30.6% At a baseline level ≥9.0% with the addition of: GLP-1 agonists: 53.0% Insulin: 43.5% Goal attainment by type of intensification was more likely in patients with HbA1c levels ≥9.0%
2020	Malaysia [73]	7646 patients with type 2 diabetes from a national diabetes registry	Retrospective observational study	Median time to treatment intensification: 15.5 months, 19 months, and 27.8 months under the best, average, and worst-case scenarios Total proportion of patients with treatment intensification: 45.4% of which 34.6 occurred only after 1 year Patients treated with more antidiabetics were less likely to have treatment intensification
2021	United Kingdom [74]	254,925 people with incident type 2 diabetes, dyslipidemia (66%) and hypertension (66%) from a primary care database	Retrospective observational study	Significant delay in initiating cardioprotective therapies irrespective of atherosclerotic vascular disease risk status across all age groups resulting in poor risk factor control at 2 years follow-up Median number of months to initiation of therapy for persons with dyslipidemia: 20.4 Median number of months to initiation of therapy for persons with hypertension: 28.1

*Type of study

These studies confirm the magnitude, the negative outcomes, and the benefits of interventions to reduce the effect of clinical inertia in diabetes management. The following conclusions can be made:

1. Clinical inertia for all diabetes goals including glucose, blood pressure, and lipoprotein profile is high and equally remarkable in patients with type 1 and type 2 diabetes: 19% in type 1 diabetes; 33–70% for HbA1, 30% for hypertension, and 30% for low-density lipoprotein (LDL) cholesterol in type 2 diabetes.
2. The glucocentric approach prevails: treatment intensification is more likely for high HbA1c than for hypertension or high LDL cholesterol.
3. Lack of glycemic control occurs at every clinical setting: outpatient, inpatient, medical and surgical.
4. Physicians have low levels of awareness about clinical inertia.
5. Even at levels of high risk, the response of clinicians to clinical inertia is insufficient representing up to 5 years of excess glycemic burden.
6. Rates of treatment intensification are low (less than 10.0%) and slow (up to 5 years).
7. Rates to initiate every therapeutic modality, including newer therapeutic classes, are low and slow, with insulin at the top (up to 9.2 years).
8. After hospital discharge, high rates of hyperglycemia (64%), persistent hyperglycemia (50%), and low rates of diabetes follow-up (20–22%) have been documented.
9. Clinical inertia is also associated with low patient adherence, disregard of glycemia, patient concerns, comorbidity and polypharmacy.
10. Intensification of therapy improves metabolic control, reducing HbA1c, blood pressure, and LDL cholesterol levels.

Factors Associated with Clinical Inertia

For factors associated with clinical inertia, in their classical review, Phillips and colleagues identified three groups of factors as the main causes of clinical inertia: (1) overestimation of care provided, physicians consider that patients are improving despite lack of change in clinical results; (2) subjective or "soft reasons" to avoid intensification of therapy ("the patient is improving"); and (3) lack of education, training, and practice organization focused on achieving therapeutic goals [10]. The third group of factors include challenges to implement clinical guidelines, such as ignorance about their existence, lack of compliance, denial, or frank rejection by physicians [5, 75, 76]. Beyond glycemic control, clinical inertia involves all the aspects of diabetes management: Worrall and colleagues showed that 53% of patients had HbA1c measurements done in the previous year and that the average number of procedures and tests conducted by family physicians in Canada was 5.9 from 11 recommendations by the Canadian Diabetes Association [75]. Table 26.2 summarizes factors associated with clinical inertia [77–85]:

Table 26.2 Factors contributing to clinical inertia

Author and reference	Description
Phillips et al. [10]	Overestimation of the care provided "Soft reasons" to avoid intensification Lack of training
Fantini et al. [6]	Organization "arrangements": individual versus in-group practice Patient characteristics: older age, comorbidities Location of practice: rural versus urban
Barth et al. [8]	Age of physicians: older clinicians more frequently work in individual practice and rely on experience; younger clinicians more inclined to accept collaborative, team-based medicine, protocols, and clinical guidelines
O'Connor et al. [77]	Physician factors: failure to initiate and titrate treatment until goals are achieved; failure to identify and manage comorbidities; ineffective clinical encounters; insufficient time; reactive, instead of proactive, care Patient factors: denial or belief that the disease is not dangerous, low health literacy, cost and amount of medications, side effects, poor communication or distrust in physicians, depression System factors: absence of clinical guidelines or disease registries, planning deficiencies, absence of outreach, support and team approach, poor communication
Reach [78, 79]	Discrepancy between the technical rationality of evidence-based medicine and the modes of reasoning of physicians "in real life" "Clinical myopia": failure to give preference to the benefits of treatment intensification
Miles [80, 81]	"Fallacious reasoning and cognitive bias": a conscious decision to withhold or omit the use of evidence-based medicine
Safford et al. [82]	Appropriate inaction; potential appropriate decisions resulting from patients' factors: lack of adherence, psychological or physical stress, lack of resources
Aujoulat et al. [83]	Providers' knowledge of and attitudes toward evidence-based guidelines: Insufficient knowledge, disagreement or distrust, lack of applicability Providers' clinical judgment and experience within specific situations Sociodemographic characteristics and medical history of patients, values, comorbidities, polypharmacy, concerns, and reluctance Providers' awareness of patients' attitudes, behaviors, preferences, adherence, literacy, and empowerment Providers' ability to make the appropriate decision within a given clinical and organizational context: reluctance or difficulty to change, clinical uncertainty, limited time, absence of multidisciplinary or team-based care

Table 26.2 (continued)

Author and reference	Description
Strain et al. [84]	Physician factors: overrating the quality of care provided, underestimating the number of patients who are not in target, use of soft excuses to avoid intensification, lack of time, blaming patients' noncompliance, paternalistic approach, knowledge or training to manage multiple chronic diseases, lack of clarity of clinical guidelines Systemic contributors: traditional clinical guidelines focused on goal-setting pathology management disregarding the importance of communication between patient, physicians and multidisciplinary teams (if available); physicians working in isolation within the health system; time constraints, delays Patient factors: non-adherence; socioeconomic factors; lack of understanding and engagement with the treatment
Kunthi et al. [85]	Clinician-level barriers: limited awareness of clinical inertia; clinicians' overestimation of their quality of care and adherence with guidelines Patient-level barriers: lack of health education, disbelief in the efficacy of therapy, concerns about effects of therapy on quality of life, fear of side effects, lack of confidence to adhere to complex regimes

Clinical Inertia in Defense of Patients

Clinical inertia, in defense of patients in counterpart to its negative implications, has also been described as a clinical safeguard, based on the results from clinical trials showing absence of clinical benefits on cardiovascular outcomes with tight glycemic control in patients with type 2 diabetes, and increases in all-cause mortality, hypoglycemia, and weight gain, particularly patients with frailty and the elderly. Comorbidities and competing health, personal, and social factors are common in patients from every age group, and interventions to correct them are essential components of management. A retrospective analysis to examine physician and patient characteristics showed that nearly all physicians have practiced clinical inertia and that the volume of patients was the most important variable, but patient characteristics including older age, obesity, and comorbidities are stronger predictors, and physicians frequently have to devote their limited time to address other medical problems and to take into account patient's priorities and preferences [76]. At the opposite end of treatment intensification lies the fourth level of prevention, quaternary prevention, originally described by Marc Jamoulle in 1995 [86]. Quaternary prevention is defined as "action taken to identify patients at risk of excessive medical treatment and to protect them from medical interference," which has become an international movement against overmedicalization that has been endorsed and embraced by general physicians and specialists worldwide [86–88]. The principles of hastening to help and doing no harm have to be considered when establishing the relative risks of clinical inertia versus overtreatment in patients with diabetes [85]. The concept of quaternary prevention is all-pervasive; it should be adopted by the diabetes care team and be expressed in every patient-provider contact [88].

Contribution of Clinical Guidelines to Clinical Inertia

One of the main goals of clinical guidelines is guiding physicians to overcome clinical inertia, but reluctance to comply with them is highly prevalent [89]. Clinical guidelines may also contribute to clinical inertia, when they focus on limited aspects, like selecting medications, in disregard of other components of successful treatment like patient education and self-monitoring of blood glucose [90]. Recent guidelines issued by the American College of Physicians (ACP) for glycemic targets in adults with type 2 diabetes addressed these challenges and proposed four guidance statements: (1) personalization of goals for glycemic control, (2) establishing an HbA1c target between 7.0% and 8.0% in most patients, (3) de-intensifying treatment in patients achieving HbA1c levels below 6.5%, and (4) liberalizing control in patients with life expectancy less than years, advancing age or severe comorbidities [91]. While the message conveyed by the revised ACP guidelines is about safety, it has arisen criticism and concern from experts and academia [92, 93]. Arguments against this approach are that while the message conveyed by the American College of Physicians guidelines is one concerning safety, it does little in terms of elaborating on the recommendations concerning an HbA1c target between 7% and 8% [93]. Newer available antidiabetics facilitate glycemic control at lower risk of hypoglycemia, and the concern is that the revised ACP statements may stimulate and validate it [93].

Treatment algorithms cannot be always evidence-based because they are unable to present all the available treatment options [94], but recent guidelines have stressed the importance and, more frequently, the influence and dominance of comorbidities and social determinants of health in the selection and intensification of therapies [95].

Awareness and measurement of clinical inertia is increasing, and it has been shown that it is more important than poor adherence to therapy by patients in the outcomes [96, 97]. It has been also shown that educating physicians is less fruitful than educating patients [98]: Roumie and colleagues, for example, published a study in which 182 providers were randomly assigned to receive several alternatives of education, including online access to the JNC 7 guidelines on prevention, evaluation, and treatment of high blood pressure, and 1341 patients with hypertension received computerized alerts and letters advocating drug adherence and face to face educa-

tion. After 6 months, patients who received education had better hypertension control and lower systolic blood pressure than patients in whom physicians were the ones who received education [98]. Analysis of physicians' responses to computer alerts to comply with the JNC 7 guidelines replicated the list of the "soft reasons" described in the landmark review by Phillips et al., including lack of agreement with the guidelines (5%), patient-based factors (17%), environmental factors (10.5%), lack of knowledge (2%), and soft arguments supporting clinical inertia in 66% ("continue the current medications and I will discuss at the next visit") [98].

Addressing Clinical Inertia

The role of clinical inertia [99] in the poor results to achieve the goals of glycemic control, hypertension, and hypercholesterolemia has been clearly established [100]. Accordingly, several strategies have been proposed to address and modify its negative effects:

1. Raise the awareness: more studies about the epidemiology and consequences of clinical inertia are required to measure its worldwide extent, including individual patient, physician and clinic factors, patient–physician relationship factors, and "complex patient" selection effects including competing health problems and nonadherence [100].
2. Measurement: clinical inertia affects the outcomes and the quality of health care; application of established methods or the development of new measures to quantify its magnitude is essential. Current measures of clinical inertia in diabetes include: (1) percentage of patients having drug therapy intensification at visits above goals of glycemic control [100], (2) proportion of patients with high HbA1c levels after drug intensification [32], and (3) predictive models to establish the probability that an individual visit would result in an increase of antidiabetic medications based on characteristics at that visit including diabetic complications, cardiovascular risk factors, psychiatric or substance abuse disorders, and comorbidities [39]. The complexities and limitations of this method have been addressed by O'Connor, including poor documentation of interventions; use of a normative, instead of a threshold value; placing excessive emphasis on glucose control; and diverting attention from other diabetes quality measures [100].
3. Physician education serves as a key strategy to facilitate intensification of therapy [101]. Targeted interventions to health providers, including (1) enhanced primary care incorporating key features of clinical trials into routine chronic disease care [100, 101]; (2) scheduled, frequent, and carefully planned office visits increased direct contact time with patients [100–102]; (3) electronic medical records to provide real-time decision support to physicians during office visits measure opportunities for intensification and variations by practice and patient characteristics [100–102]; (4) monitoring, prompts, feedback, and decision support for healthcare providers to improve systems [100–102]; (5) continued managerial momentum involving five stages: (a) review the process of diabetes care, (b) identify the highest priority goals and treatment strategies, (c) increase clinical encounters in which clinicians take appropriate action, and (d) tracking progress toward achieving goals, (e) feedback to make patient-care decisions [102]; (6) performance measures to improve care and control costs, including process (accountability) and intermediate outcome items [101, 102]; and (7) incentives and pay for performance [100–102].
4. Effective communication with patients: explanation and risk management in the real world, understanding of the progressive nature of diabetes and the accompanying need to review and adjust treatments [103]. Suitable interventions to promote patient activation, involvement in decision-making and enhance adherence including feedback, education, and support [100–103]. Delivering diabetes self-care and support education and support that patients can understand, according to personal values and preferences [95, 103, 104].

Conclusion

Clinical inertia is a huge problem with dire consequences in the outcomes and the quality of diabetes care. Despite exhaustive efforts to develop evidence-based, unbiased, and feasible clinical practice guidelines, doctors frequently do not follow them. It is the consequence of a discrepancy between the technical rationality of evidence-based medicine and the reasoning of clinical practice in "real life," marked by uncertainty and risk [105]. Overcoming clinical inertia is a big challenge; to address this need, the American Diabetes Association launched a 3-year initiative called Overcoming Therapeutic Inertia (OTI) which includes three phases—Phase 1: Convening Stakeholders, Phase 2: Charting a Course, and Phase 3: Implementing Solutions [106]. The framework of this initiative involves six elements, starting with the dire need to raise the awareness about the magnitude and consequences of clinical inertia, collecting evidence about evidence-based solutions, establishing partnerships, educational interventions, and assessing effectiveness to meet goals [106].

Like other human complex problems, reducing clinical (or therapeutic) inertia requires complex solutions, starting at medical schools, and supported by updated, continuing education and assessment of physicians' performance and

outcomes. Epidemiology, analysis of responsible factors (awareness, attitude, training, organization), and design of interventions about clinical inertia are clearly areas of opportunity to improve one of the crucial aspects in diabetes care.

Multiple Choice Questions

1. Clinical inertia:
   (a) Has been recently described
   (b) Is uncommon
   (c) Is the patient's fault
   (d) **Has been described for decades**
   (e) Is exclusive of primary care
2. Clinical inertia is defined as:
   (a) Promptness to intensify medical treatment
   (b) The trend to align with medical trends
   (c) **Inability to achieve the goals of treatment after repeated visits**
   (d) **Failure to initiate or intensify treatment when indicated**
   (e) **Recognition of a problem but failure to act**
3. Clinical inertia has been reported:
   (a) Only in diabetes management
   (b) In hypertension
   (c) In diabetes and hypertension
   (d) In acute disease care
   (e) **In the management of multiple chronic diseases**
4. The reported prevalence of clinical inertia in the management of diabetes, hypertension, and LDL cholesterol is around:
   (a) 10%
   (b) 20%
   (c) **30%**
   (d) 40%
   (e) 50%
5. Treatment intensification in patients with diabetes may be delayed up to:
   (a) 1 month
   (b) 3 months
   (c) 6 months
   (d) 1 year
   (e) **5 years**
6. Introduction of insulin in diabetes treatment may be delayed up to:
   (a) 1 month
   (b) 3 months
   (c) 1 year
   (d) 5 years
   (e) **More than 9 years**
7. Clinical inertia in patients hospitalized and with diabetes:
   (a) Is nonexistent, quality of diabetes care is optimal in hospitals
   (b) **Is associated with persistent hyperglycemia and low rates of follow-up**
   (c) Is minimal with no appreciable effects on outcomes
   (d) Has been overemphasized
   (e) Has not been investigated
8. Leading factors associated with clinical inertia include
   (a) Overestimation of the care provided
   (b) Subjective reasons to avoid intensification
   (c) Lack of training, practice limitations
   (d) **All of the above**
   (e) None of the above
9. Clinical inertia may be a resource in defense of patients
   (a) **True**
   (b) False
10. Clinical guidelines may contribute to clinical inertia
   (a) **True**
   (b) False

Patient Adherence: Challenges, Myths, and Realities

27

Joel Rodriguez-Saldana

The missing link in the cycle of clinical drug development is Pharmionics, the study of what the patient does with the drug.

John Urquarth.

Introduction

To achieve the desired results of medical interventions, patients need to keep appointments, take medications, and make lifestyle changes. Their capacity to accept and carry out these tasks is unpredictable; adherence to medical recommendations is highly variable: some people are unable or unwilling to follow all of them, and only a small proportion have high levels of "compliance, adherence or concordance" [1]. Awareness about patient adherence in diabetes is important because it is associated with clinical outcomes and costs: it is estimated that for every 25% increase in medication adherence HbA1c levels decrease by 0.34% [2]. Conversely, nonadherent patients are more likely to require hospitalization and to incur in higher health care costs [2]. Adherence is a crucial link in the physician–patient interaction in chronic disease management. Suboptimal adherence to medications is frequently the main obstacle to the success of drug therapy; it is very common, it is associated with morbidity and mortality, and it is largely neglected and misunderstood [3].

An Evolving Concept

The discordance between medical prescription and patient adherence has been described since ancient times, but finding the right term has been very difficult. In 2012, Vrijens and colleagues described the evolution of the nomenclature defining and describing adherence to medications; from 1961 to 2009, they identified 146 articles and introduced a new term to describe it as "deviations from prescribed treatments." Over five decades, the main used terms were: Adherence, Compliance, Persistence, Concordance, Pharmionics, Therapeutic alliance, Persistency, Patient irregularity, and Pharmacoadherence [3]. As of today, Adherence and Compliance continue to be the preferred terms with opposite implications and are still inaccurate to describe the attitude of patients toward medical recommendations.

Defining Adherence

Over the years, adherence became the most common term, defined "as the extent to which patients take medications as prescribed by health care providers [4]." Traditional terms like "compliance" are based on the assumption that patients are supposed or willing to obey or follow medical orders [4, 5]. These assumptions are unrealistic and continue to produce conflicting differences between patients and physicians. Patients' expectations are personal, unique, and elaborate: they arise from multiple sources including past experiences with physicians; observations and comments from relatives, neighbors, friends and colleagues; public and professional attitudes; and the media [6]. Professional beliefs are also influenced by personal experiences as patients, parents, relatives, observers, professional experience, and personality [6]. Frequently and unfortunately, when patients do not meet physicians' expectations, they are labeled as "noncompliant," implying the moral failure to behave appropriately [7]. The medical concept of compliance is far from reality but still deeply rooted among physicians all over the world, and despite their crucial influence on the outcomes, interventions to improve adherence are not aimed at patients

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_27

[5]. By comparison, terms like concordance, cooperation, agreement, and therapeutic alliance imply a "meeting of minds and perspectives of health providers and patients [3]. At long last the "compliance problem" is getting a new name and with it has created a new view of the patient's role in the doctor–patient relationship [4].

Addressing Nonadherence

Adherence rates are low even among participants in clinical trials, especially for chronic diseases [8]. The design of drug trials have come to recognize the biased and limited scope of compliance and the impact of patient's behavior on statistical power and interpretation of results [5]. Lack of adherence is associated with higher rates of hospital admission, suboptimal clinical outcomes, increased morbidity, mortality, and health care costs [8, 9].

A Brief Story of Adherence

As far back as Hippocrates, physicians were concerned that patients did not follow their advice, and the resulting negative health outcomes increased the authority of physicians' recommendations [10, 11]. Infectious diseases became the first focus of patient's compliance, especially tuberculosis, which was contagious, very frequent, affected people from all socioeconomic levels, and was highly deadly before the advent of antituberculous drugs. The introduction of the first effective antituberculous drugs in the 1940 increased blaming of patients who are unwilling to accept hospitalization to receive extended course of antimicrobials [11].

Drug compliance started to be measured in the prophylaxis against streptococcal infection, and it was shown that the frequency and number of doses was inversely proportional to adherence and effectiveness of therapy [11, 12]. Further trials among children with rheumatic fever showed that penicillin injections were more effective than oral sulfas or penicillin [13, 14]. The importance of adherence to long-term therapies increased with the discovery that blood levels of p-aminosalicylic acid were lower than expected in patients with tuberculosis [15, 16] and that complexity reduced completion of therapy [17].

Social, cultural, and economic factors affecting compliance with treatment were recognized. Scientists from other disciplines began to study the personal, family, and environmental importance of adherence to medical recommendations and to explain "illness behaviors" or "sick roles" beyond the medical perspective [18–20]. Early reports showed that physicians' expectations about patients' willingness to following medical orders were unrealistic [21]. Patients' decision to accept or reject medical recommendations results from multiple factors, including their attitude toward physicians and health, knowledge about risks associated with the disease, and personal approaches to life [22]. Studies in diverse therapeutic areas confirmed these findings: in patients with heart disease, Johannsen and associates showed that education level was associated with disregard of medical advice [23]. In patients receiving antacids, Caron and Roth reported that even in patients admitted to hospitals, most of physicians inaccurately and subjectively overestimate real adherence to treatment and that they are unable to distinguish patients who actually adhere [24]. An early review about the effectiveness of three strategies to detect defaulters: (1) direct interrogation, (2) remaining tablet counting, and (3) measuring drug metabolites showed that doctors' perceptions are related to their "social distance" with patients and reasons for noncompliance included patient's "personality," doctor's attitude, capacity of patients to understand doctor's advice, personal difficulties of patients, and economic capacity to follow medical advice [25]. Explanation, reminders, and persuasion are very important to decrease noncompliance, while authoritarian and threatening attitudes reinforce it [26]. Davis described ten categories of doctor–patient interaction, ranging from mutual antagonism, disagreement, and tension to interactions releasing mutual tensions and arising satisfaction from patients and physicians [27]. Francis and colleagues showed that 24% of pediatric outpatients were dissatisfied with their relationship to their doctors, 42.1% were highly compliant, 38% moderately compliant, and 11.4% totally noncompliant [28]. Empathy, professional attitude, and understanding or concern is associated with compliance, whereas unmet key factors, lack of warmth in the doctor–patient relation, and not receiving explanations about diagnosis and cause of the child's illness were associated with noncompliance [27]. Factors related to lack of adherence in children were almost identical to findings reported in adults [29].

More accurate and sensitive techniques to predict noncompliance were proposed, because methods used in those days were inaccurate, impractical, or alienate patients [30]. Baekeland and Lundwall recognized the importance of dropping out of treatment, its high frequency; identified patients most likely to drop out and factors responsible, personality traits and therapeutic styles, implications and interventions to reduce the risk of dropping out, including patient selection and changes in treatment settings and approaches; and also asked if patients simply abandon treatment or if they abandoned and/or were pushed out of it (if they were invited to drop-out) [31]. Rosenstock reported that compliance was associated with behavioral characteristics, including motivation, "patients' interest and concern" with their health, perceived threats posed by disease, perceived benefits of medical interventions, knowledge of the medical condition, and understanding of expected effects of treatment, including

schedules and doses of medications [32]. He acknowledged that patients do not receive adequate information about treatment because of organization factors, such as long waiting times and distancing attitudes between physicians and patients [32]. Stewart and colleagues asked patients with chronic diseases treated by family physicians in Canada what factors affect the quality of the relationship and if the doctor/patient relationship affected the outcomes, and they found that physicians' factors, including number of health problems and visits and allowing the patient to start the dialogue during visits, were associated, while patients' factors were not [33]. Time and attention to identify comorbidities and continuity in health care would increase physicians' performance [33].

Other reports confirmed the inaccuracy of physicians to predict noncompliance and the need to deal beyond the biomedical aspects of disease, as well as with social and behavioral characteristics of patients. If these factors are not integrated into decision-making, it is unlikely that treatment based exclusively on technical considerations will be effective [34, 35]. Noncompliance is the result of complex interactions of patients and providers, health beliefs, social and behavioral characteristics, the disease or disorder, the complexity of treatment, and organizational strengths and deficiencies; all of them exert strong influences amenable to modification but scarcely studied [36]. In sharp contrast with traditional medical explanations about nonadherence, 40 years ago, it was shown that (1) compliance is not related to income, social class, occupation, or education; (2) physicians are unable to predict patients' willingness or ability to comply; and (3) most of the errors in taking medications are unintentional and related to the complexity and duration of therapy, number of medications, degree and modalities of counseling, and the use of dispensers [36]. Remarkable changes have occurred in philosophical paradigms and related concepts [3].

Compliance, Concordance, or Adherence?

It is essential to find an adequate definition that could at least provide an approximate idea about what is involved when patients respond positively to physicians' recommendations, *when they comply or adhere*. "Compliance" has permeated medical science and implies the existence of a medical-centered model, while "adherence" implies that patients have more autonomy in defining and following medical treatment [37]. Glasgow and Anderson disagreed with this statement and claimed that (1) "compliance and adherence" were counterproductive terms, (2) these approaches are useless when they send the wrong message to patients and health professionals, (3) the multidimensional nature of behaviors lead to adherence, instead of the traditional idea that it is the result of the unitary patient–physician interaction, and (4) there is a dynamic, always changing nature of treatment [38]. They proposed alternative terms such as self-care or "self-management" to describe the cluster of daily behaviors that patients perform to manage their (personal) diabetes [38].

Table 27.1 shows the evolving definitions of compliance, concordance, and adherence [3, 10, 38–46]:

The story of definitions about a persons' behavior in response to "medical orders" shows that: (1) there is still not

Table 27.1 Definitions of compliance, adherence, and concordance

Year	Author(s) and reference	Term	Definition
1976	Haynes [10]	Compliance	The extent in which the patient's behavior in taking medications, following diets, or implementing lifestyle changes coincides with medical or health advice
1982	Dracup and Meleis [39]	Compliance	Extent to which an individual chooses behaviors that coincide with a clinical prescription
1987	Meichenbaum and Turk [40]	Adherence	Degree to which a patient follows instructions and prescriptions of his doctor
1993	Wright EC [41]	Compliance	Different meanings: Medication taking? Changes in diet? Advice on exercise or smoking? Keeping appointments?
1996	Urquart J [42]	Compliance	Extent to which the patients' actual history of drug administration corresponds to the prescribed regimen
1997	Houston-Miller et al. [43]	Compliance with medical recommendations	Extent to which recommendations are followed as defined
2003	World Health Organization [44]	Adherence	Extent to which a person's behavior corresponds with agreed recommendations from a health-care provider.
2005	Balkrishnan [45]	Adherence	Extent to which a patient participates in treatment after agreeing to that regimen
2012	Steiner [46]	Adherence	Interacting behaviors influenced by individual, social, and environmental forces
2012	Vrijens et al. [3]	Medication adherence	Process by which patients take their medications as prescribed

a term that accurately describes the process and personal components leading to patient's performance and (2) definitions have evolved from the reductionist view that "it all comes down" to the authority of physicians, to view adherence as a set of interacting behaviors influenced by social determinants and the ecology of health care [46]. In his definition of compliance, Wright asked "With what?" and criticized the all-inclusive approach to adhere to "everything that is ordered [41]."

Measuring Adherence

New methods to measure compliance were introduced in the 1980s, including pill bottles with microprocessors to record every bottle opening as a presumptive dose confirming that drug compliance is lower in patients receiving higher doses, and pill counts overestimated the frequency of missed doses and serum concentrations of drugs [47]. Compliance is associated with patients' satisfaction, and noncompliance cannot simply be attributed to lack of understanding or memory. Patients actively participate in the monitoring of their health problems the effects of treatment, its adverse effects, and their impact on their normal lives; they are not passively obedient or willfully disobedient in the face of medical expertise. For those reasons, collaboration in doctor–patient relationships is more constructive [48].

Early Interventions to Improve Adherence

Included: (1) letters, telephone**,** or physical reminders to reduce frequency of broken appointments [49–56]; (2) educating medical students about the importance of compliance by experiencing it themselves [52]; and (3) indirect (self-reports, interviews, pill counting, and computerized monitors) and direct methods (biologic markers, tracer compounds, drug concentrations in the patients' biologic fluids) [50]. Strategies to improve adherence involved identifying risk factors of low adherence, simplified and individualized treatment plans, patient education, and aids to improvement, such as labeling and packaging of containers and monitoring by health professionals, patients, and their families [56]. Over the years, the ability of patients to self-monitor biologic parameters including capillary blood glucose [57], blood pressure [58], body mass index [59], or adjusting doses of anticoagulants [60] has been confirmed, and the stages of parallel cooperative monitoring in chronic disease were described and documented [61]. Patients are the leaders of the success of therapy; adherence depends on their decisions.

Interventions to Improve Adherence: The Evidence

In the last two decades, robust methods were introduced to assess interventions to improve adherence to medications including meta-analysis and systematic reviews [62–64] and a series of Cochrane reviews by R Brian Haynes and his colleagues, a pioneer in this field [65–68]. Table 27.2 summarizes the design and results of these reviews:

In conclusion, the analysis of interventions to improve adherence to medications are inconclusive. Nieuwalt and colleagues claimed that "current methods of improving medication adherence for chronic health problems are mostly complex and not very effective…the full benefits of treatment cannot be realized [68]."

Table 27.2 Meta-analysis and reviews of interventions to improve patients' adherence

Date	Author(s) and reference	Methods	Results
1996	Haynes et al. [56]	Systematic review 1553 citations and abstracts screened, 252 reviewed, 13 randomized controlled trials met all the criteria. Diseases analyzed included asthma, hypertension streptococcal throat infection, acute infections, epilepsy, schizophrenia	Disparity in clinical problems, interventions, measures, and reporting of adherence Seven showed improvements in adherence, and six led to improvements in outcomes. Short-term effectiveness using counseling and written information Long-term effectiveness included combinations of quality of care, information, counseling, reminders, self-monitoring, reinforcement, family support, and supervision. Substantial improvements in adherence were not documented.

Table 27.2 (continued)

Date	Author(s) and reference	Methods	Results
1998	Roter et al. [52]	Meta-analysis 153 studies: 116 randomized controlled trials, 37 nonrandom comparisons Interventions or health problems analyzed: Prevention, immunization, or periodic screening Patients discharged from the hospital Hypertension Mental health Diabetes Cancer	Small to large effect sizes for all compliance measures No single strategy or intervention has clear advantages with another. Comprehensive interventions combining cognitive, behavioral, and affective components are more effective than single, isolated interventions.
1998	Haynes et al. [56]	Systematic review 3133 citations and abstracts screened, 345 full text reviewed, 14 randomized controlled trials met all criteria 16 interventions	Eight studies showed improvements in adherence, and six led to improvements in outcomes. Most of the studies were small, introducing the possibility of false-negative error. Some interventions are highly complex and unlikely that their effects were mediated by adherence to medication Unclear potential to generalize, replicate, and disseminate the interventions Difficulties to be carried out in nonresearch settings Most studies did not assess the separate effects of complex interventions involved in chronic disease management. None of the studies examined major clinical endpoints, short-term follow-up: less than 6 to 18 months To achieve full benefits of medical therapies, further innovations are required, including involving investigators from different clinical disciplines.
2002	Mc Donald et al. [57]	Systematic review 6568 citations and abstracts screened, including 101 review articles, 549 full text reviewed, 33 randomized controlled trials met all criteria 39 interventions Disorders studied: Hypertension Schizophrenia, acute psychosis Asthma Chronic obstructive pulmonary disease Depression Human deficiency virus Diabetes Rheumatoid arthritis Epilepsy Hyperlipidemia Acute infections	Number and type of interventions: one to six, including behavioral, cognitive, or social Interventions for short-term treatments: Counseling about the importance of adherence reinforced by written instructions Interventions for chronic treatments: Changes in dosing schedules Remaining interventions are complex and multifaceted, including care at worksites, pill containers, counseling, reminders, self-monitoring, support groups, feedback, and reinforcement. Higher rates of adherence and improvements in blood pressure and glycemic control achieved with innovative interventions, including telephone-linked computer systems for monitoring and counseling patients with hypertension and automated assessment and self-care education calls with nurse follow up for patients with diabetes
2007	Van Dulmen et al. [53]	Review of 38 systematic reviews of the effectiveness of adherence interventions published between 1990–2005	Effective interventions were found in four theoretical approaches: technical, behavioral, educational, and multifaced or complex Technical solutions simplifying therapeutic regimes increase adherence rates; in some cases, they improve clinical outcomes and reduce costs Effective interventions originate from behavioral theories Theoretical models to explain nonadherence are not effective to improve adherence. There is still a scarcity of comparative studies about the effectiveness of theoretical models or their components, which needs to be assessed

(continued)

Table 27.2 (continued)

Date	Author(s) and reference	Methods	Results
2012	Viswanathan et al. [54]	Systematic review of publications assessing the comparative effectiveness of patient, provider, systems and policy interventions that improve adherence to medications From 4124 abstracts, 62 trials about patient–provider interactions or system performance, including 19 interventions and 4 observational studies were analyzed Clinical conditions amenable to improvement: Hypertension Heart failure Depression Asthma	Factors that increase medication adherence: Lower out of pocket expenses Case management Patient education with behavioral support Limited evidence about applicability of interventions or long-term effectiveness
2014	Nieuwlaat et al. [58]	Updated search of the Cochrane library including 109 new randomized clinical trials published since the last update Studies heterogeneous for patients, medical problems, treatment regimens, adherence interventions and clinical outcomes High risk of bias	Findings in comparison with the last update: 1. Lack of convincing evidence among studies with lowest risk of bias. 2. Large heterogeneity, abandon the attempt to classify studies according to intervention. 3. Availability of the database for collaboration on subanalysis. 4. Inconsistent effects from study to study, only a minority of lowest risk of bias RCTs improved adherence and clinical outcomes.

The Role of System Deficiencies on Adherence

The decrease in the mortality by high blood pressure was associated with the appearance of new antihypertensive drugs, but low rates of persistence and huge rates of dropouts resulting in hypertensive crisis and visits to emergency rooms continued to be reported [69, 70]. In 1973, Finnerty and colleagues published a groundbreaking analysis of causes of discontinuation of antihypertensive treatment at an outpatient clinic in Washington in which they identified three leading factors: (1) long waiting times (2.5 hours), (2) deficiencies in doctor–patient relationships (patients were seen by a different physician on each visit), and (3) brief duration of the visit (7.5 minutes) and long waiting times at the pharmacy (1.8 hours) [71]. In response to these deficiencies, 25% of patients believed they were able to treat themselves, 61% agreed to be treated by medical students, and 54.4% agreed to be treated by nurses [71]. Years later, Finnerty reflected that patients dropped out of treatment not because they were uneducated, not because they did not care about their health, and not because they could not afford paying for medications [72]. They abandoned the clinic because "they were treated like cattle, herded from one room to another, left waiting for hours, to be examined by different doctors on each visit [72]." Complaints centered on the amount of time they spent at the clinic and the lack of acceptable, effective relationships with physicians [72].

Hypertension became the prototype disease to describe adherence and its causes. Rudd and Marton described three characteristics associated with failure to achieve blood pressure control: (1) behavioral factors; (2) biologic factors, individual, and unique manifestations of the disease; (3) pharmacologic factors including side effects and combinations of the three [73]. Despite publication of clinical guidelines for hypertension since the1970s, a huge gap still exists between the evidence appearing in controlled clinical trials and what clinicians do in practice and between what clinicians recommend to patients and what patients actually do at home [74]. This gap and its opposite components, clinical inertia (lack of effective physician response) and low patient adherence, are crucial obstacles to providing and receiving adequate quality of care [75]. Compliance of physicians with hypertension guidelines is very low and even worse in patients with diabetes, with the associated increase in cardiovascular risk [76]. Even among patients enrolled in phase IV controlled clinical trials of antihypertensive medications, all patients omit 10% of the doses, including 42% omissions of a single-day dose, 15% on one or two consecutive days, and 47% on multiple days; 95% of the patients miss one dose each month, 48% omit taking medications for 78 hours or more at least once a year, and 13% every 6 months [77].

Measuring Adherence in Hypertension and Beyond

Current methods to measure adherence in hypertension include the Morisky Medication Adherence Scale (MMAS), an eight-item structured, self-reported measure initially

applied in low income, minority patients [78]. Sensitivity and specificity of the MMAS to identify patients with poor blood pressure control is 93% and 53%, respectively; an adherence score in which 8 points were defined as highly adherent, 6–7 points as medium adherent, and less than 6 as low adherent patients is significantly associated with blood pressure control [78]. The MMAS is patient centered, addresses causes leading to voluntary and involuntary suspension of treatment, has been internationally validated [79, 80], and has been applied in patients with diabetes [81].

Adherence and the Complexities of Diabetes Self-Management

Decades ago and still in many places, diabetes was managed from a paternalistic approach: in postwar Germany, patients were admitted to hospitals to stabilize glucose, without receiving training or resources for self-care, and were not allowed to change insulin dosages [82]. Mülhauser and Berger claimed that patient education "had degenerated to obedience training" to follow diets based on fixed amounts of carbohydrates, proteins, and fats, prohibiting sugar intake, which had to be consumed in six to seven meals at fixed times and to obey "doctors' orders" [82]. This approach was ineffective to achieve glycemic control, and acute and chronic complications were frequent. The emotional consequences of diabetes evolved in the construction of a "diabetic personality," in which the daily challenges to confront the disease, its treatment, and consequences were used to explain and attribute poor treatment outcomes on patients in disdain of the enormous scope of expression of individual personalities in adjusting to the daily demands of a healthy lifestyle. This one-dimensional view implied adoption of an inflexible model of behavioral adjustment, rejected by many people [83]. In an early study about adherence in 60 adults with diabetes, Watkins and colleagues reported that 75% did not adhere to diet, 66% were making errors in glucose urine testing, more than 50% made errors in insulin dosage, 50% were giving themselves good foot care, only one patient was deemed completely adherent in the five areas of management, and there was a negative association between knowledge and effectiveness of self-care [84]. In other words, patients in poorer control knew more about diabetes than those under control [84]. In sharp contrast, a diabetes education program that addressed roles of physicians, health providers, patients, and the influence of patients and providers attitudes, behaviors, and skills showed improvements in adherence [85]. This program included (1) a team with a nonthreatening, nonauthoritarian approach; (2) a group process for support, sharing of experiences, and practice according to individual needs; (3) learning by experience rather than conceptual learning to small groups of patients; (4) regular assessment and raising awareness; and (5) innovative techniques inducing changes in health behavior [85].

The multiple self-care activities that patients with diabetes have to carry out on a daily basis to adhere to treatment confirm the need to distinguish the differential difficulties of adhering to medications and to lifestyle changes, but interventions to improve adherence have been inadequate: in 1986, Anderson recognized that diabetes educators lack the time and expertise to become familiar with theories of human behavior and that diabetes education has become an extension of transference of information found in most schools, based on the idea that lack of knowledge and skills accounts for most of poor self-care behaviors [86]. He also claimed that patients' behavior is strongly influenced by their personal view of diabetes and stressed the need that diabetes educators become skilled designers of patient education programs that facilitate changes according to the personal meaning of diabetes [86]. This pioneering concept was associated with the personal model of disease described afterwards by Hampson and colleagues [87].

Nonadherence in Diabetes

The complexities of diabetes management are illustrated by the large variation of adherence to medications, ranging from 36% to 93% in early studies [88–91], while a meta-analysis by Lemstra and colleagues showed that primary nonadherence to antidiabetic medications was 13.2% (95% CI 9.6–16.8) [92]. Adherence to lifestyle changes is even lower; influential factors include (1) comorbidities, (2) cost of therapy or lack of health insurance, (3) adverse family dynamics and codependency, (3) old age, (4) frequency of doses and number of medications, and (5) poor provider–patient relationships and failure in fulfilling patients' health beliefs [93]. Even among patients willing to adhere, additional barriers involve (1) cost of medications, (2) remembering doses, (3) reading prescription labels, and (4) obtaining refills [94]. Additional barriers demonstrate that adherence to one aspect of the regimen is not related to others, and psychosocial variables and situational factors are also important [95, 96]. Nonadherence is not exclusive to diabetes; it occurs in all chronic diseases [97], but it may be even worse in patients with diabetes, taking into account that typical diabetes regimes are complex, life-long, and require introducing multiple behavior changes [97]. The roles and challenges that people with diabetes have to confront were summarized by Bush [97]:

"Of all chronic diseases, diabetes is foremost in putting the responsibility for ongoing health on patients. Proper diabetes treatment requires not simply to take medications and visit the doctor, but to make true lifestyle changes… major and substantial change in behavior is easy to discuss but hard to achieve, and patients may view the treatment of diabetes

worse than the disease itself. The inability of patients to do exactly what we want is so rampant that we have made it a diagnosis: noncompliance [98]."

Methods for Measuring Adherence in Diabetes

These include indirect metrics for clinical settings, indirect metrics for research, and administration and direct metrics, clinical or from laboratory [99–103]. Adherence measures like the Morisky Medication Scale, previously mentioned in this chapter, have also been incorporated [100–103]. Table 27.3 depicts the diverse methods for measuring adherence:

In conclusion according to Anghel and colleagues, "for a method to be ideal in adherence measurement, it should be easy to apply in any setting, accurate and not expensive, and able to provide additional information regarding potential barriers, beliefs, or concerns from patients [101]."

Adherence to Antidiabetics

Table 27.4 shows examples of adherence in people with diabetes [104–114] and confirm that adherence rates are lower than expected in clinical guidelines, even for innovative medications. Median follow-up of studies with GLP-1 agonists range from 2 to 4 years, with persistence rates below 50% at 1 year [115, 116], while adherence to SGLT2 inhibitors is 59.5%, and persistence at 6 months and 1 year is 80.1% and 45.9%, respectively [117]. Taking into account the low rates of adherence and persistence in these studies "from the real world," it is intriguing to consider if these medications will achieve the effectiveness documented in clinical trials of more than 1-year duration. Giving the short duration of persistence, these innovative medications can only demonstrate, as stated by the experts, "non-inferiority as compared with placebo" … without evidence of clinical benefit beyond intermediate outcomes "in the real world [118]."

Table 27.3 Methods used to measure adherence to medications

	Source or definition	Advantages	Disadvantages
Questionnaires	Patient statements about use of medications	Simple	Inaccurate
Self-report	Patient statement of use of medication	Simple	Overestimate adherence No evidence about use of medication
Pill counting	Patient supply of remaining doses	Simple	No actual proof evidence of drug ingestion, daily adherence, or patterns of adherence
Electronic databases	Transmitted report from pharmacy or provider	Inexpensive	No information about individual adherence rates
Electronic monitoring devices	Devices incorporated in drug containers	Precise and detailed information about number of doses taken	False results from incorrect opening of the container
Medication possession ratio (MPR)	Total days supplied/number of days between the first and last refill	Inexpensive	Evidence of drug dispensation, not of actual ingestion
Adjusted medication possession ratio (AMPR)	Total days supply of all prescriptions in defined period/number of days in the defined period	Inexpensive	Evidence of drug dispensation, not of actual ingestion
Proportion of days covered (PDC)	Total days supplied/number of days in refill interval	Inexpensive	Evidence of drug dispensation, not of actual ingestion
Persistence	Period of time without discontinuation	Simple	Evidence of drug dispensation, not of actual ingestion
Daily average consumption	Total number of units dispensed/number of days between index date and date of last refill	Simple	Evidence of drug dispensation, not of actual ingestion
Direct observation	Reception and taking medication at health care facility		Unfeasible for outpatients, impractical
Drug or metabolite levels	Measurement in blood or urine sample	Accurate	Expensive Individual pharmacokinetics Drug interactions
Biologic effect	Measurement of clinical outcomes: blood glucose, blood pressure, lipoprotein profile	Simple	Unable to distinguish from other components of treatment

*Adapted from [99–102]

Table 27.4 Studies about adherence in diabetes management

Year	Author(s)	Patients and intervention	Results and conclusions
2009	Yeaw et al. [99]	Retrospective analysis of pharmacy claims in a database of more than 64 million members Proportion of days covered and persistence among new users of six commonly used chronic medication categories	Six-month persistence for oral antidiabetics (OADs): 66% Odds of discontinuation of OADs significantly lower than for other therapeutic classes
2009	Van Bruggen et al. [100]	Baseline and follow-up data of a randomized controlled trial comparing usual care with care according to a national guideline 30 general practices, 1283 patients Number of prescribed drugs and adherence indices (AI) for oral glucose, antihypertensives and lipid lowering drugs	Higher drug prescriptions in the intervention group An inverse relationship between the number of drugs prescribed during the last 6 months and patients' adherence to blood pressure medications
2010	Fischer et al. [101]	Compilation of e-prescriptions written in 1 year to identify filled prescriptions to evaluate primary non-adherence and identify predictors of nonadherence	78% of prescriptions were filled Higher adherence rates for prescriptions written by primary care physicians Nonadherence for newly prescribed anti-diabetics: 31.4%
2013	Koro et al. [102]	Retrospective analysis of patients with Type 2 diabetes from a national database	Persistence at 6 months: GLP-1 agonists: 31% and DPP-4 inhibitors: 39% Adherence at 1 year: GLP-1 agonists: 11% DPP-4 inhibitors: 18% Other medications: 16%
2016	Alfian et al. [103]	Cross sectional survey in 91 patients with type 2 diabetes using the eight-item Morisky Medication Adherence Scale (MMAS)	Adherence rates: Low: 49.4% Medium: 29.7% High: 20.9% Higher adherence contributes to improved quality of life
2017	Al-Keilani et al. [104]	Cross sectional survey to investigate self-monitoring of blood glucose adherence and predictive factors in 1079 patients with diabetes	Adherence rate: 59% Predictors: Insulin use versus oral antidiabetics Previous diabetes education Knowledge about the use of glucose monitors
2017	He et al. [105]	Retrospective analysis of database insurance claims to assess adherence (≥80.0% possession rate) and persistence (no gaps in insulin therapy during ≥90 days) to insulin therapy and associated factors 24,192 patients with type 2 diabetes	Adherence rate: 30.9% Persistence rate: 53.0% Mean time to nonpersistence: 230.3 days Patients initiated with analogs were more likely to be adherent compared with patients initiated with human insulin. Lower adherence in patients initiated with basal insulin compared with patients initiated with premixed insulin Patients with hypertension, dyslipidemia, treated with prandial insulin, or with severe hypoglycemia were more likely to be nonadherent/nonpersistent
	Lin et al. [106]	Retrospective study to assess treatment persistence and associated outcomes in 7320 patients with type 2 diabetes treated with a GLP-1 agonist in combination with basal insulin	Treatment persistence: 16.9% Median time to discontinuation: 133 days Persistent patients had greater A1c reductions, were more likely to achieve A1c <7.0%, were less likely to experience hypoglycemia, had fewer hospitalizations and were less likely to experience hypoglycemia Total medical charges were significantly lower for persistent patients

(continued)

Table 27.4 (continued)

Year	Author(s)	Patients and intervention	Results and conclusions
	Flory et al. [107]	Retrospective study of a cohort of 11,067 patients from a database including information on more than 120 million commercially insured and Medicare Advantage enrollees Unit to measure adherence: "daily medication possession probability" (MPP): days of supplied prescription/number of patients in the cohort	Clear separation of adherence between drug classes after 90 days Daily MPPs: Sulfonylureas: 0.49 Metformin: 0.46 Basal insulin: 0.39 Glitazones: 0.36 GLP-1 agonists: 0.30 DPP-4 inhibitors: 0.21 Particular attention needs to be paid to adherence issues with newer drug classes, that is, GLP-1 agonists and DPP-4 inhibitors Substantial differences between rates at which diabetes drugs are prescribed and rates at which patients actually take them
2020	Alsheri KA et al. [108]	Cross sectional analytic study self-completed questionnaire 387 patients with type 2 diabetes	68.5% reported adherence toward their medications Reasons for nonadherence: Forgetting to take medications: 67.21% Use for long periods of time: 50% Polypharmacy: 44.26% Complexity of therapeutic regime: 40.16% Lack of family support: 38.52% Side effects of medication: 35.24% Interference with meal plan: 35.24% Feeling that doses were too high: 30.32% Feeling that treatment was ineffective: 24.59% Insufficient economic resources: 13.11%
2021	Romagnoli A et al. [109]	Retrospective observational study; dispensations delivered at the pharmacy of a general hospital over 9 years Adherence and persistence estimation over 3 years using the pharmacy-refill method 19,600 patients with type 2 diabetes	Absolute adherence at 3 years: 0.68; per therapeutic class: GLP-1 analogues: 0.99 SGLT2i: 0.87% DPP4i: 0.85 Glitazones: 0.84 Sulfonylureas: 0.77 Metformin: 0.64 Alpha-glucosidase inhibitors: 0.62 Meglitinides: 0.49

Behavioral Aspects

Adherence in diabetes became a conceptual and empirical enigma. Studies related to the health belief model, social learning theory, and interpersonal relationships about determinants of adherence behaviors are important in clinical practice [119, 120]. Models explaining individual health-related behaviors include the "Health Belief Model" (HBM) [120, 121]. The basic components of the HBM originated from the "value expectancy" approach of Levin in 1944 [122], to describe behavior or decision-making under uncertainty. Its main elements include (1) the state of readiness to address a particular health problem and the perception of threat represented by illness; (2) the belief in the personal efficacy to reduce the threat, consequences, and perceived barriers involved in action; and (3) "cues to action," external, or internal "triggers" inducing the appropriate health behavior [121, 122].

In the traditional approach to health behavior change, physicians are seen as the experts who know what is best for the patient, based on the assumption that all patients should change their behavior, all have the same willingness to change, and diseases and treatments are their most important priorities [123]. This assumption is not valid: lack of concordance between patients and providers and divergences in the approach to health status have been repeatedly described in people with diabetes. Beyond agreements in perception of severity, large disparities prevail about the effect of adherence on the cost of therapy and its benefits [124]. Patient–provider discrepancies, low levels of agreement between patients and physicians (kappa =0.23) about adherence to diabetes treatment, have been reported worldwide and are influential on glycemic control [124–126].

Psychological Issues and Adherence in Diabetes

The importance of psychological aspects on diabetes was documented since the seventeenth century when Willis and Maudsley noted that prolonged depression or anxiety appeared to cause diabetes [127]. Reports from the nineteenth century provided a conceptual framework to support that emotional disruption antedates metabolic decompensation

[127]. Further studies about psychological aspects of diabetes identified four important topics: (1) association with the onset of the disease; (2) the influence of the environment on its course; (3) the immediate response and long-term personal adjustment; and (4) the reaction of the family to the illness and its impact on the family structure [128–130]. Research has shown a clear relationship between diabetes and mental health, including psychiatric disorders and problems specific to the experience of living with diabetes [130].

Russell Glasgow, a pioneer and leader on the study of behavioral aspects of diabetes and chronic disease management, described the limitations of applying traditional compliance terms in patients with diabetes, ignoring the complexity of self-care [131]. He stated that "in addition to taking medicines, people with diabetes have to carry out multiple activities including lifestyle changes and blood glucose monitoring, frequently not communicated or measured [132]." He claimed that having diabetes, treating diabetes, or developing diabetic complications have their own psychological impact, and quantitative measurements are essential to account for the complex interactions between personal and environmental factors that facilitate or hinder adjustment and coping, including adherence [133]. Glasgow and colleagues published studies about the importance of supportive and nonsupportive factors on adherence and glycemic control, including family influences [134] and psychosocial correlates on self-care behaviors [135–137]. From this perspective, adherence should be considered in the context of other factors, instead of assuming that it is simply the result of one-to-one interactions between patients and physicians. Analysis of psychosocial factors related to self-management resulted in the description of "personal models of disease," including disease-related beliefs, emotions, knowledge, and experiences [137]. Glasgow and associates described the concept of personal models of disease in diabetes and their predictive value to carry out self-care activities related to adherence and glucose control [138]. The consistency of personal models of "perceived treatment efficacy (PTE)" as barriers or facilitators to self-management has been confirmed and patient "noncompliance" may be the result of impaired PTE [139]. If patients do not believe that medical recommendations contribute to a positive impact on their health, it is understandable that they might lose motivation [139].

Behavioral Strategies to Improve Adherence

Motivational Interviewing

Having good intensions to engage in healthy behaviors to change one's life in a positive direction may not always translate into actions or behavior that is maintained [140]. Motivational interviewing arose from experiences acquired in the management of alcoholism [141], a complex disease with social, personal, and behavioral components in which the authoritative medical approach had been unsuccessful. Motivational interviewing has its roots on Bandura's self-efficacy theory, which he defined as "a judgment of one's ability to organize and execute given types of performances [142]." Bandura explained that people have always striven to control events affecting their lives and that the growth of knowledge over human history enhanced people's ability to predict events and try to control them [142]. Beliefs in supernatural levels of control (i.e., physician's authority over patient's everyday behaviors) are surpassed by conceptions that acknowledge the people's power to shape their own destiny [142]. Changing threatening health behaviors and following medical advice are important components of almost every medical interaction, but they can be difficult to accomplish; practitioners commonly end up making cursory attempts to satisfy their perception of the problem or avoiding the topic [143]. Telling or threatening people that they will "pay the consequences" if they do not change their lifestyle or take medications is rarely enough to change behavior [143]. People change and follow doctor's orders under the guidance or influence of individual, unique perceptions. Motivational interviewing promotes behavior change in a wide range of health care settings requiring lifestyle changes, including the "big four" lifestyle habits (smoking, excessive drinking, lack of exercise, and unhealthy diet [144]), adherence to treatment for obesity, diabetes, and infection with HIV [145]. Motivational interviewing is based on the recognition that advising or ordering patients to change is often unrewarding and ineffective, and a key component is to acknowledge that patients have every right to make no change [140, 146]. Instead of directive approaches, motivational interviewing requires a guiding style to engage with patients, identify strengths and limitations, encourage motivation for change, and promote the autonomy of decision making [145]. Application of motivational interviewing in diabetes management in pediatric and adult populations is highly appealing [140, 147]. It has a positive influence on diabetes outcomes, but the number of published studies is still scarce and heterogeneous, patient participation is unpredictable, and long-term assessment is scarce [147–149].

Diabetes Empowerment

There are two approaches to diabetes patient education: one is obedience based and another is based on empowerment [150]. From that perspective, adherence and compliance are dysfunctional concepts [151]. Patient empowerment (PE) stems from a broader philosophical concept of empowerment introduced by the Brazilian pedagogue Freire in the 1970s and was linked in health care in the early 1990s in the United States [152]. Born as a reaction to societal oppression and inequal-

ity, PE was adopted in other disciplines and transformed as a multidisciplinary concept. Empowerment implies that human beings have the potential to make choices and gain control of their life [152]. The unique role and responsibilities of patients in the daily treatment of diabetes can be recognized from the premise that people have the capacity to make choices and are responsible for their consequences [152–154]. The goals of diabetes empowerment are enabling patients to make informed decisions about their personal diabetes care and to be fully responsible members of the health care team [154]. Empowerment offers a practical conceptual framework for diabetes education and provides patients with the knowledge, skills, and responsibility to change, promote health, and maximize the use of available resources [155]. Empowerment is defined as "the discovery and development of one's inborn capacity to be responsible for one's own life [156]." It was designed to help patients develop knowledge, skills, attitudes, and self-awareness to assume the responsibility for their health-related decisions [154]. People are empowered when they have (1) enough knowledge to make rational decisions, (2) enough control, (3) enough resources to implement their decisions, and (4) enough experience to evaluate the effectiveness of their actions [156]. By comparison with traditional medical approaches, empowerment is not something one does to patients: empowerment begins when healthcare professionals acknowledge that patients are the ones who really have the control of their daily diabetes care [157]. Empowerment occurs when the health professional's goal is to increase the capacity of patients to think critically and make autonomous, informed decisions [154]. The success of PE seems to be due to the political views of society and loss of confidence in health-care professionals, especially physicians, who should "come down off their pedestal [152]." It has been shown that diabetes empowerment improves diabetes knowledge, medication adherence, and self-care behaviors [158], but the number of published studies is small; large-scale implementation at a national or system level has not been accomplished.

Addressing Adherence

Adherence is not dependent of characteristics traditionally perceived by physicians like sex, race, or age. Besides information and communication problems, prejudice from clinicians reduces their capacity to understand patients' needs, their resources, and willingness to change [159]. Using "adherence aids," including pill boxes, putting pills in special places, and associating pill taking with daily events like meals has shown limited effectiveness [160]. Failure of patients to attend medical visits, monitoring glucose, or taking medications impairs diabetes control, but failure of physicians to intensify therapy in patients not achieving the goals (clinical inertia) is probably more important than patients' adherence [161–163]. Adherence depends on a variety of interacting factors on increasing impact like comorbidity and polypharmacy [105]. Several studies have shown positive and significant relationships between social support and adherence to diabetes therapy, but the exact mechanism by which social support affects patients' adherence is not completely understood [164]. Emphatic engagement is also important and may even reduce the frequency of acute complications [165]. Competence and skills to overcome clinical inertia and assist patients to increase adherence, instead of just reiterating what they should be doing and putting the blame on them if they fail, is also a key component of success in diabetes care [166].

In recognition of its importance, The World Health Organization (WHO) published a report in 2003 enlisting five interacting dimensions of adherence: (1) social and economic, (2) related to health systems, (3) condition-related, (4) therapy-related, and (5) patient-related [44]. System-related factors have negative effects on adherence and outcomes, including deficiencies of health services, poor medication distribution systems, limited knowledge and training of health professionals about adherence, and effective interventions for improvement [44].Take-home messages from the WHO Report highlight the importance of adherence and the influence of patients on outcomes [44]:

1. Poor adherence to treatment is a worldwide problem of huge magnitude.
2. Poor adherence will grow as the burden of chronic disease that continues to increase.
3. The consequences of poor adherence to long-term therapies include poor clinical outcomes and increased healthcare costs.
4. Improving adherence also improves patients' safety.
5. Adherence is an important modifier of the effectiveness of health systems.
6. Increasing the effectiveness of adherence interventions will have a greater impact on population health than advances in medical therapy.
7. Patients need to be supported, not blamed.
8. Adherence is simultaneously influenced by several factors.
9. Health professionals need to be trained about adherence.

Modified from the World Health Organization report [44].

Conclusions

In a lecture "upon medical ethics," Ingelfinger stated that "if you agree that the physician's primary function is to make the patient feel better, a certain amount of authoritarianism, pater-

nalism, and domination are the essence of physician's effectiveness [167]." Millions of doctors worldwide still believe that persuasion and mind bending are necessary to be "effective physicians [11]." Seven decades of efforts led to understand adherence from the patients' perspective, starting with the need to change semantics, to advance from myths like "uncooperativeness" or "noncompliance" to adherence, still an inaccurate term [168]. A new language of medication taking has been waiting for decades and will be more important as the authority of patients in decision-making and in the successful management of chronic disease is recognized [169–175]. Steiner and Earnest suggested that to improve the language of medication taking, the terminology has to change because patients have the most important opinion about the best strategy to increase medication taking. In this novel approach, physicians have to ask about medication taking, they to be prepared and willing to reply to questions, outcomes have to be emphasized, and the importance of medication taking has to be explained to achieve the expected results of therapy [169]. Nonadherence is still barely on the radar of most practicing physicians who remain unaware about it [170]. Improving adherence requires an active process of behavioral change involving education, motivation, tools, support, monitoring, and evaluation [170]. Approaches to improving adherence and persistence include reducing treatment complexity, using medications with improved safety profiles, improving communication and patient support, and awareness about its existence and influence on outcomes [171].

Multiple Choice Questions

1. What is the best term to describe the patients' expected behavior to medical recommendations:
   (a) Obedience
   (b) Compliance
   (c) Adherence
   (d) **None of the above**
   (e) All of the above
2. Traditional methods to assess adherence include:
   (a) Direct interrogation of patients and their families
   (b) Residual medication counting
   (c) Measurement of drug metabolites
   (d) **All of the above**
   (e) None of the above
3. More than 30 years ago, it was confirmed that compliance is not related to income, social class, occupation, or education:
   (a) **True**
   (b) False
4. The word "compliance" implies:
   (a) That patients are obeying as expected
   (b) The effectiveness of treatment
   (c) **That patients are willfully disobedient in the face of medical expertise**
   (d) That results of controlled clinical trials can be replicated "in the real world"
   (e) All of the above
5. It has been shown that patients are able:
   (a) To self-monitor blood glucose levels and adjust insulin doses
   (b) To self-monitor blood pressure levels and adjust antihypertensive doses
   (c) To self-monitor body mass index to achieve sustained body weight loss
   (d) **All of the above**
   (e) None of the above
6. Discontinuation of chronic disease treatment is highly associated with:
   (a) Patients' ignorance
   (b) **Long waiting times to receive the medical visit**
   (c) **Deficiencies in doctor–patient relationships**
   (d) The economic status of patients
   (e) Insufficient intelligence to understand physicians' orders
7. The "diabetic personality" refers:
   (a) To the consequences of diabetes on mental health
   (b) **To the attribution of poor treatment outcomes on the patients' fault**
   (c) To the adaptation process to diabetes and its demands
   (d) To the existence of a single, well-defined personality of all people with diabetes
8. Total adherence to all the components of diabetes management is estimated at:
   (a) 100 percent
   (b) 80 percent
   (c) 50 percent
   (d) 25 percent
   (e) **1 percent**
9. Nonadherence to diabetes diet has been reported at:
   (a) 100 percent
   (b) **75 percent**
   (c) 66 percent
   (d) 50 percent
   (e) 25 percent
10. Errors in insulin dosage by patients have been reported at:
    (a) 100 percent
    (b) 75 percent
    (c) 66 percent
    (d) **50 percent**
    (e) 25 percent

Part V

Resources of Support for Persons with Diabetes

Challenges and Opportunities in Diabetes Education

28

Jane K. Dickinson, Melinda Downie Maryniuk, and Margaret A. Powers

Definition of Diabetes Self-Management Education and Support

The National Standards for Diabetes Self-Management Education were first developed in the United States in 1995. These standards serve as guidance for those providing diabetes education and set the standard for best practice in developing, implementing, and evaluating a diabetes self-management education program [1]. In 2011, a task force representing the Association of Diabetes Care and Education Specialists and the American Diabetes Association changed the name to National Standards for Diabetes Self-Management Education and Support [2]. In the most recent version, the standards include the following definition:

> Diabetes Self-Management Education and Support (DSMES): an ongoing process of helping people with diabetes develop problem-solving skills to enhance and improve the decision-making necessary to self-manage diabetes on a continual basis. DSMES services support measurable, meaningful, and sustainable behavior change. DSMES interventions include activities that support a person in implementing and sustaining the behaviors needed to manage his or her condition on an ongoing basis [3].

Diabetes Canada states the following:

> Self-management education (SME) is a process to facilitate individuals in decision-making, resulting in improvements in variables, such as knowledge, attitudes, and self-efficacy, as well as improvements in healthy behaviors and clinical outcomes. SME is defined as a systematic intervention that involves active participation by the individual in self-monitoring of health parameters and/or decision-making with the application of knowledge and skills. It also recognizes that patient–provider collaboration, approaches, and the development of problem-solving skills are crucial for sustained self-care. Self-management support (SMS) includes activities that support the implementation and maintenance of behaviors for ongoing diabetes self-management, including education, behavior modification, and psychosocial and/or clinical support. The goal of SME and SMS is to foster opportunities for people with diabetes to become informed and motivated to continually engage in effective diabetes self-management practices and behaviors [4].

Other countries have comparable definitions that can often be found on their websites.

Evidence Supporting the Effectiveness of Diabetes Education

Structured diabetes self-management education and support programs lead to reduced A1C [5–10], reduced all-cause mortality in people with type 2 diabetes [11], improved self-care activity [10], and sometimes result in weight loss [7]. An integrative review that studied pediatric diabetes self-management education and support programs showed that mixed programs containing both self-care aspects and psychosocial aspects, and delivered online, were most likely to influence psychosocial competencies in children and adolescents [12]. Diabetes self-management education and support has also demonstrated cost-effectiveness [11, 13] and improved quality of life in people with diabetes [6, 14, 15].

Recommendations for Diabetes Education

The American Diabetes Association states that ongoing diabetes self-management education and support are critical to preventing acute complications and reducing the risk of long-term complications. (ADA 2022) They recommend that all people with diabetes should participate in diabetes self-management education and receive the support needed to facilitate the knowledge, decision-making, and skills mastery necessary for diabetes self-care. They further state that

there are four critical times to evaluate the need for diabetes self-management education to promote skills acquisition in support of treatment plan implementation, medical nutrition therapy, and well-being. These four times correlate to times when people with diabetes may need the most assistance to achieve and/or adjust their goals and care plans for effective daily self-management [16].

The International Diabetes Federation also includes "the right to information and education" in their Charter of Rights and Responsibilities for People with Diabetes. In addition, an individualized medical nutrition therapy program, preferably by a registered dietitian, is recommended for all people with diabetes.

Diabetes Australia recommends structured diabetes education to consumers as soon as possible after diagnosis, ongoing, and on request. They also recommend diabetes education that is person-centered, promotes active learning, and has the flexibility to meet individual needs, choices, and learning styles [17]. Diabetes UK published a report titled, Diabetes Education: The Big Missed Opportunity in Diabetes Care, highlighting their view that diabetes education is an essential part of managing diabetes and avoiding long-term complications [18]. The National Institute for Health and Care Excellence also recommends structured diabetes education programs and points to Diabetes UK guidelines on their website [19].

The DAWN2 Study sought cross-national comparisons across 17 countries of perceptions on health care provision for benchmarking and sharing of clinical practices to improve diabetes care. Results of quantitative surveys of almost 9000 people with diabetes, family members, and health-care professionals drew attention to the large number of people who feel the burden of the disease and made the case for improved psychosocial care and diabetes self-management education. Specifically, about half of the people surveyed with diabetes reported diabetes has a negative impact on their physical health and emotional well-being. Just less than half (45%) reported experiencing diabetes-related distress [20]. The Association of Diabetes Care and Education Specialists promotes using a person-centered approach when working with people living with diabetes. This includes asking people how they are doing, finding out what is working and not working, and taking into consideration their personal values, needs, and preferences, and using shared decision-making when setting goals [21].

While standards from major diabetes organizations are recognized worldwide, how do these recommendations get interpreted and operationalized? Access to diabetes education and diabetes educators varies greatly around the globe. The following section includes highlights from some of the major position papers and practice guidelines, which can be tailored for diverse practice settings.

Standards for Diabetes Education

In 2019, the American Association of Diabetes Educators (AADE) announced a name change for the diabetes education specialty. Diabetes education was changed to diabetes care and education to better reflect the broader scope and focus of the specialty [22]. In the United States, diabetes educators are now diabetes care and education specialists, and in 2020, the AADE became the Association of Diabetes Care and Education Specialists. In addition, the credentialing board for the specialty is now the Certification Board for Diabetes Care and Education and accordingly, the former Certified Diabetes Educator credential is now the Certified Diabetes Care and Education Specialist (CDCES). "Diabetes educator" and "Certified Diabetes Educator" are used in this chapter, where applicable, because these terms continue to be recognized internationally.

The process and quality of diabetes education is guided by standards and guidelines. In the United States, the National Standards for Diabetes Self-Management Education and Support (National Standards, 2022) define quality diabetes self-management education and support and assist those who educate to implement evidence-based programs and services. In the United States, diabetes education services must meet the National Standards in order to bill for education services. Additionally, the standards provide expert recommendations to anyone setting up and/or improving educational services. The National Standards are reviewed and updated every 5 years by a multidisciplinary group representing the American Diabetes Association and the Association of Diabetes Care and Education Specialists. The standards define such things as who can provide diabetes education, content areas to be assessed and taught as needed, importance of providing ongoing support, and quality. The national standards provide a helpful guideline for setting up diabetes education services.

While the National Standards highlight the benefit of a team approach to diabetes education, they also acknowledge that a team is not always possible or available. To meet quality standards, it is recommended that diabetes education be delivered by a nurse, dietitian, or pharmacist with relevant background and experience. For example, in the United States, 15 hours of continuing education per year in diabetes-related topics is considered a minimum acceptable level of instruction. Qualification as a certified diabetes care and education specialist may be obtained by a wide variety of clinicians within the United States, including nurses, dietitians, pharmacists, physicians, clinical social workers, and master's level exercise physiologists [23].

Eight core content areas are defined within the National Standards. An assessment of each individual's needs

determines which elements of the curriculum are required. Content areas include the following:

- Pathophysiology of diabetes
- Healthy coping
- Healthy eating
- Being active
- Medication use (treatment options including diabetes devices)
- Monitoring (including use of diabetes devices)
- Problem solving
- Reducing risks (treating acute and chronic complications such as hypoglycemia and hyperglycemia and chronic complications such as cardiometabolic, vision, hearing, dental, and foot care)

Other recommended content areas include navigating the healthcare system, self-advocacy, and e-health education.

The National Standards highlight the importance of person-centered, interactive, and evidence-based diabetes education. The most successful approach is one in which patients and providers work together to develop an individualized education plan. Evidence-based communication and behavior change strategies are also recommended, including collaborative goal setting, motivational interviewing, and interactive teaching techniques. In addition, the Standards address the need for ongoing support, measuring participant progress, and continuous quality improvement.

Health-care professionals can look for diabetes education standards that may have been written for a country or health system in a specific region, as a variety of them do exist. Notably, the International Diabetes Federation has published a detailed collection of 32 standards that describe not only structure and process standards (recommended elements of a diabetes program similar to those described in the US National Standards document) but also content standards (describing what to assess and teach) and outcomes standards (what to measure) [24].

The roles and expectations for diabetes educators vary greatly around the world. In the United States, many diabetes educators with advanced credentialing work closely with the physician—and other health care providers—as a co-manager of the patient's care. This may involve reviewing blood glucose patterns (from meter or continuous glucose monitoring downloads) and making recommendations to the physician for treatment changes and/or adjusting insulin within established guidelines. Some diabetes educators are expected only to deliver information about diabetes to patients, having little interaction with the physician or even input from the patient. The latter is not an ideal model. Instead, collaboration and communication among all team members is most beneficial for the best outcomes.

The Association of Diabetes Care and Education Specialists has defined competencies for the diabetes educator and for nonclinical providers such as community health workers or promotors (see Table 28.1). For each of these levels, competencies (minimal skills and knowledge) have been recommended in six domains (see Table 28.2):

1. Clinical management practice and integration
2. Communication and advocacy
3. Person-centered care and counseling across the lifespan
4. Research and quality improvement
5. Systems-based practice
6. Professional practice [25]

Self-assessment worksheets, available on the Association of Diabetes Care and Education Specialists website, are useful for evaluating where additional training, and support may be needed to enhance skills in each of the domains [26].

In the past, there was a lack of clarity regarding when to provide and modify DSMES. The DSMES Consensus Report of the American Diabetes Association, the Association of Diabetes Care and Education Specialists, the Academy of Nutrition and Dietetics, the American Academy of Family Physicians, the American Academy of PAs, the American Association of Nurse Practitioners, and the American Pharmacists Association defines four critical times for diabetes self-management education and support services [16].

Table 28.1 Diabetes educator provider levels

Diabetes community care coordinators	Health professionals	Diabetes care and education specialists
Member of the diabetes care team focused on linking individuals to resources, building relationships, and supporting people with, affected by, or at risk for diabetes and cardiometabolic conditions. This includes, but is not limited to, community health workers (CHW), health educators/coaches, medical assistants (MA), certified nursing assistants (CNA), licensed practical nurses (LPN), registered nutrition/dietetic technicians (NDTR), military medics and corpsmen, pharmacy assistants/technicians, physical therapy assistants, nutritionists, dental hygienists, emergency medical technicians (EMT), and other similar roles.	Member of the diabetes care team who interacts with people with diabetes and related conditions, but whose primary focus is not diabetes. This includes, but is not limited to, registered nurses (RN), registered dietitian nutritionists (RDN), pharmacists, and other similar roles.	Experts who, as integral members of the care team, provide collaborative, comprehensive, and person-centered care and education to people with diabetes and related conditions. This includes, but is not limited to, those with the credential CDCES (certified diabetes care and education specialist) or BC-ADM (board certified advanced diabetes management) and similar roles specializing in diabetes.

Table 28.2 Competencies for those working in diabetes care and education

Domain 1: Clinical Management Practice and Integration
The diabetes care and education specialist integrates knowledge and skills into clinical practice applying principles of pathophysiology, epidemiology, clinical management, and self-management of diabetes and cardiometabolic conditions.
Domain 2: Communication and Advocacy
The diabetes care and education specialist advocates for and communicates about improved quality of care and outcomes for those living with, at risk for, and affected by diabetes and cardiometabolic conditions.
Domain 3: Person-Centered Care and Counseling Across the Life Span
The diabetes care and education specialist partners with individuals to deliver care and education conducive to behavior change and improved quality of life for self-management of diabetes and cardiometabolic conditions across the life span.
Domain 4: Research and Quality Improvement
The diabetes care and education specialist contributes to research and quality improvement activities and applies current research and evidence-based care to guide practice.
Domain 5: Systems-Based Practice
The diabetes care and education specialist applies business principles, systems practice, and population health management to support achievement of the Quadruple Aim (reduced costs, better outcomes/population health, improved patient experience, and improved work life for health care providers).[16]
Domain 6: Professional Practice
The diabetes care and education specialist engages in lifelong learning and serves as a role model of professionalism.

Source: Ref. [24]

This report specifically addresses type 2 diabetes, yet it is applicable for all types of diabetes.

Following are the four critical times to provide and modify DSMES:

- At diagnosis—to teach survival skills to address immediate requirements (safe use of medication, hypoglycemia treatment if needed, introduction of eating guidelines; to assess individual preferences and barriers to implement self-management needs)
- Annually and/or when not meeting treatment targets—to assess certain situations such as elevated A1C, unexplained highs or lows, or planning a pregnancy
- When complicating factors influence self-management—such as a diagnosis of retinopathy or cancer, or the occurrence of a stroke or factors, such as a broken arm, that affect movement like the ability to do physical activity, prepare meals, and utilize monitoring devices—that can affect glucose management
- When transitions in life and care occur
- (aging, living situation, schedule changes, or health insurance coverage).

To maximize the team approach to care and education, the Consensus Report includes a list of factors that indicate when a referral is needed (Table 28.3) and a checklist of general responsibilities for providers and their teams and the diabetes care and education specialist at each of the four critical times (Table 28.4). Figure 28.1 is a visual depiction of the four critical times and content focus areas. The figure can be used during self-management education or training of health professionals to highlight the times, content, and benefit of diabetes self-management education and support. A recent paper adopted this figure to be specific to those with type 1 diabetes [27]. Additional resources that support increased participation in diabetes self-management education and support are available at diabeteseducator.org/consensusreport.

Table 28.3 Factors that indicate referral to diabetes education services is needed

At diagnosis
• Newly diagnosed--all newly diagnosed people with type 2 diabetes should receive diabetes education. • Ensure that both nutrition and emotional health are appropriately addressed in education or make separate referral.s
Annually and/or when not meeting treatment targets
• Review of knowledge, skills, psychosocial, and behavioral outcomes or factors that inhibit or facilitate achievement of treatment target and goals • Long-standing diabetes with limited prior education • Treatment ineffective for attaining therapeutic target • Change in medication, activity, or nutritional intake or preferences • Maintenance of clinical and quality of life outcomes • Unexplained hypoglycemia or hyperglycemia • Support to attain or sustain improved behavioral or psychosocial outcomes
When complicating factors develop
Change in: • Health conditions, such as renal disease and stroke, need for steroids, or complicated medication regimen • Health status requiring changes in nutrition, physical activity, and so forth • Planning pregnancy or pregnant • Physical limitations such as cognitive impairment, visual impairment, dexterity issues, and movement restrictions • Emotional factors such as diabetes distress, anxiety, and clinical depression • Basic living needs such as access to shelter, food, health care, medicines, and financial limitations
When transitions in life and care occur
Change in: • Living situation such as inpatient or outpatient or other change in living situation (i.e., living alone, with family, assisted living, etc.) • Clinical care team • Initiation or intensification of insulin, new devices or technology, and other treatment changes • Insurance coverage that results in treatment change (i.e., provider changes, changes in medication coverage) • Age-related changes affecting cognition, vision, hearing, self-management, and so forth

Table 28.4 Checklist for providing and modifying diabetes education at four critical times

Primary care provider/ endocrinologist/clinical care team's role in diabetes education	Diabetes care and education specialist's role in diabetes education
At diagnosis (series of visits)	
• Answer questions and provide emotional support regarding diagnosis • Shared decision-making of treatment and treatment targets • Teach survival skills to address immediate requirements (safe use of medication, hypoglycemia treatment if needed, introduction of eating guidelines) • Identify and discuss resources for education and ongoing support • Make referrals for diabetes education and medical nutrition therapy (MNT)	• Assess cultural influences, social determinants of health, health beliefs, current knowledge, physical limitations, family support, financial and work status, medical history, learning preferences and barriers, literacy, and numeracy to determine which content to provide and how: • Medication – choices, access, action, titration, side effects • Monitoring blood glucose – when to check, interpreting and using glucose pattern management for feedback • Physical activity – safety, short-term vs. long-term goals/recommendations • Preventing, detecting, and treating acute and chronic complications • Nutrition – food plan, planning meals, purchasing food, preparing meals, portioning food • Risk reduction – smoking cessation, foot care, cardiac risk • Developing personal strategies to address psychosocial issues and concerns; adjusting to a life with diabetes • Developing personal strategies to promote health and behavior change • Problem identification and solutions • Identifying and accessing resources
Annually and/or when not meeting treatment targets	
• Refer for new techniques, technology, and updated information • Assess and refer if self-management targets not met to address barriers to self-care	• Review and reinforce treatment goals and self-management needs • Review barriers to treatment effectiveness • Emphasize preventing complications and promoting quality of life • Discuss how to adjust diabetes treatment and self-management to life situations and competing demands • Support efforts to sustain initial behavior changes and cope with the ongoing burden of diabetes

(continued)

Table 28.4 (continued)

Primary care provider/ endocrinologist/clinical care team's role in diabetes education	Diabetes care and education specialist's role in diabetes education
When complicating factors develop	
• Identify presence of factors that inhibit or facilitate achievement of treatment targets and personal goals • Discuss impact of complications and successes with treatment and self- management	• Provide support for the provision of self-management skills in an effort to delay progression of the disease and prevent new complications • Provide/refer for emotional support for diabetes-related distress and depression • Develop and support personal strategies for behavior change and healthy coping • Develop personal strategies to accommodate sensory or physical limitation(s), adapt to new self- management demands, and promote health and behavior change
When transitions in life and care occur	
• Develop diabetes transition plan • Communicate transition plan to new health-care team members • Establish diabetes education regular follow-up care	• Adjust diabetes self-management plan as needed • Provide support for independent self- management skills and self-efficacy • Identify level of significant other involvement and facilitate education and support • Assist with facing challenges affecting usual level of activity, ability to function, health benefits and feelings of well-being • Maximize quality of life and emotional support for the person with diabetes (and family members) • Provide education for others now involved in care • Establish communication and follow-up plans with the provider, family, and others • Develop goals and personal strategies to promote health and behavioral change and improve quality of life

Challenges in Meeting Diabetes Education Needs: Addressing the Problem

Each individual with diabetes benefits from initial and ongoing diabetes education and support to address the day-to-day behaviors that impact health and quality of life. The 422 million people diagnosed with diabetes worldwide require this intervention so each can effectively manage their diabetes on a daily basis [28]. (ADA, 2022) Diabetes education includes much more than medication teaching; therefore, it is a valuable intervention regardless of when diabetes medications are started. At diagnosis, the provider and diabetes educator has the opportunity to address fears and myths about diabetes, provide emotional support and answer questions, and set the stage for living well with a chronic disease that requires focus, hope, and resources to manage on a daily basis [16]. Also, this is a time that involves collaborative discussion and decision-making related to medications, monitoring, physical activity, complications, nutrition, risk reduction, and developing personal strategies to address psychosocial issues and concerns and to promote health and behavior change [16].

A unique comparison of diabetes education and support to metformin highlights the many medical, nutritional, and behavioral benefits of education and support (See Table 28.5) [29] and points out that if diabetes education were a pill it would be routinely prescribed. Table 28.6 further delineates these benefits and highlights the intrinsic necessity of offering access to education and support at all four critical times [16].

Challenges in meeting an individual's diabetes education and support needs include knowing what education and support is needed, having qualified staff to engage in this clinical care, and ensuring patients continually access this care as their diabetes care needs change.

Table 28.6 Summary of diabetes education benefits to discuss with people with diabetes

Provides critical education and support for implementing treatment plan	Promotes lifestyle behaviors including healthful meal planning and engagement in regular physical activity
Reduces emergency department visits, hospital admissions, and hospital readmissions	Addresses weight maintenance or loss
Reduces hypoglycemia	Enhances self-efficacy and empowerment
Reduces all-cause mortality	Increases healthy coping
Lovers A1C	Decreases diabetes-related distress
	Improves quality of life
No negative side effects	
Medicare and most insurers cover the costs	

Source: Adapted and reprinted with permission from The American Diabetes Association. Copyright 2020 by the American Diabetes Association [15]

Identify Education and Support Needs

There are a number of position statements, consensus papers, standards of care and curricula that detail topics to address in diabetes care. Many of these highlight the need to offer education in a person-centered, collaborative, engaging, and respectful manner. There are basic needs that should be addressed immediately upon diagnosis by the diabetes care team and then other needs that can be addressed soon after either through a diabetes education program or by dedicated education staff within the clinic [16].

The DSMES Consensus Report discussed earlier details on the breadth of education required for daily self-management of diabetes at the four critical times. It includes a valuable checklist for providing and modifying DSMES at four critical times (Table 28.4). The checklist summarizes the when and what of diabetes education. It offers guidance on which members of the health-care team could provide the needed education and is a useful tool for the team to discuss to ensure your patients are receiving the care they need.

Table 28.5 Comparing the benefits of diabetes education versus metformin therapy

	Benefits rating	
Criteria	Diabetes education	Metformin
Efficacy	High	High
Hypoglycemia risk	Low	Low
Weight	Neutral/loss	Neutral/loss
Side effects	Low/savings	Low
Psychosocial benefits	High	N/A

Source: Adapted and reprinted with permission from The American Diabetes Association. Copyright 2016 by the American Diabetes Association [28]

Employ Qualified Staff

Key to successful diabetes education is the method of delivery and engagement of each individual in their care. The focus of diabetes education is to address the clinical, psychosocial, and behavioral needs of individuals. Historically, preparation of educators has been more focused on teaching them facts about diabetes rather than emphasizing principles of behavior change. Clinicians who commit to offering diabetes education and support require a unique blend of the art and science of diabetes care and resources to meet the needs of each individual to ensure a flexible, person-centered approach is taken.

The diabetes educator's role was developed to address the scope of diabetes self-management education and support needs of individuals with diabetes. In the United States, the Certified Diabetes Care and Education Specialist credential identifies those who meet specific knowledge and practice

criteria related to diabetes education [23]. A Certified Diabetes Care and Education Specialist may be a nurse, dietitian, pharmacist, social worker, psychologist, nurse practitioner, or other clinician. Different clinics in different locations around the world address the coordination and offering of diabetes education and support in various ways. Research highlights the value of a team-based approach to providing diabetes education; thus, the inclusion of a Certified Diabetes Care and Education Specialist or designated diabetes educator on the typical health care team is recommended to provide and/or coordinate diabetes education [5, 16].

With this in mind, clinical teams can plan how they address the ever increasing incidence of diabetes and corresponding need for specialized staff to educate those with diabetes. In the United States, there are over 19,500 Certified Diabetes Care and Education Specialists [30]. With over 34 million people in the United States having diabetes [31], each Certified Diabetes Care and Education Specialist would be responsible for the education needs of more than 1745 people. Worldwide, this lack of diabetes educators is likely even more staggering and highlights the need for increased preparation for diabetes educators and other clinicians who accept the responsibility of addressing the initial and ongoing education and support needs of individuals with diabetes.

Ensure Ongoing Access

To address the diabetes education and support needs of people with diabetes, the clinical team can review the needs listed in Table 28.6 and assign staff to each topic. Through discussion and consideration of other resources, teams can identify how to meet the individual needs of patients. In the United States, a referral from a provider is necessary to access a formal diabetes education program. A list of credentialed education programs can be found at www.diabeteseducator.org/deap or www.diabetes.org/erp. In other countries, national diabetes organizations typically list available resources. For example, Diabetes UK lists several nationally recognized diabetes education programs for type 1 and type 2 diabetes such as DESMOND, DAFNE, X-PERT, and Aspire [32].

It is essential that providers advocate for the education and support needs of their patients. Patients may not be aware of the value and outcomes associated with diabetes education, and some may not understand its necessity in addition to medication that they take. It is especially important to highlight the ongoing need for diabetes education and support throughout one's lifetime, including when other complicating factors influence diabetes care and when transitions in life and care occur. It may be easy to become distracted or focused on a new situation, allowing diabetes care to suffer and become a greater burden on the patient. Diabetes education does not occur in a single session; rather it is an ongoing collaboration with the diabetes team. Lack of follow-up can diminish previous behavior change and successes.

Communication among staff is critical whether or not the team is utilizing the services of a designated, formal diabetes education program. A continuous review of responsibilities, challenges, and successes can lead to many positive outcomes.

Who Are the Diabetes Educators?

The diabetes self-management education and support staff may be a team of professionals representing multiple disciplines, or it may include just one discipline. Often, the location and size of the organization determine the size of the leadership and education team. Members of the health-care team can contribute to an effective diabetes self-management education and support program by collaborating and providing clear communication [16].

In the United States, the Association of Diabetes Care and Education Specialists currently has over 12,000 members and represents multiple disciplines [33]. Diabetes education certification was first granted in 1986, and there are currently 46% RNs, including advanced practice nurses, 43% RDs/RDNs, and 8% RPhs certified in the United States [30]. Diabetes education is often considered a "specialty" or "specialization"; however, it is not considered its own profession or discipline. Diabetes educators are prepared in their specific discipline and often land in the specialty serendipitously.

Diabetes educators originally assumed this role "on the job"—seeing and responding to a need. Today, the need for diabetes education is greater than ever, and there are multiple paths to becoming a diabetes educator. Several universities have certificates and specialties in diabetes [34]. Continuing education is available on diabetes topics through several universities and organizations around the world. There are also national and international meetings where people can learn about diabetes education topics (see Table 28.7).

Diabetes education can range from minimal teaching in a primary or other care provider's office to formal education with a written curriculum and multiple follow-up visits, and anything in between. Health-care professionals may serve roles separate from or in addition to diabetes education.

Developing a Diabetes Education Program

Diabetes education takes place in a variety of practice settings, including the hospital, clinic, private practice, retail, community, and in virtual tele-health (or e-health) settings. There are no limits to where diabetes education can occur.

A needs assessment is a critical first step in developing or improving a diabetes self-management education and support program in any setting [12, 35]. (National Standards, 2022). Needs assessments ensure that the education program is effective and appropriate for the target population. Considerations may include age, culture, location, transportation, staffing, time of classes, length of classes, materials, cost, and other resources. It is important to determine at the outset the philosophy or mission of the program, as well as goals and objectives. Making goals measurable allows the program to be evaluated according to goal achievement.

Major organizations have established guidelines for developing, implementing, evaluating, and maintaining diabetes self-management education and support programs that meet high standards. In the United States, the American Diabetes Association oversees the Education Recognition Program [36], and the Association of Diabetes Care and Education Specialists oversees the Diabetes Education Accreditation Program [37].

Strategies for Successful Diabetes Education

While it is ideal to have access to a diabetes educator, that may not always be possible. Physicians and other team members often find themselves having to conduct or lead diabetes education for their patients. Consider the following eight tips to improve patient education and behavior change.

Collaborate with Patients

Engaging patients in their diabetes care plan makes the physician's job easier. When patients actively participate by thinking through and choosing treatment strategies—sharing in the decision of which medicine to take or selecting strategies to lose weight—they are more likely to follow through with behavior changes. Recognize that while the physician is the expert in diabetes care, the patient is the expert in his or her own diabetes and life. Collaboration between patient and provider is essential when designing a treatment plan for long-term success.

Ask Rather than Tell

Even though time is very limited in a medical visit, the physician can usually learn more about the patient's key concerns or possible barriers to treatment by asking open-ended questions such as, "What has been the hardest part about managing your diabetes since your last visit?" or "What questions do you have about your diabetes?" or "Many people have difficulty taking their medicine as prescribed. How often in the last week did you remember to take it?" When it comes to providing information about topics such as diabetes-related behaviors, ask the patient what they *can* do instead of telling them what they *should* do.

Recognize that Words Matter

Diabetes is often associated with stigma, shame, and guilt. The words commonly used in the language of diabetes care can accentuate negative feelings [38]. Frame messages to patients in a positive, hopeful manner. Use strengths-based language focusing on what patients do well ("tell me what you do to keep your numbers in target" instead of "what are you doing that gives you so many high blood glucose levels?"). Avoid judgmental, negative words and phrases such as "your diet *failed* to bring down your blood glucose…" or "your blood glucose numbers are not good." Instead, focus on the facts and physiology by saying, "Your glucose level is still elevated. This could be due to a decline in beta cell function. They are the cells that make insulin" or "Your most recent A1C is 9.2%. This is above the recommended goal of 7%" [39, 40].

Gather Educational Resources

Look for teaching aids that are best suited to the educational levels, languages, and literacy needs of your population. While printed handouts may be a common type of teaching aid, remember that the most useful handout might be a blank sheet of paper on which the key messages are written (or drawn) and specifically tailored for that patient. Enlist the help of others in your office to collect additional resources for use in demonstrations: food models, or nutrition fact labels; and diabetes supplies such as insulin pens, glucose meters, and hypoglycemia treatment options.

Provide a Written Care Plan

Provide each patient with a written care plan including instructions on how and when to monitor glucose, agreed upon targets, behavioral goals, and action steps as well as any medication changes. Record the results of the patient's blood pressure, weight, and lab tests to help them become familiar with their own biomarkers, know their targets, and recognize what medications and actions help to bring them into the target range.

Identify Resources

Network with diabetes educators. Even if they are not close by, there may be some who are willing to provide phone consultation or teaching for your staff. Talk with representatives from diabetes pharmaceutical, device, and technology companies as they will likely be able to identify educator experts. Learn about diabetes programs or services that may be helpful to your patients, such as diabetes support groups, education programs, community walking groups, and weight management programs.

Use the Teach Back Technique

It is common for patients to forget what they've been taught, even minutes after leaving the health-care provider's office. In addition to giving them something in writing, ask the patient, "Let's review what we went over. Can you tell me the key points of what you're going to do?" or "Show me how you're going to dial up the insulin dose on your pen and where you will give your first injection." Asking for a "teach back" helps identify misunderstandings of key points prior to the person leaving the office.

Mentor Others

If accessing a diabetes educator is not a realistic possibility, consider mentoring a nurse, medical assistant, or other office employee to be a "diabetes champion." Diabetes champions could also be people living with diabetes (even patients from your office) who are successfully managing their diabetes and have been taught specific guidelines for talking with other patients. Diabetes champions can help busy physicians by obtaining and organizing teaching materials and product samples, locating and listing community resources, and providing patients with accurate information about basic topics. Such topics could include healthy eating using the plate method, tips to increase physical activity, or strategies to remember to take medicines. Using teaching aids, such as a handout or a flipchart containing scripted messages, can help ensure that key points are made consistently and that the diabetes champion does not exceed his or her scope of practice. Using office staff in this way can have a powerful impact on improving diabetes care and providing busy physicians more time to spend with other patients [41].

Examples of Diabetes Education Initiatives Around the Globe

Increasing the Role of the Pharmacist in Community Education in Saudi Arabia

The Middle East is one of the regions where diabetes is escalating most rapidly. In the Kingdom of Saudi Arabia (KSA), the prevalence has jumped from 4.3% to 13.4% in the last 30 years. Over 50% of individuals over the age of 65 have diabetes [42]. While the role of the diabetes nurse and dietitian educators is increasing, the supply is not keeping up with the demand. Taking a cue from initiatives in other parts of the world, including the United States, where retail pharmacists have been taking on greater roles in diabetes education, the Nadhi Medical Company started a program to teach Diabetes Consultant Pharmacists (DCPs) to do in-store diabetes education. A program, "Let's Talk About Diabetes," which included four short, structured lessons on topics including taking medicines and monitoring blood glucose, was developed in a collaborative partnership with Joslin Diabetes Center and under the supervision of the KSA Ministry of Health. The program started as a pilot in 11 stores in 4 different cities and has expanded to over 40 stores. Numerous beneficial outcomes have been reported including an increase in medication taking behaviors (with 54% reporting not taking medicines as prescribed over past 7 days at baseline to only 14% reporting this at follow up) to an increase in those reporting using a meal plan to help manage their diabetes (from 6% to 32%). There were 380 customers with paired A1C results, which demonstrated a reduction from 8.5% (69 mmol/mol) to 7.32% (56 mmol/mol) ($p < 0.001$) [43]. As demonstrated by this project, community pharmacists in the retail setting can play an important and effective role in diabetes education.

Using Conversation Maps® to Facilitate Education in Pakistan

Diabetes education in group settings can be very effective. Research shows participants enjoy the group interaction and also demonstrate improvements in clinical outcomes (A1C). In addition, group education programs are cost effective [44]. Conversation Maps are a set of large, colorful images or pictorial guides, designed to engage small groups of people in discussion about their diabetes. Through the discussions, facilitated by a health-care professional, people not only learn about diabetes but also discuss their beliefs, clarify misconceptions, and share their personal stories of successes and challenges, thus learning from each other. Conversation Maps have been translated into 35 languages and are available in 110 countries. A study of 172 individuals in Pakistan participating in Diabetes Conversation Maps sessions found a high level of satisfaction with this teaching method with 72% preferring the group method using the maps over individual education. The study also demonstrated a large increase in individuals reporting willingness to make a change in behaviors to improve diabetes outcomes (from 20% at baseline to 66% after the class discussions) [45].

Using Community Health Workers in Diabetes Education and Prevention in Rural India

Recognizing the limited availability of diabetes educators, especially in rural areas, trained community health workers or peer counselors can be an effective resource and has been effectively demonstrated in India. In two different interventions, community health workers were taught by a diabetes educator to provide lifestyle education aimed at reducing risks for diabetes. Dietary education focused on improving the intake of fiber and protein from low-cost resources such as nutritionally rich drumstick leaves, millets, lentils, and whole grains. Educators emphasized avoidance of sweetened drinks, and nutrition teaching methods included cooking demonstrations, recipe competitions, and model meals. Community health workers promoted and reinforced physical activity with demonstrations, competitive fun events, and dancercise events for the younger respondents. Stress relaxation instruction included the importance of meditation and breathing exercises (familiar to many of the respondents). A Certified Diabetes Educator provided individual education and counseling for blood glucose management to a high-risk group. Interventions showed improvement in obesity and diabetes-related parameters and dietary intake [46]. As the need for diabetes educators grows, the use of community health workers is an effective and recommended option. The Association of Diabetes Educators Practice Synopsis on Community Health Workers suggests roles and competencies and offers recommendations for practice [47]. The Peers for Progress website offers many examples of successful interventions and resources available for training [48].

Engaging Group Activities for Support in Japan

Activities that bring people with diabetes together, such as support groups, have long been recognized as being helpful, and the Education Center of Kenichi Yamada Internal Medicine Clinic in Sendai, Japan has successfully initiated several innovative approaches. The clinic is designed as a very warm and welcoming space and even includes an art gallery displaying paintings from a local artist. The clinic's motto, "Hand-in-hand we think and take steps together," reflects their philosophy of the importance of partnership between the patient and provider. Their clinic website shows how diabetes education activities go beyond traditional classes, by including walking groups, concerts (offered along with diabetes education), cooking classes (where everyone participates), and classes with custom-tailored conversation maps. Activities such as these build community and support between participants and their health care providers [49].

Online Diabetes Educator Preparation: Certificate and Degree Programs

As the need for diabetes educators increases, different groups have implemented solutions to increase access to instruction programs. For example, the International Diabetes Federation offers a variety of classes in English and Spanish for diabetes educators through its "School of Diabetes." In addition, the Association of Diabetes Care and Education Specialists has several certificate courses available in English [50] Table 28.6 provides a partial list of academic and continuing education opportunities in diabetes. An Internet search can also identify the most current programs available.

Additional Roles for the Diabetes Educator

Diabetes educators are often called on for their expertise. Their presence and participation in social media is growing; there are more and more virtual chats and other opportunities for diabetes educators to share their experience and knowledge. Diabetes educators are also considered thought leaders in the field and are often asked to contribute to papers, meetings, and advisory boards. In addition, diabetes educators are being asked to serve as content experts for published materials. National organizations often ask diabetes educators to serve on committees and lend their expertise to special projects.

In addition, in a systematic review that looked at strategies for improving outcomes in type 2 diabetes, the authors concluded that the diabetes educator has a very important role. The most effective approaches to mitigating therapeutic inertia and improving A1C were those that empowered non-physician providers (such as diabetes educators and pharmacists) to initiate and intensify treatment independently, supported by appropriate guidelines [51].

Diabetes education is still in its early stages around the world, and diabetes educators have an opportunity to grow this specialty. While there are currently not enough diabetes educators to serve all people with diabetes, they can prepare diabetes paraprofessionals to help meet patients' education needs; they can partner with other professionals and encourage more people to become diabetes educators. Diabetes educators are leaders in using and teaching about mobile apps for diabetes management. They know how to interact successfully with people of all ages and generations. Diabetes educators recognize the value of diabetes technology and are teaching others how to use it. There is a possible role for diabetes educators in retinal screening, which could increase the number of people who have dilated eye exams each year and in turn get referred for care as needed [52].

It is impossible to predict what the future will hold for diabetes educators. The need for well-prepared diabetes educators is unrelenting. The opportunities for online education resources are increasing every day. Diabetes educators are well positioned to oversee that work and ensure timely, relevant, consistent, and accurate information is made available to people with diabetes and their loved ones.

Multiple Choice Questions

Which of the following have been found to improve as a result of diabetes self-management education?

1. A1C
2. Quality of life
3. Self-care behaviors
4. **All of the above**

According to the DAWN2 study, which of the following statements is true?

1. **About 50% of people report diabetes has a negative impact on their emotional well-being**.
2. About 25% of people report experiencing diabetes-related distress.
3. About 15% of people who attended diabetes classes reported no improvement.
4. All of the above.

What are considered the critical times for diabetes education?

1. At diagnosis and within the first 18 months
2. At diagnosis, when A1C is elevated, when insulin is initiated
3. **At diagnosis, annually and/or when not meeting treatment targets, when complicating factors develop, when transitions in life and care occur**
4. At diagnosis, when new medications are started, after a hospitalization

Diabetes self-management education and support can be provided by

1. nurse
2. dietitian
3. pharmacist
4. **all of the above plus others**

Content areas for diabetes self-management education and support include

1. healthy eating, exercise, medications, and monitoring
2. pathophysiology, treatment, and acute and chronic complications
3. healthy coping and problem solving
4. **all of the above**

If a Certified Diabetes Educator is not available, the following people are most qualified to provide diabetes education

1. physicians
2. family members
3. peer educators or community health workers
4. **1 and 3**

For professionals, ongoing preparation in diabetes education and support topics is available through

1. informal get-togethers with colleagues
2. **online academic degree programs and continuing education**
3. YouTube videos about diabetes
4. working with patients

Words and messages are important in diabetes. Recommendations for effective communication include using

1. strengths-based language
2. empowering language
3. language based on facts and physiology
4. **all of the above**

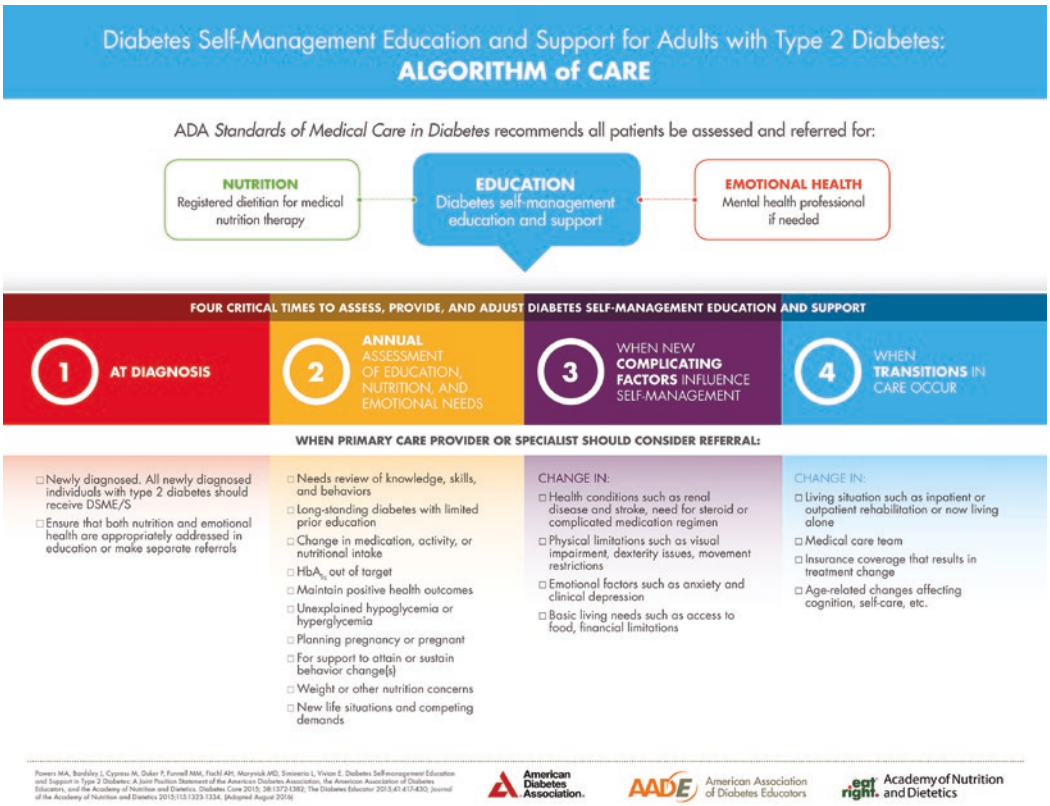
Successful strategies for diabetes education include

1. telling people what to do
2. giving people information, sending them home, and hoping for the best
3. **using the teach back technique**
4. people have enough to think about, they do not need written handouts

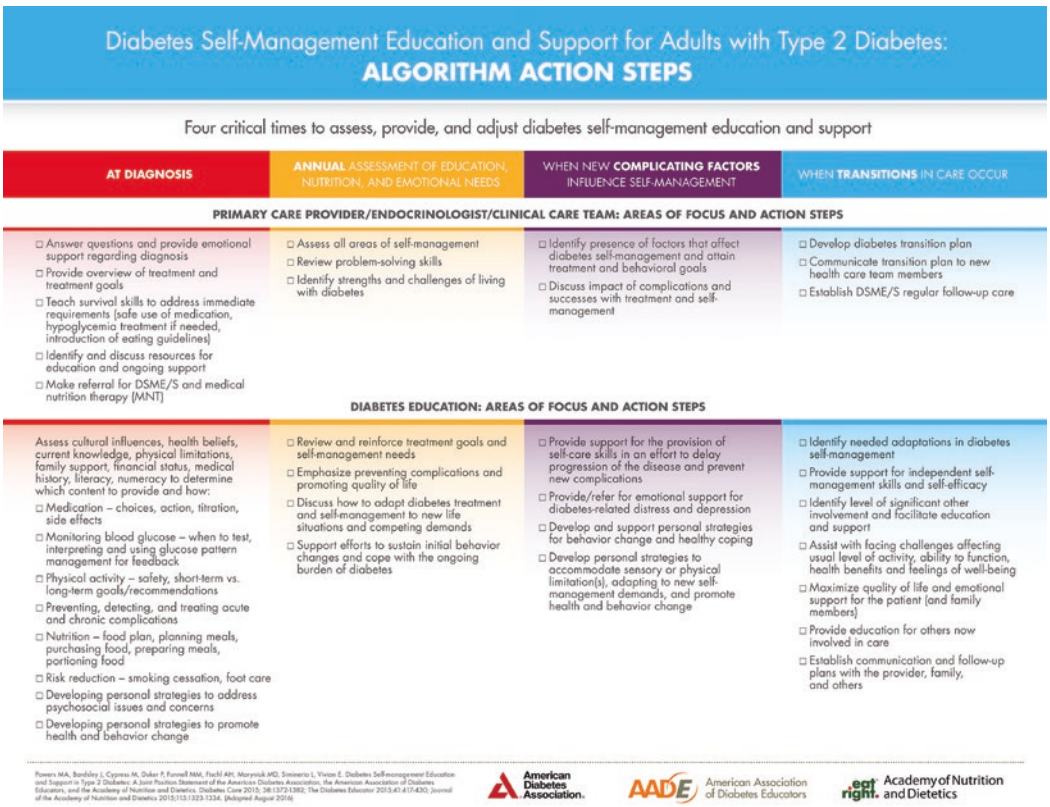
The most important sign of a successful diabetes education program is

1. lots of money coming in
2. **engaged patients**
3. lower A1C numbers
4. decreased incidence of hypoglycemia

Appendix



Diabetes Self-Management Education and Support for Adults with Type 2 Diabetes:
ALGORITHM of CARE
ADA Standards of Medical Care in Diabetes recommends all patients be assessed and referred for:
NUTRITION
Registered dietitian for medical nutrition therapy
EDUCATION
Diabetes self-management education and support
EMOTIONAL HEALTH
Mental health professional if needed
FOUR CRITICAL TIMES TO ASSESS, PROVIDE, AND ADJUST DIABETES SELF-MANAGEMENT EDUCATION AND SUPPORT
1 AT DIAGNOSIS
2 ANNUAL ASSESSMENT OF EDUCATION, NUTRITION, AND EMOTIONAL NEEDS
3 WHEN NEW COMPLICATING FACTORS INFLUENCE SELF-MANAGEMENT
4 WHEN TRANSITIONS IN CARE OCCUR
WHEN PRIMARY CARE PROVIDER OR SPECIALIST SHOULD CONSIDER REFERRAL:
Newly diagnosed. All newly diagnosed individuals with type 2 diabetes should receive DSME/S
Ensure that both nutrition and emotional health are appropriately addressed in education or make separate referrals
Needs review of knowledge, skills, and behaviors
Long-standing diabetes with limited prior education
Change in medication, activity, or nutritional intake
HbA1c out of target
Maintain positive health outcomes
Unexplained hypoglycemia or hyperglycemia
Planning pregnancy or pregnant
For support to attain or sustain behavior change(s)
Weight or other nutrition concerns
New life situations and competing demands
CHANGE IN:
Health conditions such as renal disease and stroke, need for steroid or complicated medication regimen
Physical limitations such as visual impairment, dexterity issues, movement restrictions
Emotional factors such as anxiety and clinical depression
Basic living needs such as access to food, financial limitations
CHANGE IN:
Living situation such as inpatient or outpatient rehabilitation or now living alone
Medical care team
Insurance coverage that results in treatment change
Age-related changes affecting cognition, self-care, etc.
American Diabetes Association.
AADE American Association of Diabetes Educators
eat right. Academy of Nutrition and Dietetics



Diabetes Self-Management Education and Support for Adults with Type 2 Diabetes:
ALGORITHM ACTION STEPS
Four critical times to assess, provide, and adjust diabetes self-management education and support
AT DIAGNOSIS
ANNUAL ASSESSMENT OF EDUCATION, NUTRITION, AND EMOTIONAL NEEDS
WHEN NEW COMPLICATING FACTORS INFLUENCE SELF-MANAGEMENT
WHEN TRANSITIONS IN CARE OCCUR
PRIMARY CARE PROVIDER/ENDOCRINOLOGIST/CLINICAL CARE TEAM: AREAS OF FOCUS AND ACTION STEPS
Answer questions and provide emotional support regarding diagnosis
Provide overview of treatment and treatment goals
Teach survival skills to address immediate requirements (safe use of medication, hypoglycemia treatment if needed, introduction of eating guidelines)
Identify and discuss resources for education and ongoing support
Make referral for DSME/S and medical nutrition therapy (MNT)
Assess all areas of self-management
Review problem-solving skills
Identify strengths and challenges of living with diabetes
Identify presence of factors that affect diabetes self-management and attain treatment and behavioral goals
Discuss impact of complications and successes with treatment and self-management
Develop diabetes transition plan
Communicate transition plan to new health care team members
Establish DSME/S regular follow-up care
DIABETES EDUCATION: AREAS OF FOCUS AND ACTION STEPS
Assess cultural influences, health beliefs, current knowledge, physical limitations, family support, financial status, medical history, literacy, numeracy to determine which content to provide and how:
Medication – choices, action, titration, side effects
Monitoring blood glucose – when to test, interpreting and using glucose pattern management for feedback
Physical activity – safety, short-term vs. long-term goals/recommendations
Preventing, detecting, and treating acute and chronic complications
Nutrition – food plan, planning meals, purchasing food, preparing meals, portioning food
Risk reduction – smoking cessation, foot care
Developing personal strategies to address psychosocial issues and concerns
Developing personal strategies to promote health and behavior change
Review and reinforce treatment goals and self-management needs
Emphasize preventing complications and promoting quality of life
Discuss how to adapt diabetes treatment and self-management to new life situations and competing demands
Support efforts to sustain initial behavior changes and cope with the ongoing burden of diabetes
Provide support for the provision of self-care skills in an effort to delay progression of the disease and prevent new complications
Provide/refer for emotional support for diabetes-related distress and depression
Develop and support personal strategies for behavior change and healthy coping
Develop personal strategies to accommodate sensory or physical limitation(s), adapting to new self-management demands, and promote health and behavior change
Identify needed adaptations in diabetes self-management
Provide support for independent self-management skills and self-efficacy
Identify level of significant other involvement and facilitate education and support
Assist with facing challenges affecting usual level of activity, ability to function, health benefits and feelings of well-being
Maximize quality of life and emotional support for the patient (and family members)
Provide education for others now involved in care
Establish communication and follow-up plans with the provider, family, and others

Diabetes and Mental Health: From Distress to Depression

29

Gerhard Heinze-Martin, Diana Patricia Guizar, and Napoleon Andrés Bernard

Introduction

The comorbidity between depression and diabetes mellitus was recognized by the British physician Thomas Willis in the seventeenth century; he noted that diabetes frequently appeared in individuals who had previous experiences of stress in their lives, "diabetes is a consequence of prolonged sorrow" [1, 2].

Diabetes mellitus (DM) prevalence is increasing worldwide; the World Health Organization predicts there will be 300 million people having this disease by 2025, and due to an increase in prevalence, diabetes has become an epidemic throughout the world and one of the leading causes of death, affecting approximately 422 million people globally. Depression is a frequent comorbidity of both type 1 (T1D) and type 2 diabetes (T2D) [3, 4]. The high prevalence of the comorbidity worldwide is characterized by high morbidity and mortality in patients who suffer from both diseases [5, 6]. Also, WHO reveals that 49% of the depressed people with type 2 diabetes mellitus (DM2) were misrecognized by the primary-care system. The comorbidity between diabetes mellitus and depression is a serious chronic conditions that negatively affects the quality of life, increase functional disability, and reduce life expectancy [7, 8]. The comorbidity represents a major clinical challenge as the outcomes of each condition are worsened by the presence of the other. Today, we know that people with type 1 diabetes mellitus (DM1) and DM2 have an increased risk of developing depressive symptoms, and people with depression also have an increased risk of developing diabetes [9]. However, the exact mechanisms through which these two conditions affect each other remain uncertain, and there are few integrated approaches to the problem. The American Diabetes Association recommends diabetes screening every 3 years in all subjects above 45 years of age; an earlier and more intensive testing is advised in overweight persons with other risk factors (physical inactivity, family history of diabetes, previous gestational diabetes, hypertension, hypertriglyceridemia, polycystic ovary syndrome). Depression disorder should be included among the risk factors that should drive diabetes screening [10]. There is also evidence that suggests diabetes mellitus is associated with a higher frequency of suicide, with depression being the most commonly reported psychiatric disorder in patients with diabetes who attempted suicide [11].

Definitions

- *Major Depressive Disorder.* According to the American Psychiatric Association Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5) [12] and the tenth revision of the International Classification of Diseases (ICD-10) [13], major depressive disorder is a mood disorder, made on the basis of several symptoms and the extent of functional deterioration. The diagnosis according to DSM-5 is made when at least five of nine symptoms (feelings of guilt or worthlessness, fatigue or loss of energy, concentration problems, suicidality or thoughts about death, change in weight, change in activity, change in sleep), including a minimum of one core symptom (a diminished or irritable mood, decreased interest or pleasure), lasts at least 2 weeks. The different possible combinations of depression symptoms all leading to a diagnosis are large and result in various clinical profiles of depression.

- *Distress.* The term was introduced by Hans Selye in the early 1970s; he distinguished between stress initiated by negative, unpleasant stressors (distress) and positive stress (eustress) [14] Ridner defined it as "the unique discomforting, emotional state experienced by an individual in response to a specific stressor or demand that results in harm (irritability, fear, nervousness, and sadness), either temporary or permanent to the person" [15].
- *Diabetes distress* is an emotional distress that stems from a variety of areas related to living with the burden of a chronic illness [16]. Living with diabetes can be complex, demanding, and sometimes confusing. Patients often feel frustrated, angry, overwhelmed, and/or discouraged. When the challenges of caring for diabetes affect the individual on an emotional level, it may result in diabetes-related distress [17].

Epidemiology of Comorbid Depression–Diabetes

In 2015, the prevalence of diabetes worldwide was of 1 in 11 adults, and the estimated prevalence of the impaired glucose toleration was of 1 in 15 adults. These numbers are expected to further increase, especially in the urban population, leading to more medical and economic challenges, added on top of the 12% global health expenditure currently spent on diabetes [18]. Depression is a common and serious disease with a lifetime prevalence from 11% to 15% [19]. Depression and anxiety are the fourth cause, while diabetes is the eighth cause of disability adjusted life years (DALYS) in developed countries [20]. A common cited meta-analysis (including type 1 and type 2 diabetes) showed that the overall odds of depression was twice as high for people with diabetes compared to nondiabetic controls and no significant differences in prevalence were found between these two types of diabetes [21]. Few years later, Ali and colleagues realized a meta-analysis of ten controlled studies focusing on type 2 diabetes; the prevalence rate of depression was found higher in people with diabetes compared to controls. Barnard [22] published a systematic review of four controlled studies which reported that the prevalence of clinical depression was 12.0% for people with type 1 diabetes compared to 3.2% in people without diabetes. Moussavi and colleagues [23] carried out a survey in 60 countries and found that the self-reported 1-year prevalence of depressive symptoms in diabetes was 9.3% compared to 3.2% in people without a comorbid condition. Studies indicate that during the period following the diagnosis of type 2 diabetes, important changes occur that are likely to be associated with the development of depression. Skinner and colleagues [24] found that the prevalence of depression was not significantly different from a normative sample in the first year after diagnosis, although a significant number of people had persistent depressive symptoms during that year. Use of antidepressant medication was also increased temporarily during the first year after diagnosis of type 2 diabetes [25].

Recently [26], the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) of the National Institutes of Health (NIH), in collaboration with the National Institute of Mental Health and the Dialogue on Diabetes and Depression, concluded that the prevalence of this comorbidity varies considerably by method of depression assessment; for example, prevalence rates for elevated depressive symptoms range from 12% to 27% across studies of people with type 1 and type 2 diabetes, while rates of depressive disorders, as assessed by psychiatric interview protocols, range from 8% to 15% in adults with type 1 and type 2 diabetes [27]. Nouwen and colleagues [28] in a recent meta-analysis concluded that the incidence of depression is 24% higher in people with diabetes type 2, and the presence of 2 or more complications (neuropathy and nephropathy) is associated with a greater than two-fold increase in the risk of depression in people with type 2 diabetes.

Meurs and colleagues [29] found that depression was more prevalent in people with diabetes, regardless of the fact that they had diagnosed or undiagnosed diabetes ($n = 90{,}686$).

We can conclude that based on available epidemiological studies, diabetes is associated with increased risk of depression and in the same way a depressive disorder increase the risk of metabolic diseases like diabetes. In other words, there is a bidirectional association between diabetes and depression, a complex relation that might share biological mechanisms, whose understanding could provide a better treatment and avoid complications of comorbidity. In 2015, Berge et.al and Moulton et.al [30, 31] indicated three possible directions for the association of diabetes and depression: both diseases might have a common etiology, diabetes increasing the prevalence or risk for future depression and depression increasing the prevalence or risk for future diabetes.

Mechanisms Underlying the Association Diabetes–Distress–Depression (Fig. 29.1)

Depression was an understandable reaction to the difficulties resulting from living with a demanding and life-shortening chronic physical illness that is associated with chronic and debilitating complications. De Ridder and colleagues [32] found distress is prevalent in medical patients with chronic illness because it challenges their habitual coping strategies, with most eventually reaching good psychological adjustment, but for about 30%, the adjustment phase is long lasting or unsuccessful. In diabetes, distress presents in 10–30%, depending on case mix, and can differ across settings and

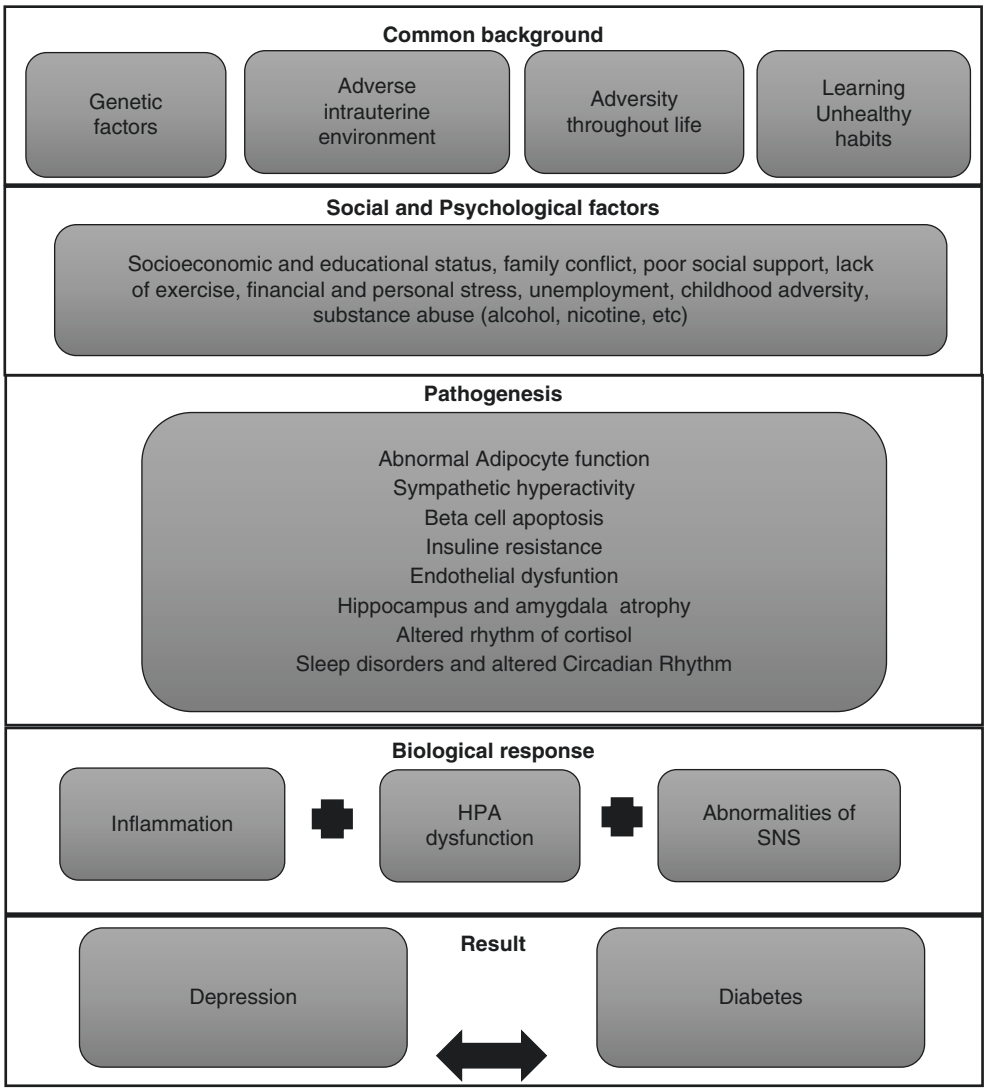

Fig. 29.1 Mechanisms underlying the association diabetes–distress–depression

countries [33]. In an observational study during 18 months in patients with type 2 diabetes in the USA, almost a third of the patients reported increased diabetes distress at least at one of three measurement timepoints, with 22% reporting high diabetes distress at all three measurement points [34]. Fisher and colleagues [35] consider emotional distress as a core, continuous dimension that underlies diabetes-related distress, subclinical depression, elevated depressive symptoms, and major depressive disorder.

Adherence to Treatment, Hygienic, and Dietetic Measures

Depression and type 2 diabetes share similar environmental and lifestyle risk factors, such as socioeconomic deprivation, social adversity, smoking, and reduced physical activity. Recent studies [33–39] showed that childhood adversity (abuse, deprivation, and neglect) and work stress have effects on depression and diabetes. Depression is associated to self-neglect and low self-esteem, which might increase risk of unhealthy lifestyles, for example, increased caloric intake, high body-mass index (BMI), poor diet, low levels of physical activity, and smoking, that generate metabolic changes and incremented the risk of Diabetes.

Lustman and colleagues [40] on a meta-analysis showed that depression in diabetes was associated with significantly worse glycemic control, although the effect size ($r = 0.17$) was small. For depression diagnosed by a standardized clinical interview, the effect size was larger ($r = 0.28$). Evidence suggests that diabetes-related distress, rather than depression, is associated with decreased glycemic control over time [41]. It is important to know that not all depressive symptoms are equally important. Nefs and colleagues [42] identified anhedonia as the strongest predictor for poor glycemic control, in contrast with Bot and colleagues [43] who identified depressed mood and somatic symptoms of depression

(sleeping difficulties, appetite problems, and psychomotor retardation) as best predictors.

The link between depression and type 2 diabetes is bidirectional: type 2 diabetes is associated with a roughly 20% increased risk of incident depression [44, 45], and depression is associated with a 60% increased risk of incident type 2 diabetes. A meta-analysis by Gonzalez and colleagues found that depression has a moderate to weak association with self-care behavior (overall r = 0·21) including missed medical appointments, diet, exercise, medication use, glucose monitoring, and foot care [46]. In a primary study, a 1-point increase in depressive symptoms scales was found to result in a 10% increased risk of nonadherence to fruit and vegetable intake and foot care. Findings of cross-sectional studies [41, 47] of the association depression–diabetes self-care showed that healthy eating, regular exercise, and low calorie intake and low-fat food showed a strong negative correlation with depressive symptoms and diabetes distress but not with the presence of clinical depression, which, according with Holt and colleagues [47], suggests the possibility that there may be a mutually reinforcing phenomenon that poorer adherence to self-care may increase blood glucose, which in turn may contribute to depressive symptoms and consequently contribute to decreased adherence to self-care behaviors.

The Hypothalamic-Pituitary Adrenal (HPA) Axis Dysfunction

Stress is a state of threatened homeostasis, evoking adaptive responses. As we already know, the major role of the HPA axis is to mediate the neuroendocrine stress response, in order to reestablish body homeostasis. As a brief reminder, the HPA axis, first corticotropin releasing factor (CRH) is synthesized by neurons in the parvocellular cell division of the paraventricular nucleus (PVN), and it is secreted into the pituitary portal blood and enters the anterior pituitary and binds to type 1 CRH cell-surface receptors, resulting in ACTH which acts on the adrenal cortex, to stimulate cortisol secretion. Cortisol inhibits the secretion of CRH and ACTH from the hypothalamus and anterior pituitary, respectively. Once cortisol is released from the adrenal cortex in response to ACTH stimulation, it functions to increase blood glucose levels through its action on glycogen, protein, and lipid metabolism [48, 49].

Chronic stress and cortisol excess can lead to:

(a) Increased portal and peripheral free fatty acids to be released into the circulation, which impairs the ability of insulin to translocate intracellular SLC2A4 glucose transporters to the cell surface and can, therefore, contribute to metabolic syndrome, insulin resistance, muscle weakness, hirsutism, increased bruisability, and type 2 diabetes [50]
(b) Accumulation of visceral fat by promoting differentiation and proliferation of adipocytes, redistributing fat from peripheral to central depots, and increasing the size and number of adipocytes [51]
(c) Hindered neurogenesis in the hippocampus and amygdala [52]
(d) Depression [53]

Several biological mechanisms have been proposed for the association between diabetes and depression throughout the life course. Gragnoli and colleagues [54] hypothesized that these biological mechanisms may reside at the level of CRH receptors which may carry genetic variants that determine protein dysfunctions responsible for HPA axis hyperactivation and for impaired cortisol-mediated feedback response in depression. The genetic variant at the level of CRHR1 that contributes to increased CRH levels in the hypothalamus may as a loss of function variant contribute to reduce insulin secretion in the pancreatic beta cell, which jointly to the prediabetic insulin-resistant state due to hypercortisolism, may lead to type 2 diabetes. In contrast, Horwath and colleagues [55] hypothesized that atypical depression is associated with a hypoactive HPA axis and hypocortisolism. However, patients with atypical depression also have insulin resistance possibly due to a noncortisol-mediated increase in visceral fat. These patients, in fact, have an increased food intake, especially carbohydrates, which may contribute to the decreased insulin sensitivity.

Conventional measures used to assess HPA axis activity showed in depression and diabetes elevated 24-hour urine free cortisol levels, failure to suppress cortisol with dexamethasone suppression test, adrenal gland enlargement, and performing the dexamethasone–corticotrophin-releasing hormone (CRH) test. The failure to suppress cortisol with the dexamethasone suppression test or the dexamethasone–CRH test suggests injury to the HPA axis a negative feedback loop and an inability of the HPA axis to appropriately terminate the stress response, resulting in excessive cortisol exposure.

Abnormalities of the Sympathetic Nervous System (SNS)

Carney and colleagues [56] documented elevated heart rate, lower heart rate variability, and high heart rate responses to physical stressors in depressed psychiatric patients compared with healthy controls. Few years later, Udupa and colleagues [57] found that depressed patients versus controls had higher low-frequency/high-frequency ratios and higher basal heart rates, suggesting a shift in SNS activity toward enhanced sympathetic tone. In a much larger study of Carol

and colleagues [58], they suggested that depression is associated with a blunted cardiovascular response to acute stress because they found that depressed patients were negatively associated with systolic blood pressure and heart rate reaction to paced auditory serial arithmetic testing after adjusting for gender, occupation, BMI, stress task performance score, medications (antidepressants and antihypertensives), and baseline cardiovascular activity.

Catecholamines are counterregulatory hormones that induce insulin resistance by acting on β3 receptors found in intra-abdominal and visceral fat and promotes lipolysis, leading to increased free fatty acid release [59]. A disease in which this mechanism is exemplified is pheochromocytoma (a rare neuroendocrine tumor involving overproduction of catecholamines), where insulin resistance, significant improvements in 24-hour urine catecholamine levels, fasting plasma glucose, and fasting insulin were notable features [60].

Inflammation and Innate Immunity

Depression

Studies in experimental animals and humans identified a close connection between the immune system and neurocircuits in the brain, which may have implications for the role of inflammation in the development of depression [61]. Two meta-analyses of cross-sectional studies [62, 63] provided evidence that patients with depression have higher circulating levels of biomarkers of subclinical inflammation, in particular C-reactive protein (CRP), interleukin (IL)-6, IL-1 receptor antagonist (IL-1ra), and tumor necrosis factor (TNF)-α, than nondepressed individuals. Stewart and colleagues [64] demonstrated that baseline depression scores and BMI were predictors of increase in IL-6, which suggests that depressive symptoms possibly precede and contribute to the inflammatory processes. Gimeno and colleagues [65] showed that baseline CRP and IL-6 were predictive of cognitive symptoms of depression. One year later, Weinstein and colleagues [66] found heightened acute mental stress reactivity in depressed individuals with higher IL-6, TNF-α, and CRP compared with controls; their results were supported by the meta-analysis of Dowlati and colleagues [67]. Recently, Khandaker and colleagues [68] found that increased concentrations of CRP and interleukin 6 predicted increased risk of depression.

Diabetes

Many studies support the association of inflammation and diabetes: Bretoni and colleagues [69] found higher CRP, IL-6, and fibrinogen levels; Aso and colleagues [70] found higher CRP, IL-6, and plasminogen activator inhibitor-1; Valle Gotlieb and colleagues [71] found higher high-sensitivity CRP (hs-CRP), oxidized low-density lipoprotein (LDL), oxidized LDL autoantibodies, and IL-6 among diabetic patients versus controls. Specifically, T2D and subclinical inflammation are linked in a bidirectional relationship [5]. The extent of chronic low-grade immune activation in T2D is exacerbated by the manifestation of macro- and microvascular complications during the progression of the disease [72]. The extent of chronic low-grade immune activation in T2D is exacerbated by the manifestation of macro- and microvascular complications during the progression of the disease [72]. It is currently not clear to what extent inflammatory processes mediate the increased risk of depression in patients with T2D. Furthermore, it remains unclear whether this association is independent of diabetic complications, which are highly prevalent in patients with longer diabetes duration. Additionally, it is not completely clarified whether associations between inflammation and depression are also present in patients with T1D. Both diabetes types share hyperglycaemia as the diagnostic criterion. However, they represent opposite ends of a continuum with different etiologies, which extends to the contribution of immune activation and inflammation [73].

Depression–Diabetes–Inflammation

Several studies proved that both depression and diabetes are associated with proinflammatory cytokines and elevation of inflammatory markers [74–78], specifically in type 2 diabetes, where raised concentrations of proinflammatory cytokines lead to pancreatic β-cell apoptosis and insulin resistance [79]. Epidemiological studies proposed innate immunity (interleukin 6 and CRP) as a possible mechanism by which depression and type 2 diabetes could develop as a result of stressors throughout the life course (abuse, neglect, or both before age 16 years, low socioeconomic status) [80]. Laake and colleagues [81] found that patients with newly diagnosed type 2 diabetes and depression were more overweight, younger, had higher concentrations of C-reactive protein (CRP) and interleukin 1-receptor antagonist and higher white-cell counts than those with type 2 diabetes who were not depressed.

Sounds logical that if inflammation is involved in pathogenesis of depression and type 2 diabetes, reduction in inflammation might be a novel treatment. Recent placebo-controlled trials with anti-inflammatory agents (interleukin 1 receptor antagonist and nonsteroidal anti-inflammatory drugs) found that they improve glycaemic control [82, 83]. However, there are no studies that have attempted to modify inflammation in treatment of depression in patients with type 2 diabetes.

Herder and colleagues [84] found that serum high-sensitivity C-reactive protein (hsCRP) and the ratio of high-molecular-weight (HMW)/total adiponectin were positively associated with depression symptoms evaluated by ADS-L

(Allgemeine Depressionsskala, Langversion) in T2D, but not in T1D. In contrast, serum levels of soluble intercellular adhesion molecule (sICAM)-1 were positively associated with ADS-L only in T1D. The latter association was significantly different between both diabetes types. No associations were observed for interleukin (IL)-6, IL-18, and soluble E-selectin. Only the association between HMW/total adiponectin and ADS-L in T2D remained significant after correction for multiple testing.

Circadian Rhythms

Sleep architecture variations can be seen before onset of depressive symptoms, suggesting that a subpopulation might be at increased risk of depressive symptoms and metabolic disturbances. Many studies found that disrupted sleep patterns (decreased slow-wave sleep and increased rapid eye movement density), sleep apnea, poor sleep quality, and altered circadian rhythms are associated with depression, obesity, insulin resistance, and type 2 diabetes [85, 86]. There is also an emerging biological pathway that proposes it could be changes in the expression of clock genes (genes that are associated with regulation of circadian rhythm), by environmental cues (light–dark cycles, food, glucose concentrations, social cues, antidepressant therapy) [87–89]. In patients with type 2 diabetes, clock gene expression has been directly associated with fasting glucose concentrations, and on depression, the rapid antidepressant actions of sleep deprivation therapy might be due to resetting of abnormal clock genes and subsequent restoration of circadian rhythms, although further studies are needed.

Antidepressant

A recent study regarding the association between the antidepressant use and the glycemic control showed that in adults with diabetes, the use of multiple antidepressant subclasses increased significantly the levels of Hb A1C, suggesting that antidepressive treatment may be a risk factor for suboptimal glycemic control [90]. Prior studies suggested that short-term antidepressive treatment of nondiabetic depressed patients has a beneficial effect and improves insulin sensitivity together with improving depression, but on the long run, the effects might be opposite [91]. Noradrenergic antidepressants are an exception and may lead to impaired insulin sensitivity even in nondiabetic patients [91]. Selective serotonin reuptake inhibitor treatment may improve the glycemic control in depressed DM2 patients and is the only class of antidepressants with confirmed favorable effects on glycemic control on both short- and long-term use [92]. Randomized controlled trials have emphasized that antidepressants vary considerably in their association with weight gain, and both hyperglycemic and hypoglycemic effects have been observed [93].

Future research should clarify the relation between baseline antidepressant use and development of prediabetes stages, and the extent to which antidepressant use has direct effects on diabetogenic pathways, rather than being a marker of depression itself.

Stage of Development

Childhood

Managing a chronic illness can be challenging, and developing effective coping strategies to overcome difficulties is essential for maintaining health, balance, and happiness. Type 1 diabetes is one of the most common chronic illnesses of childhood and requires a complex and demanding treatment regimen. While the large majority of childhood diabetes is type 1, there are increasing numbers of adolescents with type 2 diabetes who, requiring a similar treatment regimen, are subject to comparable risk factors for stress. Some aspects of diabetes management might be done by the children themselves, such as self-administration of insulin and attendance at regularly scheduled diabetes care appointments in clinics and hospitals. These aspects are demanding and can be disruptive and stressful, illustrating how children live with diabetes; the adult caregiver is mostly responsible for the complex decision-making associated with these tasks, such as dosing insulin on the basis of blood glucose readings and diet. Therefore, living with diabetes can feel overwhelming for parents and children because constant vigilance is required for proper care; the relation between depression and diabetes in childhood take into account both the child and their familial relationships [6].

Some evidence suggests that children with type 1 diabetes who grew up in an environment of high expressed emotion have poor glycemic control. Critical parenting behaviors increase depressive symptoms, with associated reduction of self-care behaviors [94]. Clinically, addition of structured behavioral group training has been shown to reduce parental stress and maintain improved glycemic control over time [95]. Children with diabetes experience higher rates of depression and other emotional problems than the general population. Recent studies suggest that children with both type of diabetes are at equal risk for psychological challenges. Depressive symptoms are particularly worrisome in youth with type 1 diabetes, given that on the lower end of risk these symptoms are related to poor self-care and on the higher end of risk are related to suboptimal glycemic care and even recurrent diabetes hospitalizations [96, 97].

Adolescence

Adolescence is a developmental stage during which youth are developing independence from parents, at the same time

that they are experiencing rapid biological and hormonal changes. Depression has been shown to interact adversely during transition from childhood to adolescence, maybe because of the increased independence and diabetes self-management, such as self-monitoring of blood glucose, dietary intake, and insulin dosing [98]. About 15–25% of adolescents with type 1 diabetes experience depression compared to 14.3% in children without a chronic illness, which translates into a rate two to three times found in the general adolescent population [99, 100]. This increased independence coincides with emergence of risk-taking behaviors, such as experimentation with tobacco and alcohol, and desire for peer approval. In view of these rapid psychological and physiological changes, diabetes-specific distress is well-characterized in adolescents with diabetes and is associated with poor glycemic control, prominent negative beliefs about diabetes, and reduced self-efficacy [101].

Adolescence is a key period for development of eating disorders, which are likewise associated with depression and the desire for peer approval. Adolescents with type 1 diabetes and disturbed eating behavior are far more likely to report depressive symptoms than those with type 1 diabetes alone, but do not consistently have poorer glycemic control, prospectively [102]. Recently, Corathers and colleagues [103] showed that high scores on the Children's Depression Inventory (CDI) were associated with decreased blood glucose monitoring frequency and increased HbA concentrations. However, Zduncyk and colleagues [104] found that the prevalence of depressive symptoms in patients with poor glycemic control was similar to those with good glycemic control. Further studies are needed for longitudinal assessment of potential benefits of depression screening on diabetes outcomes and to emphasize the apparent vulnerability of all adolescents.

Impact on Clinical Evolution and Quality of Life of Comorbid Diabetes–Depression

Diabetes produces structural changes in the brain—cerebral atrophy and lacunar infarcts—and blood flow changes of both hypo- and hyperperfusion [105]. Reductions in brain volumes restricted to the hippocampus were found in patients with diabetes, while an inverse relationship between glycemic control and hippocampal volume was present. HbA1C was described as the only significant predictor of hippocampal volume [106]. Similarly, depression is associated with neurodegenerative processes, especially at the level of the prefrontal cortex and hippocampus [107]. Severe hypoglycaemia in patients with DM2 and without antidepressive treatment was positively associated with the severity of depressive symptoms, independent of glycemic control, insulin therapy, lifestyle factors, and diabetic complications [108]. A meta-analysis estimating the association between depression and neuropathy in patients with DM2 could not clarify if the relationship is bidirectional or not. Many studies around the world demonstrates the relation between diabetes complications and depressive symptoms. Heinze and colleagues (in press, 2017) [109] presented a comparative cross-sectional study, with a systematic random sample of 206 DM2 patients (mean age 53.3 ± 8.21 years), of which 46 patients (22.3%) had depression (34 women and 12 men, mean age 52.0 ± 7.1 years). Depressed patients showed a lower mean in WHO-5 (Well-Being Index), greater discomfort on PAID (Problem Areas in Diabetes Questionnaire), and presented more complications of diabetes. Within which, neuropathy and retinopathy presented more frequently like complication. This study concluded that patients with comorbid DM2-depression showed a greater number of complications; two of which represent an impact on quality of life. Deschênes and colleagues [110] found that the number of diabetes complications at baseline was positively associated with a greater risk of elevated depressive symptoms, with the highest risk found for those with four to six complications at baseline. Cerebrovascular disease was the complication most strongly associated with incident depressive symptoms. Coronary artery disease, peripheral vascular disease, and neuropathy were also associated with the risk of depression, whereas foot problems and eye problems were not. Additionally, a greater number of diabetes complications was associated with recurrent/persistent depression, though with a small effect size. A parallel process latent growth curve model indicated that increases in diabetes complications were associated with increases in depressive symptoms during the course of the follow-up period.

Depression has a synergistic effect in patients with DM1 and DM2, increasing the risk for complications of both micro- and macro-vascular nature, increased hyperglycemia, predicting greater mortality. In older adults, the comorbidity also predicts an earlier incidence of complications [111]. Both diabetes and depression reduce the quality of life for an individual, but together they have a more negative impact [112]. Due to the negative effects on health, the rise in complications, both diseases should be recognized in an individual and treated simultaneously, in order to reduce depression and better control the diabetes. However, depression remains underdiagnosed and untreated in diabetic patients [113].

Implications for Research

There is a growing need to understand the similarities and differences between correlates of depressive symptoms, major depressive-disorder, and diabetes-specific distress (in both type of diabetes). Particularly in type 1 diabetes, further research is needed to identify risk factors and potential bio-

logical and cerebral correlates of depression, and in type 2 diabetes, further basic science research is need to identify the concurrent effects of biological processes and consistent neuroimaging correlates of the comorbidity diabetes–depression.

Multiple Choice Questions

1. What are the most frequent complications of type 2 diabetes in patients with depression?
   (a) Cerebrovascular disease and myocardial infarction
   (b) Myocardial infarction and macular edema
   (c) **Neuropathy and retinopathy**
   (d) Macular edema and retinopathy
   (e) Cerebrovascular incident and neuropathy

   Additional comment:
   The most frequently complications in type 2 diabetic patients with depression observed are neuropathy and retinopathy.

2. What are the mechanisms underlying the association diabetes–distress–sdpression?
   (a) Adherence to treatment and hygiene and dietetic measures
   (b) Hypothalamic-pituitary-adrenal axis dysfunction
   (c) Inflammation and Innate immunity
   (d) Abnormalities of the sympathetic nervous system
   (e) **All the answers are correct**

   Additional comment:
   The association diabetes–distress–depression is composed of many variables, including adherence to treatment and hygiene and dietetic measures, hypothalamic-pituitary-adrenal axis dysfunction, inflammation and Innate immunity, and abnormalities of the sympathetic nervous system.

3. What are the antidepressants that have a greater positive effect on glucose control?
   (a) **Selective serotonin reuptake inhibitors**
   (b) Tricyclic antidepressants
   (c) Serotonin-noradrenaline reuptake inhibitors
   (d) Monoamine-oxidase inhibitors
   (e) Norepinephrine-dopamine reuptake inhibitors

   Additional comment:
   Selective serotonin reuptake inhibitor treatment may improve the glycemic control in depressed DM2 patients and is the only class of antidepressants with confirmed favorable effects on glycemic control on both short- and long-term use.

4. Is depression associated with a neurodegenerative brain process, in which area has it been documented?
   (a) Hypothalamus and motor area
   (b) **Prefrontal cortex and hippocampus**
   (c) Occipital region and cerebellum
   (d) Cerebellum and hippocampus
   (e) Temporal and occipital area

   Additional comment:
   Diabetes produces structural changes in the brain—cerebral atrophy and lacunar infarcts— and blood flow changes of both hypo- and hyperperfusion. Depression is associated with neurodegenerative processes, especially at the level of the prefrontal cortex and hippocampus.

5. Patients with comorbidity: type 2 diabetes and depression present:
   (a) Less emotional complications
   (b) **Greater incidence in complications of type 2 diabetes**
   (c) Low self-esteem
   (d) Greater incidence in cardiac and renal alterations
   (e) High self-esteem

   Additional comment:
   Depression has a synergistic effect in patients with DM1 and DM2, increasing the risk for complications of both micro- and macrovascular nature, increasing hyperglycemia, and predicting greater mortality. In older adults, the comorbidity also predicts an earlier incidence of complications.

6. What is the fourth cause of disability adjusted life years (DALYS) in developed Countries?
   (a) Cancer
   (b) Type 2 Diabetes
   (c) **Depression and anxiety**
   (d) Bipolar disorder
   (e) Renal insufficiency

   Additional comment:
   Depression and anxiety are the fourth cause, while diabetes is the eighth cause of disability adjusted life years (DALYS) in developed countries.

7. Depressive symptoms increase the risk of:
   (a) **Diabetes mellitus**
   (b) Hepatic cirrhosis
   (c) Myocardial infarction
   (d) Macular edema
   (e) Cerebral infarction

   Additional comment:
   People with type 1 and type 2 diabetes mellitus have an increased risk of developing depressive symptoms, and people with depression also have an increased risk of developing diabetes.

8. Depression is associated to:
   (a) Increased caloric intake
   (b) Low levels of physical activity
   (c) Risk for developing diabetes
   (d) Worse glycemic control
   (e) **All the answers are correct**

Additional comment:

Depression is associated to self-neglect and low self-esteem, which might increase risk of unhealthy lifestyles, for example, increased caloric intake, high body-mass index (BMI), poor diet, low levels of physical activity and smoking, that generates metabolic changes and incremented the risk of diabetes.

9. Type 2 diabetes is associated with:
   (a) 0% of risk for developing depression
   (b) 10% of risk for developing depression
   (c) **20% of risk for developing depression**
   (d) 30% of risk for developing depression
   (e) 40% of risk for developing depression

Additional comment:

The link between depression and type 2 diabetes is bidirectional: type 2 diabetes is associated with a roughly 20% increased risk of incident depression [44, 45], and depression is associated with a 60% increased risk of incident type 2 diabetes.

10. The importance of establishing the diagnosis of comorbidity diabetes–depression is due to the statistics estimate that by the year 2015 the prevalence of diabetes mellitus will be:
    (a) 200 million people
    (b) **300 million people**
    (c) 400 million people
    (d) 500 million people
    (e) 600 million people

Additional comment:

Diabetes mellitus (DM) prevalence is increasing worldwide; the World Health Organization predicts there will be 300 million people having this disease by 2025, and due to an increase in prevalence, diabetes has become an epidemic throughout the world and one of the leading causes of death, affecting approximately 422 million people globally.

Continuous Glucose Monitoring in Clinical Practice: Ambulatory Glucose Profile and the Application of Advanced Glucose Sensing Technologies to Clinical Decision-Making

Roger S. Mazze and Joel Rodriguez-Saldana

Introduction

Previous studies of subjects with normal glucose metabolism (at various ages and at risk for all forms of diabetes) have shown that normal glucose tolerance is characterized by glucose levels within a very narrow range (4–7 mmol/L) and in pregnancy by an even narrower range (3–6 mmol/L). Furthermore, it has been demonstrated that any period of hyperglycemia may be consequential, leading to macro- and microvascular disease as well as accelerated and exaggerated fetal growth in pregnancy [1]. Excessively low glucose may cause brain damage and lead to death. Oscillating glucose levels, alternating between hyper- and hypoglycemia, may be more consequential, fostering oxidative stress and accelerating apoptosis. In fact, glucose variability or oscillation may prove to be more important in terms of risk of complications than hyperglycemia per se. Consequently, it has become increasingly important to measure and manage the volatility or variability in glucose excursions. Therefore, maintenance of glycemic control within a very narrow range becomes paramount in the priorities of diabetes management.

Glucose monitoring has progressed significantly over the last 100 years since Benedict described the analytical methods for measuring urinary glucose [2]. The Benedict assay was the main test for diabetes monitoring for the next 50 years until the glucose-oxidase reactions were discovered in the 1950s and later was used to measure plasma glucose, initially manually and afterwards by automated methods [2]. Further advances involved the development of glucose strips, self-monitoring of blood glucose in the 1970s, and the emergence of continuous glucose monitoring in 1999 [2]. The development of CGM was a real revolution in diabetes care because it provided the whole daily picture of blood glucose values [3]. The first needle-type continuous glucose sensor was developed by Shichiri et al. in 1982, and CGM devices based on glucose-oxidase were proposed starting from 1999, when the US Food and Drug Administration (FDA) approved the first professional "minimal needle" CGM system to be used by health care professionals, to enable the possibility of analyzing prospective data for review [4]. The first system had several limitations, including inaccuracy, which was confirmed by comparing CGM results with measurement standards [4]. Revolutionary advances in CGM technology included improved accuracy, use of smaller and less invasive devices, extended sensor life, approval for insulin dose decisions, and elimination of finger sticks, reducing the burden for patients [2]. These improvements have resulted in advances in the integration of continuous insulin infusion (insulin pumps) and automated insulin delivery (closed loop systems), along with the need to create newer CGM metrics beyond self-monitoring of blood glucose and HbA1c measurement [2]. Among these metrics, the mean absolute relative difference (MARD) is the most common metric used to assess CGM accuracy [4]. CGM comprises a sensor that measures interstitial glucose levels, a receiver or monitor that displays data and a transmitter that enables communication between the sensor and the receiver [3].

Rationale and Comparison with Other Methods of Glucose Monitoring Hemoglobin A1c (HbA1c) is the result of a nonenzymatic process that represents the percentage of circulating hemoglobin that is glycated and is used as an index of average blood glucose over 3 months [5]. It is a benchmark of blood glucose monitoring, easy to obtain and predicts the risk of microvascular and macrovascular complications [5]. HbA1c has a number of advantages: (1) lower biological variability as compared with fasting or 2-hr

glucose measurement; (2) it is an index of glycemic exposure by comparison with glucose levels, providing a window into past hyperglycemia over the prior 2–3 months; (3) it does not need to be measured in the fasting state; (4) it has fewer preanalytical factors that may affect the results; and (5) it has become increasingly familiar to patients and health providers [6]. However, HbA1 only provides an approximate measure of glucose control and is not helpful to assess glycemic variability or hypoglycemic events [5]. CGM is a helpful tool to overcome the limitations of HbA1c [5]. Time spent in range and time spent in hypoglycemia are the main CGM metrics that allow for personalized diabetes management [5]. CGM systems measure glucose levels in the interstitial fluid [2–4]. For a period of 10–14 days CGM provide reliable estimates of glucose metrics for 3-month periods, and as a result, it may be useful to estimate HbA1c levels for that period if 70% of the CGM data are available [5]. CGM is the best example of precision medicine in diabetes, albeit interstitial glucose readings have a 15-minute time lag and CGM results do not always match finger stick blood glucose readings [5]. HbA1c is invaluable for diagnosis and management of diabetes, but it does not provide information on hypoglycemic episodes or glucose variability. CGM provides detailed information on glucose patterns, it can detect hypoglycemia and short-term glucose variability and has highlighted limitations of HbA1c testing [6, 7].

With the advent of CGM, it has become feasible to visualize and potentially manage the diurnal glucose patterns of people with diabetes without confining them to hospitalization in order to detect overnight dysglycemia. It is also possible to characterize diurnal glucose perturbations and to detect the slightest abnormalities in glucose metabolism under conditions of daily living thereby improving the potential to ameliorate them. However, before continuous glucose monitoring could be translated into clinical use, it was subjected to intense scrutiny due to its mechanism of measurement. There are currently two types of CGM system technologies: real-time CGM (rtCGM) and intermittently scanned CGM (isCGM), which is often referred as "flash CGM [2]. rtCGM uses a sensor 5 mm in length placed under the skin in the interstitial fluid. Coated with glucose oxidase, it measures glucose in the interstitial fluid by converting the chemical reaction into electoral current. This "current" is stored in the sensor/transmitter and "sent" (transmitted) wirelessly as an electrical signal to a special receiver. Since the signal between the transmitter and receiver is constant, the receiver must be kept in close proximity, usually within 3 feet of the transmitter. The continuous signal is sent in 1, 5, or 10-minute intervals, dependent upon manufacturer. Also manufacturer dependent are the length of time the sensor remains in place—currently up to 7 days. Finally, the receiver can be uploaded to a computer where proprietary software produces a variety of reports.

Because the sensor is placed in the interstitial space, its measurement of glucose differs from a simultaneous measurement of glucose in blood, such as reported by SMBG capillary testing. Interstitial glucose is the result of glucose in the bloodstream being transferred into the interstitial fluid (or tissue fluid) via passive diffusion. The interstitial fluid bathes and surrounds all cells. When the volume of glucose in the blood stream (capillary system) is greater than in the interstitial fluid (ISF), the glucose migrates into the ISF. From the interstitial fluid, the glucose moves into the target cells (in insulin sensitive tissue with the assistance of insulin). Thus, there is a difference between glucose levels found in the blood and the ISF due to the lag time for the passive diffusion. The difference can be conceptualized as time sensitive. If glucose in the blood moved quickly into the ISF, the lag would be an insignificant factor. However, the time lag ranges for from 5 to 15 minutes. The difference can be significant if real-time glucose levels were guiding clinical decisions, especially under conditions of rapid change in blood glucose. To mitigate this, CGM device manufacturers use calibration to blood glucose [8]. The patient uses SMBG to obtain the current reading and enters this value into the CGM receiver. The receiver uses a proprietary algorithm to readjust the current CGM reading; consequently, the greater the number of calibrations the more accurate the CGM reading when compared to SMBG. Thus, current CGM devices require up to four calibrations each day.

The algorithm needs to take into account the time lag and value differences. Because the time lag may be a problem for patients dependent upon real-time blood glucose levels to control insulin administration either by pump to multiple daily injections and because CGM devices sound alarms when glucose levels reach low thresholds, accuracy has become a major issue with regards to routine use of CGM for clinical decisions. Additionally, because calibration values are entered manually and rely on patient skills to obtain the sample and enter the correct value, utilization of CGM for real-time diabetes management has become problematic.

In 2014, a new form of CGM was introduced. Called flash glucose monitoring (FGM), it uses the same chemical glucose oxidase mechanism for glucose measurement as CGM with updated wired enzyme sensors incorporating osmium [9]. Because this sensor technology does not produce as much "drift" as earlier sensors and has a more stable response over time in glucose measurements, it can be calibrated at the time of manufacturing and does not require recalibration by the patient. A second innovation is that the new technology allows the sensor to stay in place for 14 days.

How does the factory-calibrated system compare to a patient-calibrated version? When patients simultaneously wore the FGM system with factory calibration and with patient calibration, the difference in glucose values were negligible, but favoring the factory-calibrated system [4]. Thus, these innovations, when tested against standard CGM (with calibrations by the patient), are more closely correlated to blood glucose measured simultaneously. This is possible because the sensors are calibrated against blood samples in the manufacturing process; consequently, each batch that is produced has the same adjustment to blood glucose. It has been reported that each patient's blood glucose level and interstitial glucose level was different and required ongoing frequent calibrations (essentially SMBG values) to correct for these difference. However, there is an intrinsic problem with SMBG-based calibrations that CGM manufacturers overlooked. They made the assumption that patients would accurately, frequently, and correctly calibrate their CGM devices using SMBG meters that were constantly being reassessed for their own accuracy. In practice, however, it was possible that patients skipped SMBG, inaccurately entered calibration values, and used outdated or error-prone SMBG meters. In short, the patient calibrations were subject to more error and greater variability than factory-calibrated sensors. In additional, the wired enzyme technology was made for a more stable and consistent measurement, thus reducing the likelihood of sensor-to-sensor variability.

Another significant difference between standard CGM and FGM is how the information (glucose values) is stored, transmitted, and reported. CGM sensors constantly measured glucose and passed electrical signals to the transmitter, which converted the electrical current to a format that could be continuously transmitted to a nearby receiver. The receiver stored the data in a manner that could be uploaded to a computer which, using proprietary software, aggregated the data into a series of reports. Due to the proprietary nature of the software, the reports were not comparable among manufacturers. Some companies accumulated the data in 5-minute intervals while others used 10-minute intervals. Thus, based on the manufacturer, the graphic displays could have as many as 288 points to produce a 1-day curve.

FGM uses a novel approach to capturing, storing, and reporting glucose data. To understand this best, it is important to know that unlike CGM devices, the FGM receiver (reader) functions to capture sensor data only when the user passes the reader over the sensor, such as when the patient wants to determine how much insulin to take or how a particular meal affected the postprandial glucose level.

Both CGM and the newer FGM are advances on SMBG. Throughout the world, patients are asked to measure glucose by SMBG anywhere from once to multiple times each day. Based on these readings, clinical decisions related to medication adjustments are made by the patient and often by the doctor as well. Taken in isolation, these values are often given great clinical value. For example, a single fasting glucose may be used to titrate insulin, determine overnight glucose values, and provide an overall assessment of glycemic control. Similarly, one or two postprandial hyperglycemic value, taken 1 hr after the meal, may lead to a change in diet or medication dose (especially insulin) as would a single hypoglycemic value, which often causes a cascade of events resulting in alterations in medications. Because in most clinical practices patients are seen infrequently, three to four times a year, SMBG values take on even more significance. As based on these data as well as HbA_{1c}, the decision at the clinic may be used to determine the next several months' regimen.

Figure 30.1 depicts this clinical dilemma of using SMBG data to make decisions. Looking at just the SMBG data, a clinician would assume normal fasting and midday postprandial values with evening hyperglycemia. The SMBG provides no indication of overnight hypoglycemia. The

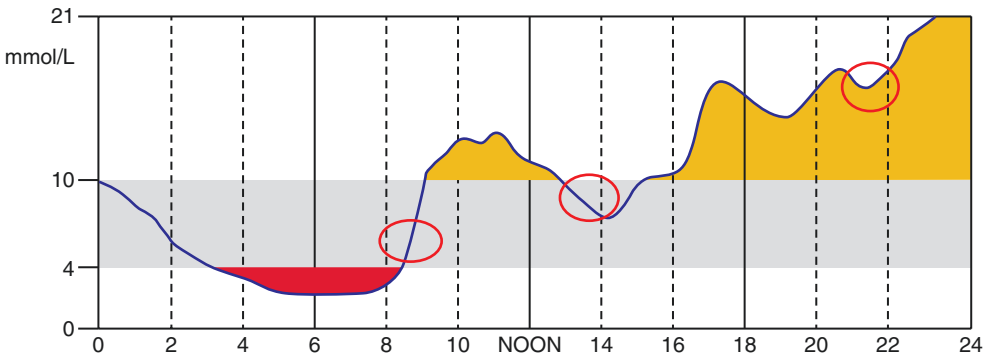

Fig. 30.1 One day of continuous monitoring with circles representing periods of SMBG data. If only the SMBG data are used, then the interpretation would suggest normal fasting glucose (7 mmol/L at 9:00), normal post mid-day meal glucose (10 mmol/L at 13:00), and significant hyperglycemia in the evening. If the continuous graph were used, it would show overnight hypoglycemia, post breakfast hyperglycemia, and midafternoon to midnight hyperglycemia

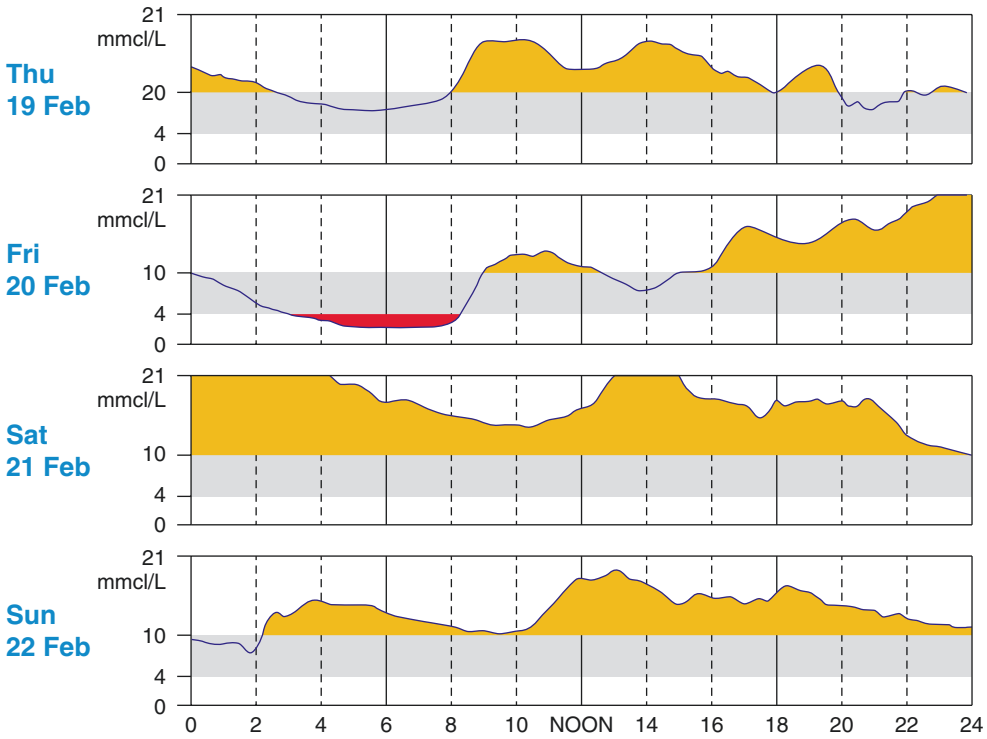

Fig. 30.2 A sequence of four days of CGM. In this sequence, while on the first day, glucose levels tend to be above the target (gray zone), then on the next day there is overnight hypoglycemia, while on the subsequent two days there is almost continuous hyperglycemia

consequences for clinical decision-making can be significant. Clearly, the complete diurnal pattern leads to a different interpretation than a single or even multiple SMBG tests. The CGM curve clearly shows that between 4 and 8 AM glucose dips below 4 mmol/L. Additionally noted in the CGM curve is the degree of instability in glucose level with more than 18 mmol/L difference between nadir and apex.

Figure 30.2 is a sequence of four consecutive days using continuous data. The first day's pattern gives no indication of impending overnight hypoglycemia, while the second day's pattern does not suggest the next 2 days of significant hyperglycemia. The first day does not appear to predict the second day, or the last 2 days in the sequence. The intraday variability is significant, since it suggests that any clinical decision based on these 4 days may be misleading.

Ambulatory Glucose Profile (AGP): an innovative approach to clinical decision-making using continuous glucose data.

Clearly, as shown in Fig. 30.2, each individual day does not appear to produce an underlying metabolic pattern that characterizes the next day. The curves appear to be unstable, reversing direction several times each day. These changes in direction appear volatile on some days and at other times smooth. This volatility from nadir (between 4:00 and 8:00 to apex (at midnight) has been associated with *oxidative stress and consequential apoptosis*. Can a clinical decision be made in the face of such volatility? Is there a discernable pattern? The ambulatory glucose profile (AGP) employs the individual glucose values that are collected via CGM and depicts these values as five continuous frequency curves as shown in the top panel of Fig. 30.3 with the 14 days (midday on the first and last days) that comprise the AGP data in the bottom panel.

Looking at the daily graphs, there does not appear to be a clear pattern. However, when the daily graphs are superimposed on one another, a pattern (AGP) emerges. Note that the range of glucose values does not differ throughout the modal day. Also note that the values do not appear to be following a normal distribution about the median (center curve). By plotting the mean the diurnal, glucose pattern would be misrepresented. It would suggest that glucose is normally distributed and that the mean and standard deviation represent both the central tendency and the dispersion of glucose values over multiple days. Instead, the median is plotted and the glucose ranges are represented as frequency distributions. In this example, hypoglycemia occurs infrequently, between 20:00 and 24:00 hrs on February 19th. This is depicted on the AGP by the inter-decile range curve as dipping into the hypoglycemic range in the diurnal pattern between 20:00 and 24:00 hrs. This would suggest that the risk of hypoglycemia is less than 10% between those hours.

Shown on Fig. 30.4 is the same AGP in Fig. 30.3 with each of the five frequency curves labeled. As illustrated in the AGP, the five curves depict the glucose dispersion. From top to bottom they are: 90th percentile, 75th percentile, 50th percentile (median), 25th percentile, and 10th percentile. The area between the 25th and 75th percentile is known as

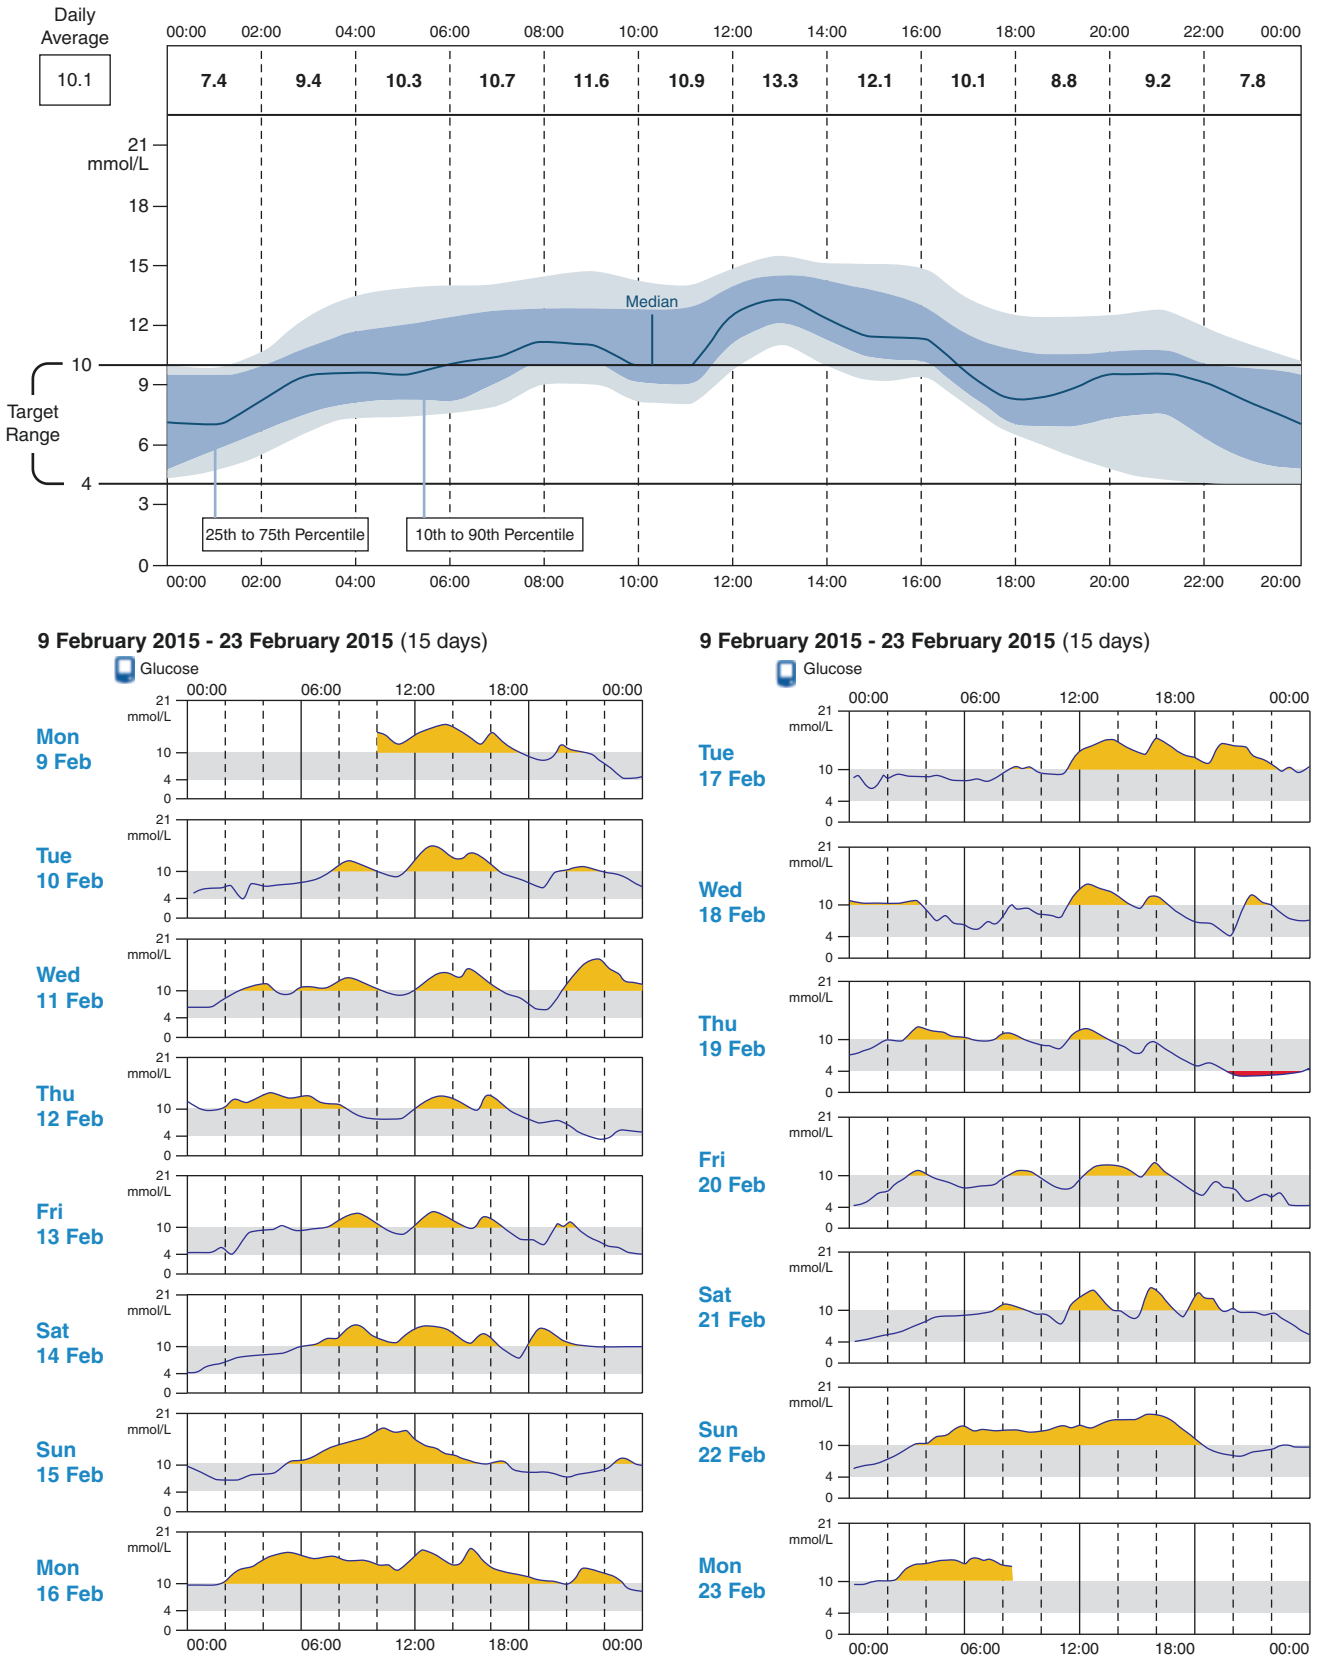

Fig. 30.3 AGP and the 14 days it represents. The top panel is an AGP which is comprised of the 14 days of data collected using CGM. The AGP disregards the dates and plots all values according to time of day. The AGP reflects the overall glucose exposure, variability, and stability for the time period. The light gray zone represents the inter-decile range, the dark gray the inter-quartile range, and the dark single center cure represents the median. The underlying pattern shows a rise in glucose throughout the day time hours with a descent beginning at 2 PM and continuing into the evening. Overnight glucose appears to rise beginning at midnight

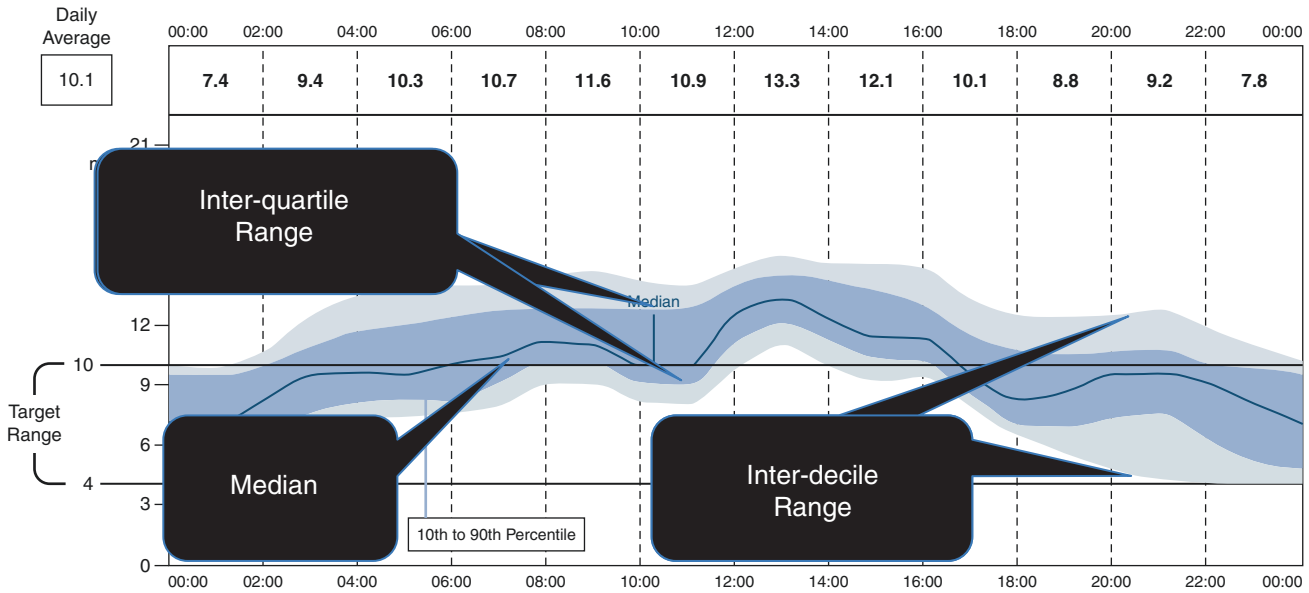

Fig. 30.4 An AGP showing its key components. The AGP comprised of five frequency distribution curves marked here by the callouts depict the glucose exposure and variability over the 14 days represented in this diurnal pattern

the interquartile range (IQR). Fifty percent of all values at each time period fall within this range. As shown in Fig. 30.4, at midday the interquartile range is 3 mmol/L (the difference between 9 and 12 mmol/L) while at midnight the IQR widens to 4 mmol/L. While the IQR is one measure of *glucose variability*, a second measure, the inter-decile range (IDR) represents the difference between the 10th and 90th percentile curves. Eighty percent of all values fall between these curves. As both the IQR and IDR narrow the certainty of where the values will fall improves. In Fig. 30.4, between midday and 16:00 hrs, the glucose ranges (or variability) are narrowest, while between 20:00 and 24:00 hrs they are widest. The five curves that comprise the AGP "force" the eye to see the overall pattern lessening the interpretive significance of outlier values. The curves provide insight into the daily perturbations in glucose metabolism that characterizes diabetes.

In order to assure clinical significance, the AGP must characterize more than glucose variability. Glucose exposure and stability are additional important characteristics of overall glycemia control. Glucose exposure is measured by the area under the time curve (AUC) and is time dependent. The question that needs to be answered is, "How much glucose is the individual exposed to over a typical or modal 24 hour period?" More specifically, "how much *excess* glucose exposure is the individual subjected to, as that constitutes the injurious exposure?" In contrast, glucose stability is a relatively new concept related to the degree of change from moment-to-moment the individual with diabetes is experiencing. Together, these two characteristics aid in the interpretation of the diurnal glucose pattern.

Shown in Fig. 30.5 are two daily profiles for which the area under the curve is measured (using a "modified" trapezoidal method) by segmenting the daily profile into 24 hourly segments. Between 6:00 and 7:00 area, under the top panel is 6 mmol/L/hr. versus 10 mmol/L/hr. for the next day shown in the lower panel. This is repeated for each hour of each day. In terms of the 14 days that comprise the standard AGP, the best representation of these data is the median of the AGP for the time period under examination. Thus, *glucose exposure* is measured by segmenting the AGP median curve into 24 equal parts each representing 1 hr (along the *x*-axis) and the height of the curve (hourly median) as the *y*-axis glucose level. Area under the curve (Fig. 30.6) is therefore: $\text{AUC} = \sum_{i=0}^{24} P_{50_i}$ where i = hr of the day and P_{50i} = the smoothed 50th percentile value for the ith hour of the day. The value is displayed as mmol/L*24 hr.

Normalization of AUC is calculated by dividing the total by the number of hours for the time period (e.g., for a 24-hr period, the total would be divided by 24). To measure glucose exposure over a specific time period, the area under that part of the curve is measured. In this example. The overall exposure is 244 mmol/L*24 hr. Normalized it would be 10.2 mmol/L/hr.

To measure excess glucose exposure the criteria is set to the median target (6 mmol/L), the targeted 24-hr exposure would, therefore, be: 144 mmol/L*24 hrs. The excess exposure is, therefore, 100 mmol/L*24 hrs (normalized to 4.2 mmol/L/hr).

Since the visual evidence shows that a single day does not appear to predict the same diurnal pattern on subse-

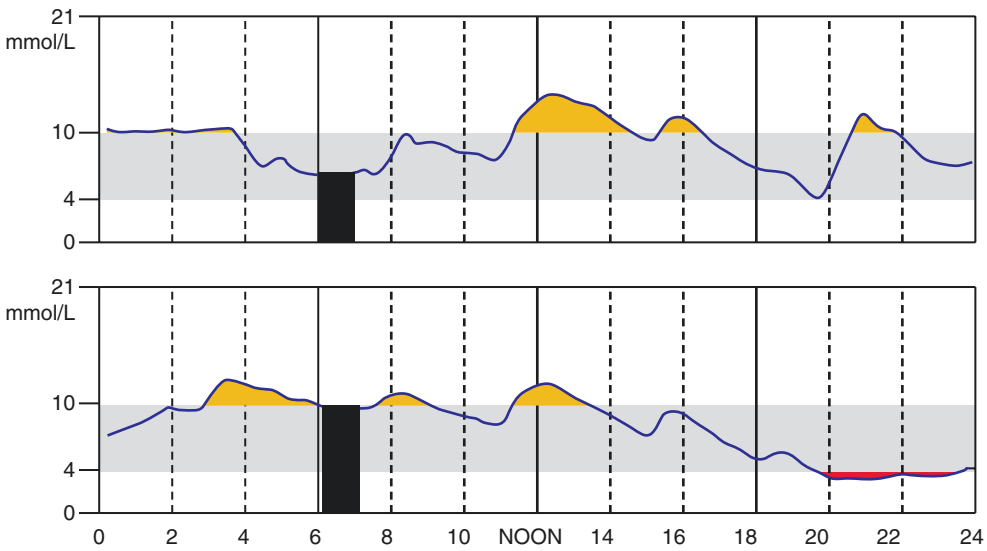

Fig. 30.5 Daily profiles showing the area under the curve between 6:00 and 7:00. The two rectangles represent the area under the curve between the time periods. Measured as height in glucose and time in hours

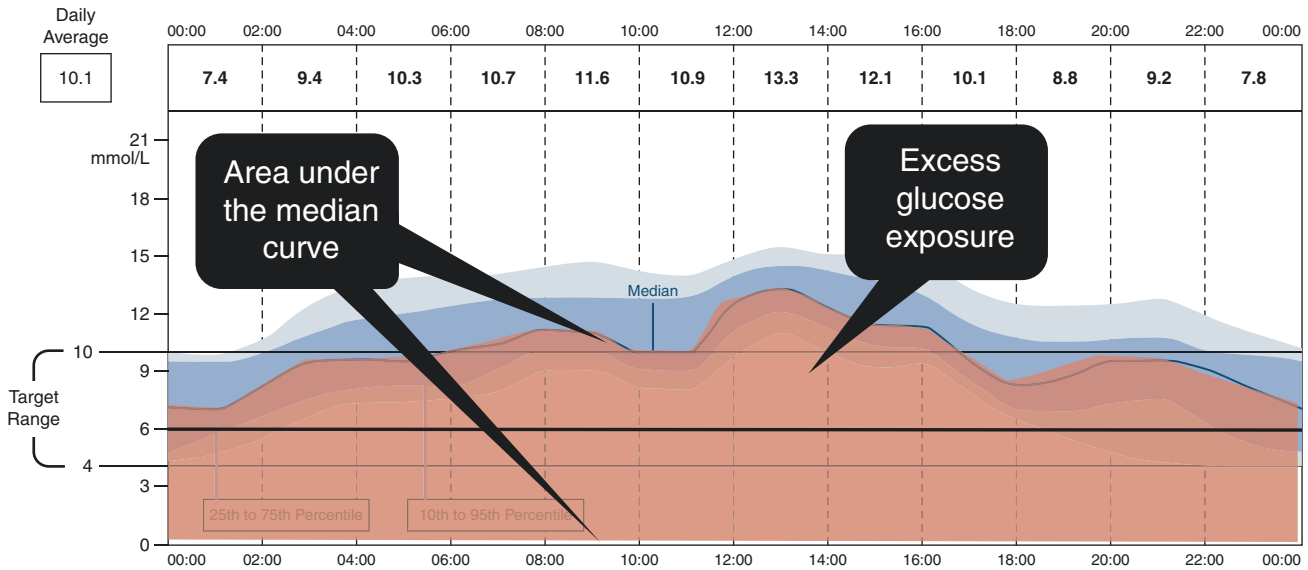

Fig. 30.6 Glucose exposure as measured by the AUC and excess exposure. Glucose exposure is shown as the darkened area under the median curve. The excess area is shown as the area above 6 mmol/L

quent days, what number of days would be required? A major multicenter trial studying this question in 185 subjects with type 1 and type 2 diabetes showed that 14 days of CGM data predicts the pattern for the next 90 days assuming there is no substantial change in treatment [10]. They found that for 3 days of sampling, the r [11] value ranged from 0.32 to 0.47 when considering "…mean glucose, percentage of values 71–180 mg/dL, percentage of values >180 mg/dL, percentage of values ≤70 mg/dL, and coefficient of variation; in contrast, for 13–15 days of sampling, the r^2 values ranged from 0.66 to 0.75. The results were similar when the analysis intervals were stratified by age group (8–14, 15–24, and ≥25 years), by baseline hemoglobin A_{1c} level (<7.0% vs. ≥7.0%), and by CGM device type." Based on these data, they concluded that "a 12–15 day period of monitoring every 3 months may be needed to optimally assess overall glucose control." Thus, it appears that the minimum amount of days of monitoring to predict exposure, variability, and stability for up to the subsequent 90 days is 14 days.

Our own studies have shown that AUC is statistically equivalent to the average of the total daily glucose exposure of the 14 days and thus is the "best fit" representative of the overall glucose exposure that characterizes the period under investigation [3]. Similarly, any time period under the median is a "best" representation of the glucose exposure for that period. To determine the prandial/post-prandial glucose exposure, the hourly medians are summed. To determine

overnight glucose exposure, the sleeping period is noted, and the AUC for that period is calculated.

Glucose stability is a measure of the moment-to-moment change in the glucose level as depicted on the AGP median curve. It is calculated by segmenting the median into hourly periods. Next, the absolute difference between the hourly values is calculated, summed, and divided by 24. The result is the average hourly change in the median. Reported as mmol/L/hr, it provides an indication of the level of stability in glycemic control.

While exposure, variability, and stability characterize overall glycemic control; hypoglycemia and hyperglycemia characterize specific clinical events. The visual examination of an AGP to detect these two dysglycemic states is dependent upon the clinical criteria established by the clinician. In the examples already presented below, 4 mmol/L is generally used to define hypoglycemia and above 10 mmol/L for hyperglycemia. These are arbitrary and in practice individual factors should be taken into consideration such as: age, duration of diabetes, treatment modality, hypoglycemia unawareness, patient goals, and long-term complications. Nevertheless, the AGP allows for quick detection of these two dysglycemic states. In Fig. 30.7 both states are readily discernible. This subject, with an HbA_{1c} of 6.4% spent 48% of his time within target with 26% in hypoglycemic and 26% in hyperglycemia. As can also be seen, the patient's overall control shows significant oscillation in the median curve indicative of poor glucose stability. However, overall exposure was 168 mmol/L*24 hrs or less than 30 mmol/L*24 hrs excess exposure. The questions remains as to whether this profile is sufficient to prevent or reduce the risk of complications.

In 2008, we undertook the first study employing CGM technology with AGP analysis to characterize glycemic control in individuals with normal glucose metabolism [1]. Initially, 62 subjects (32 with normal glucose tolerance and 30 with diabetes) participated employing CGM for 30 days. Prior to the study and following the study, HbA_{1c} was measured as well as insulin levels. HOMA was also completed at initiation to assure that the subjects with normal glucose metabolism had normal insulin resistance. The results (Fig. 30.8), since replicated in more than 250 individuals with normal glucose metabolism who monitored glucose continuously for between 5 and 30 days, give ample evidence that individuals with normal glucose tolerance share several important AGP characteristics: (1) stable glucose levels, (2) minimal variability, and (3) <4% of values within the hypoglycemic range. It has been almost axiomatic that normal glucose levels are 5.6 mmol/L and that they range from 4 to 8 mmol/L; and only under rare metabolic stress are these

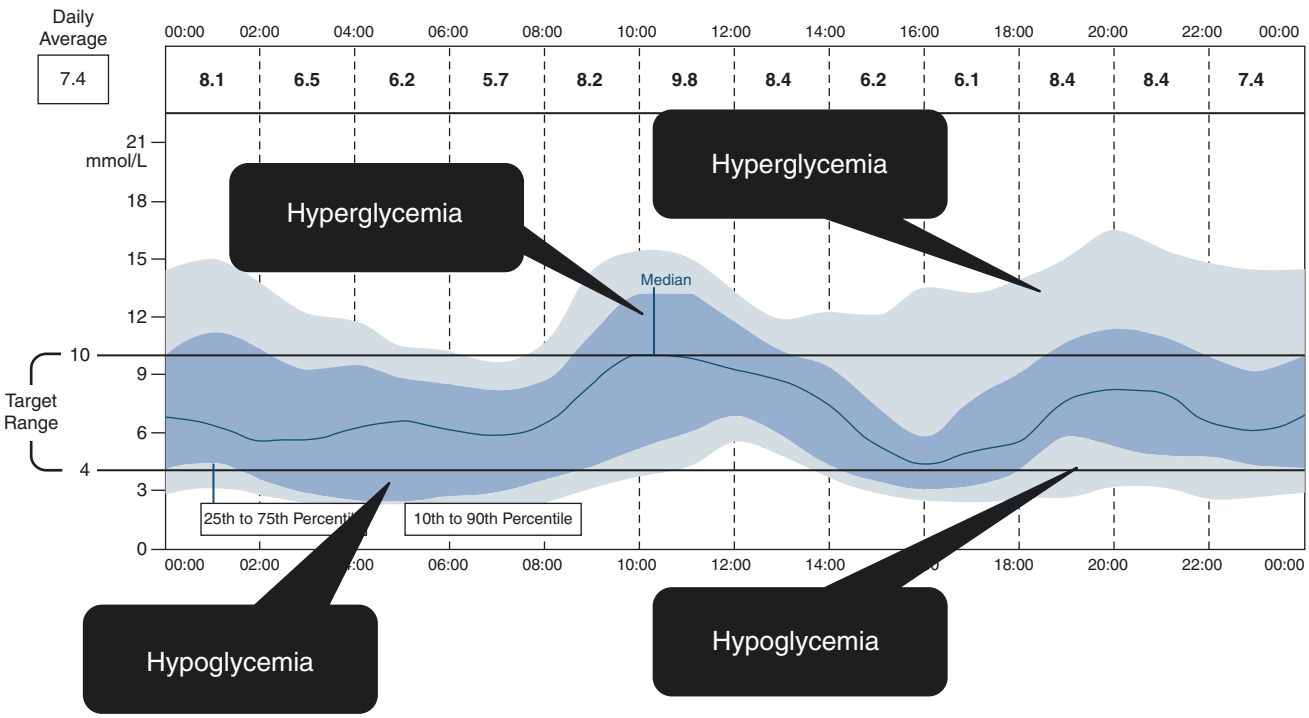

Fig. 30.7 AGP with hypoglycemia and hyperglycemia. The target was set at between 4 and 10 mmol/L. The periods marked with the callouts indicate patterns of dysglycemia. The frequency can be determined by the color of the shaded areas. The first hypoglycemic period denoted by dark shading suggests a risk of between 25 and 50% of the time while the second period suggests less than 25% of the time there will be hypoglycemic episodes. Similarly, the first major period of hyperglycemia between 8:00 and 12:00 has a 50% risk, while after 12:00 the risk drops to less than 25%

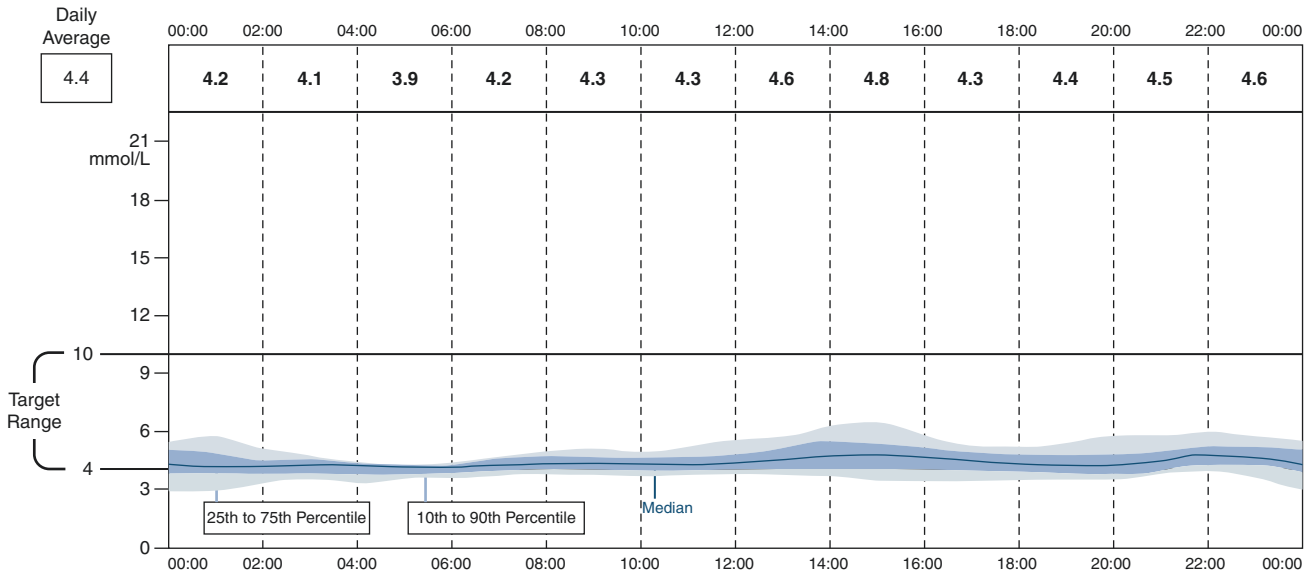

Fig. 30.8 AGP of subject with normal glucose metabolism. This is the typical profile of a person without diabetes. Note that, glucose variability is between 1 and 2 mmol/L, post prandial rises are minimal, and hypoglycemia is present

barriers broken. Interestingly, only since the advent of CGM has it been possible to provide a characteristically "normal" diurnal glucose pattern.

If the AGP of an individual with normal glucose tolerance has such tight parameters, what does this suggest about the goals of diabetes management? Have the treatment goals, which rely heavily on normalization of HbA_{1c}, been misleading? Should emphasis be placed on reduction of glucose variability and improved stability rather than primarily on glucose exposure? If so, how can this be accomplished?

When individuals with normal glucose tolerance are compared to individuals with diabetes among the most salient findings for people without diabetes are: (1) hypoglycemia ranges up to 4% in "normal" subjects; (2) glucose exposure remains within a 27 mmol/L*24 hrs range between the low and the high ends of normal; (3) IQR remains in a narrow range (<2 mmol/L); and (4) change in glucose (glucose stability) hovers at 1–2 mmol/L/hr. which is generally two-thirds more stable than subjects with diabetes.

AGP in Clinical Care

Continuous monitoring should provide a physiologic framework for clinical decision-making in three general areas: (1) detection of the underlying dysglycemia; (2) selection of the most efficacious therapy and guiding adjustments; and (3) measuring treatment effectiveness. How can it be assured that normal glycemia is achieved?

For the AGP to be an effective tool in practice, it must be applied in a systematic manner following the principles of evidence-based medicine. Essentially, it must identify (diagnose) the problem, lead to clinical decisions (find a response), and attest that the response is effective (evaluate clinical outcomes). In this section, flash glucose monitoring (FGM), is used to illustrate how systematic analysis of AGPs provides a rational approach to clinical decision-making. The patient can retrieve glucose levels by passing a receiver over the sensor that is worn on the arm (Libre FGM System, Abbott Diabetes Care, Alameda, CA). The sensor lasts 2 weeks and does not require self-calibration; it stores up to 8 hrs of readings at 15-minute intervals. The receiver stores up to 90 days of data and transmits its results to a PC. The AGP is automatically produced when the data are downloaded to a PC or Mac.

The initial or reference AGP serves to provide an overall depiction of the diurnal glucose pattern and as such has two principal functions: (1) to provide a baseline "measure" against which all future AGPs will be measured and (2) to provide a framework for analysis in which problems can be identified and addressed in systematic manner. Figure 30.9 is the AGP of a person with type 1 diabetes treated by continuing subcutaneous insulin infusion (CSII). It represents the first 2 weeks of wearing the FGM sensor. As a baseline measure, it requires a narrative description. The description addresses four primary characteristics: glucose exposure, variability, stability, and hypoglycemia. As descriptors, it adds a quantitative element (reported through the software or interpolated from the graphics) to each dimension. For example, the overall glucose exposure is 320 mmol/L*24 hrs, which is 152 mmol/L*24 hrs in excess of normal glucose levels. IQR and IDR are 66 mmol/L and 72 mmol/L, respectively. The glucose stability, or change in the median curve, averages at 11.5 mmol/L/hr. This can be seen by visual

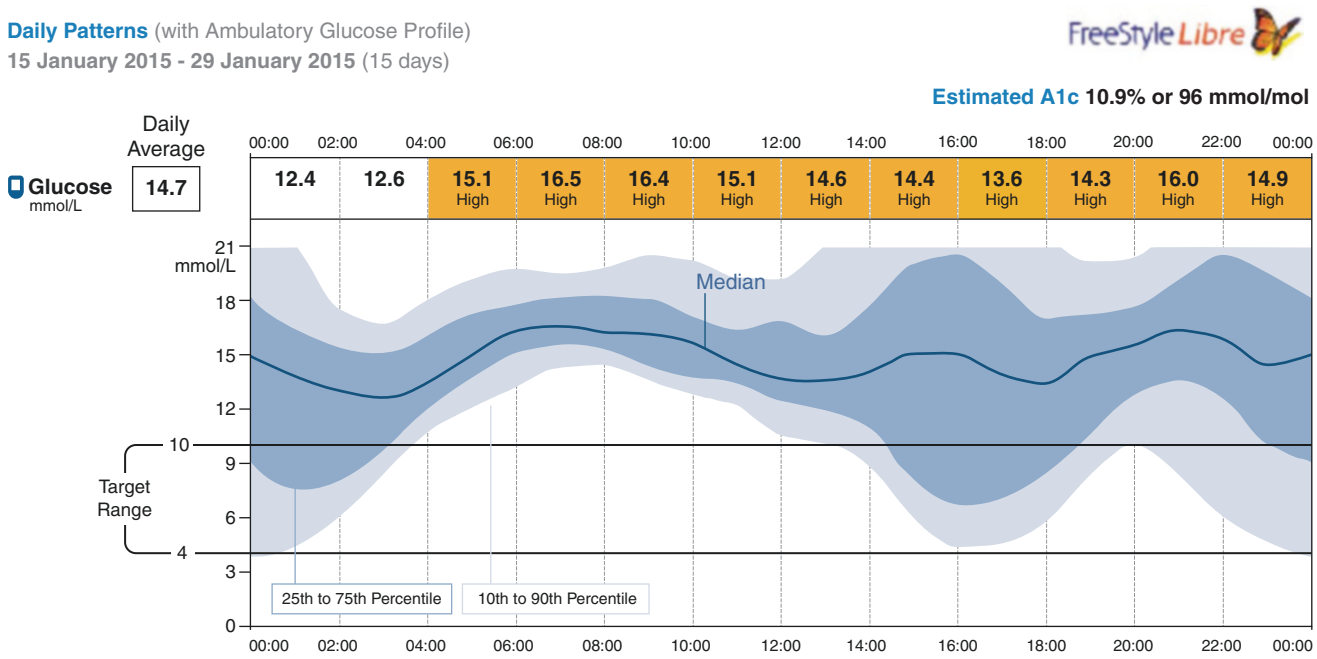

Fig. 30.9 AGP of subject with type 1 diabetes. The boxed number on the top of the AGP are the values of the median reported in two-hour intervals. The shaded boxes indicate that the criteria for "high" was set at 14 mmol/L. The target was set at 4–10 mmol/L. The glucose variability shown as IQR (the dark shaded area) and IDR (the lightly shaded area) ranges from 3 to 18 mmol/L

inspection; the median curve does not experience large swings. There appears to be virtually no hypoglycemia.

As a framework for analysis, the same four components take on a different meaning. They become clues as to the nature of the underlying problems causing the dysglycemia. For this dimension of analysis, it is important to segment the AGP into eight time periods: overnight, fasting, post breakfast, pre-midday meal, post midday meal, pre-evening meal, post evening meal, and bedtime. Some of these periods can be reduced when they overlap. Examining the AGP from this perspective while addressing exposure, variability, stability, and hypoglycemia makes for a comprehensive analysis. For example, while we already know that excess glucose exposure is high, we need to know when this occurs. In this case, it is throughout the day and overnight. Next, where is glucose variability the widest? Examination suggests 0:00–2:00, 14:00–18:00, and 22:00–24:00. Closer examination reveals that the IDC is widest in the evening and overnight. It also appears that glucose stability and hypoglycemia are not problems. The explanation for much of what is seen lies with the patient. However, before we turn to the patient's information, what conclusions can already be drawn? Without examining the HbA_{1c}, it is already apparent that the patient experiences significant and persistent hyperglycemia, suggesting that insufficient insulin is being delivered. Examining the variability suggests that the glucose levels throughout the night and late in the day is unpredictable from day to day (examining daily profiles would corroborate this). From waking to midafternoon while the glucose is high it remains stable and experiences narrow variability. This suggests a more predictable set of behaviors in terms of insulin administration, diet, and exercise. In contrast, the rest of the day and overnight the patient seems to alter behavior and insulin dose leading to wide variability. A discussion with the patient confirmed that the patient changed meal content and insulin dosing most in the late afternoon and evening as meal timing and content was unpredictable. In contrast, the patient had the same breakfast each day and did not need to adjust the basal or bolus insulin settings.

The multiple issues found in the first AGP can be addressed systematically. First and foremost, is the patient in any imminent danger, especially from hypoglycemia? In this case, the answer appears to be a resounding no. However, if one examines the three periods when the IDR dips into the near hypoglycemic range it suggests that adding insulin throughout the day and overnight is not the initial solution. Therefore, the variability needs to be reduced first; after which, the excess glucose exposure can be addressed. How is this accomplished? Since variability is primarily influenced by insulin administration and diet, these two variables must be attended to first. Limiting the number of basal and bolus settings, fixing the dietary intake to be more consistent, and educating the patient concerning carbohydrate/insulin ratios are methods of stabilizing behavior.

In the sequence of AGPs shown in Fig. 30.10, the effect of a systematic analysis followed by targeted interventions is shown. The first step was to reduce the variability by stabilizing the diet and reducing the need to adjust insulin infusion

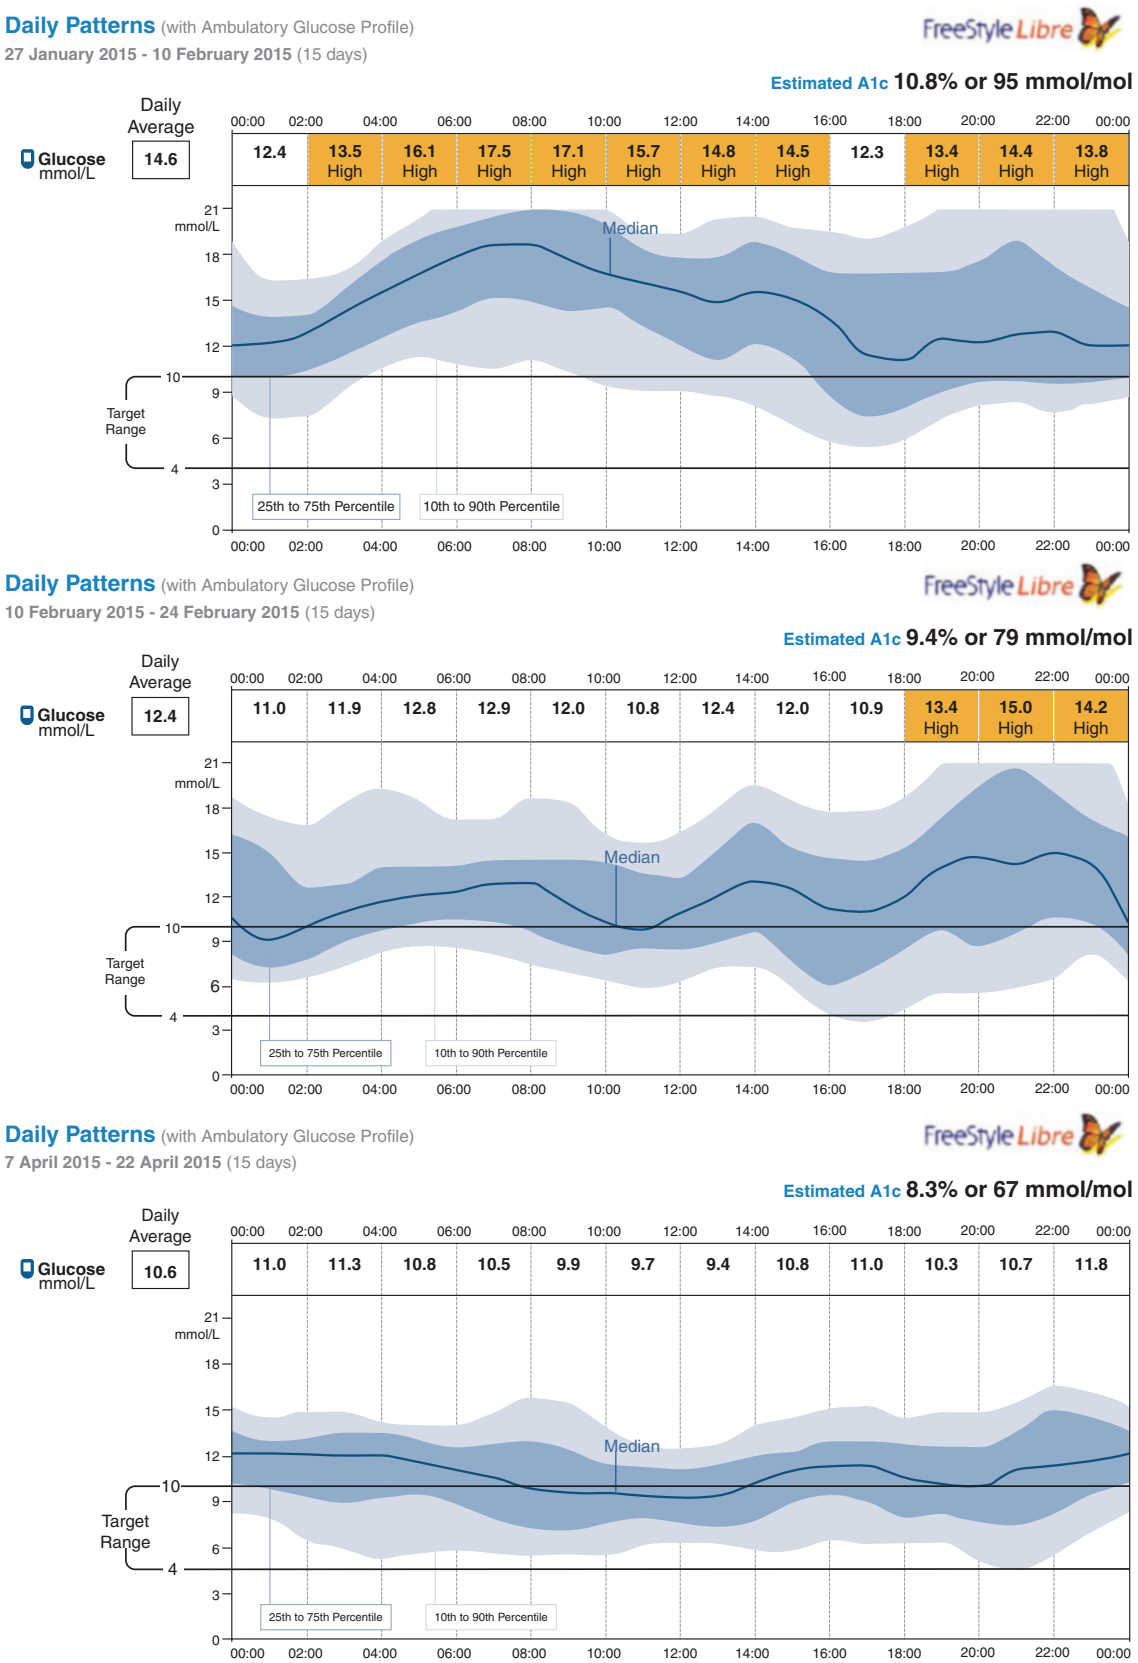

Fig. 30.10 Sequence of AGPs following intervention. The three AGPs are dated showing the impact of treatment over a four-month period. Note on top of each AGP is the median glucose level for each two-hour interval. In the first ten of 12 values were in the high range. In the final AGP none of the values reached this range. Glucose variability also reduced as did overall glucose exposure. Note that glucose stability was unaffected and there was no increased risk of hypoglycemia. HbA_{1c} reduced by 2.5 percentage points paralleling reduction in mean and median glucose levels

rates by improving the calculation of the insulin/carbohydrate ratio. Note that the variability is narrowed, but the HbA_{1c} remained unchanged. The second step was to increase the basal insulin while further improving the insulin/carbohydrate ratio. The final step, once the variability was addressed, was to increase the basal insulin and further adjust the bolus insulin. Note the improvement in the final AGP produced 4 months after the initial FGM.

Conclusion

The advent of continuous glucose monitoring nearly 20 years ago and its continued improvement have led to more efficient and long-lasting sensors reducing a major obstacle to CGM use. There is a strong evidence for CGM use in people with type 1 diabetes, and while the evidence for its use in type 2 diabetes is less robust, similar benefits have been demonstrated [12]. CGM has limitations including cost, accuracy, and perceived inconvenience, but cost effectiveness analysis have indicated that CGM is a cost-effective adjunct to type 1 and type 2 diabetes management and that its use is likely to increase as efficacy data accumulate further and its costs gradually decrease [12, 13]. In the era of COVID-19, the importance of remote glucose monitoring is highlighted now more than ever [14]. Despite these advances, there is one more obstacle to overcome. The translation of this technology into practice requires a standardization of the manner in which the data are reported combined with a systematic approach to their interpretation. Ceriello, in his study of glucose variability and after reviewing AGPs of subject with normal glucose metabolism, wrote, "In people with normal glucose tolerance, blood glucose is maintained in a very narrow range of 3.8–7.7 mmol/L, one can argue that, if the human body spends so much energy to maintain blood glucose levels within such a narrow range, it is because otherwise it would be detrimental [15]." In the series of AGPs included in the article to which he was referring, it was shown that normal glucose tolerance was a balanced state in which various physiological mechanisms worked to prevent oscillations in glucose in order to maintain glucose homeostasis [11]. The article brought forth the notion that without a graphic display of the diurnal glucose pattern, it is not possible to visualize the disruptive nature of dysglycemia. As shown throughout this chapter, when compared to the "normal state," individuals with diabetes experience wide variation in diurnal glucose patterns that without CGM could not be detected.

The AGP provides a standard approach to both a graphic and quantitative representation of CGM and FGM data. It allows for systematic analysis and interpretation. Visualization of dysglycemia, combined with measurement of glucose exposure, variability, stability, and hypoglycemia, presents a basis for standardization. AGP intervention, focusing on reducing the risk of hypoglycemia and hyperglycemia through initial lessening of glucose variability and improvement in stability followed by lowering excess glucose exposure, provides a framework for clinical decision-making.

Management of diabetes often allows a willingness to permit clinical inertia, rather than seek improvement, in part due to the daunting task of finding an effective therapy. While an HbA_{1c} greater than 9% might alarm the practicing clinician, one less than 7% might be reason to be satisfied with treatment in the absence of an AGP. From its inception, CGM with AGP analysis had an underlying purpose, to compel the physician (and patient) to take action. The AGP causes us to examine diurnal patterns suspecting that hidden behind an HbA_{1c} of 7% might be noteworthy hypoglycemia and significant hyperglycemia, as well as considerable variability and instability; all of which are disruptive factors associated with decreased quality of life and increased risk of acute and long-term complications. Finally, a word of caution: after 50 years, SMBG remains equivocal but CGM may face the same fate [16]. For CGM's potential to be fully achieved, it must be understood that it can discover underlying metabolic perturbations that would otherwise go undetected; it can measure the frequency, duration, magnitude, and distribution of glucose variability and stability under conditions of daily living which in turn lead to more precise therapies and improved outcomes [16].

Multiple Choice Questions

1. Individuals with any degree of dysglycemia are at a higher risk of glucose-related macrovascular, microvascular, maternal, and fetal complications when compared to individuals with normal glucose metabolism.
   (a) True
   (b) **False**
2. A feasible method to visualize and potentially manage diurnal glucose patterns of people with diabetes without confining them to hospitalization in order to detect overnight dysglycemia.
   (a) **Continuous glucose monitoring**
   (b) Fasting blood glucose in plasma
   (c) Capillary monitoring of blood glucose
   (d) Post-prandial blood glucose
   (e) None of the above
3. Oscillating glucose levels, alternating between hyper and hypoglycemia are indicative of:
   (a) Ineffectiveness of drug treatment
   (b) **Oxidative stress and apoptosis**
   (c) The effect of counter-regulatory hormones
   (d) The expected response of people with diabetes

(e) All of the above

4. Continuous glucose monitoring has become feasible:
   (a) To reinforce diabetes management in the hospital
   (b) To visualize and manage glucose patterns at intensive care units
   (c) **To detect the slightest abnormalities of glucose metabolism in daily living**
   (d) To adequately treat hyperglycemic crises
   (e) To reduce the burden of diabetic complications
5. Continuous glucose measurement:
   (a) Uses a 10 cm sensor intravenously placed
   (b) Uses a 1 mm sensor placed on a patch on the skin
   (c) Uses a 5 mm sensor placed in the intra-peritoneal compartment
   (d) **Uses a 5 mm sensor placed under the skin in the interstitial fluid**
   (e) Is noninvasive
6. Flash glucose monitoring (FGM), uses the same chemical glucose oxidase mechanism for glucose measurement as CGM with updated wired enzyme sensors incorporating osmium.
   (a) **True**
   (b) False
7. Simultaneous measurement of glucose in blood is important.
   (a) **Because these readings are helpful to make clinical decisions related to medication adjustments by patients and often by the doctor as well**
   (b) To identify which method is more accurate
   (c) To maintain patients' compliance
   (d) To confirm the ineffectiveness of self-monitoring of glucose
   (e) To detect and treat promptly emergencies
8. When individuals with normal glucose tolerance are compared to individuals with diabetes:
   (a) Hypoglycemia ranges up to 100% in "normal" subjects; glucose exposure remains within a 270 mmol/L*24 hrs range between the low and the high ends of normal; IQR remains in a narrow range (<200 mmol/L), and change in glucose (glucose stability) hovers at 100–200 mmol/L/hr. which is generally two-thirds more stable than subjects with diabetes.
   (b) **Hypoglycemia ranges up to 4% in "normal" subjects; glucose exposure remains within a 27 mmol/L*24 hrs range between the low and the high ends of normal; IQR remains in a narrow range (<2 mmol/L); and, change in glucose (glucose stability) hovers at 1–2 mmol/L/hr. which is generally two-thirds more stable than subjects with diabetes.**
   (c) Hypoglycemia ranges up to 1% in "normal" subjects; glucose exposure remains within a 10 mmol/L*24 hrs range between the low and the high ends of normal; IQR remains in a narrow range (<1 mmol/L); and, change in glucose (glucose stability) hovers at 1–2 mmol/L/hr. which is generally two-thirds more stable than subjects with diabetes.
   (d) Hypoglycemia ranges up to 5% in "normal" subjects; glucose exposure remains within a 28 mmol/L*24 hrs range between the low and the high ends of normal; IQR remains in a narrow range (=200 mmol/L); and, change in glucose (glucose stability) hovers at 1–2 mmol/L/hr. which is generally two-thirds more stable than subjects with diabetes.
9. Continuous monitoring should provide a physiologic framework for clinical decision-making in three general areas:
   (a) Detection of underlying dysglycemia.
   (b) Selecting the most effective therapy.
   (c) Guiding adjustments to treatment.
   (d) Measuring treatment effectiveness.
   (e) **All of the above.**
10. Compared to factory calibrated systems, patient calibration by self-monitoring of blood glucose:
   (a) Is more accurate
   (b) **Is less accurate**
   (c) Is equally accurate
   (d) Is more precise
   (e) Is less precise

Healthy Lifestyles for the Self-Management of Type 2 Diabetes

31

Karla I. Galaviz and Mohammed K. Ali

Lifestyle Behaviors Among People with Type 2 Diabetes

Unhealthy lifestyle behaviors are among the leading risk factors for disability and mortality globally. In 2019, high fasting plasma glucose, tobacco use, and high body mass index (BMI) were among the main causes of death and disability worldwide [1]. Physical inactivity is also a leading risk factor for the development of noncommunicable diseases [2] and is responsible for substantial economic burdens worldwide [3].

In people living with type 2 diabetes, unhealthy lifestyle behaviors can worsen the disease. Insufficient physical activity, low consumption of vegetables, high salt intake, and smoking are associated with poor glycemic and blood pressure control [4–6], while tobacco smoking is associated with increased risk for vascular diseases and all-cause mortality [7]. Further, individuals who are insufficiently active and follow an unhealthy diet are more likely to have diabetes-related complications than individuals following a healthier lifestyle [8].

Despite this, the prevalence of adequate physical activity, healthy diet, and avoiding smoking is far from what is recommended for people with diabetes. In the United States, 39% of adults with diabetes meet recommended physical activity levels [9], while global data show about 10% of adults with diabetes meet recommendations [10, 11]. Regarding diet, US national data show that the percentage of calories from saturated fat consumed by people with diabetes is above recommendations, while fiber intake is below recommendations [12]. Data from a study of 13 countries show participants with diabetes have poor adherence to diet and exercise self-management programs [13]. Finally, the prevalence of active smoking among people with hypertension or diabetes is 13% in Africa [14] and 25.7% in people with diabetes in the United States [15]. Overall, lifestyle behaviors of people with diabetes are far from meeting recommended levels globally.

Healthy Lifestyle as a Component of Type 2 Diabetes Management

The overarching goal of diabetes management is to expand quality of life (and possibly quantity of years lived) through preventing microvascular (retinopathy, nephropathy, neuropathy) and macrovascular (coronary heart disease, cerebrovascular disease, and peripheral vascular diseases) complications of diabetes. These complications are central drivers of morbidity and result from longstanding or poorly controlled risk factors such as elevated blood pressure, glucose, low-density lipoprotein (LDL) cholesterol, and smoking. Addressing these risk factors is recommended in several diabetes care guidelines: as an example, the American Diabetes Association 2021 Standards of Medical Care recommend people with diabetes should achieve the following treatment goals [16]:

- Hemoglobin A1c (HbA1c) levels of <7.0% (53 mmol/mol).
- Blood pressure of <140 mmHg (systolic) over <90 mmHg (diastolic).
- LDL Cholesterol levels <2.6 mmol/L (<100 mg/dL).
- Do not smoke tobacco.

Achievement of these ABCD treatment goals is low globally. For instance, in the United States, national data show that approximately 63.7% of adults diagnosed with diabetes

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_31

meet the HbA1c target, 65.5% the blood pressure target, 56.6% the LDL cholesterol target, and 80.6% the nonsmoking goal. Only 26.7% meet combined ABC targets, while 21.3% meet ABC targets and do not smoke [17]. A systematic review of Asian low- and middle-income countries found that average HbA1c (6.5–11%), systolic blood pressure (120–152 mm Hg), and LDL cholesterol levels (2.4–3.8 mmol/L) varied greatly and that recommended care goals are not being achieved widely [18]. Data from Central and South America show that the proportion of people with diabetes not meeting targets ranges from 13.0 to 92.2% for HbA1c, 4.6 to 92.0% for blood pressure, and 28.2 to 78.3% for lipids [19].

People living with diabetes can achieve the ABCD treatment goals by following healthy eating and physical activity plans, losing excess weight, avoiding smoking tobacco, or taking appropriate medications. Some people on medication can even achieve and maintain diabetes remission, which has been recently defined as achieving an HbA1c <6.5% measured at least 3 months after cessation of medication [20]. The effects of medication are augmented by lifestyle changes [21, 22], and indeed, patients who diligently adhere to healthy lifestyle behaviors can minimize their need for medications [23].

Following a healthy diet, engaging in regular physical activity, and avoiding tobacco smoking are thus the first-line management recommendations for every person living with diabetes. These lifestyle measures have been shown to improve HbA1c, LDL cholesterol, and blood pressure while also promoting weight loss even when medications are needed to lower these parameters [22]. Evidence from a meta-analysis shows that structured exercise training that consists of aerobic exercise, resistance training, or both was associated with a 0.67% decline in HbA1c levels in people with diabetes [24]. Meta-analytic evidence also shows supervised aerobic or resistance exercise reduce HbA1c by 0.30%, LDL cholesterol by 11.88 mg/dL, and systolic blood pressure by 3.90 mmHg [25]. Breaking sitting time with standing and light-intensity walking have also been found to improve 24-hour glucose levels and improve insulin sensitivity in individuals with diabetes [26].

Regarding dietary modification, a meta-analysis shows dietary changes with or without physical activity modification can lower HbA1c by 0.51% [27]. Another meta-analysis shows that low-carbohydrate, low glycemic index, Mediterranean, and high-protein diets all improve glycemic control by reducing HbA1c from 0.12% to 0.47% [28]. High-fiber diets or supplements containing soluble fiber have also been shown to reduce HbA1c by 0.55% in people with diabetes [29]. Finally, evidence regarding diabetes remission is starting to emerge: the DIRECT diet replacement intervention trial found that 36% of participants receiving a very low-calorie diet achieved diabetes remission at 24 months, compared to 3% of control participants [30]. Table 31.1 summarizes evidence from these meta-analyses.

Table 31.1 Evidence from meta-analyses reporting pooled effect estimates of lifestyle intervention on diabetes treatment goals

Avoiding tobacco smoking is the third lifestyle target of successful diabetes management. Tobacco smoking is harmful in people living with diabetes because it increases insulin resistance and deteriorates glucose control [35]. Individuals with diabetes who smoke have been found to have a higher risk for cardiovascular diseases (CVD), microvascular complications, and premature death than nonsmokers [35]. In contrast, smoking cessation among people newly diagnosed with diabetes is associated with reduced blood pressure [36]. Thus, advising people not to smoke and offering smoking cessation counseling and support to those who smoke are recommended diabetes management strategies [37].

Regarding prevention of diabetes complications, the PREDIMED trial showed participants with diabetes who followed a Mediterranean diet supplemented with extra-virgin olive oil or nuts had a 30% lower incidence of major CVD events [38]. The Look AHEAD study found no difference in CVD events between obese individuals with diabetes receiving a lifestyle modification intervention and control participants [39], but other benefits were accrued from the intervention. These additional benefits include lower disability [40], lower need for blood pressure and lipid-lowering medications [41], and lower kidney disease [42], among other benefits. Overall, these studies suggest CVD risk factors can be reduced through lifestyle modification in people with diabetes; whether this translates to lower CVD incidence may require stricter risk factor control or longer follow-up to become apparent.

Though experimental evidence is insufficient to suggest lifestyle modification lowers mortality risk in people with diabetes, more data are starting to emerge. For instance, observational evidence from a meta-analysis shows individuals with diabetes who follow a healthy lifestyle have 44% lower risk for all-cause death, 51% lower risk for cardiovascular death, 69% lower risk for cancer death, and 48% lower risk for incident cardiovascular disease than individuals with less healthy lifestyles [43]. In the US Diabetes Prevention Program Outcomes Study, which was in adults with prediabetes (i.e., those who have not yet developed diabetes), neither metformin nor lifestyle modification lowered all-cause or cardiovascular disease mortality [44]. The impact of lifestyle modification on mortality in people with diabetes is yet to be determined.

Recognizing this evidence, several diabetes care guidelines have included lifestyle management in their recommendations. For instance, the American Diabetes Association Standards of Care [16], the NICE Diabetes Management Guidelines [45], the Diabetes Canada Clinical Practice Guidelines [46], the Latin American Diabetes Association Consensus Statement [47], and the International Diabetes Federation Global Guideline for Type 2 Diabetes [48] recommend lifestyle modification for managing diabetes. Specific recommendations across guidelines vary but most recommend performing aerobic and resistance physical activity, lowering calorie intake for people with overweight or obesity, avoiding saturated fats, increasing fiber intake, avoiding added sugars, and avoiding tobacco use and excessive alcohol consumption. As an example, here are lifestyle recommendations for adults from the American Diabetes Association Standards of Care 2021 [49]:

Physical Activity

- Most adults with type 2 diabetes should engage in 150 min or more of moderate- to vigorous-intensity aerobic activity per week, spread over at least 3 days/week, with no more than 2 consecutive days without activity. Shorter durations (minimum 75 min/week) of vigorous-intensity or interval training may be sufficient for younger and more physically fit individuals.
- Adults with type 2 diabetes should engage in two to three sessions/week of resistance exercise on nonconsecutive days.
- All adults, and particularly those with type 2 diabetes, should decrease the amount of time spent in daily sedentary behavior. Prolonged sitting should be interrupted every 30 min for blood glucose benefits.
- Flexibility training and balance training are recommended two to three times/week for older adults with diabetes.

Diet:

- An individualized medical nutrition therapy program as needed to achieve treatment goals, provided by a registered dietitian/nutritionist, preferably one who has comprehensive knowledge and experience in diabetes care, is recommended for all people with type 1 or type 2 diabetes, prediabetes, and gestational diabetes mellitus.
- For all patients with overweight or obesity, lifestyle modification to achieve and maintain a minimum weight loss of 5% is recommended for all patients with diabetes and prediabetes.
- A variety of eating patterns can be considered for the management of type 2 diabetes and to prevent diabetes in individuals with prediabetes.
- Carbohydrate intake should emphasize nutrient-dense carbohydrate sources that are high in fiber and minimally processed. Eating plans should emphasize nonstarchy vegetables, minimal added sugars, fruits, whole grains, and dairy products.

Smoking:
- Advise all patients not to use cigarettes and other tobacco products or e-cigarettes.
- After identification of tobacco or e-cigarette use, include smoking cessation counseling and other forms of treatment as a routine component of diabetes care.
- Address smoking cessation as part of diabetes education programs for those in need.

Barriers to Healthy Lifestyles for Diabetes Self-Management

Adhering to recommended healthy lifestyle behaviors for diabetes self-management is a daunting task. People living with diabetes face daily lifestyle-related decisions, in addition to their everyday responsibilities, and in some cases, medication management and glucose monitoring. This is a 24/7 effort that takes place in diverse settings where barriers at the individual-, interpersonal-, community-, and system-level may arise. These barriers are discussed in this section and summarized in Fig. 31.1.

Individual-Level Barriers

Individuals living with diabetes may face psychosocial and/or socioeconomic barriers that hinder their lifestyle management efforts. Socioeconomic status, which encompasses educational, economic, and occupational status, has been found to impact lifestyle management through whether and how individuals and communities access relevant health-related resources [50]. For instance, a study in Nepal identified the cost of a healthy diet and appropriate footwear as a major barrier to healthy lifestyle behaviors for diabetes self-management [51]. In the United States, minority populations have low utilization of diabetes management support services given the high cost and poor accessibility to such services [52]. Unstable housing and food insecurity also negatively affect lifestyle behaviors and can lead to poor diabetes outcomes [50].

Individuals living with diabetes may also face psychosocial and capability barriers that hinder effective engagement in lifestyle self-management. For instance, a study from India found people with diabetes were unable to follow recommended medication and dietary guidelines due to low health literacy related to diabetes self-management [53]. A study in Nepal also identified lack of knowledge as a major barrier to diabetes self-management [54], while poor under-

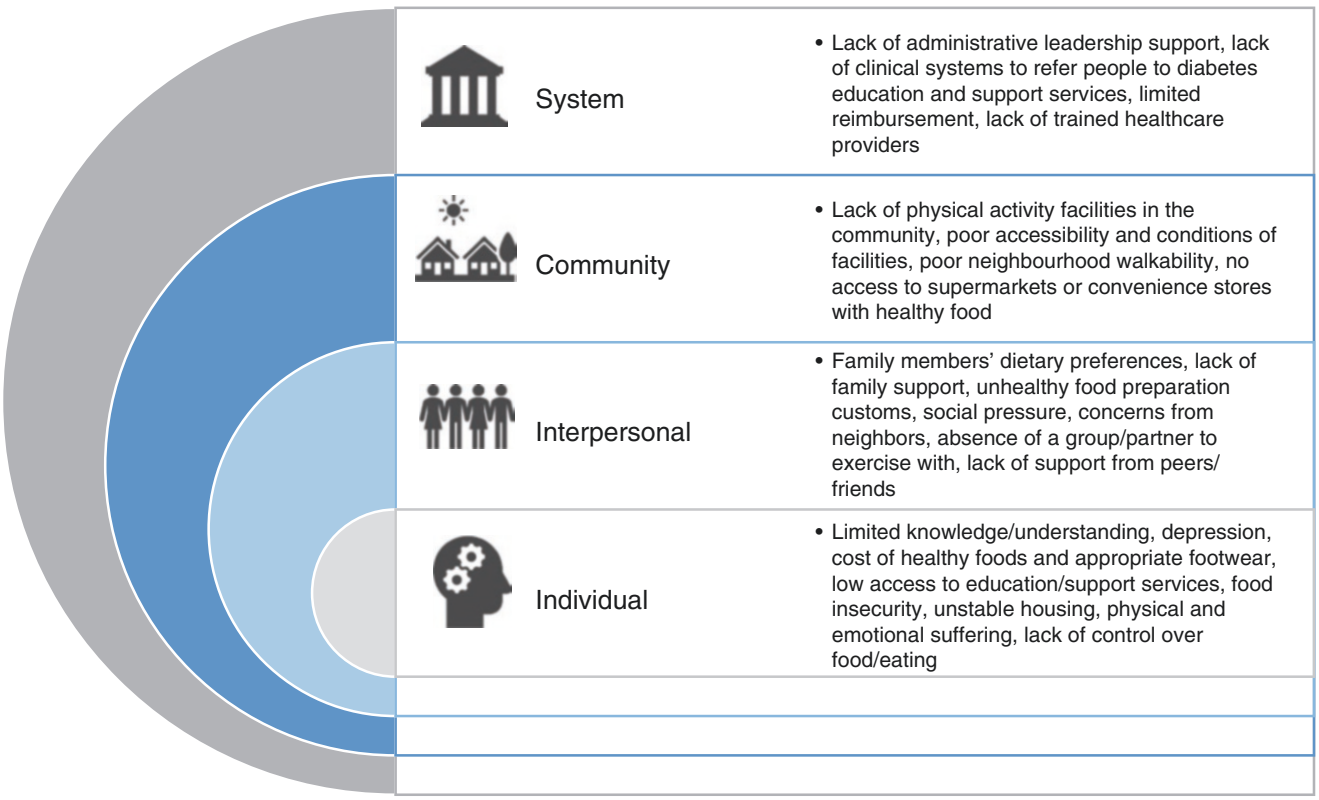

Fig. 31.1 Barriers to effective diabetes lifestyle self-management

standing of diabetes and stress have been identified as barriers to healthy eating in the US [55]. Psychological problems such as depression and diabetes-related distress are prevalent in persons with diabetes and have been found to hinder self-care [13]. Finally, physical and emotional suffering and lack of control over food/eating also hinder lifestyle self-management [56, 57].

Interpersonal-Level Barriers

Family members are the most significant source of social support for a person living with diabetes. Family support promotes diabetes treatment adherence [58] and is associated with fewer psychosocial problems and better self-management among individuals with diabetes [59, 60]. However, families can also negatively impact diabetes self-management. Unhealthy lifestyles of marital partners may increase the risk for cardiovascular disease in the partner dealing with diabetes [61], while family members' dietary preferences can deter healthy eating in those living with diabetes [62]. Further, lack of family support has been identified as a barrier to healthy eating among Hispanics with diabetes in the United States [56] and in Nepal [54]. It is important to also note that family members can also be negatively affected by diabetes as they may experience distress, anxiety and depression, frustration, and lost work/wages due to caring for a relative with diabetes [63, 64].

Friends and groups can also impact lifestyle management through sociocultural influences and modeling. For instance, unhealthy food preparation styles and social events at which food plays a significant cultural role put pressure on people with diabetes to abandon their healthy diet plans [54]. Concerns that neighbors express toward lifestyle management has been found to deter adherence to exercise plans in people with diabetes [54]. Absence of a group to exercise with and difficulty finding exercise partners are prominent barriers to maintenance of exercise routines in people with diabetes [65]. Finally, peers have been found to be both sources of encouragement for physical activity initiation and decreased motivation to be physically active [66]. As such, peers and friends could either act as facilitators of lifestyle management or deter such efforts in people with diabetes.

Community-Level Barriers

For people with diabetes, eating a healthy diet and engaging in regular physical activity may be difficult because healthy foods and physical activity opportunities are not readily available, easily accessible, or affordable in their communities. For instance, lack of recreational facilities in the community or poor accessibility and conditions of facilities can hinder physical activity in adults [67, 68]. In contrast, higher walkability of neighborhoods (e.g., with sidewalks, well-connected, greater mix of land use) has been found to be associated with promising diabetes outcomes [69].

The characteristics of the food environment can also hinder healthy eating in people with diabetes. A study among low-income US adults found people living with diabetes chose poor-quality foods because better-quality foods were out of geographic or financial reach [55]. Similarly, food environments that provide access to healthy foods (e.g., at farmers markets and supermarkets) can facilitate healthy lifestyles in people with diabetes [69]. Low-income and underserved communities are often the most affected with less supportive environmental conditions for physical activity and limited access to stores that sell healthy foods [67, 70].

System-Level Barriers

System-level barriers may hinder the access to, and uptake of, healthy lifestyle support resources. The uptake of the services is suboptimal globally: a study of from 17 countries found only 48% of people with diabetes have participated in educational programs or activities [71], while US data shows 5–7% of individuals who are eligible for diabetes self-management support through an insurance plan actually receive it [72, 73]. System-level barriers that may contribute to this include the lack of administrative leadership support, lack of clinical systems to refer people to diabetes education and support services, and limited reimbursement rates [74]. The cost of such programs is also a barrier in several countries as shown in a review that reports people do not use diabetes self-management support resources due to insufficient health insurance or inability to afford travelling to the program venue [75].

Another system-level barrier that may hinder diabetes self-management is the lack of trained healthcare providers. In the United States, specialized personnel like physical activity counselors, diabetes educators, and dieticians are in short supply [72]. Healthcare providers may also lack training in behavioral therapy and lifestyle counseling, which hinders confidence in their ability to identify psychological problems, lifestyle barriers, or to address these effectively [13]. In South Asia, language and communication discordance between patients and healthcare providers has been identified as a significant barrier to diabetes self-management support [57].

A prominent system-level barrier is the lack of reimbursement policies that support referrals to diabetes education and support in the community. For instance, current reimburse-

ment policies in the United States do not support interventions by nonphysicians or provide disincentives for interventions offered outside the clinical setting [76]. Similarly, Medicare and most health insurance plans in the United States reimburse diabetes education and support services but only if such services align with national standards and mostly when delivered in person [49]. As it is the case for most of the barriers discussed in this chapter, underserved communities are particularly affected by current reimbursement and referral models [77].

Supporting Healthy Lifestyles for Diabetes Self-Management

The barriers previously discussed represent need to be addressed to improve opportunities for people living with diabetes to engage in, and maintain, healthier lifestyles. Innovative ways to support these efforts include offering a variety of diabetes education and support options, using telehealth formats, coaching programs, just-in-time services, online resources, discussion groups, and intense programs for select groups, while leveraging community resources that support healthy behaviors [78]. In this section, we describe different strategies to improve opportunities for engaging in effective lifestyle management. These strategies are summarized in Table 31.2.

Table 31.2 Strategies to facilitate diabetes lifestyle self-management

Individual support	Social support	Community/system support
– Diabetes self-management education and support should be offered to empower individuals with the knowledge, skills, and confidence to engage in lifestyle diabetes self-management. – Education and support can be delivered by specialist nurses, dieticians, lay community health workers, and peer educators. – Education and support should be culturally and age appropriate, tailored to the individual's situation and context, involve family members, and include behavior change strategies. – Education and support can be delivered individually or in group settings, and in person or remotely using trusted telehealth tools (e.g., wearable devices, smartphone applications, and continuous glucose monitors).	– Leverage the support of families and peers to facilitate lifestyle modification. – Provide families with diabetes education opportunities. – Offer behavioral family therapies, training courses, and technologies to support families and build positive relations. – Offer flexible work schedules to help family members miss less days of work. – Identify and train peers to facilitate lifestyle diabetes management and maintain it long-term.	– Foster healthcare–community linkages to connect people with diabetes education and support resources in their community. – Build referral systems to prompt and follow referrals to community resources. – Develop multidisciplinary diabetes care teams that support lifestyle management and ensure referral follow thru. – Adopt/implement healthcare reimbursement models for lifestyle management services. – Healthcare systems should foster coordinated team care, facilitate communication among team members and patients, and connect patients with ongoing support in their communities.

Diabetes Self-Management Education and Support

Diabetes self-management education and support (DSMES) is an effective approach for helping people living with diabetes self-manage their disease. The purpose of DSMES is to empower people with diabetes by giving them the knowledge, skills, and confidence to accept responsibility for their self-management [78]. This responsibility includes collaborating with their healthcare team, making informed decisions, developing personal goals and action plans to achieve them, engaging in problem solving when issues arise, and coping with emotions and life stresses [79].

In the United States, there are national recommendations on effective DSMES to help people living with diabetes navigate their daily self-care. Specifically, the American Diabetes Association recommends healthcare providers offer and modify DSMES at four critical points: (1) at diagnosis, (2) annually or when treatment goals are not met, (3) when complicating factors appear, and (4) when transitions in care or life occur. Regarding lifestyle, these standards recommend that healthcare providers coordinate the full management plan by integrating medical nutrition therapy, DSMES, medications, and physical activity [78].

People with diabetes receiving DSMES have been found to have better clinical, psychosocial, and behavioral outcomes. For instance, a meta-analysis found group-based DSMES was associated with improvements in HbA1c, diabetes knowledge, self-management skills, and self-efficacy [80]. Another meta-analysis showed DSMES can improve quality of life among people with diabetes [81], while a systematic review found DSMES can be used to promote healthy coping [82]. Individual studies have also shown that DSMES is associated with improvements in lifestyle behaviors [83], clinical outcomes [84], and reductions in the presence of diabetes-related distress and depression [85, 86].

In terms of the content and format, education and support delivered by specialist nurses or dieticians seems to have the greatest benefits [87], though evidence also supports the use

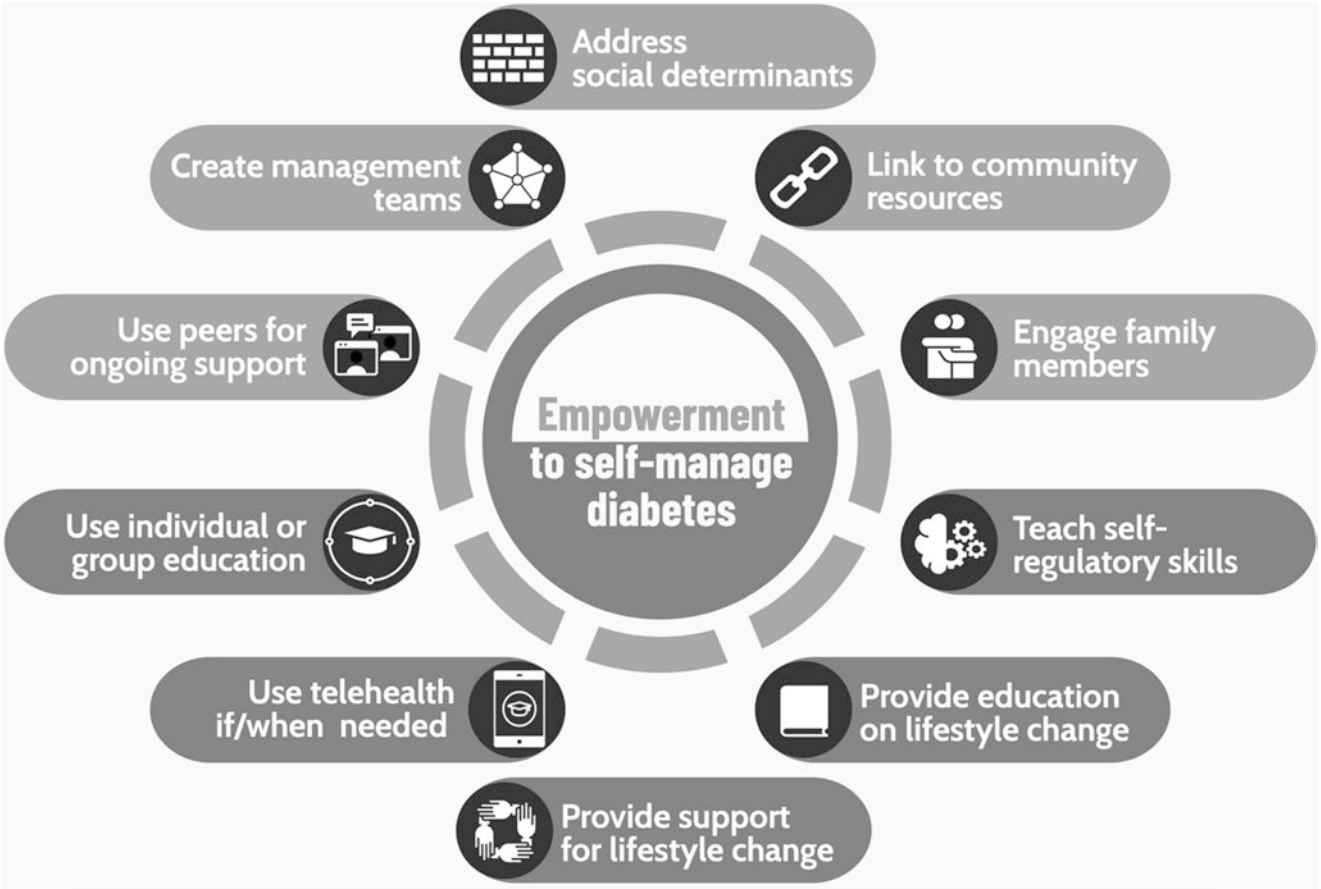

Fig. 31.2 Components for effective diabetes self-management education and support

of lay community health workers [88] and peer educators in providing ongoing support [89]. Education and support programs work best when they are culturally and age appropriate [90], tailored to the individual's situation and context [91], when family members are involved [90], and when behavior change strategies are incorporated [92]. In terms of delivery format, individual and group approaches have similar effects [93], while delivery via telehealth platforms has shown promising results [94–96]. The components of effective diabetes self-management education and support are illustrated in Fig. 31.2.

Social Support

As discussed earlier, family members can be allies or foes in terms of supporting healthy lifestyle choices within the household. Hence, family and household members should be included in, and supported by, diabetes management plans. For instance, families may benefit from psychological support and educational opportunities to improve their capability and motivation to care for their relatives with diabetes. Families should be provided with diabetes education opportunities, such as training courses or educational resources, to learn strategies to support their relatives without affecting their life. Behavioral family therapies, training courses, and technologies can all be employed to support families and build positive relations [97]. Since caring for relatives with diabetes may lead to foregone income by family members, offering flexible work schedules could help family members miss less work days.

Peer support has been found to be an effective component of successful lifestyle diabetes management. Peer support involves the transfer of experiential knowledge about lifestyle behaviors or coping strategies between people who share a particular characteristic [98]. In terms of effective components, peer support models that include lifestyle counseling, goal setting, and behavioral and social support have been found to be effective [89]. Peer support can also help address healthcare access barriers people with diabetes may face, while increasing the quality and quantity of self-management support [99]. Finally, since diabetes requires lifelong care, peer support can be employed to maintain long-term lifestyle management [100].

Evidence on the effectiveness, and the business case especially, for these initiatives may strengthen the likelihood of

employers, insurers, and healthcare systems offering reimbursement or funding for these educational and support services.

Healthcare-Community Linkages

Healthcare-community linkages are needed to connect individuals with resources to implement their lifestyle management activities. Through these links, individuals that are diagnosed/treated in a healthcare setting can be referred to places in their community where they can initiate lifestyle changes and access ongoing support to maintain such changes [101, 102]. To develop successful linkages, available community resources such as education and support programs, peer support groups, exercise facilities, and lifestyle modification programs can be catalogued and included in referral information systems. Identifying trusted resources in the community is also critical given that healthcare providers are unlikely to refer patients if they do not know about quality and accessibility of programs [103]. Healthcare–community linkages are also critical to provide healthcare services that are responsive to social determinants of health [50].

Referrals to community resources can be created through electronic or paper-based systems. For instance, referral strategies can be embedded into electronic medical records with clinical decision support systems to identify patients with diabetes that need referral to a lifestyle management program [104]. Healthcare–community linkages can be further facilitated by embedding and updating resource lists into electronic systems and automating communication technologies to refer patients to relevant community resources; these tools have been shown to improve provider referral rates and patient behavior [105]. Referring people with diabetes may not be enough to achieve effective full engagement in healthy lifestyle modification; therefore, monitoring progress to ensure people follow through and offering ongoing lifestyle support is imperative.

Follow-up and ongoing support can be provided through multidisciplinary diabetes care teams, where part of the team is based in healthcare settings and another part in the community. The role of the diabetes care team is to provide support, provide education, and empower the person with diabetes to take control over his/her/their lifestyle-related decisions [106]. Diabetes care teams may include physicians, nurse practitioners, psychologists, dietitians, exercise counsellors, and diabetes educators, while other models can also include peers [89], community health workers [88], and care coordinators [107]. Healthcare systems that foster coordinated team care, facilitate communication among team members and patients, and allow the provision of ongoing support in community settings would be needed in this endeavor.

Technology and Telehealth

Technology and telehealth approaches can be used to support lifestyle management and facilitate timely healthcare delivery. The evidence supporting the use of these approaches has been augmented by the COVID-19 pandemic, which triggered a large shift toward using these modalities. Still, the evidence specific to diabetes education and support delivery is so far modest.

Evidence from a meta-analysis shows smartphone applications can be used for reminding, monitoring, and coaching people with diabetes to improve their lifestyle behaviors [95]. Similarly, an integrative review concluded that web-based learning and mobile health applications can improve diabetes self-management behaviors [94], while Internet-based interventions that employ behavior change techniques (e.g., goal setting, action planning) and offer peer support can improve lifestyle behaviors [102, 108]. In 2021, a meta-analysis identified telemonitoring with automatic mobile transmission and real-time feedback for supporting lifestyle changes as a promising option to enhance diabetes management [33].

Telehealth has the potential to address accessibility barriers some individuals may face. Internet-based strategies and smartphone applications have been used to reach patients that do not have access to traditional healthcare services and to link them with relevant providers [94]. In situations where access to the Internet or cellular data are limited or not available, telephone calls or text messages from healthcare providers could be employed, which have been shown to promote effective self-management [109]. However, telehealth models should address the digital barriers found in rural populations, older adults, racial/ethnic minority populations, and those with low socioeconomic status and limited health literacy [110, 111].

Several tools (e.g., wearable devices) and smartphone applications are commercially available, which are decentralizing the role of self-driven lifestyle engagement. There has also been an increase in the use of continuous glucose monitors in people with type 2 diabetes to promote self-monitoring and facilitate self-regulation of lifestyle behaviors. However, the evidence regarding the reach, effectiveness, and long-term use of these tools and applications is limited. Further, securely sharing data and protecting privacy is still work under progress, which limits the widespread and full adoption of available technologies. Currently, best practices indicate only trusted technologies/telehealth platforms should be used, especially those that tailor advice to the person's engagement level, respond to health emergencies, and protect data privacy and security [112].

Finally, technology can also be used to foster healthcare-community linkages. For instance, websites can be used to publish lists of trusted education and support resources identified in the community [104], while geographic information

systems can be used to inform referral protocols [104]. Clinical decision support systems have been shown to improve patient referrals to community resources and achievement of diabetes treatment goals [104, 107, 113]. Communication technologies that automate patient referrals to community resources have been shown to improve provider referral rates and patient behavior [105] and should be considered to foster healthcare–community linkages to support diabetes lifestyle self-management.

Financing Lifestyle Diabetes Management

In this section, we examine the financing of interventions or strategies that support lifestyle management in people with diabetes through a crude lens. Delivering or covering the costs of lifestyle management programs or tools has an upfront cost; as such, these short-term investments must be balanced against potential benefits and returns. Much of this decision-making depends on how healthcare (and allied healthcare) services are financed and the perspective one is taking. At the level of the individual with diabetes, this decision is influenced by their current motivation, financial capabilities, and/or competing priorities.

From the perspective of the institution offering lifestyle management support services, some form of payment or reimbursement for them to provide this service is desired and/or required to remain financially solvent. From the perspective of the individual with diabetes, low-cost, high-value services or interventions with good outcomes and low side-effects are desired. This is especially true if the individual is also paying for the service or intervention, which is often the case in low- and middle-income countries where financial protections for healthcare (e.g., insurance) do not exist or are not widely used. This is also the case where the individual is the direct consumer of a product or tool (e.g., a wearable device or application) and is paying out of his/her/their disposable income for the promise of something that is supposed to facilitate a healthier lifestyle.

In the case of a third-party payer that "insures" healthcare service costs for individuals in a society—be this a government (e.g., the United Kingdom's National Health Service) or commercial stakeholders (e.g., private insurance companies)—a demonstration of the returns or the business case for investing in lifestyle management services or products are usually a prerequisite. The returns for third party payers are usually in the form of offsetting other high-cost healthcare expenditures like medicines, surgeries, or treating diabetes complications. This has been demonstrated in the LookAHEAD study, which showed lower need for blood pressure- and cholesterol-lowering medications among those receiving a lifestyle modification intervention [114]. This has also been recognized by the American Diabetes Association: based on the cost savings accrued from diabetes education and support services, the association recommends reimbursement by third-party payers for such services [49, 78]. However, the business case for each individual product and service available is currently limited.

The formal "business case" for lifestyle modification services has been developed and embraced by some healthcare systems and payers. Two examples include Discovery Health in South Africa and Kaiser Permanente, an integrated healthcare system and insurer in the United States. Both commercial corporations have adopted wellness into their healthcare insurance approach [115–117]. Either through calculating the potential cost offsets or as an embodiment of their mission and vision, these insurers have decided to cover the costs of wellness coaching for their members. In the United States, though these examples offer hope, the reality is that this vision is not ubiquitous and varies greatly by setting, perspective, and how health financing is set up.

Conclusion

Healthy lifestyles for diabetes self-management is a daily effort that takes place in a complex, multilayered system that includes the individual, the family, the community, and the healthcare system. Barriers that hinder effective lifestyle self-management may be encountered in each of these layers and the interaction of barriers may be different based on one's circumstances. Currently, the fragmentation of information and access across households, communities, and healthcare systems is itself a complexity that influences the likelihood that people with diabetes can engage in and maintain healthy lifestyles. As such, effective diabetes lifestyle management requires a coordinated effort focused on empowering individuals to ask about and adopt healthy lifestyle behaviors, providing ongoing support, and offering opportunities to succeed in the places where they live, play and work. This requires building efficient healthcare–community linkages, leveraging social support mechanisms, coordinating diabetes care, offering diabetes education and support resources in a variety of formats, sharing health information across settings, and financing strategies that support lifestyle modification services and referrals. Promising studies have already demonstrated the efficacy and effectiveness of clinical, community, broad societal strategies, and policies that can make lifestyle management more mainstream, accessible, and cost-effective. Such strategies should be widely adopted to realize the full potential of lifestyle management for improving the quality of life among those living with diabetes.

Multiple Choice Questions

1. The ABCD goals refer to control of:
   (a) Hemoglobin A1c and fasting blood glucose
   (b) Blood pressure and Cholesterol
   (c) Tobacco avoidance and Hemoglobin A1c
   (d) **Hemoglobin A1c, Blood Pressure, Cholesterol and Do not Smoke**
2. These are the first-line management recommendations for every person living with diabetes:
   (a) Insulin sensitizers
   (b) Low carbohydrate diet
   (c) **A healthy diet, regular physical activity, and avoiding tobacco smoking**
   (d) Injected insulin
3. Its purpose is to empower people with diabetes by giving them the knowledge, skills, and confidence to accept responsibility for their self-management.
   (a) Lifestyle modification
   (b) **Diabetes self-management and support**
   (c) Diabetes self-management support
   (d) Behavioral counseling
4. Diabetes self-management education and support should be offered at the following critical points:
   (a) At diagnosis
   (b) Annually or when treatment goals are not met
   (c) When transitions in care or life occur
   (d) **All of the above**
5. The physical activity guidelines for persons with diabetes recommend:
   (a) Adults with diabetes should engage in 300 minutes of moderate to vigorous intensity physical activity per week, spread over at least 3 days per week.
   (b) Adults with diabetes should engage in 150 minutes of vigorous intensity physical activity per week, spread over at least 3 days per week.
   (c) Adults with diabetes should engage in 150 minutes of light intensity physical activity per week, spread over at least 3 days per week.
   (d) **Most adults with type 2 diabetes should engage in 150 min or more of moderate- to vigorous-intensity aerobic activity per week, spread over at least 3 days/week, with no more than 2 consecutive days without activity.**
6. This diet has been shown to be beneficial for people living with diabetes:
   (a) Low carbohydrate
   (b) High protein
   (c) Mediterranean
   (d) **All of the above**
7. These can be used for reminding, monitoring, and coaching people with diabetes to improve their lifestyle behaviors:
   (a) **Smartphone applications**
   (b) Counseling
   (c) Peer mentoring
   (d) Diabetes self-management and support
8. It is the process of giving patients control over their diabetes by equipping them with the knowledge, skills, and resources they need to self-manage their disease.
   (a) Motivation
   (b) Education and support
   (c) Behavior change
   (d) **Empowerment**
9. It involves the transfer of experiential knowledge about lifestyle behaviors or coping strategies between people who share a particular characteristic:
   (a) Guidance
   (b) Education
   (c) **Peer support**
   (d) Behavior change
10. Effective diabetes lifestyle management requires:
   (a) **Empowering individuals, providing ongoing support, and offering opportunities to succeed**
   (b) Providing insurance for diabetes management services
   (c) Involving families in diabetes management efforts
   (d) A prompt diagnosis and treatment regime

Introduction

The overall goal of the medical treatment plan is to provide the individual with diabetes the necessary tools to achieve glucose, lipids, and blood pressure within target ranges to prevent, delay, or manage the microvascular and macrovascular complications while minimizing hypoglycemia and excess weight gain. The foundation of any diabetes treatment plan for type 1 or 2 diabetes is healthful eating and regular physical activity. Due to the progressive nature of type 2 diabetes, the treatment plan that begins with lifestyle interventions and usually metformin will evolve over time to include glucose monitoring and changes in medications. For many individuals with type 2 diabetes, the treatment plan may eventually require insulin in order to meet individual health goals, whereas with type 1 diabetes lifestyle interventions, glucose monitoring, and insulin are all integral components of management plan from diagnosis, but whatever the treatment plan, nutrition interventions continue to be critical aspects of care [1, 2]. In addition to nutrition therapy provided by the registered dietitian nutritionist (RDN), a wide range of health professionals, such as registered nurses or pharmacists, can provide nutrition education in the context of a diabetes education program. Effective nutrition therapy may be implemented in individualized sessions or in a context of group education sessions. In fact, the American Diabetes Association (ADA) recommends that all individuals be offered an individualized nutrition care plan, preferably provided by a RDN [1].

Diabetes Nutrition Therapy: The Evidence

The Academy of Nutrition and Dietetics (AND), the largest association of nutrition professionals in the world, published evidence-based nutrition practice guidelines (EBNPG) for type 1 and type 2 diabetes in adults in their Evidence Analysis Library (EAL) and in print [3]. ADA have also published nutrition recommendations in the ADA Nutrition Therapy for Adults with Diabetes or Pre-diabetes: A Consensus Report and in the annual Standards of Medical Care in Diabetes [1, 4]. Multiple research studies support diabetes nutrition therapy as an effective tactic in achieving diabetes treatment goals. Medical nutrition therapy (MNT) provided by an RDN is also cost-effective [5].

Based on the systematic review conducted by the AND, in adults with type 2 diabetes, MNT interventions implemented by RDNs resulted in significantly improved hemoglobin A1C (A1C) levels. In studies lasting 3 months, decreases from baseline A1C ranged from 0.3% to 2.0%; at 6–12 months reported decreases from baseline in A1C ranged from 0.3% to 1.8%. With ongoing MNT support for more than 12 months, continued decreases ranging from 0.6% to 1.8% were reported [3]. Although MNT interventions were effective throughout the disease process, the reduction in A1C was the greatest in studies in which participants were newly diagnosed with type 2 diabetes and/or had baseline levels > 8%. Studies have also demonstrated that ongoing RDN provided follow-up encounters ranging from three to six sessions, with a minimum of one follow-up session annually, can be helpful in maintaining glycemic improvements. During this time, it can be determined whether target goals can be achieved by implementation of MNT in combination with physical activity or whether medication(s) will need to be combined with MNT [3].

Regarding A1C outcomes in people with type 1 diabetes, MNT also contributed to significantly reduced A1C levels [3]. MNT provided by RDNs at 6 months reported that individualized MNT utilizing carbohydrate counting to optimize prandial insulin doses contributed to reduction in baseline mean A1C by 1.0% to 1.9%. Ongoing MNT resulted in sustained A1C reductions at 1 year and improved quality of life [6]. The landmark Diabetes Control and Complications Trial (DCCT) revealed that ongoing support of the RDN assisted in maintaining the mean A1C level at 6.9% in the intensive treatment arm throughout the 6.5 years of the study [7, 8]. There is strong evidence to support for individuals with type 1 diabetes to utilize the carbohydrate counting meal planning approach to adjust bolus (premeal) insulin doses (insulin-to-carbohydrate ratios) to desired carbohydrate intake. It should be noted, that these A1C reductions are similar or greater than what would be expected with treatment with currently available glucose-lowering medications for individuals with type 1 and 2 diabetes [1]. The key differences between nutrition therapy for people with type 1 and type 2 diabetes are summarized in Table 32.1.

Table 32.1 Nutrition Teaching Priorities

Type 1	Type 2
Glycemic management	Weight management; calorie reduction
Type and amount of carbohydrate	Glycemic management
Healthful eating patters	Healthful eating patterns
Fixed insulin regimen: carb consistency	Nutrient modifications (fat; sodium) based on co-morbidity risk (CVD, HTN)
MDII/Pump: flexible carb intake	Medication regimen and glucose monitoring drives degree of focus on carb type/amount.
Hypoglycemia prevention	Hypoglycemia prevention (based on medication)

In the systematic review published by AND, the effectiveness of MNT and cardiovascular disease (CVD) risk factors was also evaluated [3]. MNT was reported to have mixed effects on blood pressure and lipid profiles. The effectiveness of MNT may have been confounded by the 50% to 75% of the subjects that were noted to be taking antihypertensive and/or lipid-lowering medications. Additional long-term studies are needed at address the effectiveness of MNT on blood pressure and lipid profiles in adults with type 1 and 2 diabetes and disorders of lipid metabolism and hypertension.

Effective Nutrition Therapy Recommendations: Eating Patterns, Macronutrients, Weight Management, Fiber, Alcohol, Micronutrients/Herbal Supplements, and Weight Management

The 2019 ADA Nutrition Therapy for Adults with Diabetes and Pre-diabetes: A Consensus Report reviewed research studies of persons with diabetes following different types of eating patterns, including Mediterranean-style, vegetarian and vegan, low-fat, low-carbohydrate (26–45% total kcal) and very low carbohydrate (<26% total kcal/ketogenic diet), DASH (Dietary Approaches to Stop Hypertension), Paleo, and intermittent fasting [4]. The ADA Nutrition Consensus Report concluded that a variety of eating patterns are acceptable for the management of diabetes. It should be noted that an eating pattern represents the totality of all foods and beverages consumed, whereas an eating plan (or diet) is a guide to help individuals plan what, how much, and when to eat on a daily basis of the foods emphasized in the individual's selected eating pattern [9]. Personal preferences (e.g., tradition, culture, religion, health beliefs and goals, economics) and metabolic goals should be considered when implementing one eating pattern over another [4]. The eating pattern that the individual with type 2 diabetes chooses to follow will likely be the one that they will be able to follow long term [3]. Further research is needed to determine the most effective strategies to help persons with diabetes adopt new eating patterns. Refer to Table 32.2 for the eating patterns reviewed for ADA nutrition consensus report including a description of each eating pattern and list of potential benefits. Regardless of the eating pattern that the person chooses to follow, a variety of meal planning approaches such as carbohydrate counting, exchange lists for meal planning, or the plate method were implemented and effective. Meal planning approaches will be described in more detail later in the chapter.

While there has been ongoing research to define optimal levels of particular nutrients in diabetes nutrition therapy,

Table 32.2 Eating patterns linked with beneficial outcomes [4]

	↓DM	↓A1C	↓TG	↓CVD	↓Wt	↓LDL	↓BP	↑HDL	Incon-clusive
Mediterranean	✓	✓	✓	✓					
Vegetarian/Vegan	✓	✓			✓	✓			
Low-Fat	✓				✓				
Very Low-Fat					✓		✓		
Low-Carbohydrate		✓			✓		✓	✓	
Very Low-Carbohydrate		✓			✓		✓	✓	
DASH	✓				✓		✓		
Paleo									✓

Adapted from the ADA 2019 Nutrition Consensus Report

recent attention has focused on diet quality and the importance of a healthful eating pattern containing nutrient-dense foods with less focus on specific nutrients [10]. A recent meta-analysis linked high-quality diets (those rich in fruits and vegetables, whole grains, lean meats, legumes, nuts and seeds, dairy and low in processed foods, sugar sweetened beverages, and added fats and sodium) with a significant reduction in the risk of all-cause mortality, type 2 diabetes, and cardiovascular disease [11]. The 2021 Dietary Guidance to Improve Cardiovascular Health: A Scientific Statement from the American Heart Association reports that evidence from prospective observational studies has consistently identified an inverse association between diet quality and type 2 diabetes risk, and likewise, poor diet quality is also strongly associated with cardiovascular disease morbidity, and mortality [12].

Keeping that in mind, recommendations for an optimal macronutrient distribution for the management of diabetes continues to be a popular question. Although many research trials have attempted to identify the optimal percentages of macronutrients for a diabetes eating plan, review of the evidence reveals that there is not an ideal percentage of calories from carbohydrate, protein, and fat for all persons with diabetes [1, 3, 4]. Total energy intake rather than the source of the energy is the priority, especially for individuals with type 2 diabetes. However, even total energy intake is determined by changes that the individual with diabetes is willing and able to make. The meal plan must take into consideration personal preferences and metabolic goals when recommending one eating plan over another [3].

Because macronutrients require insulin for metabolism and influence healthy eating, they still, however, must be discussed with the individual with diabetes. Although numerous factors influence glycemic response to foods, monitoring the carbohydrate intake whether by use of carbohydrate counting or experienced based estimation remains a key strategy in achieving glucose management [1, 3, 4]. Evidence exists that both the quantity and the type of carbohydrate eaten influence blood glucose levels; however, the total amount of carbohydrate eaten is the primary predictor of glycemic response. Day-to-day consistency in the amount of carbohydrate eaten at meals and snacks is reported to improve glycemic control, especially in persons on either MNT alone, glucose-lowering medications, or fixed insulin regimens. For selected adults with type 2 diabetes not meeting glycemic targets or where reducing glucose-lowering medications is a priority, reducing overall carbohydrate intake with low or very-low carbohydrate eating plans is a viable approach [4]. Most individuals within the United States report a moderate intake of carbohydrates (44–46% of total calories), and efforts to modify habitual eating patterns are often unsuccessful over time as people generally go back to their usual eating style [13]. Whereas in persons with type 1 or 2 diabetes who adjust their mealtime insulin doses or who are on insulin pump therapy, insulin doses should be adjusted to match carbohydrate intake [3, 4].

The ADA Nutrition Consensus Report also includes recommendations for adults with type 2 diabetes with overweight or obesity. The authors recommend that it is important to encourage reduced energy intake as part of an individualized diabetes eating plan, along with enhanced physical activity [3]. In people with type 2 diabetes, a 5% weight loss is recommended to achieve clinical benefit, and the benefits are progressive. The report also recommends the goal for optimal outcomes is 15% or more when needed and can be feasibly and safely accomplished. A systematic review of the effectiveness of diabetes MNT revealed mixed weight loss outcomes in participants with type 2 diabetes [3]. Therefore, in selected individuals with type 2 diabetes, the addition of glucose-lowering agents, weight loss agents that promote weight loss, or metabolic surgery can also be used as an adjunct to lifestyle modifications, to promote greater weight loss and maintenance goals, lower A1C, and reduce CVD risk [4]. The Look AHEAD study showed the feasibility of achieving and maintaining long-term weight loss in patients with type 2 diabetes, and many participants found using a

meal replacement product for one or two meals is particularly helpful in controlling intake and improving diet quality [14].

In addition to considering meal replacements, long-term success is associated with longer interventions (at least 16 sessions of group or individual counseling) that involves meal planning, increased physical activity (200–300 minutes/week), and behavior change strategies [15, 16]. The ADA recommends for patients who achieve short-term success that a long-term (>1 year) comprehensive weight maintenance program be prescribed [1]. An eating plan that results in energy deficit, behavioral strategies, and regular physical activity are critical components of any long-term weight loss and maintenance plan [15, 16]. Weight loss interventions can be provided in usual care settings and telehealth programs [4]. Healthcare providers can show their patients modest weight loss looks like in terms of a 5–10% decrease from their starting weight. This often makes it look much more achievable than if patients think they have to get down to a seemingly unattainable "ideal" body weight (see Table 32.3).

Over the years, strategies that restrict carbohydrate have been used for diabetes management and weight loss. The National Lipid Association Nutrition and Lifestyle Task force recently published a Scientific Statement providing a comprehensive review of the current evidence base available from recent systematic reviews and meta-analyses on the effects of low-carbohydrate and very-low-carbohydrate (including ketogenic) diets on body weight, glycemic control, lipoprotein lipids, and other cardiometabolic risk factors [17]. Based on the evidence reviewed, these diets may be linked with greater short-term (≤6 months) weight loss, but longer term (>6 months) results are equivalent to other dietary approaches for weight loss. The low-carbohydrate and very-low-carbohydrate diets may have advantages related to triglyceride reduction, appetite control, and reduction in the use of medication in management of type 2 diabetes. The evidence also revealed mixed effects on low-density lipoprotein cholesterol levels with some studies showing an increase. In addition, the authors reported no clear evidence for advantages regarding effects on other cardiometabolic risk factors based on their review. Long-term studies with clinic event outcomes are needed [4]. It should be noted that these diets are contraindicated in individuals with history of elevated triglycerides, pancreatitis, chronic kidney disease, disordered eating patterns, and pregnant women. Individuals with diabetes severely restricting carbohydrate are at increased risk of hypoglycemia if using insulin and/or insulin secretagogues and, therefore, should be medically supervised [17].

Table 32.3 Reasonable weight loss goals (5–10%)

Reasonable weight loss goals (5–10%)	
If you weigh	Then aim to lose
70 kg (154 lb)	3.5–7 kg (8–15 lb)
80 kg (176 lb)	4–8 kg (9–18 lb)
90 kg (198 lb)	4.5–9 kg (10–20 lb)
100 kg (220 lb)	5–10 kg (11–22 lb)
120 kg (264 lb)	6–12 kg (13–26 lb)
140 kg (308 lb)	7–14 kg (15–30 lbs)

Evidence is lacking to recommend a higher fiber intake for people with diabetes than for the general population. Thus, recommendations for fiber intake for people with diabetes are similar to the recommendations for the general public [3]. While diets containing 44 to 50 grams of fiber daily improve glycemia, more usual fiber intakes (up to 24 grams daily) have not shown beneficial effects [4]. The mean intake of dietary fiber in the United States is reported to be 17 g per day with only 5% of the population meeting the adequate intake (25 g for adult women and 38 g for adult men or 14 g total fiber per 1000 kcal) [18]. In addition, as with the general population, individuals with diabetes should consume at least half of all grains as whole grains [9].

For people with diabetes, evidence is also inconclusive to recommend an ideal amount of protein intake for optimizing glycemic control or improving CVD risk factors; therefore, protein recommendations should be individualized [1, 3, 4]. The amount of protein usually consumed by persons with diabetes is 15% to 20% of energy intake [19, 20], has minimal acute effects on glycemic response, lipids, and hormones, and has no long-term effect on insulin requirements [21].

Evidence is also inconclusive for an ideal amount of total fat for people with diabetes, and, therefore, goals should be individualized [1, 4]. The National Academy of Medicine has defined an acceptable macronutrient distribution of fat for all adults to be 20–35% [22]. The type of fat consumed is more important than total fat in terms of metabolic goals and influencing CVD risk, with the emphasis on decreasing saturated and trans fats and replacing them with unsaturated fats. Individuals should be encouraged, however, to moderate their fat intakes to be consistent with their goals to lose or maintain weight [17].

Plant-based foods rich in unsaturated fats (oils, nuts, avocados, fish) as a component of the Mediterranean-style eating pattern are associated with improved glycemic control and improved CVD risk factors in persons with type 2 diabetes [1, 4]. Benefits have been demonstrated from both monounsaturated fatty acids (MUFA) and polyunsaturated fatty acids (PUFAs). Controversy exists on the best ratio of omega-6 to omega-3 fatty acids; however, PUFAs and MUFAs are both recommended as substitutes for saturated fatty acids (SFAs) or trans fatty acids. The amount of SFAs, cholesterol, and trans fat recommended for people with diabetes is the same as for the general population [9]. These recommendations include reducing SFAs to <10% of calories and limiting trans fat as much as possible. There is evidence from the general population that foods containing

omega-3 fatty acids have beneficial effects on lipoproteins and prevention of heart disease. Therefore, the recommendations for the general public to eat fish (particularly fatty fish) at least two times (two servings) per week is also appropriate for people with diabetes [9]. However, evidence from RCT does not support recommending omega-3 supplements for people with diabetes for the prevention or treatment of CVD despite evidence from observational and preclinical studies [1, 4].

Moderate amounts of alcohol ingested with food have minimum, if any, acute effect on glucose and insulin levels [23]. If individuals choose to drink alcohol, aim to limit daily intake to one drink or less for adult women and two drinks or less for adult men (one drink equivalent is equal to 12 oz beer, 5 oz of wine, or $1^1/_2$ oz of distilled spirits). Each drink contains approximately 15 g alcohol [4]. The type of alcoholic beverage consumed does not make a difference. The same precautions that apply to alcohol consumption for the general population apply to persons with diabetes. Abstention from alcohol is advised for people with a history of alcohol abuse or dependence; for women during pregnancy; and for people with medical problems such as liver disease, pancreatitis, advanced neuropathy, or severe hypertriglyceridemia.

However, alcohol consumption may place people with diabetes who take insulin secretagogues or insulin at increased risk for delayed hypoglycemia [23]. Consuming alcohol with food can minimize the risk of nocturnal hypoglycemia. Education and awareness of delayed hypoglycemia after consuming alcoholic beverages is important. Alcoholic beverages should be considered an addition to the regular eating plan for all persons with diabetes who choose to drink. No food should be omitted, given the possibility of alcohol-induced hypoglycemia and because alcohol does not require insulin to be metabolized [4]. In persons with diabetes, light-to-moderate amounts of alcohol (one to two drinks per day; 15 to 30 g of alcohol) are associated with a decreased risk of coronary heart disease, likely due to improved insulin sensitivity associated with alcohol consumption. Ingestion of light-to-moderate amounts of alcohol does not raise blood pressure or triglycerides, whereas excessive, chronic ingestion of alcohol does raise blood pressure and may be a risk factor for stroke [23].

No clear evidence has been established for benefits from vitamin or mineral supplements in persons with diabetes (compared with the general population) who do not have underlying deficiencies [1, 4]. Long-term metformin use is associated with vitamin B12 deficiency, suggesting that periodic testing should be considered [1]. There has been interest in prescribing antioxidant vitamins in people with diabetes, since diabetes may be a state of increased oxidative stress. Clinical trial data not only indicate the lack of benefit from antioxidants on glycemic control and progression of complications but also provide evidence of the potential harm [1, 24].

Therefore, routine supplementation is not advised. At this time, there is also insufficient evidence to support the routine use of micronutrients such as vitamin D, magnesium, and chromium, as well as use of herbs/supplements, or cinnamon for the treatment of diabetes [1, 3, 24]. In addition, herbal products are not standardized and vary in their content of active ingredients and have the potential to interact with and potentiate the effect of other medications. Therefore, it is important that individuals with diabetes report the use of supplements and herbal products to their RDN and/or healthcare provider. Without well-designed clinical trials to prove efficacy, the benefit of pharmacological doses of supplements is unknown, and findings from small clinical and animal studies are frequently extrapolated to clinical practice [3].

Individualization of the Nutrition Prescription and Eating Patterns

The first step in developing a meal plan for the person with diabetes is to base it on an individualized assessment [25]. The RDN will take a detailed history including an analysis of usual eating habits, past diets, comorbidities that affect nutrition, socioeconomic factors, cultural influences, and readiness to change in order to identify, collaboratively with the patient, the best approach to meal planning. Common approaches to meal planning with a RDN usually involve carbohydrate or calorie counting, developing sample menus, incorporating behavioral strategies such as mindful eating all while working within the eating preferences described by the patient such as a vegetarian eating style or avoiding certain food allergens. While a referral to a RDN is ideal, it may not always be realistic, and the physician is often in the position to get a patient started with basic meal planning recommendations. Thus, the physician or diabetes counselor should be prepared to ask a few key questions to help understand the patient's usual eating style and be better prepared to offer meaningful guidance. Suggested questions for an abbreviated assessment include:

- *What is your past experience with diet/meal plans?*
- *Tell me what you typically drink?(focus on learning if there are sources of significant carbohydrates from juices, sodas, or other sugar-sweetened beverages).*
- *Usual meal pattern (times/locations).*
- *How often do you eat vegetables—and what kinds?*
- *Tell me three things you think are going well with your eating pattern and three things you'd like to improve.*

Several eating patterns are associated with beneficial outcomes for people with diabetes and can be recommended by all members of the healthcare team [4, 26–29] (see

Table 32.2). No matter what eating pattern, aim for most food choices to focus on high-quality, minimally processed whole grains, vegetables, fruits, lean meats, seafood, legumes, nuts and seeds, dairy products and heart-healthy unsaturated fats and oils. As much as possible, aim to avoid sugar-sweetened beverages and minimize refined grain products, processed meats and added sugars, fats, and sodium.

The plate method has been used widely in many parts of the world as a useful method of controlling carbohydrate and calories without overwhelming patients with lists of foods and calculations of calories and carbohydrates. Recently, its effectiveness was demonstrated in research that randomized 150 adults with type 2 diabetes to either plate method approach or a carbohydrate counting approach. At 6 months, A1C improved within the plate method [−0.83% (−1.29, −0.33), $P<0.001$], and carbohydrate counting [−0.63% (−1.03, −0.18), $P = 0.04$] groups but not the control group [$P = 0.34$] [27]. Of particular interest were the additional benefits of the plate method seen in patients with lower literacy skills [27]. The ADA has created a variety of tools for healthcare providers to use in teaching patients the plate method [30] and it particularly useful for physicians, nurses, pharmacists and other non-dietitians to use when helping patients get started with meal planning. Note that the plate method can be adapted to meet the needs of multiple different cultural eating practices, using a bento box, bowl, or a banana leaf. No matter what is used to hold the food, guide the patient to identify the carbohydrate sources, and keep them limited to one section, with a similar size portion for protein foods and a larger serving allowed for nonstarchy vegetables.

Despite the effectiveness of the plate method, many patients ask for more specific guidance when it comes to carbohydrates and calories. Instead of giving a daily range for either, offering per-meal guidelines is more practical. Tables 32.4 and 32.5 offer such guidelines. In the United States, a carbohydrate (carb) serving is defined as the amount of food that yields 15 grams of carbohydrate. Thus, 1/3 cup cooked rice or pasta, ½ cup cooked oats, 1 oz slice bread, a small piece of fruit or 8 oz (240 mL) milk all have about 15 grams of carb. In other countries, the carb servings may be based on a portion size to yield a 10 gram carb serving. Quantities can be adjusted accordingly.

No matter what eating pattern is recommended, the success is due in large part to the patient's involvement in helping shape the meal plan, setting specific and realistic goals and participating in ongoing follow-up and systems of support. Ongoing support may be in the form of face-to-face visits, peer support, phone coaching, or even through the use of social media communities such as on Facebook that bring together people working together for a common goal. The healthcare provider will do well to identify resources within the community or online that can provide such support.

Table 32.4 Calories per meal: suggested ranges

Calories per meal: suggestedr		
Meal	Women	Men
Breakfast	300–400	400–500
Lunch	400–500	500–600
Dinner	400–500	500–600
Snacks	100–200	100–200

Table 32.5 Carbohydrate per meal: suggested ranges [31]

Carbs per meal—suggested ranges	
If you are male and not overweight	4–5 servings[a] 60–75 grams carb
If you are female and not overweight	3–4 servings 30–45 grams carb
If you are overweight (>10 lbs/4.5 kg)	Subtract 1 carb serving (15 grams)
If you exercise three to five times/week	Add 1 carb serving (15 grams carb)
Snacks	

[a]1 carb "serving is a portion of food equal to about 15 grams of carb such as one small apple, one small slice bread, 120 mL/4oz juice or 240 mL/8 oz milk

Conclusion

Nutrition therapy is a cornerstone of treatment for people with diabetes [31]. While the RDN is the person best qualified to develop an individualized meal plan, all healthcare team members have a role in giving patients guidance for healthy eating and ongoing support for the many behavior changes involved in maintaining dietary changes, especially those involved in weight management. Meal planning priorities and diet plans will vary based on type of diabetes, type of medications, other comorbidities, and multiple patient factors including usual eating habits and readiness to change. They will also change over time, making an annual assessment of nutrition needs and possible meal plan revisions important. In order to prepare to meet the client's nutritional needs, physicians and other healthcare providers will do well to identify dietitians with whom they can work collaboratively and/or mentor health educators or peer counselors to provide nutrition information for healthy eating using simple guidelines such as the plate method. And finally, remember that healthy eating for people with diabetes follows the same principles of what healthy eating is for everyone.

Multiple Choice Questions

1. For a person with newly diagnosed type 2 diabetes, what is a recommended weight loss goal?
   (a) 3%

(b) **5–10%**
(c) 15%
(d) 20%

2. Which of the following is a true statement about diabetes and alcohol?
   (a) People with diabetes should not drink alcohol.
   (b) Alcohol recommendations for serving size and amount are the same for both men and women.
   (c) **Hypoglycemia risk is increased in people taking insulin and/or insulin secretagogues.**
   (d) Alcohol is a good source of glucose.
3. What is the most important factor to consider when individualizing a meal plan for all people with diabetes:
   (a) Medical history and type of diabetes
   (b) Laboratory data and weight
   (c) Cultural background and food-related beliefs
   (d) Readiness to learn new behaviors and interest in changing old ones
   (e) **All of the above**
4. In the process of providing medical nutrition therapy for a person with diabetes, the goal is to improve overall diabetes control by:
   (a) Providing a written meal plan
   (b) Emphasizing portion control
   (c) **Individualizing the meal planning approach**
   (d) Using carbohydrate counting
5. For a person with type 1 diabetes who is using multiple daily injections of insulin, nutrition education priorities include all of the following, except:
   (a) Education on carbohydrate counting, flexible carbohydrate intake
   (b) Glycemic management
   (c) Hypoglycemia prevention
   (d) **Weight management, calorie restriction**
6. The American Diabetes Association recommendations include all of the statements except:
   (a) The amount of SFAs, cholesterol, and trans fat recommended for people with diabetes is the same as for the general population.
   (b) It is recommended that people with diabetes eat fish (particularly fatty fish) at least two times (two servings) per week.
   (c) **Omega-3 supplements should be recommended for people with diabetes for the prevention or treatment of cardiovascular disease.**
   (d) Plant-based foods rich in unsaturated fats as a component of the Mediterranean-style eating pattern are associated with improved glycemic control and improved CVD risk factors in persons with type 2 diabetes.
7. Your patient tells you she is taking supplements (such as cinnamon, antioxidants and Vitamin D) instead of making changes in her eating habits to manage her diabetes. The best response is:
   (a) "These products are a waste of money."
   (b) **"Micronutrients and herbal supplements may have the potential to interact with your prescribed medications, please bring them to your next appointment so we can evaluate them together."**
   (c) "Folk remedies like what you are describing don't ever work,"
   (d) "These are acceptable supplement's for people with diabetes to take as long as they are made by a reputable manufacturer"
8. Long-term metformin use has been shown to be associated with:
   (a) Iron-deficiency anemia
   (b) **Vitamin B12 deficiency**
   (c) Calcium deficiency
   (d) Weight gain
9. In adults with type 2 diabetes medical nutrition therapy (MNT) interventions implemented by RDN lasting longer than 12 months, resulted in significantly improved hemoglobin A1C levels:
   (a) 0.3%
   (b) 0.5–0.8%
   (c) **0.3–1.8%**
   (d) > 2.0%
10. Nutrition education priorities for type 2 diabetes include all the statements except:
   (a) Focus on the total energy intake rather than the source of the energy
   (b) Nutrient modifications (such as fat and sodium) based on comorbidity risk (such as cardiovascular disease and hypertension)
   (c) Changes in eating plan that the individual is willing to make
   (d) **Meal plan should include three meals and three snacks at specific times**

Evidence and Implementation of Physical Activity and Exercise in Diabetes Mellitus

33

Edtna Jáuregui-Ulloa, Juan López-Taylor, Raúl Soria-Rodríguez, and Ruth García-Camarena

Introduction

According to the World Health Organization (WHO), global health is influenced by three tendencies, (a) the aging of the population, (b) fast nonplanned urbanization, and (c) globalization, all of these resulting in unhealthy conducts and environments. As a consequence, noncommunicable diseases (NCDs) have increased in both high- and medium-income countries worldwide, accounting for 71% (41 million) of annual deaths which 4% (1.6 million) are attributable to diabetes mellitus, making it the fourth leading cause of death for NCDs [1–3].

Physical inactivity is considered the fourth attributable cause of mortality in the world.

Besides, behaviors like smoking and poor nutrition and excessive alcohol consumption are responsible for many of the diseases and the premature deaths related to chronic diseases [4]. Today physical activity (PA) is of great importance, since it has been correlated with health benefits and in the fight against the main NCDs, such as overweight and obesity, diabetes, hypertension, osteoporosis, cardiovascular disease and cancer. PA has also been found to be an important factor in maintaining mental health and socioemotional stability and improving the immune system [5–7].

The purpose of this chapter is to provide the physician with information on: (1) clarification of concepts related to human movement; (2) evidence of the benefits of PA and exercise in diabetes at the metabolic, enzymatic, molecular, muscular, immune, and mental levels; (3) effects of PA in relation to its intensity; (4) exercise prescription using the five A's model; and (5) finally a brief summary of the recommendations, indications, and contraindications of PA, in patients with diabetic complications.

Although the emphasis of this chapter is about the evidence and implementation related to physical activity and exercise, it should not be forgotten that this is just one part of the cornerstone of the treatment for diabetes mellitus, together with the nutritional and pharmacological aspects. However, nowadays it is agreed that diabetes management is multifactorial, and the health professional must be prepared to positively influence the change of behavior toward a healthy lifestyle and promote the physical, emotional, social, intellectual, spiritual, and occupational individual well-being, as well as improve the individual's physical fitness, quality of life (QOL), and metabolic control [8] (Table 33.1).

Key Concepts About Physical Activity and Exercise

Human Movement

Represents a complex behavior that is influenced by personal motivation, health and mobility issues, genetic factors, and the social and physical environments in which people live [10].

Physical Activity

Caspersen and colleagues [11] were the first ones to define physical activity as "the bodily movement produced by the contraction of skeletal muscle that increases energy expenditure (heat) above the basal level." This generic definition for physical activity has endured during all these years and has been supported by different institutions and authors, having, maybe, the maximum exposure by the famous document supported by the US Secretary of Health in 1996, "Physical Activity and Health: Report of the Surgeon General." Since then, this landmark review of research on physical activity and health has been the basis for public policies in many countries [11].

Physical activity has four dimensions, which are type of activity, frequency, duration, and intensity of performing activity, and four domains, which are leisure, occupation, transport, and housework. Physical activity can either be classified as structured or incidental [12]. The first one can be considered exercise which is planned, with purpose, and promotes health. The incidental physical activity is not planned and usually is the result of daily activities at work and home or during transport [13].

There is another related term that has been frequently used to describe the physical activity type such as aerobic physical activity in which the body's large muscles move in a rhythmic manner for a sustained period of time. Aerobic activity, also called endurance activity, improves cardiorespiratory fitness. Examples include walking, running, swimming, and cycling. Based on the intensity of the activity, it can be classified as low, moderate, and vigorous physical activity (Table 33.2).

Table 33.2 Resume of physical activity classification based on METs, VO2máx, FCM, PSE, and intensity [9]

Intensity	METs	VO2máx (%)	FCM	PSE (6–20)
Behavior sedentary	<1.5	<37	<57	<9
Light	1.5–3.0	37–45	57–63	9–11
Moderate	3.0–6.0	46–63	64–73	12–13
Vigorous	>6	64–90	77–84	14–17

MET (metabolic equivalent of energy) is a common unit to express exercise intensity. One MET represents the resting energy expenditure during quiet sitting. *VO2max* maximum oxygen consumption, *FCM* maximum heart rate, *PSE* subjective perception of stress

Physical activity intensity is conceptualized as the rate of physical work performed by an individual and is expressed in terms of resting metabolic equivalents (METs). Maximal MET capacity is not certainly important by itself but becomes important when one considers the relative cost of a task or activity. Low physical activity includes light activities such as all incidental movements between >1.5 METs and < 3 METs; moderate physical activity (≥3–6 MET's); and intense or vigorous activity >6 MET's [14]. The greatest benefit of regular physical activity is the increase in physical work capacity (PWC), which is defined as the maximal rate at which a person can expend energy. On the other hand, physical inactivity is insufficient to meet current physical activity recommendations [15] (Table 33.2).

Exercise

It is a subcategory of physical activity where the activity is planned, structured, and repetitive, with the primary purpose of improving or maintaining physical fitness, physical performance, or health. "Exercise" and "exercise training" frequently are used interchangeably. Another used term is nonexercise activity thermogenesis (NEAT), which represents those activities of daily living other than exercise per se and includes such activities as sitting, standing, walking, and fidgeting [16].

Physical Fitness

Physical fitness has been defined as the ability to carry out a daily task with vigor and alertness, without undue fatigue

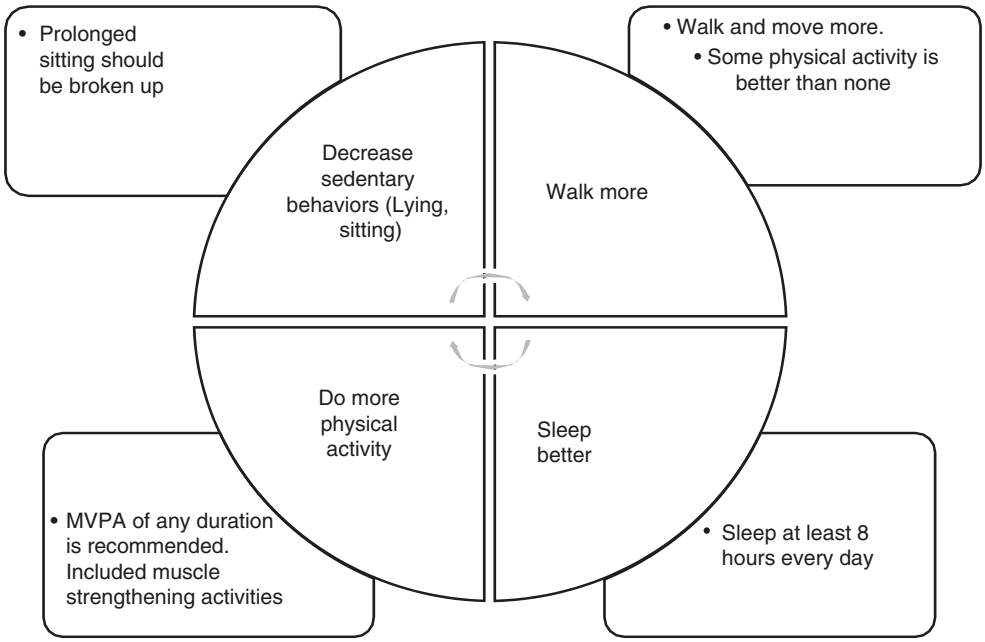

Fig. 33.1 Recommendations for physical activity/exercise in individuals with diabetes mellitus

and with ample energy to enjoy leisure-time pursuits and to meet unforeseen emergencies." The health-related components of physical fitness are (1) cardiorespiratory endurance, (2) muscular endurance, (3) muscular strength, (4) flexibility, and (5) body composition [11].

Sedentary Behavior

Sedentary behavior is considered as any activity that has an energy expenditure lower than 1.5 METs such as sitting, reclining, or lying posture (Tremblay, 2017). A group of experts sustains that sedentary behavior has an independent and qualitatively different effect on human metabolism, physical function, and health outcomes [16].

Physical Inactivity

Physical Inactivity is defined as noncomplying with the minimum international recommendations for PA for the health of the population [7].

As we can see, there are different concepts that are defined by energy expenditure or as a behavior (Fig. 33.1). All this terminology can be revised more profoundly at the "Terminology Consensus Project Sedentary Behavior Research Network" (SBRN) [17].

Evidence of Benefits of Physical Activity and Exercise on Diabetes Mellitus

This section addresses the benefits of physical activity and exercise related to metabolic, enzymatic, mitochondrial, endothelial, immunological, and mental disorders related to diabetes mellitus. Table 33.3 shows the different types of exercise (aerobic and resistance) that has found greater evidence to counter or reduce the incidence of complications from diabetes.

Aerobic and anaerobic exercise have positive effects in most metabolic parameter and in cardiovascular risk factors [25, 33, 34]. Some of the benefits are related to blood glucose control and HbA1c control (evidence level A), lipid profile improvement, reduction of systolic and diastolic blood pressure, reduction of body weight (level B) and adiposity [35], and lower total mortality rate (evidence C) [36, 37]. Recently, evidence shows that regular exercise can work as an antioxidant and as an anti-inflammatory factor [38, 39].

In the last years, resistance training has been shown to be beneficial in the metabolic management of the patient [40]. According to the American College of Sports Medicine, the recommendation is to perform muscle work (resistance exercise) consistently [41] (Table 33.4).

Another important benefit that has been shown is in the reduction of postprandial hyperglycemia, which is highly associated with complications of DM. Also, there is evidence that increasing exercise intensity has a higher reduction on blood glucose levels after meals [42] (Table 33.5).

Table 33.3 Summary of the main alterations and effects of diabetes in the body, as well as the benefits of physical activity and the type of exercise recommended

Type of exercise	Disorders	Effects of disorders	Benefits of physical activity and exercise on alterations	Evidence of benefits of physical activity and exercise
	Enzymatic			
Resistance	PFK1 –M deficiency	The deficiency of the enzyme PFK1 M leads to alterations in the action or secretion of insulin, which can be a risk factor for developing diabetes mellitus [18].	The adoption and maintenance of PA are important aspects for the control of glucose, the action of insulin and the reduction of risk of developing DM [19].	Qadir, et al. (2021). Effectiveness of resistance training and associated program characteristics in patients at risk for type 2 diabetes: a systematic review and meta-analysis.
Aerobic	Glycogen synthase (GS)	People with IR have shown an alteration in insulin signaling and a reduction in glycogen synthase, affecting muscle glycogen synthesis [19].	Exercise promotes an increase in GS affinity for glucose [20].	Jensen, et al. (2013). Effect of acute exercise on glycogen synthase in muscle from obese and diabetic subjects.
	Metabolic			
Aerobic	Hyperglycemia	Chronic exposure of cells to high glucose levels favors the development of microvascular conditions in the patient [21].	Muscle contraction increases insulin-independent glucose uptake through the translocation of GLUT-4 to sarcolemma and T tubules [22].	Gao, et al. (2021). The therapeutic effects of mild to moderate intensity aerobic exercise on glycemic control in patients with type 2 diabetes mellitus: A meta-analysis of randomized trials
Aerobic	Insulin resistance	Insulin resistance (IR) alters the elimination of glucose, resulting in a compensatory increase in insulin and hyperinsulinemia. In addition, IR increases metabolic changes as dyslipidemia, arterial hypertension and endothelial dysfunction [23].	The sustained activation of AMPK, GS, increased expression of GLUT-1, GLUT-4 and hexokinase II, facilitate the resintesis of muscle glycogen by glucose uptake and by insulin sensitivity [21].	Tarabi et al., (2015). The Effect of 8 Weeks Aerobic Exercise on Insulin Resistance in Type 2 Diabetes: A Randomized Clinical Trial
Aerobic	Metabolism of lipoproteins	Increase in triglycerides and reduction in high-density lipoprotein (HDL), increasing the risk of dyslipidemia [24].	Exercise increases the ability of skeletal muscle to use lipids as an energy source instead of glycogen. In addition, it has been shown that aerobic PA increases HDL levels, affecting the reduction of developing dyslipidemia [25, 26].	Wang et al. (2017). Effects of aerobic exercise on lipids and lipoproteins.
	Mitochondrial functions			
Aerobic	Formation of reactive oxygen species (ROS)	Oxidative stress in the blood vessels and beta cells of the pancreas. Accumulation of mitochondrial damage promotes the aging process and affects the beta cells of the pancreas resulting in insufficient insulin synthesis [21].	Exercise-induced ROS generation results in increased activity of antioxidant enzymes (SOD, catalase glutathione peroxidase) and nonenzymatic antioxidants (coenzyme Q10, glutathione, lipoid acid), which subsequently lead to increased resistance to oxidative stress [27].	Simioni et al. (2018). Oxidative stress: role of physical exercise and antioxidant nutraceuticals in adulthood and aging
	Endothelial			
Aerobic	Vascular injury	Circulating endothelial cells facilitate the formation of atherosclerotic plaques due to the high flow of free fatty acids in insulin-resistant tissues. This condition is considered a risk factor for the development of macrovascular conditions [21].	It improves vascular function, including the production and bioavailability of endothelium-derived substances such as NO, which are antiatherogenic. Exercise also influences arterial structure, including external remodeling that increases the arterial diameter [28].	American Diabetes Association. (2016). Physical activity/exercise and diabetes: A position statement of the American Diabetes Association
	Immunological			

Table 33.3 (continued)

Type of exercise	Disorders	Effects of disorders	Benefits of physical activity and exercise on alterations	Evidence of benefits of physical activity and exercise
Aerobic	Inflammatory markers	Chronic inflammation favors the presence of inflammatory markers (IL-1, IL-2, IL-12, IL-18, TNF-α) decreases the action of NK cells and the expression of antioxidant genes. Which results in the patient with DM being more susceptible to getting sick [21, 29].	It stimulates the secretion of anti-inflammatory cytokines IL-10 and TGF-β, responsible for inhibiting inflammatory cytokines. There is also an increase in leukocytes, neutrophils, killer natural cell, and lymphocytes [27].	Nieman, et al. (2020). Exercise immunology: Future directions. Da Silveria et al., (2020). Physical exercise as a tool to help the immune system against COVID-19: an integrative review of the current literature
	Mental			
Aerobic	Depression	People with DM have recorded a lower value of brain-derived neurotrophic factor (NFBD), which may be a factor in the development of neurovascular conditions. In addition, it has also been correlated between decreased BDNF and depression [30, 31].	PA optimizes the level and function of the neurotransmitter system (e.g., glutamate, GABA, serotonin, dopamine, and noradrenaline) in turn, changes in neurotransmission mediate changes in the expression of the BDNF gene in various regions of the brain (e.g., hippocampus, nucleus accumbens, and amygdala) [32]	Phillips et al., (2017). Brain-Derived Neurotrophic Factor, Depression, and Physical Activity: Making the Neuroplastic Connection.

Table 33.4 Abbreviations

DM	Diabetes mellitus
PFK1–M	Phosphofructo-1-kinase/muscle subtype in humans.
PA	Physical activity
IR	Insulin resistance
GS	Glycogen synthase
SOD	Superoxide dismutase
NO	Nitric oxide
IL-1	Interleukin-1
IL-2	Interleukin-2
IL-12	Interleukin-12
IL-18	Interleukin-18
TNF-α	Tumor necrosis factor alpha
NK cells	Natural killer cells
TGF-β	Transforming actor of beta growth
NFBD	Brain-derived neurotrophic factor
GABA	Gamma-aminobutyric acid

Table 33.5 Summary of the evidence of the percentage of changes and benefits of exercise in the different metabolic, cardiovascular mortality in individuals with diabetes mellitus

Component	Effect	Level of evidence
Blood glucose control	(a) Aerobic exercise: Decreases blood glucose 57 mg/dL (b) Resistance: Decreases blood glucose 10 mg/dL	A
HbA1C control	(a) Aerobic exercise: Decreases HbA1c between 0.4 to 1.2% (0.66% average). (b) Resistance exercise: Decreases HbA1c 0.3%. (c) Combined: Decreases HbA1c 0.34%.	A

Table 33.5 (continued)

Component	Effect	Level of evidence
Serum lipid profile	(a) Aerobic exercise: Decreases total cholesterol from 23 mg/dL a 0; LDL decreases from 14 mg/dL a − 1.1 mg/dL with a 6.4 mg/dL average; HDL increases 5 mg/dL or an increase compared with basal of 12%; triglycerides showed no change (b) Resistance exercise: Total cholesterol decreased 3 mg/dL; LDL decreased 6 mg/dL; HDL increased 1 mg/dL	B
Reduction of SBP and DBP	(a) Aerobic exercise: SBP decreases in average 19 mmHg. DBP decreases 8 mmHg. (b) Resistance exercise: SBP decreases an average of 20 mm hg. DBP decreases 13 mmHg.	B
Reduction of body weight, primarily body fat	(a) Performing 1 hour of moderate aerobic exercise reduces body fat [7, 16]; individuals who maintain weight loss for at least 1 year typically perform approximately 7 hours per week of moderate to vigorous exercise intensity	B
Reduction of mortality	(a) It has been shown that exercise is associated with a 1% reduction of HbA1c levels; this is associated with a decreased risk of cardiovascular events in 15–20% and 37% of microvascular events due to this; exercise could reduce mortality by these events Observational studies suggest that the greater the physical activity, the lower the risk of global mortality. Additionally, exercise improves cardiopulmonary efficiency and physical and mental health	C

The Importance of the Intensity Levels of Activities/Exercise in Patients with Diabetes Mellitus

Physical activity intensity (low, moderate, and vigorous) is an essential variable on exercise prescription to improve specifics health and physical fitness parameters (2). Table 33.6 shows the principal criteria and the used definitions to categorize each intensity.

Low Intensity

Low intensity activities are considered as the one that expend between 1.5 to 3 METS. There is strong evidence of an inverse dose-response relationship between physical activity and the risk of type 2 diabetes. Risk reductions are observed with up to 5–7 hours of low-intensity physical activity and leisure time [43].

Is important to mention that replacing 30 minutes of sedentary behaviors with the same amount of time with low level intensity activities has an association with the reduction from 6% to 31% risk of DM2 [44].

Moderated Intensity

Moderate intensity physical exercise stimulates cellular immunity through the secretion of anti-inflammatory cytosins such as IL10 and TGF-β, responsible for inhibiting inflammatory cytosine. There is also an increase in leukocytes, neutrophils, natural killer cells and lymphocytes [27, 29].

Table 33.6 Intensity of activities in patients with Diabetes Mellitus

Intensity	MET	Activities
Low	1,6 a < 3	*Recreational cycling 6 mph *Home activities (dusting, straightening up, changing linen, carrying out trash) *Car wash and wax *Hatha yoga *Stretching exercises
Moderate	3 a < 6	*Lawn mowing *Running 4mph *Golf *Walk with the dog *Swimming
Vigorous	6 a < 9	*Running 5mph *Play basketball *Play tennis *Mountain biking *Fitness classes

Table 33.7 FITT for people with diabetes

	Aerobic	Anaerobic resistance	Anaerobic resistance
Frequency	3–7 days a week.	2–3 days a week.	≥2–3 days a week.
Intensity	Moderate to vigorous*	Moderate to vigorous*	Slight discontent
Time	150 min/week at moderate to vigorous intensity.	1 to 3 series of 10 to 15 repetitions. 8 to 10 exercises.	8–10 exercises with 1–3 series of 10 to 15 repetitions
Type	Activities using large muscle groups.	Body weight, resistance bands, or resistance machines	Static or dynamic
Suggestions for safe practice of exercise	Monitor your blood glucose level before and after the exercise session. Avoid muscle contractions or physical work in the body area where insulin has been given. Avoid physical activity in the afternoon or evening, or with the peak of action of the medication. Doing exercise with someone else. Stay hydrated.		

* Moderate aerobic intensity 64% to 73% maximum heart rate
* Vigorous aerobic intensity 77% to 84% maximum heart rate
* Moderate anaerobic resistance 50–60% 1 RM
* Vigorous anaerobic resistance 70–85% 1 RM

Vigorous Intensity

High-intensity exercise in the HIIT modality has been shown to reduce hyperglycemia and postprandial hyperglycemia in patients with type 2 diabetes mellitus [45]. It also increases metabolic health [46].

Physical Activity Recommendations for People with Diabetes

The recommendations for the diabetic patient on physical activity and exercise are the ones proposed by the American College of Sports Medicine [47] and are summarized in Table 33.7.

But what do we have to recommend? This is an important question that has to be answered based on main principles: first, people have to move more; second, they need to be more active; third, they have to decrease their sedentary behaviors, and eventually, they will be able to improve their fitness by doing more exercise, control their diabetes, and perform a sports activity. In summary, we cannot run if we cannot learn to walk first. The secondary principle would be that the practice of physical activity should be a joy, a real desire to do it for pleasure, or a well-being that causes it and what is associated. Therefore, physical activity recommendations should not be considered as something mandatory to comply instantly and not a rule for all goals [7].

Based on this argument, all the recommendations of physical activity particularly in individuals with diabetes should promote healthy lifestyles, wellness (physical, emotional, social, intellectual, spiritual, occupational), improved fitness [48], improved functionality, and quality of life (QOL) [49], but also, we should limit physical inactivity [8], avoid sitting for a prolonged time [50], walk more [51], and sleep better (Fig. 33.1).

Note: Adapted from the recommendations of the 24 hours of movement (in Tremblay, MS., et al. "Canadian 24-hour movement guidelines for children and youth: an integration of physical activity, sedentary behaviours, and sleep." *Applied Physiology, Nutrition, and Metabolism* 41.6 (2016): S311–S327: and adjusted to the recommendations for adults from the WHO 2020. (In:Bull, FC., et al. World Health Organization 2020 guidelines on physical activity and sedentary behaviours. British journal of sports medicine, 2020, vol. 54, no 24, p. 1451–1462.

Counseling, the Five A's, and Motivational Interviewing

How to prescribe exercise in people living with diabetes? Caring for the individual with diabetes mellitus through the prescription of exercise has been reported to achieve metabolic control and limit the development of macro- and microvascular complications [52]. Besides, this, studies suggest the need for a larger volume of physical activity for decreasing the cardiovascular risk factors of patients with diabetes. In this situation, prescribing the correct dose of exercise becomes necessary [53]. An exercise prescription consists of mode (type), frequency, intensity, duration, and progression. Determining the appropriate mode depends upon patient preference and safety issues regarding the state of T2DM or other conditions. Frequency, intensity, and duration are specific to the type of activity and should be tailored to the patient's abilities to perform the activity safely. The health professional should address periodic progression to maintain the exercise stimulus needed to promote continued health improvements and prevent "plateauing." Based on the current scientific research [54, 55], this chapter proposes recommendations that enable healthcare professionals to advocate for their patients with T2DM by offering safe and effective treatment options and decreasing the noncompliance to exercise recommendations. It is necessary to use a systematic process in the care and management of individuals with diabetes. Evidence shows that lifestyle counseling in primary care is strongly associated with rapid control of glycosylated hemoglobin, blood pressure, and lipid profile [56]. The clinical evaluation to prescribe that the patient with diabetes mellitus first complies with the recommendations of physical activity and then with indicating physical exercise with the intention of improving their metabolic control, reducing risks for exercise, and adapting their limitations requires a systematic process that helps us cover all these aspects. The concept of formed exercise prescription was previously defined to have the following components: written, structured advice on exercise with details of frequency, intensity, type, timing, and progression [57] (Table 33.8).

Table 33.8 Wellness screening for physical activity and exercise recommended in patients with DM. Note: Based and adapted from ACSM's Guidelines for Exercise testing and Prescription. American College of Sports Medicine. 7th edition. 2006

Characteristic	Results
Lifestyle assessment • Use of drugs, tobacco, alcohol, • Sleep. • Leisure activities. • Moving activities. • Mental health. • Physical activity patterns and sedentary behaviors. • Assessment of perceptions about nutrition and physical activity (from 1 to 10: How important is the physical activity for your health? And how important is for you to be active everyday?	
Levels of physical activity and energy expenditure • Assess the level of physical activity with the IPAQ questionnaire (IPAQ, international physical activity questionnaire), • Calculation of energy expenditure (intake/expenditure).	
Risk for physical activity • PAR-Q the physical activity readiness questionnaire for everyone. • Risk presence questionnaire. • Applying the ACSM preparticipation screening algorithm.	
Physical activity (PA) behaviors • Behavior change level or stage questionnaire. • Self-efficacy and self-determination for PA, • Barriers and facilitators to physical activity.	
Medical • Postural angles of skeletal structure. • Body composition nutritional status. • Laboratory profile (kidney function, visual capacity, EKC electrocardiogram, dysautonomic complications).	

Because one of the most frequent complications in individuals with DM is cardiovascular complications, it is important to apply the algorithm of recommendations for exercise preparticipation health screening of the American College of Sports Medicine ACSM [58].

A systematic method of approaching the patient with diabetes is required to prescribe exercise safely. One of the practical processes to perform the proper prescription of the exercise is to apply to counsel using the five A's (Fig. 33.2). Studies show that educating the patient through counseling is effective but will depend on who performs it and how they perform it [59]. Counseling is defined as the methodical and systematic process to change from behaviors to healthy behaviors in individuals.

The objective of applying the counseling is to comply with goals. This process determines the patient's proposed goals, which are defined by the clinical evaluation findings.

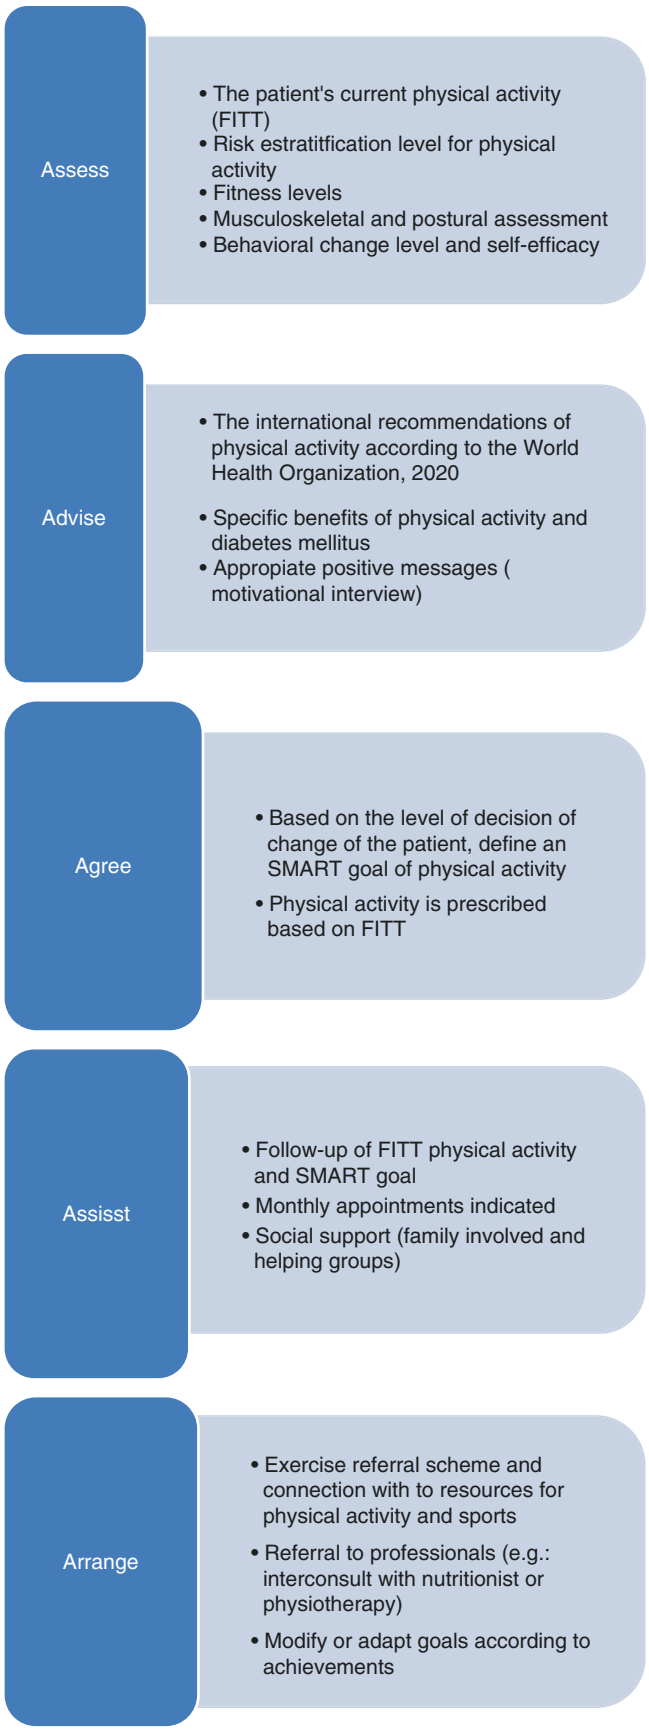

Fig. 33.2 Elements of physical activity counseling using the five A's model and emphasized the SMART goals (acronym of Specific, Measurable, Achievable, Reliable, and Time-bound) and FITT characteristics of physical activity: (Frequency, Intensity, Type, and Time of exercise or physical) activity. Note: Adapted from the five A's by Glasgow RE, Emont S, Miller DC. Assessing delivery of the five "As" for patient-centered counseling. Health Promot Int. 2006;21(3):245–55. The description of each A is adapted from: Meriwether RA, Lee JA, Lafleur AS, Wiseman P. Physical activity counseling. Am Fam Physician. 2008;77(8)1029–1136

The process to set these goals is known as SMART Goals, an acronym for Specific, Measurable, Achievable, Realistic, and Timely.

Experiences tell us that the approach of the individual with diabetes is to work with the behaviors and can be based on the motivation to exercise or be more active. One of the techniques that work for behavior change is motivational interviewing (MI). At primary care, it can be a motivational strategy for the individual to achieve effective changes in their control. Besides this, the purpose of MI in individuals with diabetes is to understand the reasons patients have to address their physical inactivity and build and strengthen their motivation to change this aspect. Why it has worked in diabetes management is because it is recognized that MI is patient-centered and establishes that behavior change is the patient's responsibility, is influenced by the motivation it receives, and by the beneficial changes it is presenting [60, 61].

Finally, exercise prescription activities through support groups are also equally effective for the metabolic control of patients since the influence of others with the same condition strengthens healthy behaviors. In addition, in the group activities, educational and exercise workshops have been applied that favor the control of the disease. In this sense, the workshop occupies a predominant role as a precursor of behavioral changes. A workshop is defined as a work methodology that integrates theory, technique, and practice, in which the three elements mentioned are fed back and improved continuously. It is a modality where the theoretical and technical knowledge acquired is applied consciously and assimilates relevant concepts and principles that put them into practice. In summary, the workshops are an important alternative that allows a closer insertion in the real world [62, 63].

We can summarize that exercise counseling can have many steps, which can help to approach the person con diabetes.

Exercise in the Presence of Specific Long-Term Complications of Diabetes

Diabetic Retinopathy The patients with retinopathy should be screened to have a well-defined stage of the disease from nonproliferative (NPDR) to proliferative (PDR) degeneration. With patients with NPDR, we should avoid physical activities that can dramatically increase blood pressure, such as powerlifting. On the other hand, patients with PDR should avoid vigorous aerobic or resistance exercise because of the risk of triggering vitreous hemorrhage or retinal detachment; we must avoid vigorous exercise; jumping, jarring and head-down activities, and breath holding [64]. By other hand, breathing exercises are highly recommended.

Peripheral Neuropathy Decreased pain sensation in the extremities results in an increased risk of skin breakdown and infection and of Charcot joint destruction. This is why some prior recommendations have advised nonweight-bearing exercise for patients with severe peripheral neuropathy. Regular aerobic exercise may also prevent the onset or delay the progression of peripheral neuropathy in both type 1 and type 2 diabetes. Studies have shown that moderate-intensity walking may not lead to an increased risk of foot ulcers or re-ulceration in those with peripheral neuropathy [65]. Physical activities like swimming, cycling, chair exercises, arm exercises, and everything that does not require the feet are the most recommended in these patients (moderate weight-bearing exercise). Proper care of the feet is needed to prevent foot ulcers and lower the risk of amputation; keep feet dry and use appropriate footwear, silica gel or air midsoles, and polyester or blend socks (not pure cotton); **Autonomic neuropathy** can increase the risk of exercise-induced injury or adverse events through decreased cardiac responsiveness to exercise. Autonomic neuropathy is also strongly associated with cardiovascular disease in people with diabetes. The patient's symptoms are postural hypotension, impaired thermoregulation, impaired night vision due to impaired papillary reaction, and unpredictable carbohydrate delivery from gastroparesis predisposing to hypoglycemia, which should be recognized before you recommend exercise. People with diabetic autonomic neuropathy should be screened and should receive physician approval and possibly an exercise stress test before embarking on physical activity levels more intense than usual because this may cause postural hypotension, chronotropic incompetence, delayed gastric emptying, altered thermoregulation, and dehydration during exercise. Low-intensity exercises that do not modify blood pressure such as water activities, stationary bike, and seated exercises are some physical activity recommendations. Patients with postural hypotension must avoid activities with rapid postural or directional changes to prevent fainting or falling. Cardiac autonomic neuropathy patients should have a physician approve and possibly undergo symptom-limited exercise testing before exercise. Patients with blunted heart rate response use heart rate reserve and ratings of perceived exertion to monitor exercise intensity. In general, autonomic neuropathy people should avoid exercise in hot environments and hydrate well [66, 67].

Chronic Kidney Disease Physical activity can acutely increase urinary protein excretion. Vigorous exercise should be avoided the day before urine protein tests are performed to prevent false-positive readings [2]. Both aerobic and resistance training improve physical function and quality of life in individuals with kidney disease, all activities can be beneficial, but exercise should begin at a low intensity and vol-

ume if aerobic capacity and muscle function are substantially reduced; avoid exercises that sharply increase blood pressure: violent physical activities, Valsalva maneuvers, and lifting weights.

Exercise increases physical function and quality of life in individuals with kidney disease. Supervised, moderate aerobic physical activity undertaken during dialysis sessions may be beneficial and increase compliance. We must emphasize hydration and blood pressure control; electrolytes should be monitored when exercise is done even more during dialysis sessions [68].

Cardiovascular Diseases We can include some diseases in this category like coronary artery disease, exertional angina, hypertension, myocardial infarction, stroke, and peripheral artery disease. For coronary artery disease, coronary perfusion may actually be enhanced during higher intensity aerobic or resistance exercise; all physical activities are okay; consider exercising in a supervised cardiac rehabilitation program, at least initially. Congestive heart failure is most commonly caused by coronary artery disease and frequently follows a myocardial infarction. In this scene, the recommendation is to avoid activities that cause an excessive rise in heart rate and focus more on doing low or moderate-intensity activities. In Peripheral artery disease, lower extremity resistance training improves functional performance; low or moderate-intensity walking, arm ergometer, and leg ergometer preferred as aerobic activities are recommended [69].

Summary

- Patients with possible cardiovascular (CV) disease, microvascular, neuropathy, or nephropathy complications and should undergo a medical evaluation, which will include medical history, physical examination (including eye screening examination, foot examination, and neuropathy detection), resting EKG and possibly stress test.
- The stress exercise test should be performed in all patients considered with high risk for CV disease and for the dose of exercise prescription, for risk stratification, to detect silent coronary disease and to detect abnormal hypertensive responses.
- It is highly recommended to give a follow-up of the diabetes complications.

Part VI

Drug Therapy

The "Old" Oral Antidiabetics

34

Ingrid Mühlhauser, Susanne Buhse,
and Joel Rodriguez-Saldana

Introduction

Treatment of patients with type 2 diabetes aims to avoid acute symptoms of hyperglycemia and to prevent macro- and microvascular complications. In recent years, the number of glucose-lowering drugs increased to unprecedented levels. The American Diabetes Association (ADA) lists seven drug classes of available glucose-lowering agents in the last edition of their standards of medical care in diabetes [1]. All are proven to decrease HbA1c-levels or postprandial glucose excursions, but evidence on patient-relevant outcomes, such as cardiovascular mortality, amputations, or retinopathy, is sparse. Reduction of HbA1c-values is often used as a surrogate outcome measure to assess the efficacy of antidiabetic medication. However, its appropriateness has been disproven [2, 3]. In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study [4, 5] and the Veterans Affairs Diabetes Trial (VADT) [6, 7], a rigid treatment regime with low HbA1c-targets did not result in better patient-relevant outcomes. Patients in the intervention arm of the ACCORD study even had a higher risk of mortality, and consequently, the study was terminated earlier [4]. Other drugs have been withdrawn from the market because of a negative benefit-risk ratio, for example, phenformin, which increased the risk of lactic acidosis or rosiglitazone that reduced HbA1c-values but increased cardiovascular risk [8]. In recent years, pharmaceutical companies decided to withdraw several new antidiabetic agents from the German market, such as vildagliptin and canagliflozin, because no additional benefit over usual care could be demonstrated and therefore health insurances would not have covered additional costs.

In 2012, the ADA and the European Association for the Study of Diabetes (EASD) recommended patient-centered care including shared decision-making (SDM) [9] and reasserted this position in further statements [10]. SDM is a particular form of communication between patients and their health care professionals. It focuses on the mutual exchange of information in order to involve patients in the decision-making process [11]. Therefore, patients need understandable information on probabilities of benefits and harms of treatment options [12–14]. The question to be answered is, what option is the best to prevent diabetes-related complications and yet in line with individual patient values and preferences? Supportive tools in that process are patient decision aids, which help patients to weigh up pros and cons of diabetes treatment [15, 16].

This chapter gives an overview of older classes of antidiabetic agents and their efficacy. It is based on a systematic inventory published in 2015 and updated in the first edition of The Diabetes Textbook [2]. Sulfonylureas (SU) and biguanides are the oldest classes of oral glucose-lowering agents. Later, thiazolidinediones (TZDs), alpha glucosidase inhibitors (AGIs), and meglitinides were approved. Table 34.1 shows the old drug classes and their compounds that are still available in the United States or Europe. Newer classes, such as sodium-glucose cotransporter 2 (SGLT-2) inhibitors and dipeptidyl peptidase-4 (DPP-4) inhibitors, will be described in other chapters of this book.

According to recent guidelines [1, 7, 14, 17], this chapter focuses on the efficacy of metformin and SU monotherapies compared with other monotherapies as well as comparisons of metformin-based combinations. At the end of this chapter, we give an example of our decision aid for patients with type 2 diabetes and how diabetes educators share evidence-based information with their patients [18–20].

Table 34.1 Overview of older classes of antidiabetic agents[a]

Class	Compounds[b]	Mechanism of action
Biguanides	• Metformin	Multiple sites of action. Not fully understood. Increase of insulin sensitivity by increasing peripheral glucose uptake, decrease of intestinal glucose absorption, and decrease of hepatic glucose production
Sulfonylureas (SU), second and third generation	• Glyburide (Glibenclamide) • Glimepiride • Glipizide • Gliclazide	Stimulation of insulin release in pancreatic beta cells. Decrease in hepatic clearance of insulin. Additional extra-pancreatic mechanisms of actions have been described
Thiazolid-inediones	• Pioglitazone • Rosiglitazone (withdrawn from many markets)	Reduction of insulin resistance in target cells through transcription of several genes involved in glucose and lipid metabolism
Alpha glucosidase inhibitors (AGI)	• Acarbose • Miglitol	Inhibition of alpha-glucosidase, which delays intestinal degradation of complex carbohydrates and thus prolongs post-prandial glucose absorption
Meglitinides	• Nateglinide • Repaglinide	Stimulation of insulin release in beta cells. Rapid acting stimulation. Weaker binding affinity and faster dissociation than SU

[a]Adapted from [2]
[b]Available in Europe (EMA) or the US (FDA) [1]

Methods

We updated our search from April 2014 [2]. In a first step, we searched PubMed and the Cochrane library for systematic reviews and meta-analyses published from May 2014 to the end of November 2021. Systematic reviews were considered if they included randomized controlled trials on the efficacy of metformin, sulfonylureas, thiazolidinediones, meglitinides, or alpha-glucosidase inhibitors as monotherapy or combination of two or three drugs. There is a growing number of network analyses. They typically comprise indirect comparisons when there is no head-to-head comparison available. Network analyses are methodologically challenging and can lead to false results and interpretations if differences between studies were not adequately considered [21]. Treatment of type 2 diabetes is complex, and as a result, RCTs in meta-analyses are usually heterogeneous. We therefore excluded network meta-analyses. In addition, inclusion criteria, such as study duration, sample size, target group, and drug classes, vary between systematic reviews. Hence, following our previous methodological approach [2], we extracted RCTs from the reviews that fulfilled our inclusion criteria: (1) patient-relevant primary endpoint, that is, macro- and microvascular complications, cardiovascular mortality, total mortality, and quality of life; (2) intention-to-treat analysis; (3) follow-up of at least 24 weeks and adequate sample size; and (4) hard clinical endpoints that had to be reported. Finally, we searched for further studies and screened the websites of the National Institute for Health and Care Excellence (NICE), the Agency for Healthcare Research and Quality (AHRQ), and the German Institute for Quality and Efficiency in Health Care (IQWIG) for new reports and guidelines.

Results

The search update for systematic reviews and meta-analyses resulted in 516 records. Most of them were network analyses. Although the Food and Drug administration (FDA) and the European Medicines Agency (EMA) changed licensing regulations toward cardiovascular outcome trials for glucose-lowering drugs in 2008, reviews mainly focused on surrogate endpoints, such as HbA1c-level. We identified one systematic review on the efficacy of metformin compared to no intervention, placebo, or lifestyle intervention [22], a meta-analysis comparing metformin and SU as monotherapy [23], a systematic review and meta-analysis to assess the effectiveness and safety of the addition of metformin to standard insulin therapy in children with type 1 diabetes aged 6–19 years [24], and an umbrella review of systematic reviews with meta-analysis to assess the efficacy and safety of metformin [25]. Regarding sulfonylureas, we identified two randomized clinical trials comparing glimepiride with dipeptidyl peptidase -IV inhibitors (DPP-IVi): a multicenter, randomized controlled trial to compare the efficacy and safety of glimepiride with saxagliptin in patients with type 2 diabetes inadequately controlled with metformin [26] and a randomized controlled trial comparing the effect of treatment of glimepiride versus linagliptin on cardiovascular safety in patients with type 2 diabetes [27]. With respect to sodium-glucose co-transporter-2 inhibitors (SGLT2i), we identified a randomized controlled trial comparing the efficacy and safety of empagliflozin in patients with type 2 diabetes inadequately controlled on metformin [28] and a randomized controlled trial comparing the efficacy and safety of glimepiride versus ertugliflozin in patients with type 2 diabetes inadequately controlled with metformin [29]. Four trials evaluated the effects of TZDs [30–33]. Systematic reviews about the effectiveness and safety of alpha-glucosidase inhibitors and meglitinides could not be identified. Regarding overall comparisons, a systematic review assessed the efficacy of eight classes of diabetes medications including metformin, sulfonylureas, and alpha-glucosidase inhibitors [34]; two meta-analyses by the Agency for

Healthcare Research and Quality (AHRQ) evaluating all available glucose lowering drugs [35, 36]; a meta-analysis involving 301 clinical trials to assess the efficacy and safety of all classes of oral and injectable antidiabetics, including insulin [37]; and a systematic review including 453 trials comparing the efficacy and safety of nine classes of antidiabetics including monotherapies, add-on to metformin-based therapies and monotherapies versus add-on to metformin therapies [38]. This report includes RCTs and observational studies on (1) comparisons of monotherapies (metformin, thiazolidinediones, sulfonylureas, DPP-4 inhibitors, SGLT-2 inhibitors, and GLP-1 receptor agonists), (2) comparisons of metformin alone and metformin-based combinations, and (3) comparisons of metformin-based combinations where the second drug was one of the monotherapies or insulin treatment. The evidence was graded separately for both study types. The AHRQ search update was performed through December 2016. Our search for more recent RCTs from January 2016 to November 2021 yielded 310 records.

Metformin

Metformin belongs to the class of biguanides. It is the only still licensed compound of its class after phenformin was withdrawn from the markets. In the University Group Diabetes Program (UGDP) [39, 40], the first large RCT that evaluated the efficacy of glucose lowering drugs on macro- and microvascular outcomes, phenformin, was associated with an increase of cardiac mortality. In contrast, metformin is internationally recommended as initial drug treatment for people with type 2 diabetes [1, 9, 17, 29, 30]. This is mainly based on the results of the UK Prospective Diabetes Study (UKPDS), published in 1998 [41]. About 4000 patients with newly diagnosed type 2 diabetes were enrolled in this RCT. The study objective was to assess the efficacy of intensive blood glucose-lowering therapy compared to conventional treatment (primarily with diet). Patients in the intensive treatment group were supposed to achieve a fasting plasma glucose level of less than 6 mmol/L. The fasting plasma glucose target of the conventional treatment arm was less than 15 mmol/L with no symptoms of hyperglycemia. Non-overweight patients were randomly assigned to intensive treatment with insulin, intensive treatment with sulfonylureas, or conventional therapy with diet. A subgroup of overweight patients had the additional possibility to be randomized to intensive treatment with metformin [41, 42]. A total of 342 patients were assigned to metformin and 411 patients to conventional control with diet [43].

The median HbA1c-level of the intensive treatment group with metformin was 7.4% during the 10 years of follow-up. The conventional group had a median HbA1c-level of 8.0%. Compared to conventional treatment, patients in the metformin monotherapy arm showed significant reductions in *any diabetes-related endpoint*, a composite endpoint comprising the following outcome measures: sudden death, death from hyperglycemia or hypoglycemia, fatal or nonfatal myocardial infarction, angina, heart failure, stroke, renal failure, amputation of at least one digit, vitreous hemorrhage, retinopathy requiring photocoagulation, blindness in one eye, or cataract extraction. Moreover, *diabetes-related death*, *all-cause mortality*, and *myocardial infarction* significantly decreased in the intensive treatment group with metformin.

Based on these results, metformin became the first-line drug for patients with type 2 diabetes who do not achieve their HbA1c target with diet and other lifestyle interventions alone. However, the results of the UKPDS have not yet been reproduced [2, 44]. The UKPDS was a study with an open-label design, which may lead to overestimated results. The protocol was changed during the study. The initially defined significance threshold of 1% was later changed to 5%. The significant difference in reduction of total mortality and myocardial infarction in the metformin group was above the threshold of 1% [44].

Antihypertensive treatment or statins may have a greater effect on mortality than metformin [45]. This may also explain the results of the UKPDS follow-up study [46], which reported significant reductions in total mortality and cardiovascular mortality for all intensive treatment groups 10 years after the main publication of the UKPDS results. Considering the high risks of bias of the UKPDS, the interpretation of the follow-up results as long-term effect of intensive early glucose control might be misleading [47]. In addition, only about one third of the initially randomized patients were analyzed in the follow-up study.

A meta-analysis that included 13 studies comparing metformin as monotherapy or add-on therapy to diet, placebo, or no treatment found no significant effects on all-cause mortality, cardiovascular mortality, or microvascular complications [48]. Of the included RCTs that assessed patient-relevant outcomes as the primary endpoint [41, 49–51], only UKPDS [41] showed a beneficial effect for treatment with metformin.

In the UKPDS, metformin monotherapy was also associated with a decrease in *any diabetes-related endpoint* and *all-cause mortality* compared to intensive treatment with sulfonylurea or insulin [41]. Data on metformin compared to SU alone were not reported in the UKPDS [23].

The study on the Prognosis and Effect of Antidiabetic Drugs on Type 2 Diabetes Mellitus With Coronary Artery Disease (SPREAD-DIMCAD) [52] compared metformin with the SU glipizide in 304 Chinese people with type 2 diabetes mellitus and coronary artery disease. The targeted HbA1c-level was less than 7% for both groups. The primary endpoint was *recurrent cardiovascular events*, a composite outcome measure comprising nonfatal myocardial infarc-

tion, nonfatal stroke, arterial revascularization, cardiovascular death, and all-cause mortality. The study results showed a significant reduction in this endpoint in favor of the metformin group. However, there is a substantial risk of bias that limits the validity of the study results. The study was retrospectively registered, and there is no study protocol published. Data from 5 years of follow-up were analyzed, but the study drug was only administered for 3 years. It was not reported whether the study treatment was maintained after this time.

A meta-analysis on the effects of SU monotherapy compared to metformin monotherapy did not find any differences between treatment groups regarding all-cause or cardiovascular mortality [23]. A potential benefit of SU over metformin was identified in nonfatal macrovascular outcomes, but definitions of that composite endpoint were heterogeneous. There were no data on microvascular outcomes for a meta-analysis. Results of that meta-analysis were mainly based on "A Diabetes Outcome Progression Trial" (ADOPT), a multicenter, randomized controlled, double-blind trial with 4 years of follow-up [53]. Patients with untreated diabetes were randomized to metformin, glibenclamide, or rosiglitazone. The primary endpoint was *time to treatment failure*, defined as fasting plasma glucose level of more than 180 mg per deciliter after 6 weeks at maximum tolerated dose of the study drug. As this is not a clinical hard endpoint, we excluded this trial from our overview. However, there was no difference regarding all-cause mortality or fatal myocardial infarction between the glibenclamide and metformin groups [23, 53].

Compared to sulfonylureas alone, the combination of metformin and sulfonylureas significantly increased *death from any cause* and *diabetes-related death* in overweight and non-overweight patients in the UKPDS [41]. The meta-analysis by Boussageon et al. [48] confirmed a significant increase in all-cause and cardiovascular mortality for metformin plus SU compared to metformin monotherapy. The results were mainly based on the UKPDS. After excluding this study, no group difference was seen in both endpoints.

The Hyperinsulinemia: The Outcome of Its Metabolic Effects (HOME) trial evaluated the efficacy of metformin in the Netherlands [51]. The RCT included 390 overweight and obese patients with type 2 diabetes. Metformin added to insulin therapy was compared to insulin monotherapy. After about 4 years, there was no difference between groups regarding cardiovascular and total mortality or microvascular outcomes (progression of retinopathy, nephropathy, and neuropathy) but a significant reduction in a combined macrovascular endpoint for patients with metformin plus insulin treatment. This composite endpoint included a total of 13 separate outcome measures, for example, myocardial infarction, heart failure, stroke, diabetic foot, percutaneous transluminal coronary angioplasty, nontraumatic amputation, and sudden death. Patients' characteristics were unequally distributed between the study groups at baseline. For example, in the metformin group, there were fewer smokers (19% vs. 30%) and more patients with antihypertensive medication (47% vs. 39%). In addition, the number of non-completers differed between the metformin plus insulin study arm ($n = 65$) and the insulin alone arm ($n = 48$), mainly because of adverse events.

A systematic review that analyzed RCTs published until February 2017 [22] found similar results regarding the efficacy of metformin. The authors identified no more recent RCTs than earlier meta-analyses, but study selection was not completely transparent. The UKPDS [41] was included in the meta-analysis, but only the combination of metformin and SU compared to SU alone, not the comparison of metformin with diet or metformin monotherapy with SU. Moreover, the authors included the 10 years follow-up UKPDS in their analysis, and observational studies were excluded. In fact, the level of evidence of the UKPDS follow-up publication [46] is quite similar to observational studies due to the already mentioned risks of bias [44, 47].

Compared with other interventions, metformin does not increase the risk of mild or severe hypoglycemia. The main adverse events associated with metformin are gastrointestinal, especially diarrhea. There have been warnings of lactic acidosis due to metformin. A Cochrane review [54] and the AHRQ report [36] did not find an increased risk of lactic acidosis with the use of metformin. Up to 2016, metformin was not recommended for patients with moderate to severe kidney function. Following this advice to practicing physicians might be one reason for a low number of reported cases of lactic acidosis. In 2016, the Food and Drug Administration (FDA) and the European Medicines Agency (EMA) changed their recommendations to allow the use of metformin in patients with moderately reduced kidney function (GFR = 30–59 mL/min) [55, 56]. The FDA explicitly recommends assessment of risks and benefits in patients with metformin whose GFR fall below 45 mL/min/1.73 m^2. Starting metformin in patients with eGFR between 30–45 mL/min/1.73 m^2 was not recommended [56].

Sulfonylureas

The first-generation SU tolbutamide and chlorpropamide were introduced in the 1950s. In the UGDP, tolbutamide increased mortality risk. Nonetheless, both substances were extensively used even after publication of the UGDP in many countries. Today, first-generation SU have been replaced by the second- and third-generation SU. SU are recommended as initial drug therapy if metformin is contraindicated or not tolerated by patients [1, 17, 18]. The com-

parative effects of SU to metformin are already described in the metformin part of this chapter. We additionally searched for systematic reviews and RCTs on the efficacy of SU as monotherapy compared to diet, placebo, or lifestyle interventions.

As in our original overview [2], the only RCT that met our inclusion criteria was the UKPDS [42]. In the UKPDS 33, the effects of intensive blood-glucose control with either SU or insulin were compared to conventional treatment. A total of 615 patients were assigned to glibenclamide, and 896 received conventional treatment, which comprised dietary advice. Over 10 years, median HbA1c values were 7.2% for glibenclamide and 7.9% for conventional therapy. More patients in the conventional treatment arm had reached the primary endpoint *"any diabetes-related endpoint"* and microvascular complications, but there were no significant effects on macrovascular outcomes. The effect on the microvascular outcome was mainly attributed to fewer cases of retinal photocoagulation [42]. Patients in the SU group gained more weight (1.7 kg) than patients in the conventional treatment group, and more patients receiving SU had major hypoglycemic events (1.4% vs. 0.7%) over 10 years (Table 34.2).

Thiazolidinediones

Thiazolidinediones were introduced in the 1990s. The first agent of this class, troglitazone, was withdrawn from the market because of the increased risk of severe liver damage and toxicity. The remaining compounds, rosiglitazone and pioglitazone, were under selling restrictions or withdrawn in some countries due to safety issues. Meta-analyses showed an increased risk of myocardial infarction in patients who received rosiglitazone [57, 58]. One of the included studies was the RECORD trial with a mean follow-up of 5.5 years [59]. A total of 4447 patients who were treated with metformin or SU monotherapy were randomized to additional rosiglitazone or additional metformin/SU. Patients of the rosiglitazone group had a twofold greater risk of fatal and nonfatal heart failure compared to patients with metformin plus SU treatment. There was no difference between groups regarding the combined primary endpoint, *cardiovascular death or cardiovascular hospitalization*. Patients receiving rosiglitazone therapy reported significantly more bone fractures. Further adverse effects of rosiglitazone comprised weight gain and edema [59]. Findings from the ADOPT trial confirmed higher cardiovascular risks and other adverse effects associated with rosiglitazone [53].

Table 34.2 Metformin and sulfonylurea, identified evidence on efficacy of single RCTs

Comparison	Outcome	Events in groups (%)	Effect RR [95% CI]	ARR [95% CI]	Participants	Study/risk of bias
Intensified therapy with metformin vs. conventional therapy with diet	Any diabetes-related endpoint	98 (28.7) vs. 160 (38.9)	0.68 [0.58, 0.87]	10.3 [3.55, 17.0][a]	Overweight and obese patients with newly diagnosed T2DM Metformin $n = 342$ diet $n = 411$ Follow-up: 10.7 years	UKPDS 34 (1998) [41]: Open-label design, change of protocol and primary endpoint during study, insufficient blinding, limited information on accompanying treatment during the study
	Diabetes-related death	28 (8.2) vs. 55 (13.4)	0.58 [0.37, 0.91]	5.2 [0.8, 9.59][a]

[a]Calculated with data from the original study publication

The FDA restricted access to rosiglitazone, which was part of the Risk Evaluation and Mitigation Strategy (REMS), and the RECORD trial showed several risks of bias. The RECORD trial was an open-label trial with low statistical power. An unplanned interim analysis was conducted, which could have repealed blinding. Patients' compliance to rosiglitazone was low. In December 2015, based on an independent review of the study, the FDA stated that REMS was no longer needed and that the benefits of rosiglitazone outweighed the risks. In their Standards of Medical Care in Diabetes, the American Diabetes Association recommended TZD as add-on therapy or monotherapy if metformin was contraindicated [58].

In our updated search, we identified a meta-analysis on the effect of pioglitazone on cardiovascular outcomes, which also included participants with pre-diabetes and insulin resistance [32]. The primary endpoint was major adverse cardiovascular events (MACE) comprising cardiovascular death, nonfatal myocardial infarction, and nonfatal stroke. The use of pioglitazone in patients with diabetes was associated with lower risks of MACE, and the incidence of myocardial infarction or stroke did not differ between the pioglitazone and control groups. Pioglitazone was also associated with an increased risk of heart failure, bone fracture, edema, weight gain, and hypoglycemia [32]. The largest included RCT was the PROactive trial [60]. Patients with type 2 diabetes and previous stroke were randomized to receive pioglitazone or placebo, and the mean study duration of the study was 34.5 months. Albeit there was a reduction in the combined endpoint, *death from any cause, nonfatal MI,* and *stroke* for patients randomized to receive pioglitazone, patients in this group had significantly higher risks of heart failure, edema, and weight gain in addition to a nonsignificant higher rate of bladder cancer [60]. In the meta-analysis, no significant differences were found in bladder or any cancer risk [32]. Another meta-analysis reported a significantly higher risk [31], but it was mainly based on the results of the PROactive trial. A systematic review on the effects of TZD on bone fractures confirmed an increased risk of fractures in women who use rosiglitazone or pioglitazone [30]. The National Institute for Clinical Excellence (NICE) recommends pioglitazone when metformin is contraindicated but explicitly points out the risks of adverse events (Table 34.3) [18].

Table 34.3 Thiazolidinedione, identified evidence from RCTs

Comparison	Outcome	Events in groups (%)	Effect RR [95% CI]	ARR [95% CI]	Participants	Study/risk of bias
Rosiglitazone + metformin or SU vs. metformin + SU	Primary endpoint (CV death or CV hospitalization)		n.s.		Overweight and obese patients with T2DM Rosiglitazone $n = 2220$ Met+SU $n = 2227$ Follow-up: Mean 5.5 years Treatment target: HbA1c ≤ 7.0%	RECORD (2009) [59]: Misleading primary endpoint, high non-compliance, low statistical power, unplanned interim analysis
	All-cause mortality		n.s.			
	Cardiovascular mortality		n.s.			
	Myocardial infarction		n.s.			
	Stroke		n.s.			
	Fatal and nonfatal heart failure	61/2220 vs. 29/2227	2.11 [1.36, 3.27][a]	−1.4 [−2–27, −0.62][a]		
	Fractures	185/2220 vs. 118/2227	1.57 [1.26, 1.97]	−3.0 [−4.51, −1.57][a]		
Pioglitazone + other glucose-lowering drugs vs. placebo + other glucose-lowering drugs	Primary endpoint (all-cause mortality, nonfatal MI, stroke, acute coronary syndrome, coronary or leg arterial revascularization, amputation above ankle)		n.s.		Obese patients with T2DM and high CV-risk Pioglitazone $n = 2605$ Placebo $n = 2633$ Follow-up: 2.9 years Treatment target: HbA1c <6.5%	PROactive (2005) [60]: Misleading interpretation of data, definition of secondary endpoint afterwards
	Main secondary endpoint (death from any cause, nonfatal MI, stroke)	301 (11.6) vs. 358 (13.6)	0.85 [0.74, 0.98][a]	2.0 [0.25, 3.84][a]		
	Death		n.s.			
	Heart failure	281 (10.8) vs. 198 (7.5)	RR 1.43 [1.21, 1.71][a]	−3.3 [−4.83, −1.71][a]		
	Edema without heart failure	562 (21.6) vs. 341 (13.0)	RR 1.67 [1.47, 1.88][a]	−8.6 [−10.66, −6.59][a]

[a]Calculated with data from original study publication

Alpha Glucosidase Inhibitors and Meglitinides

The ADA and the EASD do not explicitly recommend the use of AGIs due to their modest effects, but they accept that AGIs *"may be tried in specific situations"* [9]. Two Cochrane reviews including patients with type 2 diabetes and patients with impaired glucose tolerance did not find significant effects of AGIs on mortality or morbidity [61, 62]. We did not include the STOP-NIDDM trial in this overview because of its high risk of bias, which was extensively discussed in the literature. The Acarbose Cardiovascular Evaluation Trial (ACE) [63] evaluated the efficacy of acarbose on cardiovascular death, nonfatal MI, and nonfatal stroke in patients with impaired glucose tolerance and coronary heart disease. This RCT was completed in April 2017, and the results showed that patients received acarbose achieved a statistically significant reduction on 18% in the relative risk of diabetes, without reduction in the risk of major adverse cardiovascular events (MACE).

Meglitinides same as SU belong to the drug class of insulin secretagogues. Compounds of this class are nateglinide and repaglinide. In contrast to SU, they are rapid-acting secretagogues. The ADA and the EASD stated that meglitinides may be used as an alternative to SU in patients with irregular meal schedules [10]. In case repaglinide is considered as alternative to metformin, the NICE guidance on *Type 2 diabetes in adults* suggests physicians to inform patients that there is no licensed non-metformin-based combination with repaglinide [15]. There is no evidence on effects regarding clinically relevant and long-term outcomes with the use of meglitinides [64].

Conclusion

In conclusion, the older classes of oral antidiabetic agents still play central roles in diabetes care, but evidence on macro- and microvascular risk is lacking or insufficient.

The applicability of the results of clinical trials is limited due to the short duration of the studies [35]. Most studies assess the efficacy of medications on intermediate outcomes rather than long-term hard clinical endpoints [34, 35, 38]. Intermediate outcomes or surrogates must be interpreted with caution. Medications decreasing HbA1c-values do not necessarily reduce morbidity or mortality. In some cases of withdrawn drugs, blood glucose levels decreased, while risks of hard clinical endpoints did not change or even increased. Whenever RCTs included patient-relevant endpoints, they were mostly assessed as secondary endpoints or adverse effects. Available studies were often too small to identify any differences between groups. Composite outcome measures, such as *any diabetes-related endpoint* or *macrovascular complications*, which usually comprise endpoints of varying importance and validity, are challenging to interpret and may lead to overinterpretation of single outcomes.

The authors of the AHRQ report [36] concluded that the efficacy of all diabetes medications regarding all-cause mortality, cardiovascular and cerebrovascular morbidity as well as retinopathy, nephropathy, and neuropathy is still uncertain. The report showed moderate strength of evidence that sulfonylurea monotherapy compared with metformin alone was associated with an increased risk of cardiovascular mortality. This result was mainly based on two RCTs: ADOPT with patients with newly diagnosed diabetes and SPREAD-DIMCAD, which included patients with coronary heart disease. In contrast, the meta-analysis by Madsen et al. [23] did not find any differences between SU and metformin monotherapy of total or cardiovascular mortality but a potential benefit of SU regarding nonfatal macrovascular outcomes. However, definition of the composite endpoint differed between studies [23].

In the AHRQ report [36], evidence on intermediate outcomes, such as HbA1c values, was graded as high, and effects on HbA1c values were comparable between most oral antidiabetic agents. Monotherapy comparisons of metformin with sulfonylurea and metformin with TZDs show similar effects with respect to reduction in HbA1c values [65]. Moreover, metformin monotherapy reduced body weight more than TZDs or SU, though the clinical relevance of these differences may be debatable. Metformin monotherapy shows greater weight reduction when compared with the combination of metformin and SU or metformin plus TZDs, respectively [36, 66]. In addition, metformin was favored over SU monotherapy, the combination of metformin and TZDs, and over the combination of metformin and SU regarding hypoglycemia [67]. The risk of hypoglycemia is higher for SU than for TZDs [36], albeit differences in the risk of hypoglycemia have been documented, probably explained by differences in chemical structure, pharmacogenetic and pharmacodynamic properties between sulfonylureas [68].

Despite there is only one RCT with a small sample size, which demonstrated an effect on hard clinical endpoints, metformin is internationally recommended as first-line drug for patients with type 2 diabetes. It is used as comparator for the evaluation of new medications although high-quality evidence on patient-relevant outcomes is missing. Thus, the role of metformin as "gold standard" is questionable. Despite a huge number of studies and a stunning total of 427 meta-analysis until 2021, evidence on metformin in observational studies generally does not seem reliable, due to substantial heterogeneity between studies, small-study effects, and excess significance, while evidence from randomized trials suggests only a few effects with strong evidence for additional benefits [25].

Shared Decision-Making

Even though there is no single perfect treatment of hyperglycemia in patients with type 2 diabetes, decisions about treatment policies and diabetes drug therapy are made for thousands of patients every day. For many decades, the dominant approach to making decisions about treatment in the medical encounter has been one of paternalism, but in recent years, this model has been challenged by doctors, patients, medical ethicists, and researchers who advocate more of a partnership relation between doctors and patients [69]. Shared decision-making is a personalized and patient-centered approach [70] described by Charles, Gafni, and Whelan in 1997 to help patients and clinicians to select the treatment that best fits individual patient needs, values, and preferences [71]. It is a special way of conversation between patients and healthcare professionals comprising various elements, such as clarifying the patient's situation, noticing that there is more than one treatment option, information about benefits and harms of the treatment options, and weighing up the pros and cons considering patient values and expectations. Patient decision aids are tools to promote SDM. They are proved to improve patients' knowledge about treatment options and about probabilities of benefits and adverse effects of each option. Moreover, they help patients to find the option that is most important to them [16]. Decision aids can be used to prepare patients for the consultation with their clinician or within consultations [15]. We have developed an evidence-based patient decision aid on the prevention of myocardial infarction and a corresponding group counselling session in which diabetes educators help patients to understand the information and to define and prioritize own treatment goals regarding statin uptake, smoking cessation, and HbA1c and blood pressure goals [19, 20]. The intervention (informed shared decision-making program; ISDM) was evaluated in a proof of concept RCT [19]. Patients of the ISDM group achieved higher levels of risk comprehension and realistic expectations about benefits and harms of treatment options. For the following cluster RCT with family practices, we added a structured SDM training for physicians and a patient-held documentation sheet to the intervention in order to optimize the consultation in terms of SDM [72]. The study results showed that the whole ISDM program could be successfully implemented in everyday practice. Patients and clinicians of the ISDM group pursued common treatment goals significantly more frequently than the control group [73].

Figure 34.1 displays a 100-stick figure pictogram and bar graphs to visualize probable effects of more or less intensified glucose control on the combined diabetes-related endpoint (UKPDS 34) as used in our patient decision aid and group teaching session [19, 20, 72].

Effects on *"any diabetes related event"* can be explained as follows:

The term "any diabetes related event" is a collective term for different complications of diabetes. It included death from hyperglycemia (high blood sugar) or hypoglycemia, heart attack, angina, heart failure, stroke, kidney failure, amputation, vitreous hemorrhage in the eye (bleeding from abnormal blood vessels in the eye, which can lead to blindness), damage to the retina, blindness of one or both eyes, or eye surgery for cataract.

In the following, you can see the results from the UKPDS [41]. This is a study that was performed in Great Britain and lasted 10 years.

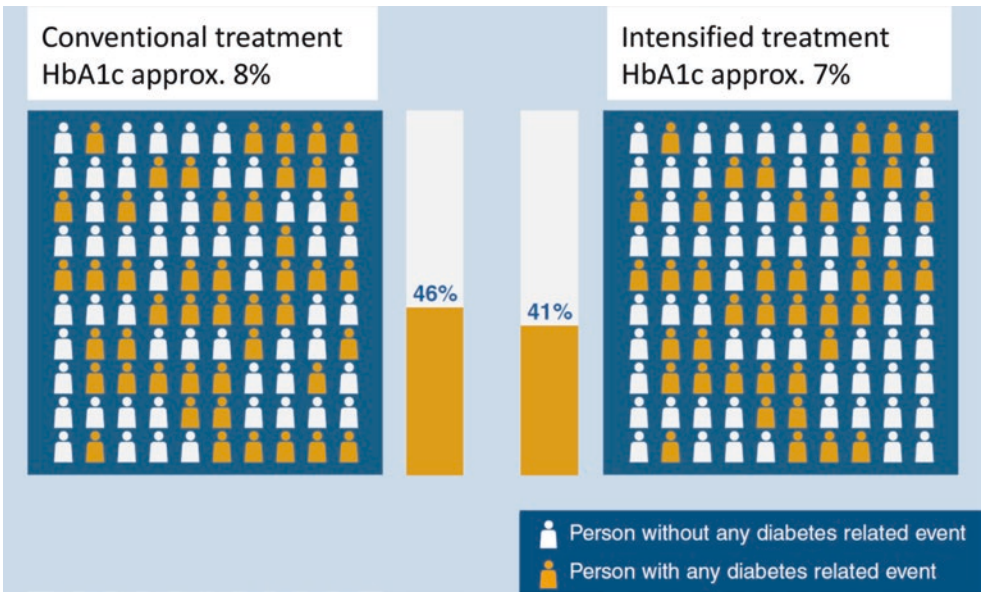

Fig. 34.1 Blood sugar control and "any diabetes-related event"

Imagine two groups, each with 100 patients with type 2 diabetes followed for 10 years.

One group was treated intensively with medication to control blood sugar levels. Patients of that group achieved an average HbA1c of 7%.

The comparator (control group) was treated conventionally with less intensive medication and achieved an average HbA1c of 8%.

- In the group with conventional treatment, "any diabetes-related event" occurred in 46 of the 100 patients during the 10 years period.
- In the group with intensive control, "any diabetes-related event" occurred in 41 of the 100 patients during the 10 years period.

That means, intensive blood sugar control over 10 years prevented "any diabetes-related event" in *5 of 100 patients*. The remaining 95 of 100 people had no benefit from the intensive treatment over a period of 10 years because they also experienced a diabetes-related event (41 patients) or because they would not have experienced any event even with conventional treatment (54 patients).

Intensively treated patients also experienced harm due to hypoglycemia. An additional 7 out of 100 people suffered severe hypoglycemia with intensive treatment compared to the comparator group over 10 years [41].

Communication of uncertainties is challenging. No one can say if one particular patient would benefit from intensive treatment. Presenting the data helps patients to weigh up the pros and cons making a decision, which meets personal preferences and values. Moreover, the effects of antihypertensive treatment and statin intake should be taken into consideration. For example, intensive blood pressure lowering over 8 years (achieved RR 145/82 mmHg) prevented "any diabetes-related event" in 16 out of 100 patients [74].

According to ADA and EASD recommendations [9, 10], clinicians should talk with patients about the pros and cons of medications to achieve individual treatment goals. In our ISDM program, diabetes educators explain benefits and harms of evidence-based options to prevent cardiovascular complications. They guide patients to estimate their individual heart attack risk and then calculate their risks with and without statin intake and to estimate comparable effects of hypertensions or blood glucose control [19, 72].

Since efficacy of single diabetes medications seems uncertain [36], information about antidiabetic agents can only focus on intermediate outcomes, such as weight change, HbA1c values, hypoglycemia, and other side effects. Montori's research group developed and evaluated diabetes medication choice decision aid cards on intermediate effects to be used during the clinical encounter [75]. Patients had improved knowledge and were more involved in the decision-making process [75]. Another decision aid addressed statin choice to prevent myocardial infarction in patients with type 2 diabetes [76, 77]. There are also interactive and web-based decision aids that are supposed to foster shared decision-making and goal setting [78] and patient decision aids on special treatments, such as starting insulin [79].

Communication of quality of data is challenging. Patient decision aids are supposed to provide the best available evidence. However, sometimes, there is no good evidence, but patients have the right to know. Information on level of evidence is provided in guidelines and should be included in the patient information material.

Diabetes care is complex and has to be individualized. The level of evidence of antidiabetic agents on patient-relevant outcomes is low, and it has been shown that treatment of hypertension is more effective than treatment of blood glucose [42]. New therapeutic classes have enlarged the scope of antidiabetics, and their cardiovascular and renal benefits are advantageous by comparison with the "old antidiabetics" [80]. Beyond these achievements, the first antidiabetics continue to be part of the clinical armamentarium because of efficacy and costs. Last but also very important, involving patients in decision-making and making informed choices should be standard in the medical encounter.

Multiple Choice Questions

1. Which is the aim of the treatment of type 2 diabetes?
   (a) Fasting blood glucose control
   (b) Avoid acute symptoms of hyperglycemia and prevent macro- and microvascular complications
   (c) Post-prandial blood glucose control
   (d) Increase the use of medications
   (e) Weight reduction and control
2. Rigid treatment regimes with low HbA1c targets:
   (a) Have resulted in better patient-relevant outcomes
   (b) Have produced equal patient-relevant outcomes
   (c) Are associated with higher risks of mortality
   (d) Improve health-related quality of life
   (e) Reduce hospital admissions and costs
3. What was the argument to withdraw several new antidiabetic agents from the German market?
   (a) No additional benefit over usual care could be demonstrated and health insurances would not have covered additional costs
   (b) Higher costs compared with traditional medications
   (c) Higher risk of hypoglycemia
   (d) Unacceptable risk of nondiabetic ketoacidosis
   (e) All of the above
4. According to the recent ADA and EASD recommendations, clinicians should not discuss with patients the pros and cons of medications to achieve individual treatment goals.

(a) False
(b) True

5. What is the mechanism of action of metformin?
   (a) Reduction of insulin resistance in target cells through transcription of several genes involved in glucose and lipid metabolism
   (b) Inhibition of alpha-glucosidase, delaying intestinal degradation of complex carbohydrates and prolonging post-prandial glucose absorption.
   (c) Multiple sites of action, including increase of insulin sensitivity by increasing peripheral glucose uptake, decrease of intestinal glucose absorption, and decrease of hepatic glucose production
   (d) Stimulation of insulin release in pancreatic beta cells. Decrease in hepatic clearance of insulin. Additional extra-pancreatic mechanisms
   (e) Increase insulin sensitivity by skeletal muscle
6. What is the mechanism of action of glyburide?
   (a) Reduction of insulin resistance in target cells through transcription of several genes involved in glucose and lipid metabolism
   (b) Inhibition of alpha-glucosidase, delaying intestinal degradation of complex carbohydrates and prolonging post-prandial glucose absorption
   (c) Increase of insulin sensitivity by increasing peripheral glucose uptake, decrease of intestinal glucose absorption, and decrease of hepatic glucose production
   (d) Stimulation of insulin release in pancreatic beta cells. Decrease in hepatic clearance of insulin. Additional extra-pancreatic mechanisms.
   (e) Increase insulin sensitivity by skeletal muscle
7. What is the mechanism of action of thiazolidinediones?
   (a) Reduction of insulin resistance in target cells through transcription of several genes involved in glucose and lipid metabolism
   (b) Inhibition of alpha-glucosidase, delaying intestinal degradation of complex carbohydrates and prolonging post-prandial glucose absorption
   (c) Increase of insulin sensitivity by increasing peripheral glucose uptake, decrease of intestinal glucose absorption, and decrease of hepatic glucose production
   (d) Stimulation of insulin release in pancreatic beta cells. Decrease in hepatic clearance of insulin. Additional extra-pancreatic mechanisms.
   (e) Increase insulin sensitivity by skeletal muscle
8. What is the mechanism of action of alpha-glucosidase inhibitors?
   (a) Reduction of insulin resistance in target cells through transcription of several genes involved in glucose and lipid metabolism
   (b) Inhibition of alpha-glucosidase, delaying intestinal degradation of complex carbohydrates and prolonging post-prandial glucose absorption
   (c) Increase of insulin sensitivity by increasing peripheral glucose uptake, decrease of intestinal glucose absorption, and decrease of hepatic glucose production
   (d) Stimulation of insulin release in pancreatic beta cells. Decrease in hepatic clearance of insulin. Additional extra-pancreatic mechanisms
   (e) Increase insulin sensitivity by skeletal muscle
9. The evidence sustaining that sulfonylurea monotherapy compared with metformin alone was associated with an increased risk of cardiovascular mortality comes from:
   (a) Experiences of primary care practitioners
   (b) Two clinical trials: ADOPT with patients with newly diagnosed diabetes and SPREAD DIMCAD, which included patients with coronary heart disease
   (c) Pharmaco-vigilance reports
   (d) Conclusions of consensus groups
   (e) The results of the Diabetes Control and Complications Trial (DCCT)
10. Moderate strength of evidence suggest sulfonylurea monotherapy compared with metformin alone was associated with:
   (a) Higher risk of cardiovascular mortality
   (b) An increase in metabolic control
   (c) Lower weight gain
   (d) Reducing oxidative stress and pro-inflammatory molecules
   (e) Lower risk of severe hypoglycemia

History of Incretins

Discovery of the Incretin Effect

In the last two decades, analogs of the incretin glucagon-like peptide-1 (GLP-1) became an important pillar of the therapy of type 2 diabetes (T2D). Still, incretins are a fascinating focus of current research. The term "incretin" denotes the entity of hormones that are secreted by the mucosal cells of the intestine and increase the secretion of insulin from the β-cells of the pancreas. The history of studies examining incretin effects goes far. The first comprehensive experiment proving the effects of incretins on the pancreas of animals was reported already as early as in the year 1902 by English physiologists Bayliss and Starling [1]. In this groundbreaking early research, the jejunum of a dog was cut from all nervous connections including those to the pancreas, but the blood vessels between the intestine and the pancreas were kept intact. The introduction of a liquid mimicking chyme into the jejunum resulted in an increase of pancreatic secretion. Authors concluded absolutely correctly that "*since this part of the intestine was completely cut off from nervous connection with the pancreas, the conclusion was inevitable that the effect was produced by some chemical substance finding its way into the veins of the loop of jejunum in question and being carried in the blood-stream to the pancreatic cells*" [1]. Today, we know that incretins belong to the group of these "*chemical substances*," which are secreted after the ingestion of food.

In the 1960s, it could be demonstrated, also in humans, that orally administered glucose induced a greater insulin response than intravenously (IV) administered glucose [2–4]. This effect was then termed the "incretin effect," and in 1971, the first hormone contributing to this effect was isolated: the peptide hormone called gastric inhibitory polypeptide (GIP, later also termed glucose-dependent insulinotropic peptide) was identified in the intestinal mucosa of a dog. Already at this early stage, an important property of the incretins could be demonstrated for GIP: its

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_35

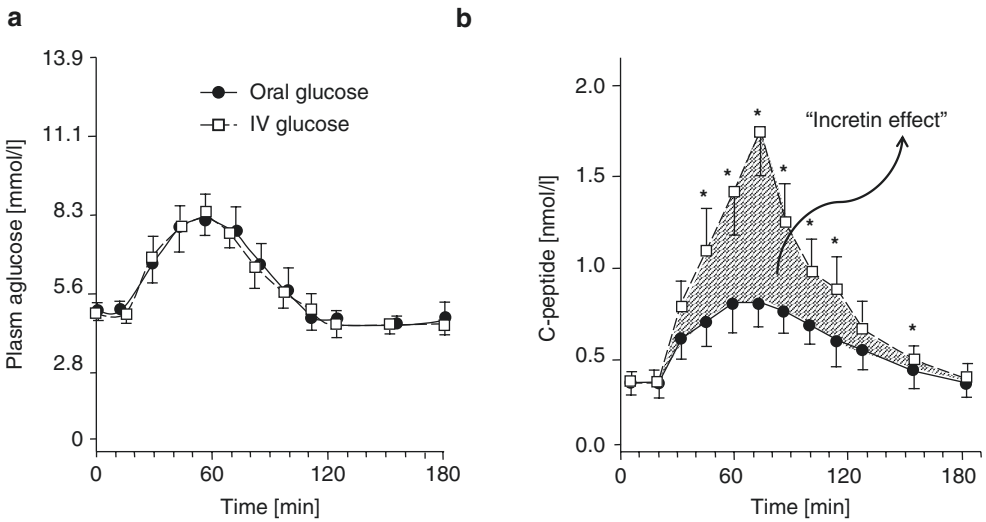

Fig. 35.1 Mean (± standard error of the mean) peripheral venous plasma glucose (**a**) and C-peptide (**b**) concentrations after oral (empty squares) and intravenous (IV, full circles) administration of 50 g glucose in six healthy, normal weight participants aged 28–33 years. *IV* intravenous, * $p < 0.05$ between oral and IV glucose administration. (Modified from [6])

insulinotropic effect is blood glucose dependent. Only if blood glucose is elevated GIP induces insulin secretion [5]. In 1985, a second peptide with the same blood glucose-dependent insulinotropic effects was discovered in rats and later also found in humans and termed glucagon-like peptide-1 (GLP-1). In humans, by comparing insulin secretion of the pancreas after IV glucose administration versus oral glucose administration, it could be demonstrated that in healthy, normal weight adults, incretin action is responsible for at least half of the total insulin secreted [6] (Fig. 35.1). Today, we know that circulating GIP concentrations are tenfold higher than GLP-1 concentrations, but GLP-1 seems to be more potent than GIP.

First Clinical Usage

In 2005, with exenatide, the first drug was approved, which pharmacologically uses the incretin effect. Exenatide is an analog of endogenous GLP-1 and activates the GLP-1 receptor, leading to an increase in insulin secretion of the β-cell if blood glucose is elevated. Shortly after, with sitagliptin, the first member of a second drug class using the incretin effect was approved for the treatment of T2D. Sitagliptin is an inhibitor of the enzyme dipeptidyl-peptidase 4 (DPP-4), which degrades endogenous GLP-1. By blocking the enzyme, the drug increases endogenous GLP-1 concentrations and thus increases the incretin effect.

In this chapter, we will highlight the physiological actions of the incretins GLP-1 and GIP in the human body (with a focus on GLP-1), summarize, and discuss clinical data of drugs using the incretin pathways in the treatment of T2D. Furthermore, we will give an outlook on emerging possibilities of incretin use in diabetes treatment.

Mechanisms of Physiologic Action of Endogenous GLP-1

Stimulation of GLP-1 Secretion

GLP-1 is a 30-amino acid peptide hormone, created by cleavage of the processor peptide proglucagon. The physiologic function of GLP-1 is the mediation of metabolization of ingested nutrients, analog to the function of insulin. Its main sites of secretion are the L-cells of the distal ileum and colon, but GLP-1 is also secreted in other parts of the intestine, in the pancreas, and also in the brain. In the intestine, proglucagon is cleaved into GLP-1 and several other peptides. Production of GLP-1 in the L-cells of the distal ileum and the colon happens as a response to intraluminal nutrients. After meal digestion, intraluminal fats in the distal parts of the ileum bind to fatty acid receptors on the surface of L-cells, leading to GLP-1 secretion. Intestinal sugars are most likely detected by the classic sweet taste receptor of the taste receptor type 1 (T1R)-family, the T1R3. Receptor binding on the surface of the intestinal L-cell leads to GLP-1 secretion. Probably, also the sodium-glucose cotransporter 1 contributes to intraintestinal sugar-mediated GLP-1 release [7]. Furthermore, digested peptides elicit GLP-1 secretion, whereas the molecular mechanisms are not yet fully understood (Fig. 35.2).

Effects on the Pancreas

Endogenous GLP-1 has several important effects involved in the consumption and digestion of food (Table 35.1). The most important GLP-1 effect for the treatment of diabetes is the stimulation of insulin secretion of the β-cells of the pancreas. GLP-1-independent insulin secretion of the β-cell,

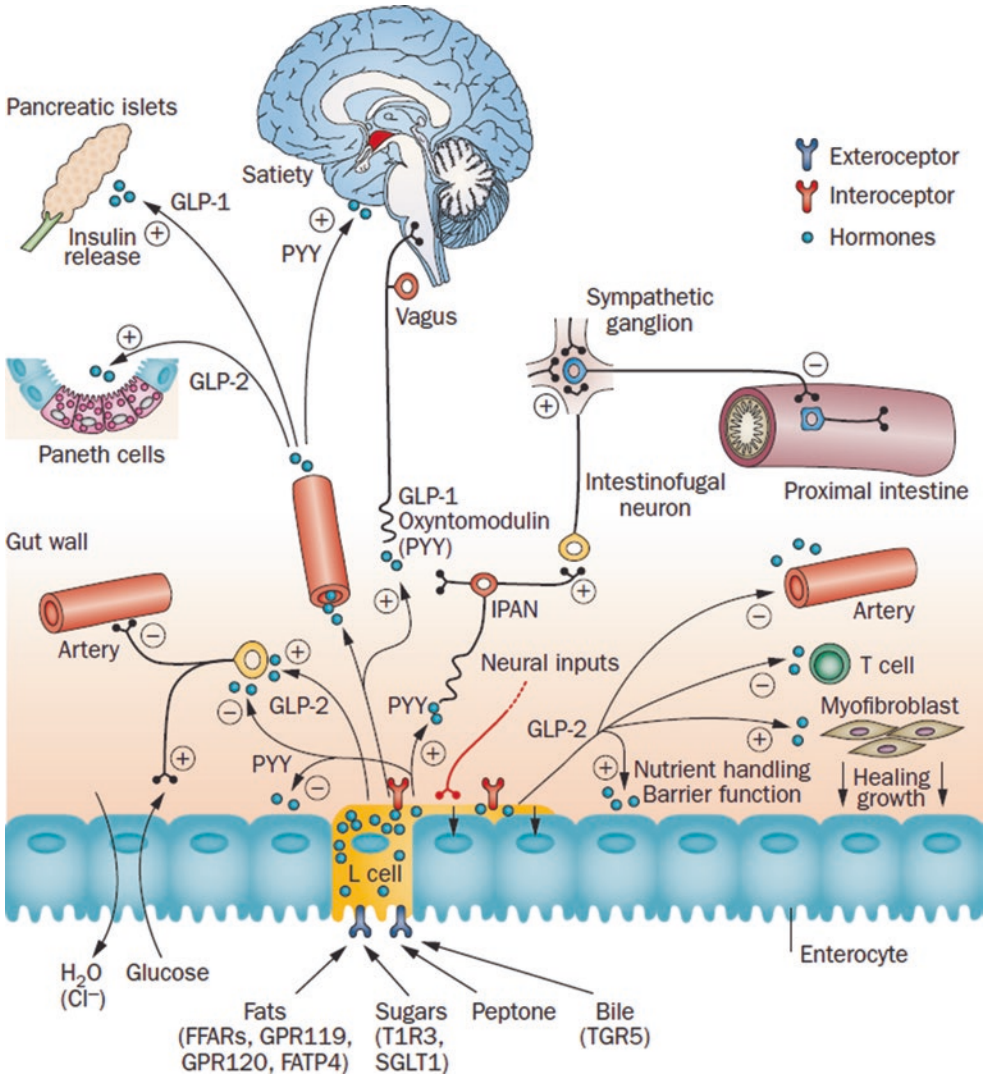

Fig. 35.2 Physiological actions of intraintestinal nutrients (fats, sugars, peptides) and bile on the L-cell of the distal ileum and elicited signal transduction in the regulation of anabolic metabolism. The L-cell expresses exteroceptors for free fatty acids, sugars, protein fragments (peptones) and bile acids. L-cells release the hormones glucagon-like peptide-1 (GLP-1), GLP-2 (another cleavage product of proglucagon, co-secreted with GLP-1, also acting in the intestine, but not yet fully understood), peptide YY and oxyntomodulin. These hormones have actions on a range of effectors, including enterocytes, enteric neurons, vagal sensory neurons and intrinsic primary afferent neurons, blood vessels, lymphocytes, myofibroblasts and the hypothalamus. Through vagal afferents, GLP-1 acts on the brain and mediates satiety. Via further downstream signaling, slowed gastric emptying, inhibition of gastric acid secretion, and the stimulation of insulin release are elicited. L-cells also express interoceptors that receive signals from the internal milieu, including from neurons and hormones. + stimulation, − inhibition, *FFARs* free fatty acid receptors, *GLP* glucagon-like peptide, *IPAN* intrinsic primary afferent neuron, *PYY* peptide YY. (From [7])

briefly summarized, happens as follows: glucose diffuses into the β-cell through the glucose transporter type 2 and is processed to adenosine triphosphate (ATP), which leads to a closure of outward ATP-sensitive potassium channels. This elicits a depolarization of the cell membrane, making it more likely for voltage-dependent calcium channels to open. Intracellular calcium influx is thus enhanced, which is the stimulus for the exocytosis of the insulin carrying vesicles.

The underlying mechanisms how GLP-1 increases insulin secretion in a glucose dependent manner are complex and not yet fully uncovered (details in [8, 9]). In short, glucose-dependent GLP-1 effects happen at several points of the intracellular signal cascades (Fig. 35.3). Binding of GLP-1 to its receptor on the β-cell surface leads to the transformation of ATP to cyclic adenosine monophosphate (cAMP). The higher the blood glucose, the more ATP is available, and thus the more cAMP is produced. Cyclic AMP then activates protein kinase A and another messenger protein, which leads through several further steps to an increase in cytoplasmic free calcium concentrations. That finally triggers exocytosis of insulin-containing vesicles into the bloodstream (Fig. 35.3). Some data also suggest that there are mechanisms

Table 35.1 Organ specific and systemic effects of endogenous GLP-1

	Parameter	Effect

GLP-1 glucagon-like peptide-1, *T2D* type 2 diabetes, ↓ decreases, ↑ increases

how GLP-1 directly increases insulin secretion, independently from the presence of glucose [10]. However, in the clinical use of GLP-1 receptor agonists, these mechanisms seem to be neglectable.

The stimulation of insulin secretion of the β-cell is not the only glucose-lowering effect of GLP-1. GLP-1 also is a strong inhibitor of glucagon secretion from the α-cells of the pancreas, a further mechanism of GLP-1 to lower blood glucose. In patients with type-1 diabetes with C-peptide levels of zero, it was shown that GLP-1 administration also leads to a marked decrease of blood glucose concentration [11]. Which further factors lead to GLP-1 effects on glucose metabolism is subject to current research.

Effects on Intestinal Motility

Another very important physiologic function of GLP-1 and other gastrointestinal hormones (other important ones are peptide YY [PYY] and cholecystokinin [CCK]) is the control of the secretion of digestive enzymes and of gastric and intestinal motility [7]. As described above, intraluminal fats in the distal parts of the ileum bind to fatty acid receptors on the surface of L-cells. This leads to GLP-1 and PYY secretion and via signal transduction from GLP-1 receptors to intestinal nerves and vago-vagal reflexes to the inhibition of gastric emptying and gastric acid secretion. This reflex is termed the ileal break, because nutrients (fats) arriving in the ileum slow the motility of upper parts of the digestive tract.

Effects on the Central Nervous System

In addition to its pancreatic and intestinal location, the GLP-1 receptor is also expressed in many other regions of the human body, suggesting a much broader function than insulinotropic and gastrointestinal effects. From animal data, we know that the GLP-1 receptor is also expressed widely in the brain, with highest concentrations in the hypothalamus, the homeostatic center of the brain. In anaesthetized mice, several experiments using manganese-enhanced magnetic resonance imaging were performed. High dosages of intraperitoneally injected GLP-1, which alike in humans also reduces energy intake in mice, showed significant reductions in signal intensity in nuclei of the hypothalamus, which are known to mediate hunger: similar signal reductions in these regions occurred when animals were fed with food unrestricted in calories [12]. As a further prove of direct intracerebral action of GLP-1, in a study with free-feeding mice, it was shown that the GLP-1 analog liraglutide suppressed food intake and body weight in a dose-dependent manner not only when administered intraperitoneally or IV but also when injected directly into the third cerebral ventricle [13].

Also in humans, the hypothalamus regulates many vegetative processes, including the control of body homeostasis and metabolism. These effects have already been investigated in behavioral experiments, and as well with neuroimaging, mainly with functional magnetic resonance imaging (fMRI), in order to localize brain areas involved in this regulation. In a placebo-controlled fMRI study with 24 obese men, participants had a significant decrease in mean energy intake and hunger ratings after a single dose IV administration of the GLP-1 analog exenatide. It is known that patients can have variable responses to drugs of the GLP-1 analog class, and the effects observed in this study varied strongly among participants. The participants could be divided into two equally sized groups, one with >10% reduction of energy intake and the other with <10% reduction of energy intake through exenatide application. Functional MRI scans of patients given a food picture presentation task showed that the drug increased connectedness of the hypothalamus only in the group where the drug had a >10% reduction of energy intake. In the group where no anorectic effect was observed, no hypothalamic response was seen, suggesting that the anorectic effect of the GLP-1 analog is mediated via the hypothalamus [14]. Other fMRI studies with different experimental designs have shown that also activity in areas of the brain, which are part of the dopaminergic reward system, is altered by GLP-1 infusions [15].

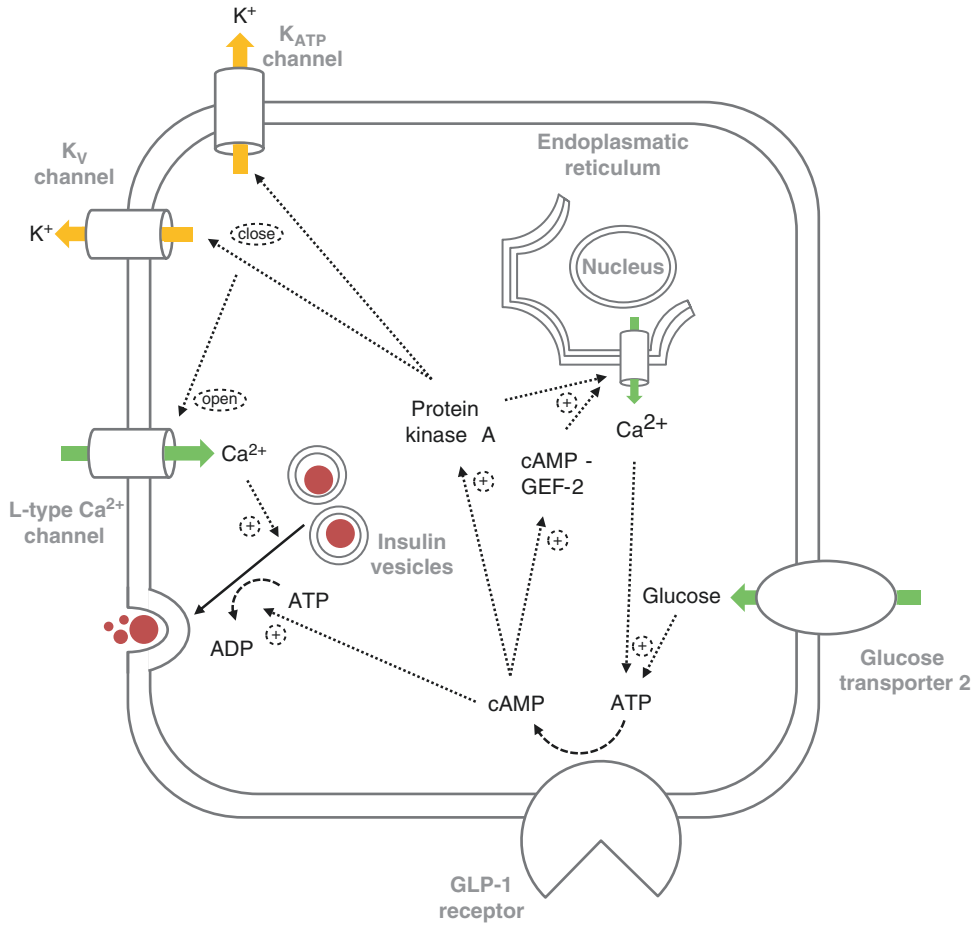

Fig. 35.3 Glucose-dependent insulinotropic glucagon-like peptide-1 (GLP-1) effects in the β-cell. An important mechanism of the glucose dependency of GLP-1 action is mediated via intracellular adenosine triphosphate (ATP) concentrations. The higher the blood glucose level, the more glucose enters the β-cell via the insulin-independent glucose transporter type 2 and is metabolized to ATP. Binding of GLP-1 to the GLP-1 receptor on the β-cell surface stimulates the G-protein of the adenylate cyclase, which results in transformation of ATP to cyclic adenosine monophosphate (cAMP). Cyclic AMP then activates two central proteins responsible for the further transmission of the GLP-1 signal: protein kinase A and cAMP-regulated guanine nucleotide exchange factor 2 (cAMP-GEF-2). Protein kinase A contributes to closing the ATP-sensitive potassium channel (K_{ATP}) and the delayed rectifying potassium channel. Closure of these two outward potassium channels increases intracellular positive potentials and thus facilitates membrane depolarization and opening of inward L-type calcium channels. Increased cytoplasmic free calcium concentrations trigger exocytosis of the insulin containing vesicles. This action is further potentiated by increased cAMP levels. Protein kinase A and cAMP-GEF-2 both trigger calcium release from intracellular stores in the endoplasmic reticulum, again enhancing the calcium dependent actions leading to insulin release. *ADP* adenosine diphosphate, *ATP* adenosine triphosphate, *Ca^{2+}* ionized calcium, *cAMP* cyclic adenosine monophosphate, *cAMP-GEF-2* cAMP-regulated guanine nucleotide exchange factor 2, *GLP-1* glucagon-like peptide-1, *K^+* ionized potassium, *K_{ATP} channel* ATP-sensitive potassium channel, *K_V channel* delayed rectifying potassium channel. (Modified from [8])

Mechanism of Action of GIP

GIP was discovered earlier than GLP-1, and the GIP receptor has been well characterized. However, initial pharmacological studies focused on GLP-1 receptor agonists. The emphasis on GLP-1 therapy derived from several reasons: animal research led to the assumption that GIP administration promoted obesity and impaired lipid metabolism, and human single-dose trials with GIP agonists in patients with T2D found worsened postprandial hyperglycemia. But later investigations of physiologic GIP actions showed that the detrimental GIP effects only occur in hyperglycemia and uncontrolled diabetes. In euglycemia and well-controlled diabetes, GIP receptor activation by GIP analogs has beneficial effects in the human body. There are reports of increased β-cell survival by GIP through signaling pathways independent of GLP-1, supporting the hypothesis that the two incretins are not redundant and may complement one another. GIP research leads to the development of dual GLP-1/GIP co-agonists, of which the first one (tirzepatide) already showed good clinical results in phase 3 studies (see below) [16].

Pharmacological Substances

Exenatide

The first GLP-1 analog approved for the treatment of diabetes was exenatide in 2005 in its formulation, which is administered twice daily, making it the lead substance of the GLP-1 analog class. Exenatide is the synthetic version of exendin-4, a peptide originally isolated from the saliva of the lizard Gila monster. It has an amino acid homology of about 50% with the endogenous human GLP-1 molecule. Mainly due to the substitution of the amino acid alanine in position two by glycine, the molecule is much more resistant to cleavage by DPP-4 than endogenous GLP-1, increasing plasma half-life from 2–5 min to 2.4 h after subcutaneous (SC) administration. It is licensed to be prescribed with or without oral hypoglycemic agents and with or without additional insulin.

Liraglutide

It was followed by the once-daily administered liraglutide in 2009 (Europe) and 2010 (USA). Liraglutide's peptide structure is much closer to the human GLP-1, having a 97% sequence identity with native GLP-1. The molecule binds to human albumin and has a much longer half-life than exenatide of 13–15 h after SC administration. The typical initial dose is 0.6 mg injected SC once daily. The dose can be increased to a maximum of 1.8 mg daily in the treatment of T2D. Because of its weight-reducing effect, the drug was also filed for approval for weight reduction in obesity, also in the absence of diabetes, and got an approval in 2014 (USA) and 2015 (Europe). The dose if used for weight reduction is 3 mg per injection, also applied once daily [17].

In its cardiovascular outcome trial (CVOT) named LEADER [18], the drug met the criteria for cardiovascular safety as defined by the United States Food and Drug Administration (USFDA) (Box 35.1). In the trial, reductions in the primary composite outcome (death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke) were demonstrated (hazard ratio [HR] 0.87, confidence interval [CI] 0.78–0.97, $p = 0.01$). Furthermore, a decrease in cardiovascular death (HR 0.78, CI 0.66–0.93, $p = 0.007$) and all-cause mortality (HR 0.85, CI 0.74–0.97, $p = 0.02$) as compared to placebo treatment were seen (Table 35.2). The number needed to treat for patients with T2D and high cardiovascular risk to prevent one death (death from any cause) in 3 years was 98 [18].

[c]Least-squares mean

[d]Not yet approved

[e]1:1 ratio, in publication results reported together as one mean value

Of note, additional monitoring of liraglutide was demanded by regulatory authorities because of a significant increase of medullary thyroid cancer in animals treated with the drug. This risk could not yet be fully ruled out in humans, probably due to the very low incidences of medullary thyroid cancer in observed populations.

Exenatide LAR

In 2011, a long-acting formulation of exenatide was approved for the therapy of T2D and termed exenatide long-acting release (LAR). The exenatide molecule is attached to so-called microspheres, small particles in the case of exenatide LAR of 0.06 mm size. The exenatide LAR microspheres are made of molecules of lactic and glycolic acid (poly-lactic-co-glycolic acid), which is the most common material from which microspheres are prepared. The drug is loaded onto the surface of and into the microsphere and then released as the matrix materials degrade. The characteristics of the binding of the molecule on the surface and the internalization into the microsphere explain the suboptimal pharmacokinetics of exenatide LAR: in the first 2 days after SC application, exenatide plasma concentrations increase rapidly. This rapid absorption of the molecule is due to the loosely bound exenatide on the surface of the microspheres. The internalized drug from inside the vesicles is not released until 2 weeks later. It takes up to 7 weeks for the drug to be completely released [25]. In the CVOT, the EXSCEL trial, initially >7000 patients with T2D were treated for up to 5 years, and the mean treatment duration was 3.1 years. A primary composite outcome event (death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke) occurred in 11.4% of patients in the exenatide LAR group versus 12.2% patients in the placebo group (HR 0.91, CI 0.83–1.00, $p = 0.06$ for superiority) [19]. Thus, the drug proved to be safe, but could not statistically significantly show a significant benefit on cardiovascular outcome despite the high number of included patients.

Dulaglutide

Dulaglutide was the next once-weekly GLP-1 analog approved for diabetes treatment. USFDA approval was granted in 2014. To yield a pharmacokinetic, which allows a once weekly application, a molecule with 90% amino acid sequence homology to endogenous human GLP-1 is linked to an F_c fragment of human immunoglobulin G4 (IgG4). The F_{ab} fragments are substituted by two GLP-1 molecules; at each of the two F_c parts of the heavy chains, one GLP-1 molecule is bound. Binding to the F_c parts of IgG slows absorption due to the larger molecular size. The designed molecule is relatively resistant to degradation by DPP-4, and renal clearance is slowed. After a single SC administration, maximum serum concentrations are reached after about 2 days. Steady-state concentrations are achieved between 2 and 4 weeks after once-weekly administration.

In the CVOT REWIND, after a very long mean treatment duration of 5.4 years, the primary composite outcome of nonfatal myocardial infarction, nonfatal stroke, or death from cardiovascular causes (including unknown causes) occurred 12.0% of participants in the dulaglutide group and in 13.4% of participants of the placebo group (HR 0.88, CI 0.79–0.99, $p < 0.05$). All-cause mortality did not differ significantly between groups (10.8% vs. 12.0%, HR 0.90, CI 0.80–1.01; $p = 0.067$). In the dulaglutide group, 47.4% of participants reported a gastrointestinal adverse event compared with 34.1% during placebo treatment ($p < 0.0001$). At the end of the trial, hemoglobin A1c (HbA1c) in the drug group was 0.6% points lower than in the placebo group ($p < 0.0001$), and body weight was 1.5 kg lower ($p < 0.0001$) [20].

Lixisenatide

A further GLP-1 analog was approved in 2016 for the US American market: lixisenatide. It is a polypeptide consisting of 44 amino acids with a single proline substitution and a modified C-terminus of six lysine molecules. Its chemical structure makes it more resistant to degradation by DPP-4 than exenatide and needs to be injected once daily. Still, with a plasma half-life of 2.7–4.3 h, it is removed from circulation much faster than liraglutide, which is also administered once daily. The CVOT of lixisenatide was named ELIXA [21]. A total of 6068 patients with T2D and a history of myocardial infarction (83%) or hospitalization for unstable angina (17%) within the last 6 months were randomized to lixisenatide or placebo treatment. The primary composite endpoint consisted of cardiovascular death, myocardial infarction, stroke, or hospitalization for unstable angina. In the *verum* group, during the time of observation, an endpoint occurred in 406 patients (13.4%) and in the placebo group in 399 patients (13.2%) (HR 1.02, CI 0.89–1.17). Thus, in this study, no superiority to placebo could be demonstrated, but cardiovascular safety was proven for lixisenatide during the initial 2 years of treatment of patients with T2D and very high cardiovascular risk. In Europe, the drug was also approved for clinical use, but, for example, in Germany, the drug is not available as a single compound because government and health insurances did not see an additional benefit compared to already existing GLP-1 analogs. However, in 2020, a fixed combination drug of lixisenatide and insulin glargine was introduced to the German market.

Semaglutide

The latest GLP-1 analog approved for clinical usage is semaglutide. It shares a 94% structural homology with native GLP-1 and has a similar molecule structure as liraglutide but is more stable in the human body because it is less susceptible to degradation by DPP-4. Its plasma half-life is about 1 week, and the drug is administered once weekly. In the phase 3 CVOT named SUSTAIN [22] SC applied semaglutide significantly improved glycemic control during the 2 years of treatment. HbA1c was reduced by 0.7% points in the lower-dose group (0.5 mg semaglutide once weekly) and by 1.0% points in the higher-dose group (1.0 mg once weekly). The drug also reduced bodyweight significantly by 2.9 kg compared to placebo in the 0.5 mg group and by 4.3 kg compared to placebo in the 1.0 mg group. Side effects were similar compared to other GLP-1 analogs already on the market. The cardiovascular profile was noninferior to placebo. Gastrointestinal disorders such as nausea, vomiting, and diarrhea occurred more frequently in the treatment group, as expected for a drug of the GLP-1 analog class (51.5% of treated patients with 0.5 and 1.0 mg vs. 35.5% for placebo). In 11.5% of the 0.5 mg and 14.5% of the 1.0 mg groups, treatment had to be stopped due to gastrointestinal disorders versus 5.7 and 7.6% for placebo.

As known from all drugs of the GLP-1 analog class, pulse rate was increased by the medication. The mean heart rate in the treatment group, compared to placebo, increased by 2.0 bpm for 0.5 mg and by 2.5 bpm for 1.0 mg ($p < 0.001$ for both comparisons). Another important negative effect of the treatment was an increase in retinopathy complications (e.g., vitreous hemorrhage or blindness). Diabetic retinopathy complications occurred in 50 patients (3.0%) of the semaglutide group and only in 29 (1.8%) of the placebo group (HR 1.76, CI 1.11–2.78, $p = 0.02$). The authors of the study suggest that the rapid lowering of blood glucose concentrations in the treatment group might be an explaining factor, but cannot rule out direct drug-related effects. Lipase and amylase levels were significantly higher in the semaglutide group than in the placebo group, but acute pancreatitis occurred more frequently in the placebo group than in the semaglutide group (12 vs. 9 events).

In this CVOT, after 2 years of treatment, there was no significant reduction in all-cause mortality (3.8% in the treatment group vs. 3.6% in the placebo group) or cardiovascular mortality (2.7 vs. 2.8%). However, there was a significant reduction in the composite endpoint of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke of 6.6 versus 8.9% (HR 0.74, CI 0.58–0.95, $p = 0.02$ for superiority) [22]. The injectable drug was approved for the treatment of T2D in 2017 in the United States and in 2018 in the European Union, Canada, and Japan.

Semaglutide is the first GLP-1-analog; also an oral preparation was approved, about 2 years after the SC drug. The oral version is co-formulated with an "absorption enhancer," a molecule that causes a localized increase in pH. This leads to an increased solubility of the drug and to a decreased enzymatic activity in its close environment, thus protecting the drug from intragastric enzymatic degradation. The CVOT PIONEER-6 demonstrated noninferior cardiovascular safety of oral semaglutide versus placebo, but could not show superiority. The hazard ratio of the primary outcome, a composite of death from cardiovascular, causes nonfatal myocardial infarction or nonfatal stroke, after about 1.5 years of trial duration was 0.79 (CI 0.57–1.11). The HbA1c was reduced by 0.7% points as compared to placebo, and body weight was reduced by 3.4 kg [23].

Just like for liraglutide, also for semaglutide, a preparation including also a higher dosage was approved under a different brand name for the treatment of obesity, also in the absence of T2D. In the phase 3 study (SELECT), overweight and obese patients without a history of diabetes are treated for 2.5–5 years with the drug. The primary outcome measure is the occurrence of a composite endpoint consisting of CV death, nonfatal myocardial infarction, or nonfatal stroke. The study is the first CVOT to evaluate superiority in major adverse cardiovascular events reduction for an antiobesity medication. It is expected to be completed by the end of 2023 [26].

Efpeglenatide

Efpeglenatide is a GLP-1 analog consisting of a modified exenatide molecule attached to the F_c fragment of IgG (similar to the IgG modification of dulaglutide). At the time of the research for this book chapter, approval was not yet granted, but in 2021 data of the phase 3 trial, AMPLITUDE-O was published. During a median follow-up of 1.8 years, a major adverse cardiac even occurred in 7.0% of participants in the efpeglenatide group and 9.2% of the placebo group (HR 0.73, CI 0.58–0.92, $p < 0.001$ for noninferiority, $p < 0.01$ for superiority). Adjusted for the placebo treatment group, HbA1c was reduced by 1.2% points in the efpeglenatide group and body weight by 2.6 kg (both statistically significant). With these data, efpeglenatide is the first derivative of exendin-4 to demonstrate positive cardiovascular outcomes [24]. In a short 16 weeks phase 2 study, efpeglenatide was also beneficial and safe when administered in a higher dose only once a month. Further studies are needed to evaluate the long-term efficacy and safety of efpeglenatide once monthly [27].

Tirzepatide

Tirzepatide is the first incretin drug applied for approval in the United States and the EU (in 2021) using a dual incretin receptor agonism. The compound is an analog of human GIP, which was modified to also activate the GLP-1 receptor, but to a lesser extent than the GIP receptor. It is injected once weekly SC. The phase 3 trials are conducted under the study name SURPASS. In the latest trial, tirzepatide was tested in patients with T2D and medication with insulin glargine. Mean HbA1c reduction after 40 weeks of tirzepatide treatment adjusted for placebo effects was −1.5% points in the two groups with the highest dosages (for both groups $p < 0.001$). Mean body weight change from baseline was −9.1 and −10.5 kg in the two mentioned groups (both $p < 0.001$). The most common treatment-emergent adverse events in the tirzepatide groups versus placebo group were diarrhea (12–21% vs. 10%) and nausea (13–18% vs. 3%) [16]. The CVOT SURPASS-CVOT is estimated to be completed by the end of 2024.

Comparisons of Clinical Data from Available Trials and Discussion of Clinical Effects

GLP-1 analogs proved to decrease HbA1c and body weight in long-term treatment (example for liraglutide 3 mg in Fig. 35.4). The mean reduction in HbA1c of 0.75–1.5% in the first half year of treatment in phase 3 and CVOTs is seen in all drugs of this class. But as inclusion criteria and study protocols of the clinical studies are not consistent, a direct comparison of the substances is not possible with these data.

To compare substances, head-to-head trials have been conducted comparing HbA1c and body weight lowering effects of GLP-1 analogs. The once weekly formulation of exenatide was found to reduce HbA1c stronger than the twice daily formulation, and liraglutide 1.8 mg was superior to both formulations; however, differences were small (0.2 and 0.3% points lower HbA1c). There were no differences in HbA1c reduction between liraglutide 1.8 mg and dulaglutide. Lixisenatide was not inferior to exenatide twice daily, but inferior to liraglutide 1.8 mg (again small differences in HbA1c effects) [29]. The SUSTAIN 7 study compared semaglutide with dulaglutide. It found HbA1c reductions of 1.8% points for semaglutide 1.0 mg vs. 1.4% points for dulaglutide 1.5 mg. Patients taking semaglutide also lost more weight than those taking the equivalent dose of dulaglutide [30]. Also in trials comparing semaglutide 1.0 mg with exenatide LAR and liraglutide 1.2 mg, semaglutide was superior in HbA1c and weight reduction [31]. In the STEP 8 study, the weight loss efficacy of semaglutide 2.4 mg in patients without diabetes was tested against the daily injectable liraglutide 3 mg. The study showed a significantly greater average body weight reduction of 15 kg with semaglutide, compared with 7 kg under liraglutide 3 mg [32].

Also with the not yet approved GLP-1/GIP co-agonist tirzepatide, a comparator trial with semaglutide has been published (SURPASS-2). HbA1c reductions of up to 2.3% points during 40 weeks of tirzepatide treatment were significantly greater than the 1.9% point reduction achieved with semaglutide. Tirzepatide also resulted in significantly greater weight reductions, of up to 5.5 kg more than seen with semaglutide [33]. We did not report about the GLP-1 analog albiglutide, for which CVOTs and comparator studies have been

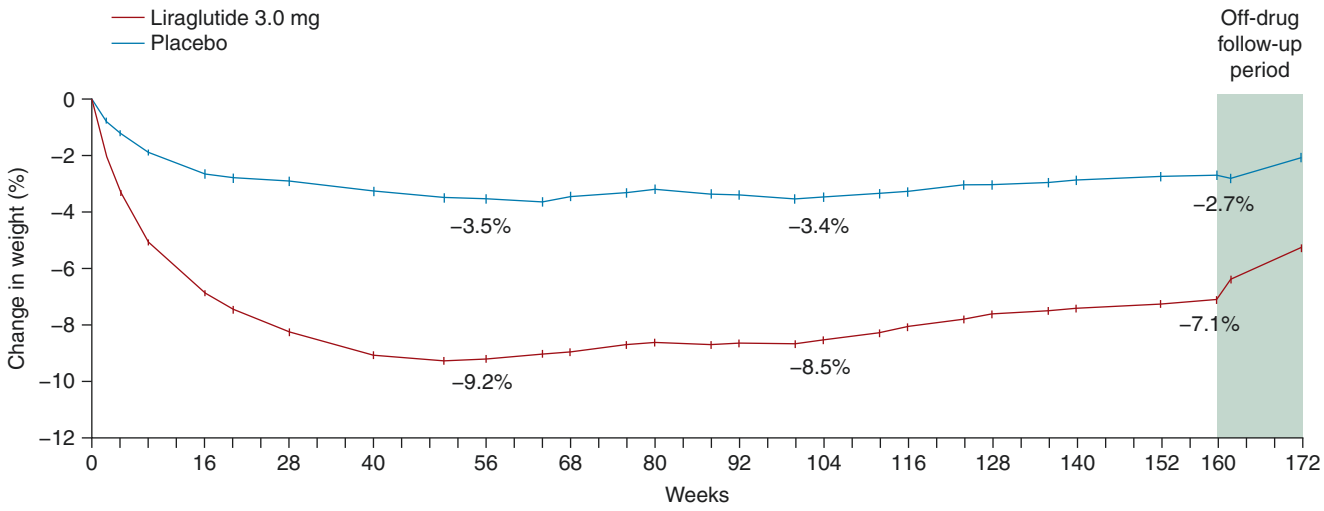

Fig. 35.4 Mean relative change in bodyweight for participants in a randomized, double-blind trial with liraglutide 3 mg and placebo during 3 years of treatment. Data shown are the observed means (with standard error) of the full-analysis set (patients who completed each scheduled visit). * $p < 0.0001$. (From [28])

performed, because in 2017 and 2018, the manufacturer withdrew the drug from worldwide markets, according to their own information for economic reasons.

To sum up GLP-1 analog comparator studies, of today's available GLP-1 agonists, semaglutide seems to be the most effective in terms of HbA1c reduction in T2D and in weight reduction. The GLP-1/GIP co-agonist tirzepatide seems to have an even higher efficacy than semaglutide and may improve pharmacological T2D and obesity treatment if approved.

As of today, the available drugs with a reduction in the primary composite cardiovascular endpoint are liraglutide, dulaglutide, and semaglutide after SC injection. A reduction of cardiovascular and all-cause mortality was found for liraglutide and oral semaglutide. An overview about cardiovascular outcome data of GLP-1 analogs can be seen in Fig. 35.5 and in Table 35.2.

The differences in blood glucose control between the pharmacologic agents cannot explain why liraglutide, dulaglutide, and semaglutide, but not lixisenatide and exenatide LAR, had positive cardiovascular outcomes. Different study designs may well be the cause for these discrepancies. However, it cannot be ruled out that there are different beneficial effects of the drugs with positive cardiovascular outcome than mere lowering of blood glucose. Or lixisenatide and exenatide LAR cause other negative effects regarding cardiovascular events but were not identified in available clinical trials.

Pipeline of Incretin-Based Substances for Diabetes and Obesity Treatment

Due to the elegant mechanism of utilizing physiological incretin receptor pathways in the treatment of T2D and obesity, the drug development pipeline of potential incretin-based candidates is full. Today, the greatest interest lies in the development of substances activating two (like tirzepatide), or even more, different incretin receptor types simultaneously.

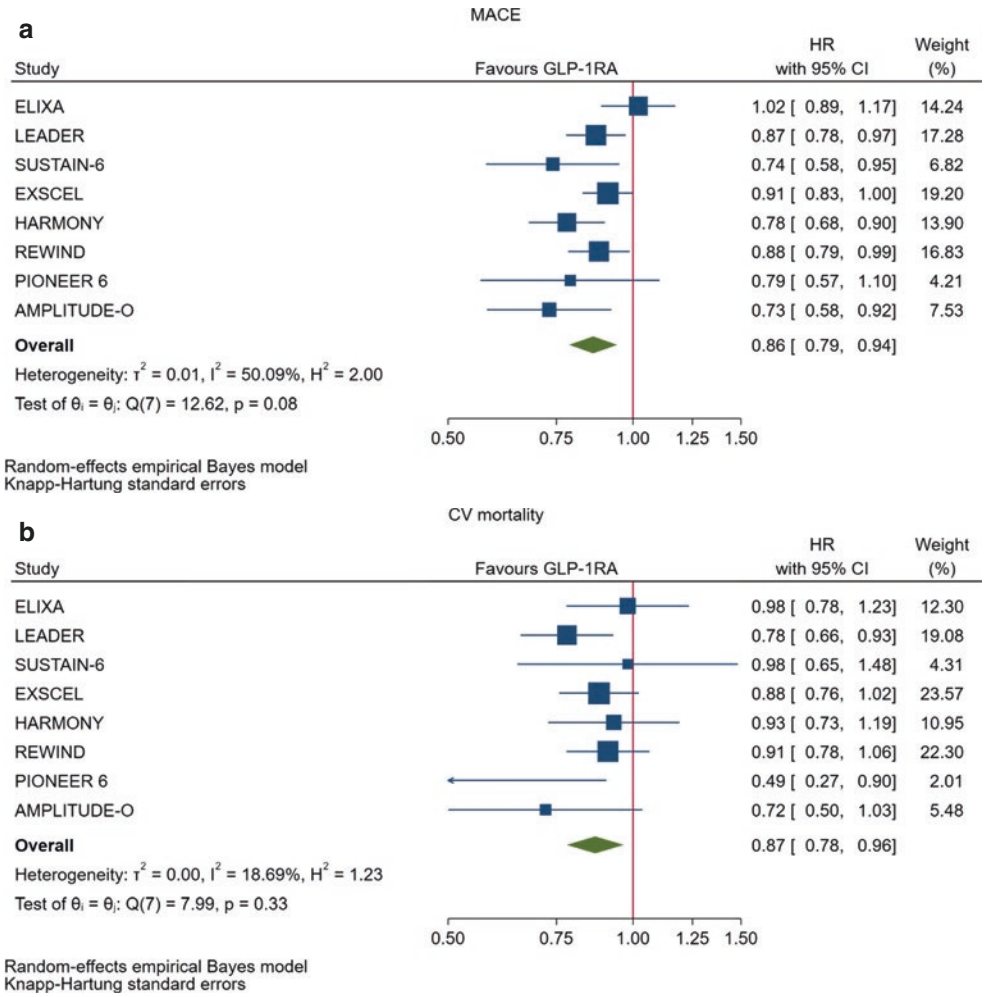

Fig. 35.5 Forest plots of the meta-analysis of cardiovascular outcome trials with GLP-1 receptor agonists versus placebo treatment on major cardiovascular events (**a**) and cardiovascular mortality (**b**). The results are expressed as hazard ratio (HR). For study active components and other specifications, see Table 35.2. *CI* confidence interval, *CV* cardiovascular, *GLP-1RA* glucagon-like peptide-1 receptor agonist, *MACE* major cardiovascular events. (From [34])

An interesting candidate is cotadutide, a dual receptor agonist based on the molecular structure of oxyntomodulin, which is another gastrointestinal peptide that is as GLP-1 physiologically secreted from the L-cells of the intestine after oral nutrient uptake. Cotadutide activates both the GLP-1 and the glucagon receptor with similar activity. The drug developers suggest that the blood glucose-increasing effect of glucagon is compensated by the glucose-lowering action of GLP-1 but that the glucagon agonism leads to appetite suppression and further weight loss. A phase 2b trial in overweight and obese patients with T2D with daily SC injections of the drug was already published. Weight loss after 1 year of treatment in the high-dose group was −4.3% of the baseline weight (placebo-adjusted) and higher than in the comparator study group with single GLP-1-activation through liraglutide 1.8 mg with only −2.6% of bodyweight. HbA1c reduction in the cotadutide high-dose groups was −0.7% points (placebo-adjusted) and similar to the liraglutide group [35].

Another promising target for diabetes and obesity treatment is the CCK receptor 1. CCK is another gastrointestinal peptide hormone secreted from enteroendocrine cells of the duodenum in response to a meal. Its physiologic functions include the inhibition of gastric emptying, the stimulation of exocrine pancreatic secretion, and the stimulation of production and secretion of bile. A dual GLP-1 and CCK receptor co-agonist showed in diabetic mice enhanced beneficial effects on HbA1c, glucose tolerance, and pancreas function restoration as compared with semaglutide [36].

Clinical development also started with a compound with agonism on three peptide receptors: on the GLP-1, the glucagon, and the GIP receptor. The investigated substance, which was not yet given a commercial name, is structurally based on the exendin-4 sequence. It was then modified to also significantly activate the glucagon and the GIP receptor and to avoid cleavage through DPP-4. Studies in obese mice and in monkeys showed enhanced effects on each of the metabolic outcomes, superior to those achieved with dual GLP-1/glucagon receptor agonists. In the first-in-man (phase I) study, the compound was well tolerated, and further clinical trials can be expected [37].

Side Effects of the GLP-1 Analog Class

Side effects of GLP-1 analogs—unlike classical off-target adverse effects as known from other drugs (like, e.g., muscle and joint pain in statin therapy)—include physiological effects of GLP-1 receptor activation. The most pronounced side effect is gastrointestinal intolerability. This includes abdominal fullness, meteorism, belching, flatulence, nausea, and vomiting. In the semaglutide CVOT, the placebo-adjusted rate of gastrointestinal symptoms was 16%. A further frequently discussed side effect of GLP-1 analogs is the increased risk of pancreatitis. Shortly, after market introduction of exenatide, the USFDA issued an alert reporting 30 cases of pancreatitis associated with the drug. Several post market surveillance studies have followed up on this issue, and the debate is still ongoing whether GLP-1 analogs (and DPP-4 inhibitors) increase the risk of pancreatitis. Currently, existing data does not support increased risks of pancreas damage due to GLP-1 analogs or DPP-4 inhibitors. In a meta-analysis combining all available GLP-1 analog CVOT data, a hazard ratio of 1.05 (CI 0.78–1.40) was found for pancreatitis and 1.12 (CI 0.77–1.63) for pancreatic cancer [38]. However, especially for pancreatic cancer, the follow-up duration of those trials ranging from a median of 1.3 to 5.4 years may not be long enough for already giving an all-clear signal.

DPP-4 Inhibitors

An alternative way of utilizing the beneficial incretin effects on glucose metabolism is inhibiting the GLP-1 degrading enzyme DPP-4 and thus prolonging endogenous GLP-1 plasma half-life. However, the glucose-lowering effect of DPP-4 inhibitors is much smaller than the effect of a direct agonism on the GLP-1 receptor elicited with GLP-1 analogs. The first DPP-4 inhibitor approved for the treatment of diabetes was sitagliptin in 2006. Indication for prescription is poor glycemic control in T2D. It has to be prescribed in combination with diet and exercise, with or without other oral hypoglycemic agents and with or without insulin. Available tablets are of 25, 50, and 100 mg, and there are fixed combinations with other oral antidiabetic drugs available. The usual sitagliptin dose in adults with good renal function is 100 mg once daily. Adverse reactions occur seldom and include headache, nausea, and rash. Hypoglycemia can occur if treatment is combined with other blood glucose-lowering drugs. Excretion happens mainly unchanged, and only about 15% of the drug is metabolized in the liver, largely by the cytochrome P450 system (CYP3A4 and 2C8), making liver injury by the drug a rare side effect. A CVOT was performed (named TECOS) and proved cardiovascular safety [39].

In 2007, the second DPP-4 inhibitor was approved for the treatment of T2D, vildagliptin, and in 2009, the third drug of this class was approved, saxagliptin. However, in the cardiovascular outcome study for saxagliptin with T2D patients at increased risk for cardiovascular disease (SAVOR-TIMI [40]), there was a warning sign for increased mortality as compared to placebo treatment: there was a trend for an increase in all-cause mortality (HR 1.11, CI 0.96–1.27) based on about 800 observed deaths, which was driven by non-cardiovascular deaths [40]. Furthermore, the study showed a statistically significant 27% increased rate for hos-

pitalization due to heart failure in the drug group: 3.5% of patients who were treated with saxagliptin were hospitalized for heart failure compared to only 2.8% of patients treated with placebo (HR 1.27, CI 1.07–1.51, $p = 0.007$). In 2015, the USFDA released a warning stating "*A potential increase in all-cause mortality with saxagliptin was observed*." A later large retrospective cohort analysis could not find an increased risk of heart failure for saxagliptin compared with the use of other antidiabetic drugs [41], and the CVOTs of the DDP-4 inhibitors sitagliptin, alogliptin, and linagliptin did not find an increased risk for heart failure for these three substances. The debate about the SAVOR-TIMI results is still ongoing.

Many other chemical compounds have been developed up-to-date inhibiting DPP-4 by variable molecular mechanism. Approval status in the different countries differs, and many of the substances are only approved in either Asian countries, the European Union, or the United States. Among DPP-4 inhibitors approved for the treatment of T2D in the United States, implying the conduction of a cardiovascular outcome study, alogliptin, the cardiovascular outcome study is called EXAMINE [42]. Another DPP-4 inhibitor approved for T2D treatment is linagliptin, the study name CARMELINA [43]. For gemigliptin, anagliptin, teneligliptin, trelagliptin, omarigliptin, and evogliptin, currently no (cost and time intensive) cardiovascular outcome studies are planned, and accordingly, no approval in countries requiring these studies will be possible.

The effects of DPP-4 inhibitors on HbA1c are modest. In the four placebo-controlled CVOTs mentioned above, HbA1c reduction versus placebo was 0.2–0.4% points. Significant reductions in body weight did not occur. Favorable effects of DPP-4 inhibitors on all-cause mortality, cardiovascular mortality, myocardial infarction, or stroke in patients with T2D could not be demonstrated up to date [44].

Concluding Remarks

- GLP-1 analogs reduce HbA1c and body weight of patients with type 2 diabetes consistently in clinical studies. In CVOTs, HbA1c was reduced between 0.3 and 1.0% points, body weight by about 0.7–4.3 kg compared to placebo. After an initial decrease in both parameters, in about the first half year of treatment plateau is reached, and treatment needs to be continued to maintain this effect.
- For liraglutide, dulaglutide, and semaglutide, positive results of CVOTs are available: liraglutide reduced the primary composite cardiovascular, as well as cardiovascular mortality and all-cause mortality. Dulaglutide reduced the occurrence of the primary composite cardiovascular endpoint, semaglutide in the SC formulation the occurrence of the primary composite endpoint and in the oral formulation cardiovascular and all-cause mortality.
- The most common side effects of GLP-1 analogs are dyspeptic complaints including abdominal fullness, meteorism, belching, flatulence, nausea, and vomiting. In <10% of patients, these complaints led to a discontinuation of treatment in clinical studies. Still under review are reports of pancreas damage and of medullary thyroid carcinoma. But as seen from current data, it is rather unlikely that these events in the studies were related to GLP-1 agonist treatment.

Box 35.1 Cardiovascular Outcome Trials (CVOTs)

The United States Food and Drug Administration (USFDA) issued a declaration in 2008 that all new diabetes drugs have to rule out an excess cardiovascular risk. This decision was driven by the high prevalence of cardiovascular disease in diabetes (accounting for approximately 70% of deaths) and by concerns about a study claiming an increased cardiovascular risk for rosiglitazone, which was published shortly before [45]. In these cardiovascular outcome trials (CVOTs), cardiovascular safety is defined by the USFDA as an upper bound of the two-sided 95% confidence interval for major adverse cardiovascular events of less than 1.8 preapproval and 1.3 postapproval. Furthermore, CVOTs are used to analyze if groups treated with new diabetes drugs show statistically significantly less cardiovascular events groups treated with than placebo.

Multiple Choice Questions

1. How do GLP-1 analogs exert their blood glucose-lowering effect? By.
   (a) Increasing **insulin secretion of the pancreatic β-cell**
   GLP-1 analogs bind to the GLP-1 receptor expressed on the surface of pancreatic β-cells and stimulate the adenylyl cyclase pathway, resulting in increased insulin synthesis and increased release of insulin.
   (b) Directly acting on glucose transporters (GLUT-family)
   (c) Blocking the sodium/glucose cotransporter 2 (SGLT-2) in the kidney
   (d) Inhibiting the enzyme alpha-glucosidase in the intestine
   (e) Inhibiting the enzyme dipeptidyl peptidase-4 (DPP-4)

2. Which effects are *not* known for GLP-1 analogs?
   (a) Increasing insulin secretion
   (b) Reducing blood glucose concentrations when elevated
   (c) Promoting satiety
   (d) Decreasing intestinal motility
   (e) **Reducing pulse rate**
   GLP-1 analogs do not reduce pulse rate. On the contrary, in clinical studies, a slight increase in pulse rate has been noted in GLP-1 treated patients.
3. What was the average HbA1c change yielded by GLP-1 analog therapy in type 2 diabetes in the cardiovascular outcome trials?
   (a) Increase of more than 1.0 percentage points
   (b) Increase of >0–1.0 percentage points
   (c) No change in HbA1c
   (d) **Decrease of > 0–1.0 percentage points**
   In approval studies, GLP-1 analogs reduced HbA1c compared to placebo treatment between 0.3 and 1.0 percentage points (Table 35.2).
   (e) Decrease of more than 1.0 percentage points
4. Which of the following diabetes drugs does *not* directly bind to the GLP-1 receptor?
   (a) Exenatide
   (b) **Sitagliptin**
   Sitagliptin is an inhibitor of the dipeptidyl peptidase 4 (DPP-4) and does not directly bind to the GLP-1 receptor.
   (c) **Dulaglutide**
   (d) Liraglutide
   (e) **Semaglutide**
5. Which of the following answers is *not* a typical side effect of the GLP-1 analog class?
   (a) Nausea
   (b) Increase in pulse rate
   (c) **Hypoglycemia**
   Due to the glucose dependent insulinotropic effect of GLP-1, hypoglycemias are not a typical side effect of GLP-1 analogs.
   (d) Diarrhea
   (e) **Vomiting**
6. For which of the following GLP-1 analog preparation a reduction in all-cause mortality could be demonstrated?
   (a) Semaglutide SC
   (b) Lixisenatide
   (c) **Liraglutide**
   For liraglutide in the cardiovascular outcome trial, a reduction in all-cause mortality was demonstrated.
   (d) **Exenatide** LAR
   (e) **Dulaglutide**
7. What is the mechanism how in exenatide LAR plasma half-life is prolonged?
   (a) **Attachment to and incorporation in so-called microspheres.**
   The long-acting formulation of exenatide (exenatide LAR) was created by binding the exenatide molecule to the surface of a microsphere and by incorporating the molecule into the microsphere. This prolongs the absorption of the exenatide molecule after SC application.
   (b) **Binding** of exenatide to human albumin
   (c) **Expression** of exenatide by body cells after mRNA injection
   (d) **Increasing** the exenatide concentration in the drug solution
   (e) Binding of exenatide to an absorption enhancer
8. Which of the following GLP-1 analogs is injected twice daily?
   (a) **Exenatide**
   Exenatide is injected twice daily in the treatment of type 2 diabetes
   (b) **Liraglutide**
   (c) **Dulaglutide**
   (d) **Exenatide** LAR
   (e) **Semaglutide**
9. Which of the following GLP-1 analogs was approved for the treatment of obesity also in the absence of type 2 diabetes?
   (a) Exenatide
   (b) **Liraglutide**
   Liraglutide in the formulation of 3 mg, injected once daily was approved for the treatment of obesity also in the absence of type 2 diabetes
   (c) **Dulaglutide**
   (d) **Exenatide** LAR
   (e) **Lixisenatide**
10. For which of the following GLP-1 analogs an oral formulation is available?
   (a) Exenatide
   (b) Liraglutide
   (c) Dulaglutide
   (d) **Semaglutide**
   Semaglutide is approved in an oral formulation taken once daily.
   (e) Lixisenatide

- First neuroimaging study, which investigates the central nervous effects of GLP-1 analog administration in humans with functional MRI, demonstration changes of hypothalamic activity after GLP-1 analog administration, which are accompanied by decreased hunger and reduced energy intake.

Glossary

Glucagon-like peptide 1 (GLP-1) Peptide hormone produced mainly in the L-cells of the distal ileum and the colon. Increases insulin secretion of the **β**-cells of the pancreas when blood glucose is elevated. Analogs of GLP-1 were the first incretin mimetics approved for the treatment of type 2 diabetes.

Gastric inhibitory polypeptide (GIP, later also termed glucose-dependent insulinotropic peptide) Peptide hormone produced in the enteroendocrine cells of the duodenum and the jejunum. Increases insulin secretion of the **β**-cells of the pancreas when blood glucose is elevated.

Functional magnetic resonance imaging (fMRI) Technique to assess brain perfusion and thus receive information about the activity of different areas of the brain.

Sodium-Glucose Cotransporter 2 Inhibitors

36

George Dailey III and Joel Rodriguez-Saldana

Introduction

The concentration of glucose in plasma is held within narrow limits primarily to ensure fuel supply to the brain; the kidneys play a key role in glucose homeostasis by ensuring that glucose is not lost in the urine [1]. Contrary to common belief, the liver is not the only gluconeogenic organ although it does produce 80% of the endogenously derived glucose; the remaining 20% is produced by the kidney, which also contains the necessary gluconeogenic enzymes [2]. In non-diabetic individuals, the kidney filters approximately 180 mg of glucose daily [2]. Ninety percent of this is absorbed via the energy-dependent sodium-glucose cotransporter receptor moving from the tubular lumen to the arterioles via GLUT 4 glucose transport back into the circulation; the remaining 10% is reabsorbed in the distal collecting tubule leaving no glucose excreted into the urine [2]. Both at the liver and kidney, insulin is a potent inhibitor of gluconeogenesis; most of the filtered glucose is reabsorbed by the cotransporter enzyme SGLT2, and the remaining 10–20% is reabsorbed by the cotransporter SGLT1 [3]. Although the kidneys freely filter plasma glucose, none appears in the urine [1]. Glucose reabsorption from the glomerular filtrate by SGLT2 and SGLT1 occurs at different segments of the apical membrane of cells in the proximal tubule and from the passive exit of glucose through the basolateral membrane to the plasma via GLUT2, and at the expense of the extrusion of three sodium ions for every tw potassium ions entering the cell [1–3]. Glucose produced by renal gluconeogenesis is completely consumed by the kidney, but in patients with type 2 diabetes, insulin resistance increases the production of glucose in the kidney and liver despite high levels of fasting glucose [3].

One of the most important entries into the diabetes therapy armamentarium is the sodium-glucose cotransporter 2 inhibitors (SGLT 2 inhibitors), which first reached the US and European markets in early 2013. The idea for this mechanism of action is derived from the identification of an older drug, phlorizin, originally derived from the bark of an apple tree as a treatment for malaria [4]. Phlorizin caused marked increase in urinary glucose excretion through competitive inhibition of SGLT2, the principal transporter of renal glucose reabsorption and of SGLT1, a lesser glucose transporter in the kidney [3]. Phlorizin was useful for mechanistic studies in animal models but was too toxic for use in patients [5]. Additionally, there is a naturally occurring mutation in this co-transporter found in less than 1% of the population from the analysis of familial renal glucosuria, a rare genetic disorder of renal glucose transport [6, 7]. These patients have been known for decades since the original study of Hjärne of three generations of a single family [8, 9]. They have glucosuria with normal plasma glucose unless they also happen to have diabetes, which occurs rarely in this population. They seem to live perfectly normal lives except for increased risk of vaginal candidiasis related to glycosuria. Work began in the 1990s looking for less-toxic analogs of phlorizin, which led to the currently available marketed drugs with the discovery of dapagliflozin and canagliflozin [10, 11].

The Emergence of Sodium-Glucose Cotransporter-2 Inhibitors (SGLT2i)

These drugs have rapidly become extremely valuable tools in treating diabetes. Most of the published data has come from type 2 diabetes trials although in recent years an increasing number of studies about their use in type 1 diabetes have also been published. All the currently available SGLTi reduce both fasting and postprandial hyperglycemia and HbA1c between 0.6–1.0% [12–14]. There is also associated weight loss averaging 1–5 kg in most patients, presumably related primarily to caloric loss from excreted glucose [12]. The mechanism of action is independent of insulin itself and therefore should

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_36

remain effective at all stages of the disease and work in a complementary fashion with other antidiabetics [12]. The risk of hypoglycemia with the use of SGLTi as monotherapy is similar to the use of other agents unless they are paired with sulfonylureas or insulin [15]. Several other interesting metabolic consequences have been identified including somewhat elevated plasma glucagon and ketone body production, which will be elaborated on further in this chapter, in addition to cardiorenal and pleiotropic effects [16–21].

As of December 2021, the FDA and European agencies have four agents for clinical use: canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin. Six additional compounds have undergone clinical trials: tofogliflozin [22], luseogliflozin [23], bexagliflozin [24], sotagliflozin [25], remogliflozin [26], ipragliflozin [27], and recent basic research that has confirmed the SGLT2 inhibitor properties of swertisin, a novel islet cell differentiation inducer [28, 29]. Table 36.1 shows the current list of SGLT2 inhibitors including FDA-approved and non-FDA approved.

The efficacy and safety data appear similar for the drugs studied to date, and very few head-to-head trials are available for direct comparison. The efficacy and side effects appear similar in most trials. In general, phase 3 trials have shown a HbA1c reduction of 0.7–1.0% as monotherapy or in addition to other antidiabetic agents including insulin.

Mechanism of Action

In diabetes, there is an apparently maladaptive *increase* in the tubular threshold from the normal of 180 mg up to 220–240 mg making it even harder to eliminate excess serum glu-

Table 36.1 SGLT Inhibitors

Name	Dosage	HbA1c reduction	Additional benefits	Comments
Canagliflozin	100, 300 mg/day	0.77–1.03%	Reduced risk of cardiovascular death, myocardial infarction or stroke (CANVAS) Blood pressure reduction	Risk of lower limb amputations
Empagliflozin	10, 25 mg/day	0.66–0.78%	Reduced risk of heart failure and cardiovascular death (EMPA-REG OUTCOME, RECEDE-CHF) Blood pressure reduction (EMPA-REG BP) Effective in patients with previous stroke or myocardial infarction	
Dapagliflozin	5, 10 mg/day	0.82–0.89%	Reduced risk of cardiovascular death and hospitalization from heart failure (DECLARE-TIMI) LDL cholesterol reduction	
Ertugliflozin	5, 15 mg/day	0.99–1.16%	In patients with chronic kidney disease stage 3A, reduce HbA1c, body weight, systolic blood pressure, maintaining glomerular filtration rate (VERTIS-CV)	Reduce dose in patients with glomerular filtration rate <60 mL/min/1.73 m^2
Tofogliflozin	5, 10, 20, 40 mg/day	0.56–0.68%	Post-marketing surveillance showed consistent reductions in HbA1c and body weight; 12.6% of patients reported adverse drug reactions (ADR), including serious ADR in 1.5% of patients	By comparison with other SGLT2 inhibitors, clinical and real-world studies remain sparse
Luseogliflozin[a]	2.5, 5 mg/day	0.37–0.60%	Significant decreases in HbA1c and body weight, especially in patients with higher body mass index	By comparison with other SGLT2 inhibitors, clinical and real-world studies remain sparse
Bexagliflozin[a]	5, 10, 20 mg/day	0.55–0.80%	Significant decreases in HbA1c, fasting blood glucose and body weight Similar incidence of adverse events in all active arms	By comparison with other SGLT2 inhibitors, clinical and real-world studies remain sparse
Sotagliflozin[a]	200, 400 mg/day	0.42%	Significant decreases in HbA1c, body weight and systolic blood pressure Reduced incidence of heart failure by 32%, myocardial infarction by 28%; neutral effects on all-cause mortality, cardiovascular mortality and stroke Reduced risk of cardiovascular death, emergency visits and hospitalization from heart failure (SCORED)	Increased incidence of diarrhea, genital mycotic infections, volume depletion and diabetic ketoacidosis
Ipragliflozin[a]	50 mg/day	0.24–1.30%	Significant decreases in HbA1c, fasting blood glucose (8.2–46.5 mg/dL), body weight and triglycerides	By comparison with placebo, no differences in blood pressure, low density lipoproteins or uric acid By comparison with other SGLT2 inhibitors, clinical and real-world studies remain sparse
Remogliflozin[a]	100, 250 mg/day	0.72%	Significant decrease in fasting and postprandial blood glucose: 17.8 mg/dL and 39.2 mg/dL respectively Overall incidence of adverse events: 8.5%, including genital mycotic and urinary tract infections; hypoglycemia incidence: 1.3%	By comparison with other SGLT2 inhibitors, clinical and real-world studies remain sparse

[a]Still not Approved by the FDA

cose. In the presence of SGLT 2 inhibitors, the threshold for glucose elimination is reduced to about 40 mg, allowing much more glucose loss. This tends to reduce both fasting and postprandial glucose levels [30]. As there is caloric loss from increased glucose excretion, weight loss is usually seen as well in the range of 2–3 kg in most studies. Approximately two thirds of the loss is secondary to fat loss and one third from fluid loss. A molecule of sodium is also excreted with each molecule of glucose resulting associated with a net loss of body sodium and to a small reduction in systolic blood pressure averaging about 5 mmHg. This may be beneficial since most patients tend to have some sodium excess. However, in patients somewhat sodium or volume depleted, this could result in excessive blood pressure reduction and dehydration. In the United States, the Food and Drug Administration (FDA) has reported approximately 100 cases of acute kidney injury to patients placed on these drugs. Many cases are seen in older patients with some renal dysfunction who are also taking loop diuretics. Therefore, cautious is advised in these patients, starting with lower doses and observing the initial response.

Individual Profiles

Canagliflozin was approved by the FDA in the United States in March of 2013 for use in patients with type 2 diabetes mellitus, and it was the first of the SGLT2 inhibitors to be released in the market. The initial dose is 100 mg daily and can be increased to 300 mg in those tolerating the medication if GFR is ≥60 mL/min/1.73 m^2. Fixed doses of canagliflozin in combination with metformin are available in 50/500, 50/1000, 150/500, and 150/1000 mg [31]. Glucosuric effects are estimated to be an excretion of approximately 100 g of urinary glucose per day. It has the most largest glucosuric effect among approved SGLT2 inhibitors. In addition to its main effect as an SGLT2 inhibitor, canagliflozin induces weak inhibition of SGLT1, which is located in both the gut and renal tubules. SGLT1 inhibition is thought to have effects in lowering postprandial hyperglycemia by delaying intestinal glucose absorption, an observation from studies published in 2013 [32].

Comparative Efficacy and Safety of Canagliflozin with Oral Antidiabetics

The efficacy of canagliflozin has been studied as add-on therapy to metformin in comparison with other antihyperglycemic agents such as DPP4-inhibtors and sulfonylureas according to a randomized, double blinded trial was published in 2013 comparing the efficacy of canagliflozin with sitagliptin in patients on monotherapy with metformin ≥1500 mg daily. After 52 weeks, both sitagliptin 100 mg and canagliflozin 100 mg were effective in lowering HbA1C by an average of 0.73%, while canagliflozin at a dose of 300 mg/day decreased HbA1C by 0.88% [33]. Both canagliflozin doses were superior in weight reduction (3.8% and 4.2%) compared with a decrease of 1.3% in the sitagliptin group [33].

In 2015, canagliflozin was compared with glimepiride in a phase 3, randomized, double blinded, 104 week-long study as add-on therapy for diabetic patients already on therapeutic doses (≥1500 mg today daily) of metformin [34]. Canagliflozin decreased HbA1C by an average of 0.65% for the 100 mg dose and 0.74% for the 300 mg dose in comparison to glimepiride, which resulted in an average 0.55% reduction. The use of canagliflozin was associated with a lower risk of hypoglycemia, with a prevalence of 40% in the glimepiride group and only 6 and 8% in the canagliflozin 100 mg and 300 mg groups, respectively. Weight loss was observed with canagliflozin, as opposed to weight gain for patients on glimepiride, with an average loss of 4.1% (3.6 kg) of pretreatment body weight for the 100 mg and 4.2% (3.6 kg) for the 300 mg groups [34].

Comparative Efficacy of Canagliflozin with Insulin

Data about the use of canagliflozin in patients on insulin therapy were published in one of the reports of the CANVAS trial comparing canagliflozin and placebo to patients on basal or basal-bolus insulin for 18 weeks with a 52-week follow-up [35]. The addition of canagliflozin to insulin improved glycemic control: HbA1c was 8.3% in both groups; at 18 weeks, reductions in HbA1c of 0.62% and 0.73% for canagliflozin 100 mg and 300 mg, respectively, were observed in comparison to placebo with persisting differences in HbA1c after 52 weeks with a reduction of 0.58% in the 100 mg group and 0.73% in the 300 mg group in comparison to placebo [35]. There were differences in weight and blood pressure reduction as well. A weight loss of 1.9% and 2.4% was seen for each canagliflozin dose. Systolic blood pressure decreased by an average of 3.1 and 6.2 mmHg and diastolic blood pressure by 1.2 and 2.4 mmHg in each of the canagliflozin groups [35]. In another randomized controlled trial, the efficacy and safety of canagliflozin was compared with liraglutide in patients with type 2 diabetes previously controlled with multiple doses of insulin (MDD) [36]. Basal insulin was maintained, and bolus insulin was randomly switched to canagliflozin, 100 mg/day or liraglutide, 0.30.3–0.9 mg/day for 24 weeks [36]. Changes in HbA1c were comparable between treatments, and both treatments maintained HbA1c levels as baseline with stable glucose variability and no severe hypoglycemia at 24 weeks, with reduced total insulin doses and improvements in quality of life [36].

Safety and efficacy of canagliflozin has been evaluated in patients with preexisting chronic kidney disease with GFRs between ≥30 and ≤50 mL/min/1.73 m^2. Placebo-subtracted differences in A1c values were seen for the 100 mg and 300 mg groups from baseline (0.27% and 0.41%). Lower body weight and blood pressure for both doses in comparison with placebo were also documented [37].

Dapagliflozin was approved for treatment in patients with type 2 diabetes mellitus in the United States in 2014 as an adjunct to diet and exercise. It is a highly selective SGLT2 inhibitor. The initial dose is 5 mg, which can be increased to 10 mg orally daily. It is available in combination with metformin as well [31].

Dapagliflozin has been observed to be non-inferior to sulfonylureas and superior to DPP-4 inhibitors as add-on therapy to metformin. Monotherapy comparing metformin and dapagliflozin has been evaluated in treatment naïve patients. Results from this study demonstrated non-inferiority between metformin and dapagliflozin. Dapagliflozin as monotherapy decreased HbA1C by an average range of 0.55–0.9% in comparison to 0.73% with metformin [38]. Dapagliflozin is also effective in lowering HbA1c when added to metformin. A 52-week double-blinded trial with patients having HbA1c values between 8% and 12% at baseline showed significant improvement [39]. Dapagliflozin added to metformin decreased HbA1C an average of 1.2%, which was significantly lower than the combination of saxagliptin with metformin (0.9%). This study also compared triple therapy with all three agents and found superiority to dual therapy by reducing HbA1c by up to 1.5%. Weight loss was superior in the dual therapy dapagliflozin and metformin group with an average loss of 2.8% (2.1 kg) and in the triple therapy group, which lost an average of 2.4% (2.1 kg) compared to the saxagliptin and metformin group (no significant change seen) [39]. The efficacy of dapagliflozin has been compared to sulfonylureas: glipizide was compared to dapagliflozin and resulted in non-inferiority at 52 weeks [40]. This trial was extended for 2 years, and a sustained decrement in HbA1C was observed with dapagliflozin compared with glipizide (0.32% vs 0.14%) [40]. An additional 52-week, randomized trial compared the efficacy and safety of dapagliflozin as monotherapy or combined with saxagliptin versus glimepiride in patients with type 2 diabetes previously receiving metformin [41]. Mean HbA1c change from baseline was −0.82 with dapagliflozin alone, −1.20% with dapagliflozin plus saxagliptin, and −0.99% with glimepiride [49]. Fasting blood glucose decreased significantly with dapagliflozin plus saxagliptin compared with glimepiride and was similar when not in combination [41]. Both dapagliflozin regimens decreased body weight and systolic blood pressure; the combined incidence of hypoglycemia was lower with dapagliflozin, and genital infections were more frequent [41].

Empagliflozin the FDA-approved empagliflozin as an antihyperglycemic agent to be used in patients with type 2 diabetes mellitus in the United States in 2014. It is available in a starting dose of 10 mg, which can be increased to 25 mg daily in patients with a GFR ≥ 45 mL/min/1.73 m^2. Its glucosuric effects are estimated to be 78 g of glucose per day. Like canagliflozin and dapagliflozin, it also has weight loss and blood pressure-lowering effects.

Empagliflozin has been studied as add-on therapy to metformin in comparison to sulfonylureas as well as triple therapy with DPP-4 inhibitors and metformin. A double -phase 3, 104-week long study in patients with poor diabetes control on monotherapy with metformin was randomized to either glimepiride or empagliflozin therapy [42]. At baseline HbA1c levels between 7% and 10%, empagliflozin 25 mg significantly decreased HbA1c a mean of 0.11% more than glimepiride. Adverse events were similar in both groups, but there was a marked difference in the frequency of hypoglycemia between the empagliflozin and glimepiride groups (2% vs 24%) [42]. A 208-week extension of this trial, the adjusted mean difference in change from baseline in HbA1c with empagliflozin versus glimepiride, was statistically significant, and hypoglycemic episodes occurred in 3% of patients on empagliflozin and 28% on patients receiving glimepiride [43]. Addition of empagliflozin 10 mg and 25 mg was compared to placebo in a 24-week long, double-blinded trial with poorly controlled type 2 diabetic patients on linagliptin and metformin combination therapy [44]. By comparison with placebo, the empagliflozin 10 mg and 25 mg groups were observed to have a −0.79% and −0.7% difference in HbA1c from baseline. Addition of empagliflozin to linagliptin and metformin had no added adverse effects. Weight loss and blood pressure benefits were seen in both empagliflozin groups. Hypoglycemia occurred more frequently in the empagliflozin 25 mg group versus the placebo group in this trial (2.7% vs 0.9%) [44]. Positive outcomes and improvement in glycemic control have been observed with the use of empagliflozin with other agents including sitagliptin, pioglitazone, and insulin therapy (both basal and basal/bolus regimens) [45–48]. Recent comparisons between 25 mg empagliflozin and one-weekly 1 mg oral semaglutide have shown significant differences on HbA1c and body weight versus empagliflozin [49, 50].

Cardiovascular Benefits of SGLT2 Inhibitors

Approvals for most new antidiabetic agents in the United States have included a requirement for generally large-scale cardiovascular outcome trials primarily to be certain they do not increase cardiovascular risk. The first of these for this new class was presented at the European Association for the Study of Diabetes (EASD) in September 2015. In contrast to previous studies, this one for empagliflozin (EMPA-REG Trial) showed striking benefit particularly in cardiovascular mortality (38% relative risk reduction), hospitalizations for congestive heart failure (35% relative risk reduction), and death from any cause (32% relative risk reduction). Death from any cause was reduced by 32% [51]. This was much less striking for myocardial infarctions and nonexistent for stroke benefit. The median duration of this trial was 3.1 years. Remarkably, the survival curves began to diverge within about 3 months of beginning the trial. Although there was an expected reduction in plasma glucose, it seems unlikely that this effect could result in a benefit of this magnitude so quickly. A proposed mechanism for such rapid benefits has been reduction in arterial stiffness. Sodium and glucose loss reduces extracellular fluid volume and blood pressure. This reduces car-

diac pre and after load and myocardial metabolism, improving both systolic and diastolic function. All of this may play a role in the observed rapid reduction in hospitalizations for heart failure and cardiac death. The majority of subjects were treated with platelet inhibitors, statins, and adequate blood pressure control. Therefore, the benefits appear to be over and above these standard therapies [52]. In addition to their established efficacy as antidiabetics, clinical trials comparing the use of empagliflozin with GLP-1 agonists have shown that the use of SGLT2 inhibitors is associated with consistent reductions in hospitalization for heart failure among type 2 patients with and without cardiovascular disease (CVD), although the absolute reduction is greater in patients with CVD (Fig. 36.1) [53].

What could account for these remarkable improvements? The known effects of the drug are unlikely to account for the magnitude of this effect. Reduction in arterial stiffness had been observed with these drugs verified by arterial ultrasound compression [54]. The onset of heart failure sets in motion a cascade of effects, which may lead to a vicious cycle of vasoconstriction with activation of the adrenergic nervous system and the renin-angiotensin-aldosterone system including the tubular glomerular feedback in the kidney, which may alter this adverse sequence of events. The sum total of these changes likely reduce cardiac preload and afterload and improve myocardial oxygen supply [55].

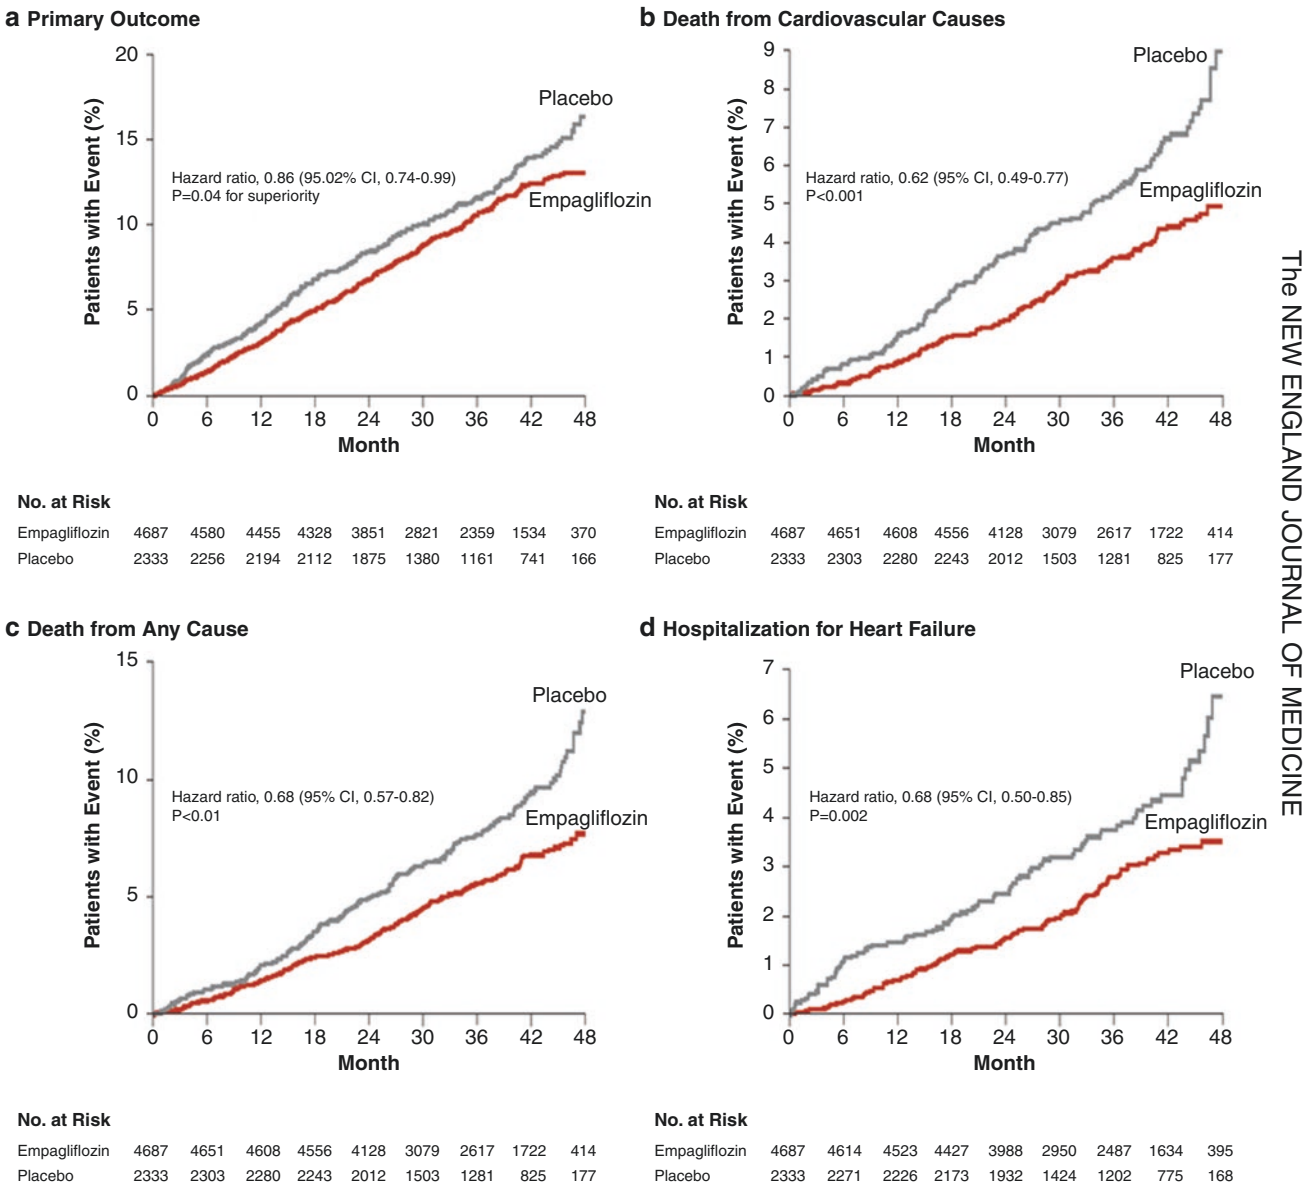

Fig. 36.1 Cardiovascular outcomes and death from any cause. Shown are the cumulative incidence of the primary outcome (death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke) (Panel **a**), cumulative incidence of death from cardiovascular causes (Panel **b**), the Kaplan–Meier estimate for death from any cause (Panel **c**), and the cumulative incidence of hospitalization for heart failure (Panel **d**) in the pooled empagliflozin group and the placebo group among patients who received at least one dose of a study drug. Hazard ratios are based on Cox regression analyses (Zinman NEJM 2015)

The first report of the results of the cardiovascular and renal outcomes CANVAS trial for canagliflozin was published in 2017 [56]. The rate of the primary outcome, a composite of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke was lower with canagliflozin than with placebo, occurring in 26.9% versus 31.5 participants ($P < 0.001$) [56]. Renal outcomes were not statistically significant, but the results showed possible benefits of canagliflozin on the progression of albuminuria and the composite outcome of a sustained reduction in glomerular filtration rate, the need for renal replacement therapy, or death from renal causes. Adverse reactions showed and increased risk for amputations at the level of toe or metatarsal [56]. The first report of the DECLARE-TIMI 58 dapagliflozin cardiovascular outcome trial was published in 2019 [57]. In the primary safety analysis, dapagliflozin met the prespecified criterion for noninferiority to placebo with respect to major adverse cardiovascular events (MACE) defined by cardiovascular death, myocardial infarction, or ischemic stroke. Patients in the dapagliflozin group had lower rates of cardiovascular death or hospitalization for heart failure, without between-group difference in cardiovascular death [57]. Diabetic ketoacidosis was more common with dapagliflozin than with placebo (0.3% vs 0.1%) as was the rate of genital infections leading to discontinuation (0.9% vs 0.1%) [57]. The first report to assess cardiovascular outcomes with ertugliflozin from the VERTIS CV trial showed equal rates of major cardiovascular events (11.9%) in the ertugliflozin group and with placebo [58]. Death from cardiovascular causes or hospitalization for heart failure occurred in 8.1% of patients in the ertugliflozin group and 9.1% of patients in the placebo group, and the hazard ratio for death from cardiovascular causes was 0.92 [58]. Amputations were performed in 2.0% of patients who received the 2 mg dose and 2.1% of patients who received the 15 mg dose, as compared with 1.6% of patients who received placebo [58].

Renal Effects

Renoprotective effects of SGLT2 inhibitors were also analyzed in the EMPA-REG, CANVAS, DECLARE-TIMI 58, and VERTIS trials [53, 56–59]. In a subsequent preplanned sub-study (EMPA_REG Renal), significant benefits were observed in those having renal dysfunction with estimated glomerular filtration rates (GFR) of 30–60 mL/min [59]. There is a transient small drop in GFR seen on initiating these drugs that is possibly related to diuresis and volume contraction. However, as can be readily seen from Figs. 36.2 and 36.3, the net result was positive for preservation of renal function com-

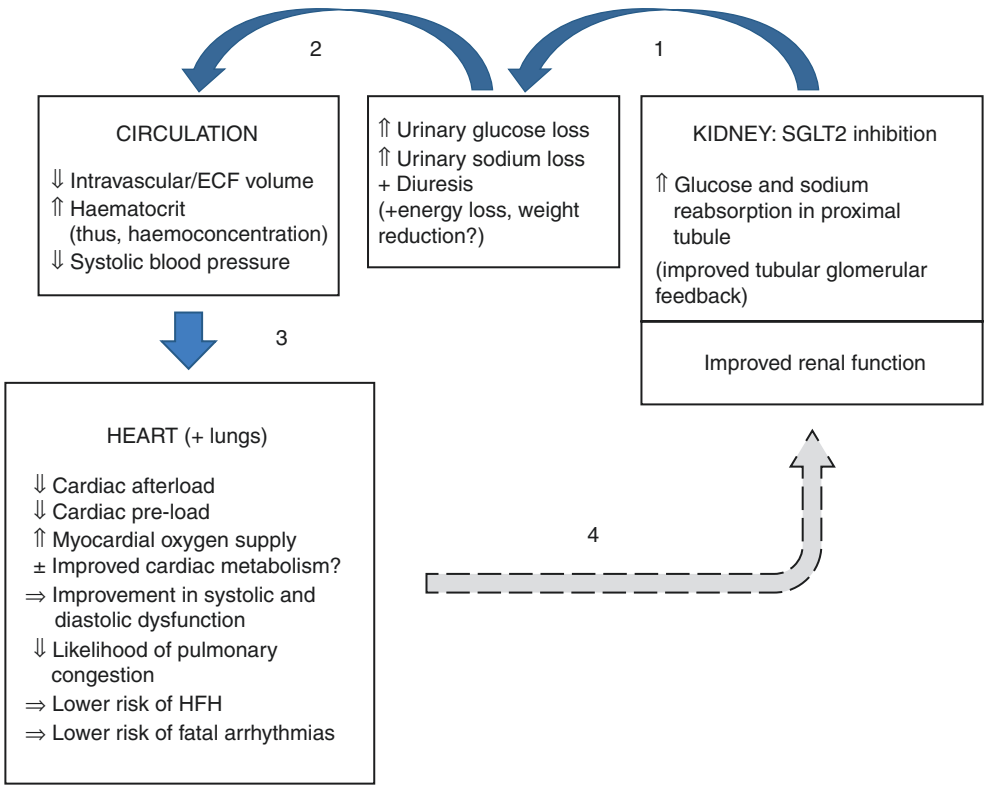

Fig. 36.2 Potential pathway linking empagliflozin (and possibly other SGLT2 inhibitors) with lower risks for HFH (and, linked to this, death due to cardiovascular disease). By increasing fluid losses via urinary glucose and sodium losses (1), intravascular volumes and systolic blood pressure are reduced and there is a significant rise in hematocrit (2). These latter effects may also be, to a small extent, assisted by weight loss. These changes in turn lessen cardiac stressors (pre- and afterload) and may also help improve myocardial oxygen supply (3). The net result is a likely improvement in cardiac systolic and diastolic function, lessening chances of pulmonary congestion, thus lowering risks of HFH and fatal arrhythmias. These cardiac function benefits will, in turn, feed back to improve renal blood flow and function (4). In this way, the cardio-renal axis is improved at a number of levels with SGLT2 inhibitor therapy (Sattar dibetologia 2016)

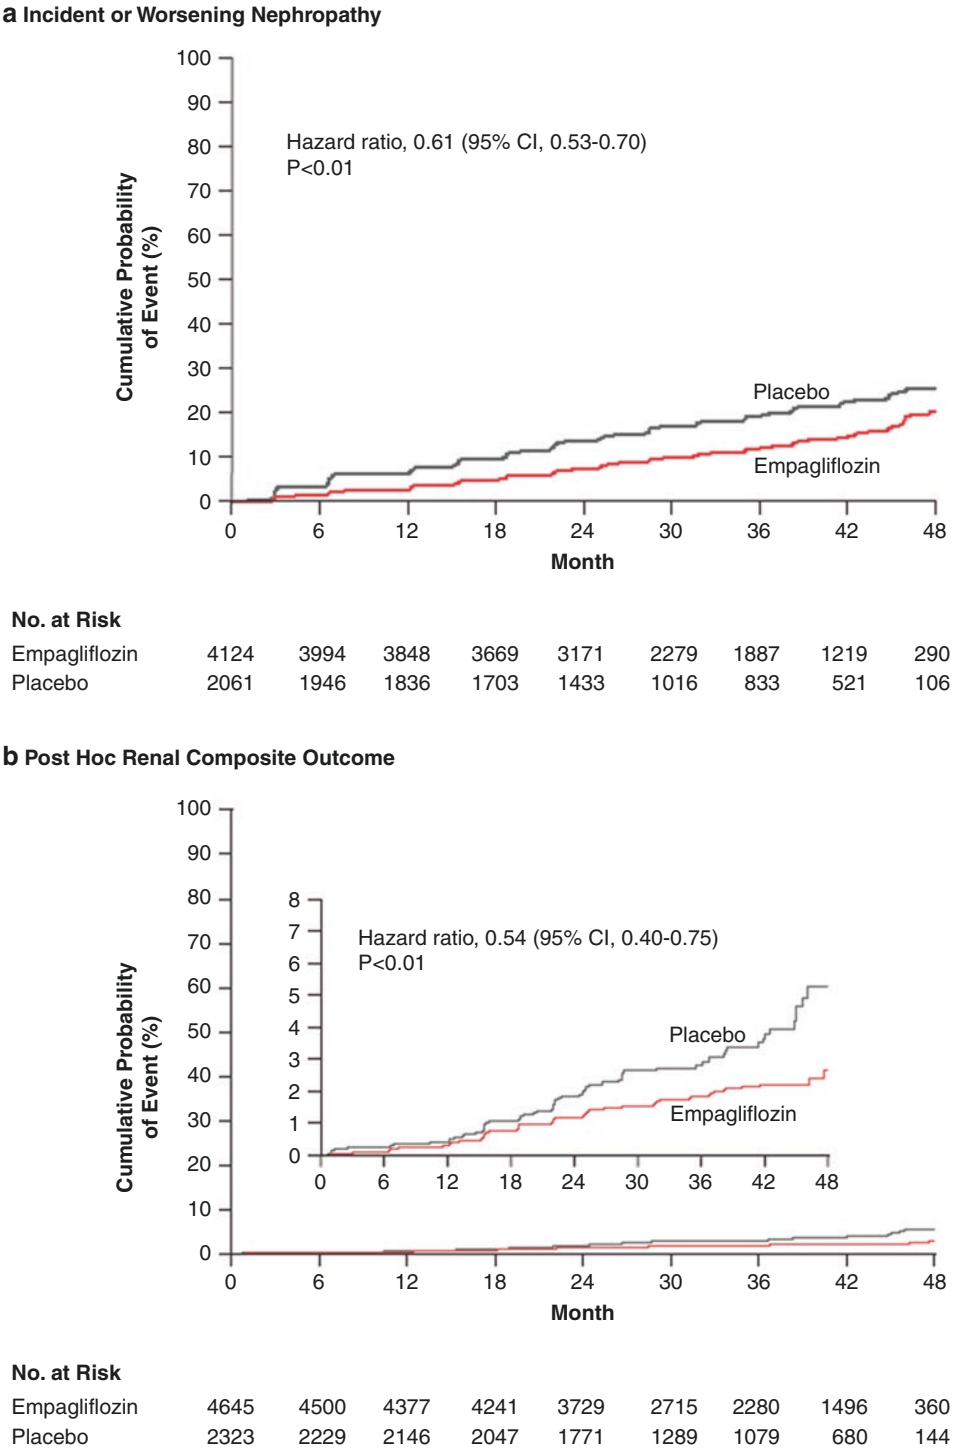

Fig. 36.3 Kaplan–Meier analysis of two key renal outcomes. Shown are estimates of the probability of a first occurrence of a prespecified real composite outcome of incident or worsening nephropathy (Panel a) and of a post hoc renal composite outcome (a doubling of the serum creatinine level, the initiation of renal-replacement therapy, or death from renal failure (Wanner NEJM 2016 panel **a** & **b** and Panel **a**)

pared to the placebo treated arm in which there was small continuing loss of eGFR. Renal endpoints of newly appearing or worsening nephropathy and progression to macroalbuminuria were reduced by 29% and 38%, respectively. Hard renal endpoints of doubling of serum creatinine and need for renal replacement were reduced by 44% and 55%, respectively, although the latter endpoint occurred in relatively few subjects. These subjects were treated with standard of care with 79–85% receiving angiotensin-converting enzyme inhibitors or angiotensin receptor blockers. Therefore, the benefits are additive and over and above those seen with treatments known to be effective [59]. A recent sub-analysis from the VERTIS trial in patients with an estimated glomerular filtration rate (GFR) 30 to < 60 mL/min showed that in addition to reduction in HbA1c, body weight, and blood pressure, patients receiving ertugliflozin maintained baseline GFR levels [60]. The prospect of significantly reducing the decline of GFR in chronic diabetic chronic kidney disease is exciting [61].

The Canagliflozin and Renal Events in Diabetes and Established Clinical Evaluation (CREDENCE) compared canagliflozin versus placebo in patients with type 2 diabetes and chronic kidney disease [62]. Canagliflozin significantly reduced the risk of the primary composite outcome: end-stage renal disease, doubling of serum creatinine, renal, or cardiovascular death. The CREDENCE trial was stopped early for efficacy after an interim analysis and recommendation from the independent Data Monitoring Committee [63]. Overall, the results of the CREDENCE trial showed that canagliflozin could be safely administered to patients with diabetic nephropathy, despite an initial drop in glomerular filtration rate. Ongoing kidney disease-focused outcome trials including DAPA-CKD and EMPA-KIDNEY will provide further information about the use of SGLT2 inhibitors in patients with type 2 diabetes and different stages of chronic kidney disease [64].

Other Metabolic Effects: Increased Ketogenesis a "Superfuel?"

SGLT2 inhibitors are known to increase glucagon, beta-hydroxybutyrate, and ketone body production. In this sense, they appear to shift metabolism from glucose to fat oxidation. Ketone bodies are readily taken up by the myocardial cells as fuel. Myocardium has the highest myocardial oxygen consumption at 8 mL O_2/100 g of tissue followed by 5 mL O_2 for kidney and 3 mL for brain tissue. It is postulated that an increased availability and use of ketone bodies could be beneficial to metabolically stressed organs [65, 66]. There is experimental evidence that this may result in more efficient oxygen sparing and cardiac work for any given level of demand. This could provide another mechanism for more rapid cardiac benefit in addition to a variety of potential pleiotropic effects beyond glucose lowering on a variety of diseases, including nonalcoholic fatty liver disease and obesity [14, 21].

Safety and Tolerability

SGLT2 are safe and well tolerated [12]. Rates of discontinuation in clinical trials are low, but according to their mechanism of action, they cause osmotic diuresis, volume depletion, and dehydration [12, 14]. Patients at risk, including those with frailty, the elderly, or taking diuretics, should be monitored and advised about these effects.

Genitourinary Infections

The most common adverse events is a higher risk for lower urinary tract infections, vulvovaginitis and vaginitis of bacterial and mycotic origin, which was documented in clinical trials and case reports [12, 14, 16]. A study by Lega et al. reported a five times higher risk of genital mycotic infections in patients treated with SGLT2 inhibitors, increasing in the first month of therapy and enduring for the duration of treatment [67]. Glycosuria resulting from diabetes provides a favorable substrate for microorganism growth, which is enhanced by the pharmacologic glycosuria induced by SGLT2 inhibitors [68]. Incidence rates of mycotic genital infections in clinical trials are 6.0% and more common in women [68]. The incidence of bacterial infections ranges from 4.0% to 9.0%, while severe infections occur in 0.4% of patients [68]. Severe forms of genitourinary infections include pyelonephritis, emphysematous pyelonephritis, and Fournier gangrene, a perineal disease of acute onset and rapid progression [69].

Ketoacidosis

There has been concern about increased ketone body production particularly in very insulin-deficient patents such as type 1 diabetics. There are several case series raising this concern of ketoacidosis. The rate appears to be low in type 2 diabetes. The mechanism of action could be related to decreased insulin levels, which leads to unopposed glucagon production and lipolysis, which leads to ketogenesis. Risk factors and precipitants for diabetic ketoacidosis related to SGLT-2 inhibitors are sepsis, dehydration, surgeries, decrease in insulin dose administration (for those on insulin), and a low carbohydrate diet [69]. The risk of ketoacidosis could be minimized by educating all patients upon initiation of therapy that nausea, vomiting, and dehydration require checking for ketones, and such symptoms should prompt them to seek medical attention [70].

Additional side effects include amputations and bone fractures.

Conclusion

SGLT-2 inhibitors are the newest pharmacologic resource for management of type 2 diabetes. Since their approval and release into the market in the United States in 2013, multiple studies have proven both efficacy and positive cardiovascular and renal outcomes. Their use has also enhanced our knowledge on fuel metabolism and the use of ketones as a source of energy. Although generally well tolerated, clinicians should be on alert for possible adverse effects of dehydration and even normoglycemic diabetic ketoacidosis. The use of these agents is expected to rise given their marked improvements in HbA1c in addition to beneficial effects on weight, blood pressure, and cardiovascular outcomes.

Multiple Choice Questions

1. In patients with diabetes, the tubular threshold for the excretion of glucose:
   (a) Is decreased
   (b) Is adapted and increased
   (c) **Is maladapted and increased**
   (d) Is not different from people without diabetes
   (e) Is able to eliminate excess serum glucose
2. In the presence of SGLT 2 inhibitors, the threshold for glucose elimination is reduced:
   (a) Approximately 10 mg
   (b) Approximately 20 mg
   (c) **Approximately 40 mg**
   (d) Approximately 80 mg
   (e) Approximately 100 mg
3. Weight loss with the use of SGLT 2 inhibitors is estimated in the range of:
   (a) 1–3 kg
   (b) **2–3 kg**
   (c) 3–4 kg
   (d) 4–5 kg
   (e) 5–6 kg
4. Weight loss from the use of SGLT 2 inhibitors is secondary:
   (a) **To fat loss**
   (b) To muscle loss
   (c) **To fluid loss**
   (d) All of the above
   (e) None of the above
5. Inhibition of SGLT 1, located in the gut and renal tubules, results in:
   (a) **Lowering postprandial hyperglycemia**
   (b) Lowering fasting blood glucose

(c) Lowering blood pressure
(d) Increasing glucose uptake
(e) Increasing intestinal glucose absorption

6. Range doses of canagliflozin:
   (a) 5–10 mg daily
   (b) 10–25 mg daily
   (c) 50–100 mg daily
   (d) **100–300 mg daily**
   (e) 150–200 mg daily
7. Range doses of dapagliflozin:
   (a) **5–10 mg daily**
   (b) 10–25 mg daily
   (c) 50–100 mg daily
   (d) 100–300 mg daily
   (e) 150–200 mg daily
8. Range doses of empagliflozin:
   (a) 5–10 mg daily
   (b) **10–25 mg daily**
   (c) 50–100 mg daily
   (d) 100–300 mg daily
   (e) 150–200 mg daily
9. The results of the EMPA-REG Trial showed that the use of empagliflozin was associated:
   (a) With a 38% relative risk reduction in cardiovascular mortality
   (b) With a 35% relative risk reduction for congestive heart failure
   (c) With a 32% relative risk reduction of death from any cause
   (d) **All of the above**
   (e) None of the above
10. Cardiovascular benefits from the use of SGLT 2 inhibitors have been attributed to:
   (a) The effect of additional medications standard cardiovascular therapies
   (b) **Reduction in arterial stiffness**
   (c) Regression of atherosclerotic plaques
   (d) Their anti-hypertensive effects
   (e) Inhibition synthesis of advanced glycation products (AGEs)

Use of Insulin in Outpatient Diabetes Management

37

Raquel N. Faradji, Elena Sainz de la Maza, Ana Paula Díaz Barriga Menchaca, and Juan Ramón Madrigal Sanromán

Objectives

To know:

- The indications for insulin use
- The different insulin types and action times
- The different insulin regimens
  - How to initiate
  - How to adjust
- The insulin adverse effects
- The insulin storage and injection recommendations

Introduction

As time passes, clinical practice addresses a greater number of patients with diabetes, and the available drugs for diabetes treatment increase. Insulin is one of the most potent drugs for glucose control. Insulin therapy is a must for all patients with type 1 diabetes (T1D) and those patients with type 2 diabetes (T2D) who do not achieve their goals in glycemic control with antidiabetic oral or other injectable agents. It can be used from T2D diagnosis, in later stages of the disease, or at times of diabetes decompensation.

Understanding insulin management is vital for every physician that treats diabetes and for every patient that lives with diabetes. The best treatment is the one that tends to be most similar to the physiologic secretion of insulin in the pancreas. This pattern has a peak in insulin secretion stimulated by meals and a basal secretion throughout the rest of the day. Basal insulin secretion is necessary for maintaining optimal glucose regulation in liver, muscle, and adipose tissue. Basal insulin is essential for modulating glucose production from the liver. The insulin peak after meals stimulates glucose uptake by tissues and stops endogenous production [1].

If there is an absolute insulin deficiency (T1D), a physiological secretion of insulin should be imitated with a multiple daily injection regimen, preferably in a basal-bolus manner.

If there is a relative insulin deficiency (T2D), insulin could be indicated to treat the hyperglycemia that occurs at certain times of the day, for example, at dawn, when elevation of cortisol levels leads to an increase in hepatic glucose production. Increase in glucose levels at dawn can be an important cause for basal insulin initiation in T2D patients. Oral medications help stimulate the secretion of endogenous insulin (sulfonylureas, glucagon-like peptide-1 receptor agonist-GLP-1ra, dipeptidyl peptidase-4-DPP-4 inhibitors) and cover the prandial requirements. When oral drugs fail, prandial insulin therapy may be added to meals where glucose levels are elevated (basal-plus) or at every meal (basal-bolus). In the latter case, metformin is usually continued, but sulfonylureas are suspended. It must be pointed out that before adding prandial insulin, one could add a GLP-1ra. In the author's experience, the combination of metformin with DPP-4 inhibitors or GLP-1ra and basal insulin can be very useful in many patients with low insulin requirements and can provide sustained glycemic control for a long time.

Insulin therapy should always be individualized. The aim is to improve glycemic control of patients living with diabetes. Glycemic control is normally measured through glycosylated hemoglobin A1c levels, pre-prandial glucose levels, and 2 h postprandial glucose levels, based on self-

Table 37.1 Glycemic targets

	Fasting glucose (mg/dL)	Postprandial glucose (mg/dL)	HbA1c %	TIR (70–180 mg/dL) %
No diabetes	70–99	≤139	≤5.6	>95
Adults (AACE)	<110	≤140	≤6.5	>70
Adults (ADA)	80–130	≤180	≤7.0	>70
Older adults (low risk)	90–130	≤180	≤7.5	>70
Older adultos (high riesgo)	100–180	<200	≤8.5	>50
Children/adolescents	70–130	90–180	<7.0	>70
Pregnancy	63–99	100–129	<6.0	>70 (63–140 mg/dL)

Based on Battelino T et al. 2019 [2], American Diabetes Association 2022 [3], AACE 2020 [4], ISPAD 2018 [29]

monitoring of blood glucose (SMBG) and recently time in range (TIR) based on continuous glucose monitoring (CGM) (Table 37.1). The goal is to have >70% time in range (70–180 mg/dL/3.9–10 mmol/L) and with the least glycemic variability (coefficient of variability less than 36%) [2]. An adequate glycemic control will help decrease the incidence of diabetes complications, which are a severe public health problem.

According to the degree of glycemic control, insulin can be administered with a simple regimen (basal insulin with nocturnal dosage of intermediate-acting (NPH) or a long or ultra-long-acting insulin analogue plus oral antidiabetics or other injectable drugs) or a more complex regimen (multiple daily injection regimen with NPH and regular or fast-acting insulin analogue twice a day, premixed insulin twice a day, basal-plus prandial or basal-plus GLP-1ra or a basal-bolus regimen).

Hypoglycemia is the main adverse effect of insulin use. Self-management education and self-monitoring and recording of blood glucose are vital to adjust insulin dosages and decrease the risk of hypoglycemia.

Patient Selection

Indications for insulin use are:

1. Patients with T1D, due to absolute insulin deficiency (if insulin is stopped, they could develop diabetic ketoacidosis).
2. Patients with T2D. They initially have an insulin resistance predominance: however, over time, they lose the ability to secrete insulin, which leads to different insulin deficiency/insulin resistance states, having different requirements according to progress in the natural history of the disease.

   Insulin is indicated in patients with type 2 diabetes (T2D):

   (a) Newly diagnosed patients who are very symptomatic, or in catabolic state with random hyperglycemia (>200 mg/dL or 11.1 mmol/L) and glycosylated hemoglobin A1c (A1c) > 9% or >75 mmol/mol.

   (b) Newly diagnosed patients in whom there is doubt as to whether they have T1D, T2D, or latent autoimmune diabetes in adults (LADA).

   (c) Patients who fail to obtain good glycemic control with oral antidiabetics (3 or more) or GLP-1ra at maximum tolerated doses, despite time of diagnosis.

   (d) Patients who have transient moderate to severe worsening of glycemic control such as in the case of surgery, pneumonia or any infection, acute myocardial infarction, hospitalization, use of glucocorticoids, etc.

   (e) Patients with diabetes who start with insulin from diagnosis to decrease the glucotoxicity and lipotoxicity in order to favor the rest of the insulin-producing beta cell and to try to preserve its function. It is well known that timely insulinization could restore beta cell function in type 2 diabetes.

   (f) Patients who have progression of chronic diabetes microvascular complications. Insulin is used to try to avoid further progression.
3. Pregnancy. Pregnant patients with previous diagnosis of diabetes and patients with gestational diabetes. Detemir and aspart insulin analogues are FDA approved for its use in pregnancy; however, NPH and regular insulin have traditionally been used. Although glargine and lispro insulin have been used safely during pregnancy, they are not FDA approved for its use.

Clinical Guidelines

Many guidelines and algorithms for T2D treatment have appeared in recent years [3, 4]. In general, all guidelines are based on trying to reach glycemic levels closest to normal while trying to avoid hypoglycemia. The goals for each patient with T2D should be individualized, and when glycemic control is not reached, treatment with oral antidiabetics should be scaled. Before choosing an antidiabetic drug, it is indicated to assess the risk of cardiovascular disease, one usually starts with monotherapy, and guidelines recommend to initiate an SGLT2 inhibition and/or GLP-1 receptor ago-

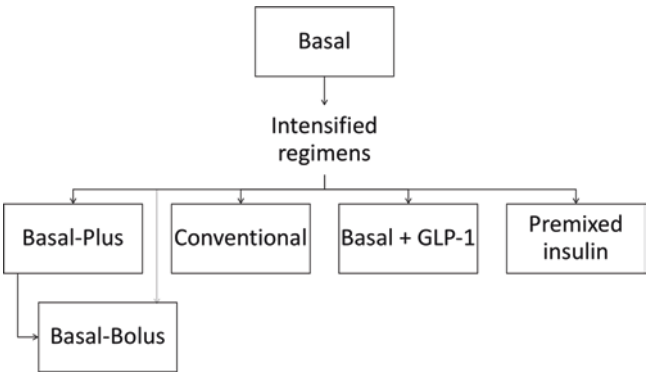

Fig. 37.1 Intensification of insulin regimens

nist with demonstrated cardiovascular disease benefit; otherwise, metformin is always indicated. If the A1c goal is not reached after 3 months, the treatment is scaled to dual therapy, and again if the A1c goal is not reached after 3 months, it can be scaled to triple therapy. In most guidelines [3, 4], basal insulin initiation is considered as an option at dual or triple therapy, although one must take into account the risk of hypoglycemia. If with triple therapy the goal is still not reached, then basal insulin therapy or intensification to combination injectable therapy should be considered. Combination injectable therapy includes basal-plus prandial insulin, basal plus GLP1-ra, basal-bolus, and the conventional regimen. If insulin is used, combination therapy with a GLP-1ra is recommended for greater efficacy and durability of treatment effect (Fig. 37.1).

The early introduction of insulin should be considered. If the patient is symptomatic, catabolic, with glycemia above 200 mg/dL (11.1 mmol/L), and/or A1c greater than 9 or 10%, then insulin should be started from the beginning.

The 2022 American Diabetes Association guidelines [3] point out that:

- The progressive nature of T2D should be regularly and objectively explained to the patients.
- It should be avoided to use insulin as a threat, describing it as a failure or punishment.
- In patients who are not achieving glycemic goals, insulin therapy should be promptly initiated.
- It is important for the patient to have a self-titration algorithm, based on SMBG.
- People who are on insulin using blood glucose monitoring should be encouraged to check when appropriate based on the insulin regimen (this includes fasting, prior to meals and snacks, at bedtime, prior to exercise, etc.)
- Continuous monitoring glucose (CGM) should be offered for diabetes management in people with diabetes on multiple daily injections (MDI) or CSII who are capable of using devices safely.

Insulin Types and Time of Action (Table 37.2 and Fig. 37.2)

Insulin is a molecule formed by two peptidic chains (α and β) linked by two disulfide bridges. The insulin currently available is produced by recombinant DNA technology.

There are human insulins and human insulin analogues. The use of the insulins described below is for subcutaneous administration (regular and aspart insulin can also be administered intravenously in the hospital). Injected insulin is absorbed subcutaneously into the systemic circulation.

Most of the insulin formulations are dispensed in 100 units/mL or U100. If no indication is made, we are referring to U100.

Most of the information that is known, comparing the different types of insulin, has come from several "treat to target trials" [5–8], where the insulin dose of the different arms of a study was titrated to achieve a certain glycemic control and the incidence of hypoglycemia and weight gain was compared between the different arms.

Human insulins are rapid or regular-acting insulins (R) and intermediate-acting insulin (NPH). Rapid or regular-acting insulin is identical to human endogenous insulin. It is clear in solution. It takes 30 min to absorb after being subcutaneously injected. Regular-acting insulin has its peak of action 2–3 h after being administered and has a time of action of 4–6 h. This insulin is used as a prandial insulin or bolus, and it helps control postprandial glycemia. In cases of extreme insulin resistance, Regular Insulin U500 (500 units/mL) is available in the United States.

NPH or intermediate-acting insulin is a regular-acting insulin that is in solution with protamine, which makes it appear milky. It has a longer time of action, having its peak at 8–10 h after being injected, and its duration up to 10–14 h. However, at higher insulin doses, the duration of action is higher.

The advantages of human insulins (rapid and NPH) are the low costs and high availability in the market. The disad-

Table 37.2 Types of insulin and times of action

Types of insulin	Class	Start of action	Max peak	Duration
Fast-acting Lispro Aspart Glulisine	Analogues	5–15 min	30–90 min	3–4 h
Rapid-acting (regular)	Human	30–45 min	2–3 h	4–6 h
Intermediate (NPH)	Human	2–4 h	8–10 h	10–14 h
Long-acting Glargine U100 Detemir *Ultra-long- acting* Degludec Glargine U300	Analogue	1.5–2 h	No peak	18–24 h 24–40 h

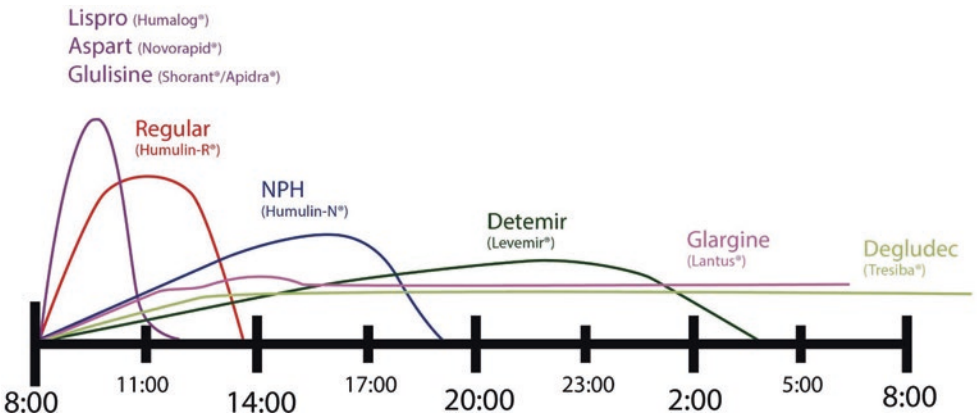

Fig. 37.2 Times of insulin action

vantages include that, due to its peak and duration of action, the risk of hypoglycemia is higher, especially if the patient does not have a strict feeding regimen, to match insulin peak and duration of action. In addition, NPH insulin has greater variability in its absorption and bioavailability, so it is less predictable, and in general, there is a higher incidence of hypoglycemia with its use.

In last decades, several insulin analogues have appeared in order to mimic more physiologically insulin action.

There are three fast-acting insulin analogues: lispro, aspart, and glulisine. Due to molecular modifications, after a subcutaneous injection, it takes 0–15 min to start their action, peak at 30–90 min, and last between 3–4 h. These analogues are used prandially or in bolus.

There are newer, faster-acting insulins, called ultrarapid acting; these insulins allow dosing to occur at the start of or even during a meal to better control postprandial glucose peaks. The first ultrarapid insulin, called fast-acting insulin aspart (Fiasp), was approved by the FDA in 2017 and contains insulin aspart formulated with 2 additional excipients, L-arginine that acts as a stabilizing agent and niacinamide that accelerates absorption in the site of injection [9, 10]. Another ultrarapid insulin, called ultrarapid lispro (Lyumjev), was approved by the FDA in 2021. It is a novel insulin lispro formulation developed to more closely match insulin secretion and improve postprandial glucose control. The approval trial (PRONTO-PUMP-2), demonstrated that it was superior in both 1-h and 2-h postprandial glucose reduction when delivered 0–2 min before meals [11].

There are two long-acting insulin analogues: glargine (U100; 100 international units per ml) and detemir. Insulin glargine is in solution at pH 4.0, but when injected at neutral pH, it forms crystals, and therefore, its absorption is slower. Insulin detemir has a 14-carbon fatty acid bound to the amino acid 29 of the beta chain, therefore having a higher affinity to albumin. This increases its half-life. These two insulins take 1.5–2 h to start its action and generally do not peak (although clinically they appear to have a small peak at 6–8 h from injection), and their duration of action is between 18 and 24 h. They are used as basal insulin one or two times per day. Both have shown to cause less hypoglycemia than NPH insulin. If insulin detemir is compared with glargine, the former has shown a discrete lower weight gain. The ORIGIN study [12] showed that insulin glargine given to patients with impaired fasting glucose and impaired glucose tolerance or T2D had similar cardiovascular outcomes to those patients that received the standard care.

There are two ultra-long-acting insulin analogues: degludec and glargine U-300.

In 2013, insulin degludec appeared in the market. Degludec insulin has a glutamic acid spacer bound to amino acid 29 of the beta chain and then a 16-carbon fatty acid. These changes allow it to be in di-hexamers in solution and, when injected, forms multi-hexamers. The monomers are then released one by one. Degludec has no peak and has a half-life of 24 h. It has low variability, can be applied once a day, and has flexibility in the injection schedule. In addition, a lower incidence of nocturnal hypoglycemia has been documented with this insulin, compared with glargine U100. Insulin degludec is available at U100 (100 units per mL) or U200 concentration (200 units/mL). In the United States, both formulations exist. In Mexico, only the U100. Both act similarly. Insulin Degludec was approved by the FDA in 2015. The DEVOTE study [13] (Trial Comparing Cardiovascular Safety of Insulin Degludec versus Insulin Glargine in Patients with Type 2 Diabetes at High Risk of Cardiovascular Events), published in the NEJM in August 24th, 2017, showed that Degludec was non-inferior to glargine U100 with respect to incidence of cardiovascular events and again demonstrated a much lower risk of severe hypoglycemia and nocturnal hypoglycemia.

Another prolonged-acting insulin analogue appeared in the market, and this is insulin glargine U300 [14, 15] (300 international units per mL). By being more concentrated, it forms a compact subcutaneous depot with a smaller surface area, to produce a more gradual and prolonged release. Compared to Glargine U100, it has shown lower event rates

of nocturnal hypoglycemia. Glargine U300 can be injected with a 3 h flexible regimen.

There are pharmacokinetics studies [16] that compare degludec to Glargine U300. The clinical studies have not shown a significant difference in the rate of hypoglycemia between the two types of insulin [17].

In general, the advantages of insulin analogues are as follows: more bioavailable, less variable, more predictable, more physiological, better glycemic control, and less hypoglycemia.

The disadvantages are higher number of injections and higher cost.

There are once-weekly basal insulins under development (preclinical to phase 2 studies) that promise to have greater convenience, easy to overcome clinical inertia, better treatment adherence, ensure glycemic control, and low risk of hypoglycemia.

Premixed insulins have a fixed proportion of intermediate insulin with rapid- or fast-acting insulin. Insulin 70/30 consists of 70% NPH and 30% rapid-acting insulin. There is premixed insulin with 70% intermediate-acting insulin (aspart-protamine, NPA) and 30% insulin aspart. There are two premixed insulin concentrations: one with 75% intermediate insulin (lispro-protamine, NPL) and 25% insulin lispro and the other with 50% insulin NPL and 50% insulin lispro, which is more physiological and could be used three times per day, before each meal.

The advantages of premixed insulin are mistake minimization, ease of use, increased treatment adherence, and fewer injections.

The disadvantages are fixed dose and less flexibility and may increase the risk of hypoglycemia if a fixed meal schedule is not followed.

There is a co-formulation (IDegAsp, Ryzodeg) 70% insulin degludec and 30% insulin aspart solution in a pen. The advantage of this co-formulation is that it has a significant reduction in the incidence of nocturnal hypoglycemia compared to the premixed insulin with NPA and insulin aspart 70/30. This co-formulation can be applied once or twice per day and is a useful and simple alternative for patients with T2D.

In addition, there are two new combinations between long-acting insulin analogues and GLP-1ra [18]. These are degludec insulin with liraglutide (iDegLira) and insulin glargine with lixisenatide (iGlarLixi).

The combination of degludec insulin with liraglutide (100 units/mL and 3.6 mg/mL, respectively) is indicated once daily, as an adjunct to diet and exercise, to improve glycemic control in adults with T2D inadequately controlled on basal insulin (less than 50 units daily) or liraglutide (less than or equal to 1.8 mg daily).

The combination insulin glargine and lixisenatide (100 units/mL and 33 μg/mL and 100 units/mL and 50 μg/mL respectively) is indicated for once-daily dosing covering 15–60 units of insulin glargine and 5–20 μg of lixisenatide.

The advantages of these combinations are the lower risk of hypoglycemia, decreased insulin doses, less weight gain, and the possibility of lower cardiovascular risk, when compared to basal-bolus insulin regimens.

Describing further the use of these two combinations is beyond the scope of this chapter, but one should be familiarized with these new options. The reader is invited to review the prescribing information for each country, when available. Both were approved in the United States by the FDA in 2017.

Inhaled Insulin [19–22]

There have been several lines of research work to administer insulin through other routes, being the inhaled form, the one that has reached the market. Exubera, an inhaled form of rapid acting insulin developed by Pfizer, became the first inhaled insulin product to be marketed in 2006, but due to poor sales, it was withdrawn from the market in 2007. Afrezza, developed by Mannkind, uses a different technology (technosphere) and was approved by the FDA in 2014 for use in both T1D and T2D. It contains recombinant human insulin dissolved with powder (fumaryl diketopiperazine). Once inhaled, technosphere insulin is rapidly absorbed upon contact with lung surface. Both components, insulin and powder (fumaryl diketopiperazine) are almost completely cleared from the lungs of healthy individuals within 12 h of inhalation. As it has rapid absorption, it can be used as prandial insulin. Currently, it is dispensed in a small inhaler, and insulin cartridges come in 4, 8, and 12 units. It may cause hypoglycemia, cough, and throat pain/irritation, as well as acute bronchospasm in patients with asthma and COPD. As of this writing, it is only available in the United States.

Insulin Management Regimens (Figs. 37.1 and 37.3 and Appendix)

As already mentioned, insulin can be used from T2D diagnosis, in its late phases, or at times of diabetes decompensation.

All insulin regimens have a "starting" and "adjustment" phase.

In the "starting phase," the prescribed dose is calculated, as it will be seen later in each regimen.

In the "adjustment phase," it is observed through SMBG and how the person responded to therapy, and adjustments are made to avoid hypoglycemia and hyperglycemia.

In the adjustment phase:

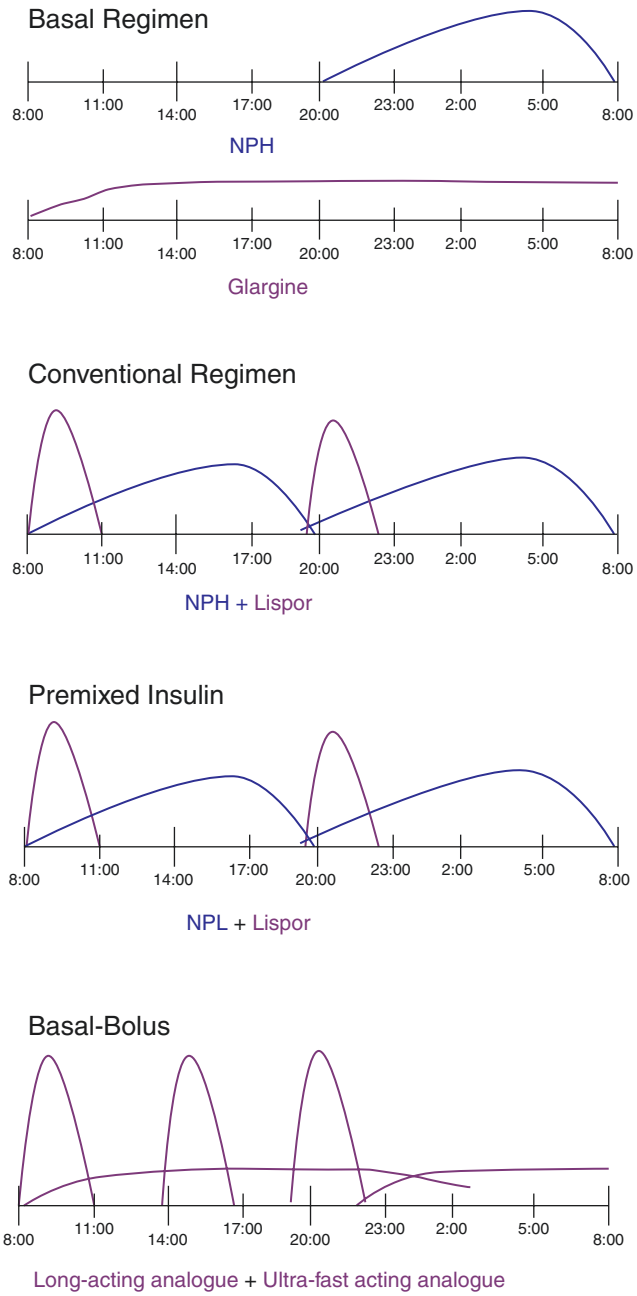

Fig. 37.3 Insulin regimens

- The insulin dose that affects fasting or preprandial glucose is adjusted according to whether there is hyperglycemia (>120–130 mg/dL- 7 mmol/L) or hypoglycemia (<70–80 mg/dL- 4 mmol/L).
- The insulin dose that affects postprandial glucose is adjusted according to whether there is hyperglycemia (>180 mg/dL- 10 mmol/L) or hypoglycemia (<100 mg/dL- 5.6 mmol/L).
- Only one dose is adjusted at a time.
- Adjustment is imperative when there is hypoglycemia.
- If there is hyperglycemia, it is preferred to observe the pattern over 3 days. Then, the adjustment consists of increasing or decreasing ≈2 U the dose of insulin, which was responsible for that glucose value.

Basal Insulin Regimen [1]

When basal insulin is prescribed, an intermediate-acting, long-acting, or ultra-long-acting nocturnal insulin injection is chosen; however, with some of the long- and ultra-long-acting insulin analogues (detemir, glargine U100 or U300, degludec), it could also be administered in the morning.

For nocturnal dosing, intermediate-acting insulin (NPH), long-acting insulin analogues (glargine U100, detemir), or ultra-long-acting (degludec, glargine U300) may be chosen. The advantages of insulin analogues are that they cause less nocturnal hypoglycemia. The starting dose is usually 10 units or 0.2 units/kg/day.

When intermediate-acting insulin or detemir insulin is used, dose adjustment should be done every 3 days. The adjustment consists in increasing or decreasing the dose 2–3 units (or 10–20% of basal dose), depending on whether there is hyperglycemia or hypoglycemia according to the monitoring of fasting glucose, until the glycemic control goal is achieved. With these insulins, when the basal total dose is greater than 0.3 units/kg/day (22–26 units), it is advisable to divide the dose into two injections (morning and evening) to avoid nocturnal hypoglycemia.

When glargine or degludec insulin is used, dose adjustment is preferably done every 5–7 days (although it can be adjusted earlier if the person is not controlled). With these insulins, it is generally not necessary to fractionate the dose into two injections, unless the insulin glargine U100 or detemir is not lasting 24 h.

It should be mentioned that if a patient who is already using NPH insulin switches it to glargine U100 (perhaps to avoid an increased risk of nocturnal hypoglycemia), 80% of the NPH dose should be used. That is, if 20 units of NPH insulin were used, when switching to glargine U100, only 16 units of NPH should be used. If a patient is changed from insulin glargine U100 to insulin degludec, prescribing information indicates that the same dose should be used, but in the author's experience, patients require a 20% lower dose of degludec. In addition, when changing from insulin glargine U100 to U300, a higher dose may be required (10–20% more dose).

Intensive Regimens (Figs. 37.1 and 37.3)

Over time, some patients that use basal insulin may require prandial insulin coverage, and this can be done with the different insulin regimens:

- Conventional regimen: NPH twice per day plus rapid- or fast-acting insulin analogues two or three times per day.
- Premixed insulin: Twice or three times daily.
- Basal-plus: Basal plus prandial insulin for a single meal coverage.
- Basal-plus a GLP-1ra.
- Basal-bolus: Basal plus prandial insulin for more than one or for all meals.

Conventional Insulin Regimen

In this regimen, the patient uses NPH insulin and rapid-acting insulin or fast-acting insulin analogues twice a day. The advantages of this regimen are that usually only two injections per day are needed and of lower cost and that the morning rapid-acting insulin covers lunch/snack and morning NPH covers the glucose elevation caused by food intake at lunch/late lunch.

The disadvantages are that it is not flexible, and the patient must have a strict feeding schedule to avoid hypoglycemia, and there is an increased risk of nocturnal hypoglycemia.

The initial dose usually starts in 0.5 units/kg/day.

The total insulin dose is divided in 2/3 in the morning and 1/3 in the evening.

The morning dose (pre-breakfast) is further fractionated in 2/3 for NPH insulin and 1/3 for rapid or fast-acting insulin.

The evening dose (pre-dinner) is fractionated in 2. Half for the NPH insulin and half for the rapid or fast-acting insulin (pre-dinner insulin) can also be divided into 2/3 NPH and 1/3 rapid- or fast-acting insulin.

Insulin should be injected 30 min before meals if it is a rapid-acting insulin and 0–15 min prior meals if it is fast-acting insulin analogue.

In case the conventional regimen is used with NPH and rapid-acting insulin, it is of vital importance for the patient to include snacks:

- In some countries, lunch is eaten at noon, and a snack will be required around 3:00 or 4:00 p.m.
- In others, the main meal of the day is at around 3:00 p.m., and a snack will be required around 11:00 a.m. to 12:00 noon.
- In addition, a snack must be included before going to sleep.

However, if the conventional regimen is used with NPH and fast-acting insulin analogues, snacks may or may not be needed. However, for countries where lunch is eaten at noon, usually a small snack (15 g of carbohydrates) will be needed at 3:00 or 4:00 p.m. In general, a snack will be required at bedtime.

Example

Sixty-year-old male that weighs 72 kg. If his dose is calculated at 0.5 units/kg/day, he would need a total of 36 units. Two thirds are going to be injected before breakfast (24 units) and one third before dinner (12 units). Of the 24 units that should be administered before breakfast, 16 units are NPH and 8 units of rapid- or fast-acting insulin. Of the 12 units that have to be injected before dinner, 6 units are NPH, and 6 units are rapid- or fast-acting insulin, although this last dose can be adjusted downward if the patient eats a small meal.

Subsequently, treatment adjustments are made.

If there is morning hyperglycemia, it should be ruled out that it is not secondary to a 2:00–3:00 in the morning hypoglycemia followed by hyperglycemia (Somogyi phenomenon or excessive carbohydrate intake to correct said hypoglycemia) or because of the Dawn phenomenon (surge in cortisol production from 3:00 to 8:00 in the morning, with increased hepatic glucose production). This is ruled out by checking the blood glucose before dinner, after dinner, at 3:00 a.m., and upon awakening.

If hypoglycemia occurs, the dose of NPH can be reduced by 2–3 units, and see if morning hypoglycemia is avoided. If not, NPH can be administered at night (10:00–11:00 p.m.), so that its peak of action is at 6:00–7:00 a.m., when the patient awakes. If nocturnal hypoglycemia cannot be avoided, NPH insulin could be switched to a long- or ultra-long-acting analogue such as glargine U100, detemir, degludec, or glargine U300.

If there is no Somogyi phenomenon and fasting glucose is elevated, then the nocturnal NPH insulin dose should be increased by 2 units every 3 days until the glycemic control goal is reached (70–80 mg/dL–120–130 mg/dL–4–7 mmol/L).

Once fasting glucose is controlled, SMBG is required before and 2 h after each meal for the next 2–3 days order to see if there are any glucose patterns. In order to adjust the morning dose of NPH insulin, and then the doses of rapid or fast acting insulin that are applied before meals.

- If there is hyperglycemia (>130 mg/dL—7 mmol/L) before lunch or dinner, morning NPH insulin can be increased by 2 units. If there is hypoglycemia, then the dose is reduced by 2 units.
- The rapid- or fast-acting insulin dose applied before meals is adjusted in case of 2 h postprandial hyperglycemia (>180 mg/dL–10 mmol/L) or postprandial hypoglycemia (<100 mg/dL–5.6 mmol/L). The insulin dose is increased or decreased by 2 units, respectively.

Premixed Insulin

Premixed insulins contain a similar proportion to that described above of intermediate insulin (50–75%) and rapid- or fast-acting insulin (25–50%); a "conventional" treatment

can be initiated. In this case, the dose is calculated in the same way (0.5 units/kg/day), which is divided in 2/3 before breakfast and a 1/3 before dinner.

The adjustment is made in a similar manner to that described in the conventional regimen.

The dose of insulin injected before dinner is adjusted by assessing fasting blood glucose.

The dose of insulin that is injected before breakfast is adjusted by assessing premeal glycemia.

For someone who has breakfast at 7:00 in the morning, main meal at 16:00 h. and dinner at 23:00 h, the premixed total insulin could be divided in three, and each third is given before breakfast, main meal, and dinner. The appropriate adjustments, are made according to SMBG results.

Basal Plus

The stepwise study [23, 24] proposes that patients who already use long-acting insulin should initiate fast-acting insulin before a single meal (the most abundant or the one with the highest postprandial glucose levels) and gradually increase injections in different meals to achieve a better glucose control. Although rapid-acting insulin may be used, fast-acting insulin analogues are preferred.

There are three ways to calculate this dose:

(a) Starting an initial dose of 2–4 insulin units of fast-acting insulin analogues could be administered before that meal and adjust depending on 2 h postprandial glucose levels. Increasing or decreasing by 2 units until an adequate postprandial glucose level is achieved.
(b) Calculating the prandial insulin at 0.1 units/kg.
(c) Calculating the prandial insulin as 10% of the basal dose. If the HbA1c is lower than 8%, one may consider reducing the basal dose, by the same amount of units of the prandial insulin that was started.
(d) Calculating one insulin unit for each carbohydrate portion (15 g), taking into account that the patient shouldn't eat more than 4 portions of carbohydrates (60 g) per meal. So, 4 units of insulin would be administered for 60 g of carbohydrates.

Adjustments should be made, by increasing or decreasing 2 units until the postprandial glycemic target (140–180 mg/dL–7.8–10 mmol/L) is reached.

A new way to start the basal-plus regimen is by using the co-formulation of degludec insulin (70%) and aspart insulin (30%) called Ryzodeg. This can be started with a dose of 0.2–0.3 units/kg/day. This must be injected before the main meal or the one that most increases the postprandial glucose levels.

Basal-Plus GLP-1ra

One could also have a regimen of basal insulin plus a GLP-1ra, either in combination or given separately. In general, the insulin dose will need to be adjusted downward, when adding a GLP1ra.

Basal Bolus

The basal-bolus regimen has more schedule flexibility, lower weight gain, and lower risk of hypoglycemia than the conventional regimen. However, for the flexible basal-bolus regimen, carbohydrate counting is required, and the patient must have the capacity and willingness to do mathematical calculations. With this regimen, it is not necessary for the patient to make snacks. If the patient does not want to count carbohydrates, he can be given a fixed diet and a fixed amount of fast-acting insulin before each meal (fixed basal-bolus). In the basal-bolus regimen, the patient starts with 0.5 units/kg/day.

Fixed Basal Bolus

In the fixed basal-bolus regimen, the patient starts with 0.5 units/kg/day. The total insulin dose is fractionated in the following way:

- 50% of the total insulin dose is the basal one. It can be used with insulin glargine U100 or U300, detemir, or degludec. These are usually administered once a day. In the case of glargine U100 or detemir, they may need to be divided in two doses (12 h apart), if it is observed that a single dose is having a peak or if the effect lasts less than 24 h.
- 50% of the total dose is for the boluses, which cover meals and correct elevated blood glucose levels. For boluses, fast-acting analogues such as lispro, aspart, or glulisine are usually used, although rapid-acting insulin can also be used. Usually, the assigned dose for the boluses is divided between the 3 meals of the day.

For example, if a patient weighs 72 kg and we calculate his dose at 0.5 units/kg/day, he would need a total of 36 units per day. Half of them, which is 18 units, are used for the basal and the other half for the bolus. If the 18 units are divided between the 3 meals of the day, the patient would have to inject 6 units before each meal.

If the patient is going to eat a small meal, he can inject only 4 units, but if it is a large meal, he is going to need 8 insulin units.

In addition, the correction factor can be calculated in case the preprandial glucose is above 150 mg/dL, and an extra dose of fast-acting insulin can be administered to correct glucose levels, for example, 1 unit per 50 mg/dL above 150 mg/dL. That is, if the patient had 250 mg/dL of glucose, in addition to the 6 units of the meal bolus, 2 more should be added to correct glucose levels. A total of 8 insulin units should be injected before said meal.

Flexible Basal Bolus (Figs. 37.4, 37.5, and 37.6, Appendix)

It also starts with a dose of 0.5 units/kg/day, and also, 50% of the insulin is basal and 50% prandial (Fig. 37.4).

To calculate the boluses, the insulin-to-carbohydrate ratio and the correction factor are used.

The insulin-to-carbohydrate ratio shows how many grams of carbohydrates are covered by the injection of one unit of insulin. Said ratio is usually initially calculated by the 450 rule [25], meaning that it is obtained by dividing 450 by total daily insulin dose (TDD), when fast-acting insulin is used.

As an example, if the person uses a total of 30 units of insulin per day, then we divide: 450/30 = 15. That is, one unit

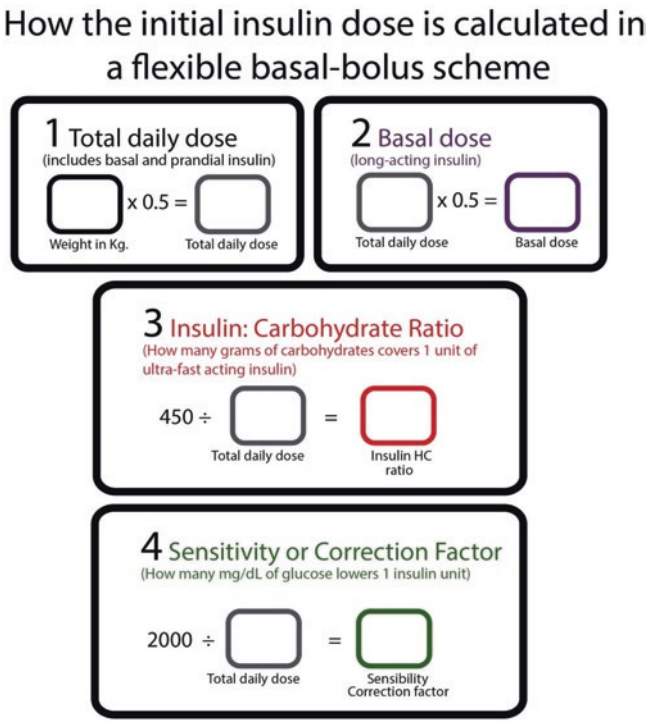

Fig. 37.4 How the initial insulin dose is calculated in a flexible basal-bolus scheme

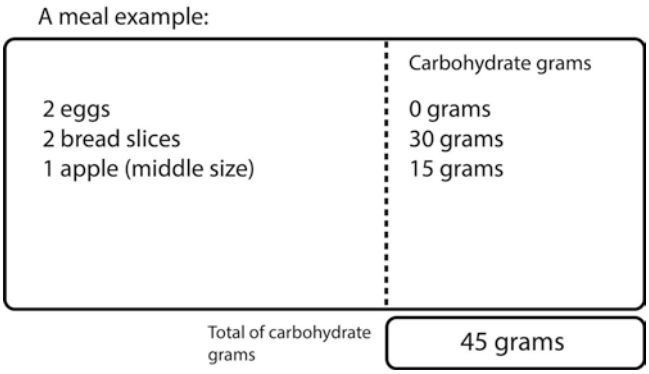

Fig. 37.5 A meal example

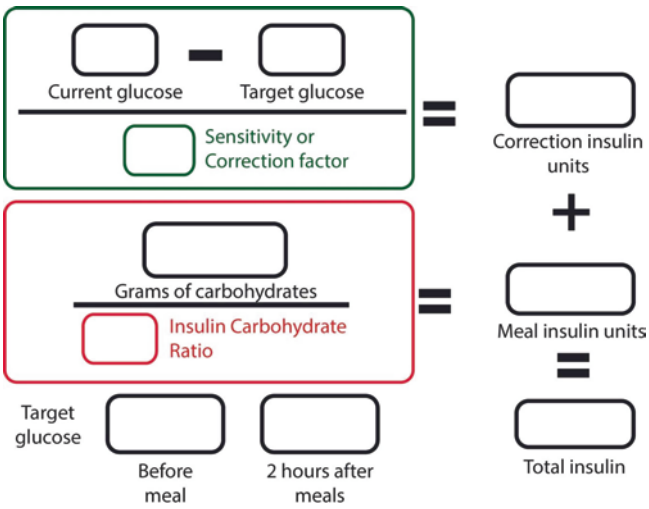

Fig. 37.6 Calculations that the patient makes to decide the insulin bolus (for both correction and meal coverage)

of fast-acting insulin would be injected for every 15 g of ingested carbohydrates. For example, if 45 g of carbohydrates are eaten, the patient would inject 3 units of fast-acting insulin (45/15 = 3) (Fig. 37.5).

It is important to tell the patient to preferably limit his carbohydrate intake to a maximum of 60 g per meal so that insulin works better.

It must be pointed out that the actual insulin-to-carbohydrate ratio could be calculated by dividing 300–500 by the TDD, although starting at 450 is safe.

The sensitivity or correction factor shows how many mg/dL of glucose are lowered by the injection of one unit of insulin. This is commonly calculated by dividing 2000/TDD (if using mmol/L, it can be done by dividing 100/TDD).

Continuing with the example: 2000/30 = 66.66 that can be rounded to 70 mg/dL.

The initial goal is 150 mg/dL of glucose. If the patient has 220 mg/dL of glucose and wants to reach 150 mg/dL, the difference is 70 mg/dL. Divided by the correction factor of 70 mg/dL, it resolves that the patient has to inject himself 1 unit of extra fast-acting insulin to his prandial insulin dose.

It must be pointed out that the actual sensitivity factor could be calculated by dividing 1500–2000 by the TDD, although starting at 2000 is safe. For deeper reading on the initial insulin-carbohydrate ratio and correction factor, please refer to the papers by John Walsh et al. [26, 27].

Figure 37.6 shows how a patient must do all the calculations to decide the insulin dose he should inject before each meal.

During the adjustment phase, the patient should perform SMBG before all meals and preferably 2 h postprandial and 2 h after a correction has been administered.

If the patient presents with hyper- or hypoglycemia 2 h after a meal, it should be checked if the carbohydrate count-

ing was adequate. If an error was not detected, the insulin-to-carbohydrate ratio should be changed. For example, in the case of hyperglycemia, the ratio could be changed from 1:15 g to 1:12 g of carbohydrates. If the patient was injecting 4 units for 60 g of carbohydrates, now he will be injecting 5 units for the same quantity of carbohydrates.

In the case of hypoglycemia, the insulin-to-carbohydrate ratio could be changed from 1:15 g to 1:20 g of carbohydrates. If the patient was injecting 4 units every 60 g, now he is going to inject himself with 3 units.

Also, in the case of hyperglycemia or hypoglycemia after a correction bolus, all factors that contributed to this situation should be reviewed (exercise, stress, illness, fasting, menstruation, etc.). If no reason is found, the correction factor should be changed.

In the case of hyperglycemia after a correction, the sensitivity factor can be changed from 1:70 mg/dL to, for example, 1:50 mg/dL.

In case of hypoglycemia after a correction, the sensitivity factor may be changed from 1:70 mg/dL to 1:100 mg/dL, for example.

It is important to stress out that the insulin-to-carbohydrate ratios and the sensitivity factors may be different throughout the day.

Basal Bolus with Sliding Scale

This regimen is a variation of the fixed and flexible basal-bolus regimens, where the total daily dose (TDD), the percentage of the basal dose, and the dose for the boluses are calculated the same way as in the fixed basal-bolus, but a table or sliding scale is given to the patient so that depending on the patient's pre-prandial glucose, insulin units are injected.

The quantity of insulin is also initiated at 0.5 units/kg/day. This dose is fractionated in 50% basal and 50% for boluses. The bolus dose is also divided by 3, and that is the number of insulin units that should be injected before every meal. The correction factor is also calculated with the formulas previously described in the flexible basal-bolus. An example of the table for basal bolus is shown below.

Glucose (mg/dL)	Before breakfast	Before lunch	Before dinner	2-h postprandial
<70				
71–100				
101–150				
151–200				
201–250				
251–300				
301–350				
351–400				
>400				

For example, if a patient weighs 72 kg and the starting dose is 0.5 units/kg/day, he would need 36 units per day. He would use 18 units for the basal dose and 18 units for the bolus dose. 20 units are further divided by three meals. So, he would have to inject himself 6 units of fast-acting insulin before every meal. The correction factor is calculated by dividing 2000/36, which is equal to 55 mg/dL, and this is rounded to 50 mg/dL. It is important to tell the patient to have a fixed amount of carbohydrates per meal (e.g., 45–60 g).

The table is filled in the following way:

Glucose (mg/dL)	Before breakfast	Before lunch	Before dinner	2-h postprandial
<70	3	3	3	0
71–100	4	4	4	0
101–150	6	6	6	0
151–200	7	7	7	0
201–250	8	8	8	2
251–300	9	9	9	3
301–350	10	10	10	4
351–400	11	11	11	5
>400	12	12	12	6

Insulin Pumps

Insulin can be applied with syringes, pens, and insulin pumps. Insulin pumps are electromechanical portable devices that function through batteries and administer rapid- or fast-acting insulin through a catheter connected to a subcutaneous cannula in the patient's abdomen. The cannula is changed every 3 days. The insulin from the insulin pump is located in a deposit or cartridge, and it is automatically administered through a basal dose. Plus, the patient programs a feeding bolus (prandial) or a correction bolus. For more information, please refer to Chap. 38

Insulin Adverse Effects

The adverse effects of insulin include hypoglycemia, edema, and weight gain. If the patient always injects the insulin in the same place, he could develop lipohypertrophy and lipoatrophy. In order to avoid these situations, the place in which the insulin is injected should be rotated. To avoid hypoglycemia, it is important to educate the patient regarding SMBG technique and tight glucose monitoring, as well as hypoglycemia treatment. For more information, please refer to Chap. 45.

Before initiating intensive therapy with insulin, it is important to rule out the presence of proliferative retinopathy through a dilated-pupil fundus examination. If present, the blood glucose target should be reached at a slower rate. It is known that pre-existent, diabetic proliferative retinopathy can increase initially with intensive insulin therapy, although it later improves [28].

Storage and Insulin Application Techniques

Insulin is stored in the refrigerator, not in the freezer, and should be taken out 30 min before use. If desired, the insulin in use may be maintained at room temperature, as it is stable for 28 days. Insulin Degludec is stable for 2 months outside the refrigerator at room temperature.

Insulin can be applied using syringes, pens, or insulin pumps. Syringes of 30, 50, and 100 units exist. Most of the 30 unit syringes have the measure of half units, which are very useful for people who are very sensitive to insulin or for children. Those of 50 units go from unit to unit and those from 100 units from two to two units. Syringe needles range from 6 to 13 mm in length.

There are rechargeable and disposable pens. In the rechargeable ones, the 3 mL cartridge is inserted and can be reused with new cartridges. The disposable ones come with an integrated 3 mL cartridge and are thrown away when finished. The needles for the pens are 4–8 mm long, and the lowest thickness is 32G. Insulin should be injected subcutaneously. To avoid intramuscular injection, it is best to use the shorter needles.

The insulin NPH and the premixed insulins should be mixed by turning the bottle between the hands (like rolling a pen between hands) to bring it to a uniform suspension. Do not shake to avoid bubbles. Once mixed, the lid of the vial is cleaned with a cotton swab moistened with alcohol. The plunger of the insulin syringe is pulled up to the number of insulin units that the patient requires. Air is injected into the insulin vial to break the vacuum effect and to facilitate the exit of the insulin. Immediately, afterward, the insulin bottle is turned around, without removing the syringe. Then the syringe is removed, taking care that no bubbles form. The top of the syringe plunger should be in the line of insulin units.

When insulins are mixed up in the same syringe, the rapid-acting insulin or the fast-acting insulin analogues are extracted first and secondly the NPH insulin. NPH mixed with rapid-acting insulin is stable in the syringe and can be left in the refrigerator for later use (e.g., if one prepares insulin for another person to use later). NPH mixed with insulin analogues (lispro, aspart, glulisine) is not stable; therefore, it should be injected immediately after it is loaded. Insulin glargine cannot be mixed with any fast-acting or ultra-rapid-acting insulin because of its pH. The syringe needle should not touch the fingers of the patient, cotton swab, or anything else, as it would contaminate and could cause skin infections.

Insulin application technique is as follows:

1. Select a site for injection.
2. Clean the skin with a cotton swab.

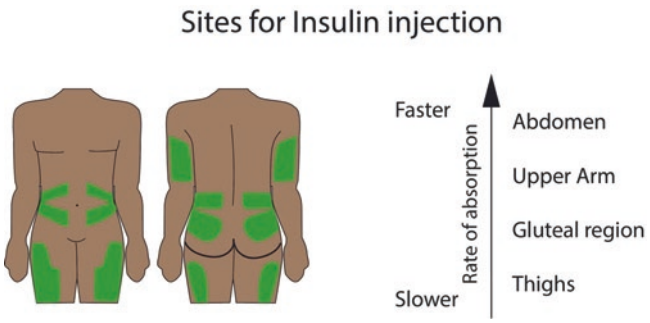

Fig. 37.7 Sites for insulin injection

3. Pinch approximately 2–3 cm of skin.
4. Hold the syringe in the same manner as a pencil is taken.
5. Insert the needle into the fold formed between the fingers in a 45° angle (thin patient) or 90° (obese patient).
   (a) The faster the needle is inserted, the less it hurts.
6. Release the crease.
7. Push the plunger gently until all the insulin has passed.
8. Wait 10 s before withdrawing the needle.
   (a) It is drawn in the same direction as it was introduced, gently pressing with a cotton swab at the injection site. Do not rub or massage the area.

Factors that affect insulin absorption should be taken into account such as:

- Site (Fig. 37.7)
- Depth of injection
  - Intramuscular. If injected by mistake, absorption will be faster.
- Dose
  - The higher the dose, the longer the effect of insulin.
  - This does not apply to insulin lispro, aspart or glulisine.
- Exercise
  - If insulin is injected in a site that it is about to be exercised, absorption will be faster.
- Temperature
  - At higher temperature, insulin absorption is faster and vice versa.

Conclusions

The different types of insulin have been reviewed as well as the different regimens of insulin application. When using basal insulin, the initial dose is 0.2 units/kg/day. An insulin titration algorithm should be given to the patient so that he can reach his glycemic goal faster. If the basal insulin dose reaches 0.3–0.5 units/kg/day, one must divide the basal insulin in two doses per day. Also, one should start considering adding prandial insulin, especially if the glycemic goal has

not been reached. One must be careful not to use the basal insulin to cover the prandial requirements.

When a more complex insulin regimen needs to be implemented, one has to decide whether to use the conventional regimen, the premixed insulins, a basal plus prandial, a basal plus GLP-1ra, or a basal-bolus regimen.

In general, for the conventional or basal-bolus regimen, the starting dose is 0.5 units/kg/day. This will then be divided between basal and prandial insulin. Basal-bolus insulin can be given in a fixed schedule, in a flexible schedule (insulin-to-carbohydrate ratio and sensitivity factor), or with a sliding scale.

In patients with T2D, if metformin use can be maintained, lower doses of insulin are required. Sulphonylureas should be discontinued to decrease the risk of hypoglycemia. In addition, if GLP1ra are used, lower insulin doses will be required, and the risk of hypoglycemia will be lower.

Most patients will achieve good glycemic control with 0.5–1.0 units/kg/day. Adolescents may require 1.0–1.5 units/kg/day. When more than 1.5 units/kg/day are required, then there is important insulin resistance.

The physician should analyze and suggest the regimen that will best help the patient achieve the individual goal of glycemic control.

This will decrease the incidence of complications of diabetes, which are already a severe problem in public health because of the high economic, social, and emotional cost that is involved.

Concluding Remarks

1. There are several types of insulin, depending on their insulin action time:
   (a) Fast acting (lispro, aspart, glulisine)
   (b) Rapid acting (regular)
   (c) Intermediate acting (NPH)
   (d) Long acting (detemir, glargine U100)
   (e) Ultra-long acting (degludec, glargine U300)
2. The main insulin adverse effects are hypoglycemia and weight gain.
3. Glargine U100 and detemir insulin cause less hypoglycemia than NPH insulin.
4. Detemir insulin causes less weight gain than glargine U100 and NPH.
5. Degludec and Glargine U300 cause less hypoglycemia than Glargine U100.
6. There are several insulin regimens, and each has an initiation phase and an adjustment phase. One should choose the regimen that best fits the patient.
7. Insulin regimens include the following:
   (a) Basal
   (b) Intensive regimens:
   - Conventional
   - Premixed insulin
   - Basal-plus prandial insulin
   - Basal-plus GLP-1ra
   - Basal bolus
     – Fixed
     – Flexible
     – Sliding scale
     – Insulin pump therapy

Multiple Choice Questions

1. Which insulin helps control glucose production by the liver?
   (a) Basal
   (b) Prandial
2. Which type of diabetes is characterized by an absolute insulin deficiency?
   (a) Type 1 diabetes
   (b) Type 2 diabetes.
   (c) Neonatal diabetes
   (d) MODY
3. To avoid diabetic ketoacidosis, patients with type 1 diabetes mellitus should continue their treatment with:
   (a) Insulin
   (b) Sulphonylureas
   (c) Metformin
   (d) Thiazolidinediones
4. Which is the main adverse effect of insulin therapy?
   (a) Blindness
   (b) Hyperglycemia
   (c) Hypoglycemia
   (d) Diabetic ketoacidosis
5. Which one is NOT an indication for initiation of insulin therapy?
   (a) Patients with type 1 diabetes
   (b) Newly diagnosed patients with type 2 diabetes who are very symptomatic
   (c) Patients with type 2 diabetes who have a glycosylated hemoglobin A1c $\leq$ 7%
   (d) Patients with type 2 diabetes who have progression of chronic microvascular complications
6. Examples of fast-acting insulin analogues are:
   (a) Rapid insulin
   (b) Insulin lispro, aspart, and glulisine
   (c) Insulin detemir and glargine
   (d) NPH insulin
7. Are some advantages of insulin analogues EXCEPT:
   (a) Less predictable
   (b) More physiological
   (c) Provide better glycemic control
   (d) Less hypoglycemia

8. Which is usually the starting dose for basal insulin?
   (a) 0.8 units/kg/day
   (b) 0.6 units/kg/day
   (c) 0.4 units/kg/day
   (d) 0.2 units/kg/day
9. Which is NOT an intensive insulin regimen?
   (a) Basal + GLP-1
   (b) Basal plus
   (c) Basal
   (d) Premixed insulin
10. Which is NOT true about insulin storage?
   (a) It should be stored in the freezer.
   (b) Should be taken out 30 min before its use.
   (c) May be maintained at room temperature for 28 days.
   (d) Should be stored in the central compartments of the refrigerator.

Appendix: Initial Doses for Each Regimen

Basal insulin:

0.2 units/kg/day or 10 Units (Usually in the Evening)

Conventional Insulin Regimen:

0.5 units/kg/day

Divide

Option A

2/3 in a.m. (2/3 NPH, 1/3 rapid or fast acting).

1/3 in p.m. (1/2 NPH, 1/2 rapid or fast acting).

Option B

1/3 before every meal (1/2 NPH, 1/2 rapid or fast acting).

Basal Bolus Insulin Regimen:

Fixed basal-bolus

0.5 units/kg/day

−50% for basal doses.

−50% for prandial doses, divided in three equal doses. One for each meal.

Flexible basal-bolus.

0.5 units/kg/day (Total Daily Dose: TDD)

−50% for basal doses.

−50% for prandial doses.

Insulin to Carbohydrate Ratio (I:CHO ratio).

I:CHO ratio = 450/TDD.

Prandial bolus: Total of carbohydrate grams/I:CHO ratio.

Correction Factor:

mg/dL: Correction Factor = 2000/TDD.

mmol/L: Correction Factor = 100/TDD.

Pre meal target glucose: Initially 150 mg/dL (~8 mmol/L), later on 120 mg/dL (~7 mmol/L). If the patient is stable and is able to identify hypoglycemia, target glucose could be lowered to 100 mg/dL (5.55 mmol/L).

Post meal target glucose: 180 mg/dL (10 mmol/L).

Correction bolus = (Current glucose – Target glucose)/ Correction factor.

Total Bolus: Prandial Bolus + Correction Bolus.

Insulin Pump Therapy

38

Raquel N. Faradji, Elena Sainz de la Maza, and Juan Ramón Madrigal Sanromán

Learning Objectives

- To identify the components of continuous subcutaneous insulin infusion (CSII) therapy.
- To assess the advantages, disadvantages, and considerations of CSII.
- To apply how to calculate the initial dose settings and the fine-tuning adjustments step by step.
- To describe the key issues of CSII on special situations.

How It Works: The Basics

Continuous subcutaneous insulin infusion (CSII) therapy uses a portable device that delivers rapid human insulin or fast-acting insulin analogues subcutaneously, via a cannula. The insulin delivery system tries to mimic the endogenous pancreatic insulin secretion and does this via two different features:

1. Basal rate: preprogrammed micro-boluses every few minutes throughout the day.
2. Bolus: patient can give extra insulin doses to cover food intake or to correct an elevated blood glucose (BG) level.
   (a) *Food bolus:* the patient indicates to the pump the BG level at that moment and the carbohydrate intake (in grams or portions), and the pump calculates the insulin amount, based on the insulin-to-carb ratio (ICR).
   (b) *Correction bolus:* the patient introduces the BG level at that moment, and the pump calculates the insulin amount based on the insulin sensitivity factor (ISF) and the BG target.

Insulin Pump Candidates

- Patients with type 1 diabetes (T1D) or type 2 diabetes (T2D) on intensive insulin therapy.
- Women with diabetes who are pregnant or are planning a pregnancy.
- Patients' age or diabetes duration should not be a determining factor in the transition to this therapy [1, 2].

Patient Requirements

- Responsible and psychologically stable.
- Motivated to achieve optimal BG control.
- Able and willing to carry out the tasks of this therapy safely and effectively and to maintain frequent contact with a healthcare team provider with full training and comprehension of CSII therapy.
- Able and willing to check their BG levels at least four times a day.
- Pediatric patients must have a motivated and committed family with a good understanding of diabetes self-management principles [1, 3].

Advantages of CSII Therapy

- The micro-boluses, as low as 0.025 international units (IU) in some devices, allow to adjust with more precision to the requirements of the patient, which reduces hypoglycemia risk.
- The basal infusion can be temporarily augmented, reduced (temporal basal rates), or suspended, which can be useful to maintain BG control during sick days or exercise.
- The significant reduction in the number of insulin injections from 4 or more each day to one infusion set change every 3 or 4 days.
- Different bolus delivery options, described later in this text.

Disadvantages of CSII Therapy

- Psychosocial issues: as the user has to wear a device attached to his body day and night.
- Most of the available models in the market may be disconnected for periods no longer than 1 h, for example: taking a bath, swimming, or having high contact sports.
- Running out of insulin infusion for more than 2 h increases the risk of diabetic ketoacidosis (DKA). This can occur either because of remaining disconnected, air bubbles in the catheter, cannula obstruction, for example. This is the reason why patients have to check their BG often (at least four times a day). And if the BG is higher than 240 mg/dL (13.3 mmol/L) in two occasions, they must take action and correct with insulin injection and insulin, insulin reservoir, and infusion set change. They should be trained to always carry with themselves an extra infusion set change and an insulin delivery device like insulin pen or syringes and an insulin vial.

Types of Insulin Pump

There are different kinds of insulin pumps in the market:

- With tubing: insulin pump device connected via a catheter (from 18 to 43 inches length) to a subcutaneous cannula.
- Without tubing (patch pumps): insulin infusion device that includes the cannula, reservoir, and infusion mechanism inside. Some models include the controller components on the pump, and others communicate wirelessly with a separate controller device. The insulin pump configuration is set in the controller device, both for the basal rate and the bolus calculation. They are waterproof, and some are approved for depths of 25 ft for 60 min.
- With or without continuous glucose monitoring (CGM): Some models are just compatible with a CGM and give hypo- and hyperglycemia alarms, but the device does not take any action with the information the CGM provides. Other models are integrated with the CGM system and can take some actions to prevent hypoglycemia, such as stopping the infusion at a low glucose reading (low glucose suspend feature-LGS, Medtronic) or stopping the infusion when a hypoglycemia is predicted in the 30 min (PREDICTIVE, Medtronic 640G). There is a new model that has an algorithm for the basal rate and corrects for hyper- or hypoglycemia automatically (Medtronic 670G).

Initial Settings

Initial Total and Basal Insulin Dose

Initial *total daily insulin dose (TDD)* may be calculated (Fig. 38.1):

– With the patient's weight (0.5 × patient's weight in kg or 0.23 × patient's weight in lb)
– Making and adjustment (usually a 25% reduction, if A1c is in target) to his previous total insulin regimen by multiple daily injection (MDI)
– Or a mix of both approaches using the average

Then, 50% of that dose is used as the *total daily basal dose* and can be divided equally in 24 h (IU/h).

In addition, if a patient has been reasonably well controlled on MDI, on a basal-bolus regimen, one could do the conversion from the total basal insulin analogue dose to the *total daily basal dose*, by reducing it by 5–25%. It must be pointed out that when converting from glargine insulin to CSII, one must reduce the dose at least 20%. When converting from degludec insulin to CSII, the reduction may be lower (5–15%).

The basal dose may be set in the pump configuration in insulin IU hour by hour, and some devices may have the possibility to set different basal rates at each 30-min interval.

– When initiating the basal rate, one can initiate with a constant basal rate per hour for the 24 h, for example, 0.5 IU per hour, or with different basal rates for different time frames, depending if it is known that the patient presents dawn phenomenon (higher rate) or early morning hypoglycemia (lower rate).
– Insulin pumps may have the possibility to configure different basal patterns, for example, a higher one for sick days and a lower one for exercise days.

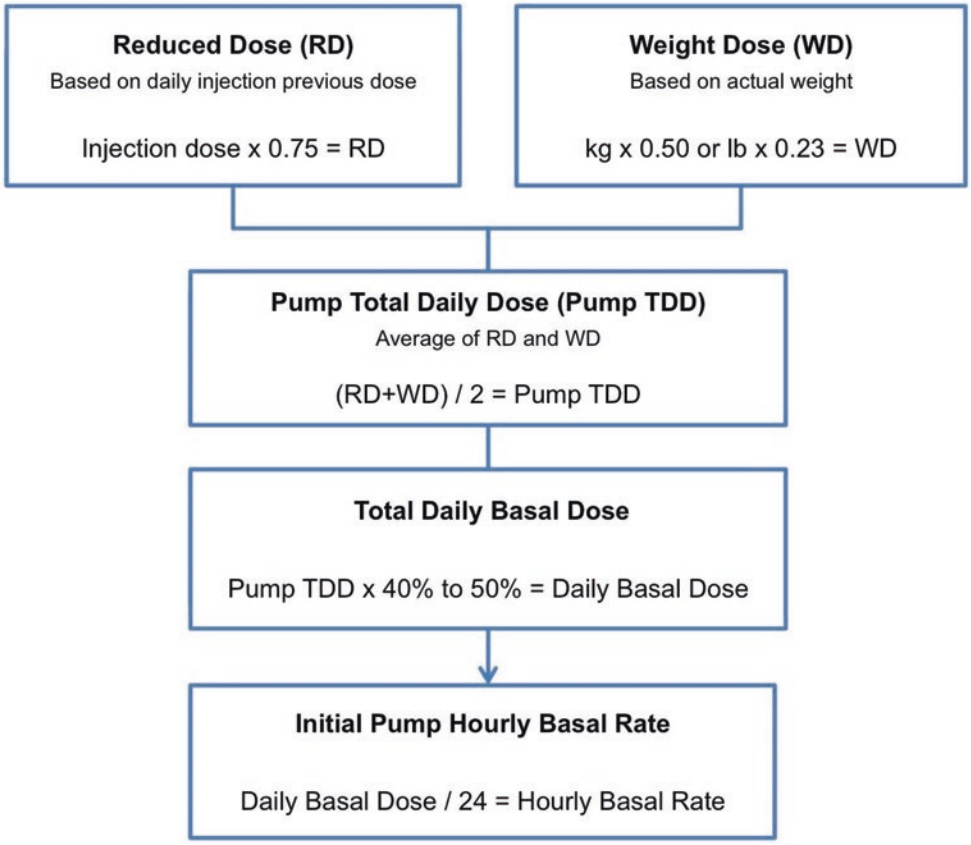

Fig. 38.1 Initial pump hourly basal rate. (Adapted from medtronic protocol [3])

– Another function of CSII devices is to set temporary basal rates anytime, with durations from 30 min to 24 h. Temporal basal infusion may be programed by insulin units or by percentage. For example, if the patient has an unplanned physical activity, he can set a basal reduction of "X%" during "X" hours.

Initial Bolus Calculation

Initial bolus calculation settings include the following:

– *Insulin-to-carb ratio (ICR):* This means how many grams of carbohydrate will be covered by the infusion of one unit of fast-acting insulin. For optimal control, a patient may need different ICRs during the day. *If a patient on multiple daily injections has established an ICR that provides reasonable post-prandial glucose control, the pump therapy settings can be done using that ICR. If a patient is not yet carb counting or does not have an accurate food log, use the 450 Rule (450/total daily dose)* (Fig. 38.2) [3].
– *Insulin* sensitivity *factor (ISF)***:** This factor indicates the mg/dL or mmol/L of BG that is lowered by the infusion of one unit of fast-acting insulin. *If a patient on multiple daily injections has an established ISF that currently provides reasonable correction doses, the pump therapy settings can be started using that ISF. For patients who have frequent hypoglycemia or hypoglycemia unawareness, use the 2000 Rule (2000/TDD)* (Fig. 38.3) [3]. Please refer to Chap. 37, for more details on these calculations.

Fig. 38.2 Initial insulin-to-carb ratio (ICR) [3]

Fig. 38.3 Initial insulin sensitivity factor (ISF). (Adapted from [3])

– *Active* insulin *(AI):* Some devices include a bolus calculator feature that also considers the active insulin from a previous bolus and estimates the adjustment to reduce the hypoglycemia risk. In order to program that, the settings should include active insulin in hours. *The length of time fast-acting insulin lowers the blood glucose level varies in each individual. Usually, it can be set from 3 to 5 h* [3].
– *Blood glucose target range (BGTR):* This is the range of BG levels that we want the patient to achieve. With this information, the bolus calculator feature will determine if a correction is needed. *When determining target ranges, keep in mind, these are not the same as ADA or AACE BG guidelines; instead, they are the values the pump "targets" when correcting high or low BGs and should be individualized, especially, in patients with history of severe hypoglycemia or hypoglycemia unawareness* [3].
– *Insulin bolus delivery* can be done in three different ways:
  Normal bolus: The total bolus estimation is delivered at that moment.
  Square wave bolus: The total bolus estimation is delivered during a lapse of time defined by the patient. It can be anywhere from 30 min to 8 h, for example. It is usually used when consuming food high in fat and protein.
  Dual wave bolus: This bolus is a mix between the normal and the square wave bolus. The patient can set a percentage of the bolus to be given now (normal) and a percentage of the bolus to be given over a lapse of time (square wave bolus). This type of bolus can be used for meals high in carbohydrate, fat, and protein, such as pizza.

Adjustments Step by Step

Here is a step by step example of fine-tuning adjustments:

Step 1. Calculate initial doses

Total daily dose, basal hourly rate (Fig. 38.4), ICR (Fig. 38.5), and ISF (Fig. 38.6)

Step 2 Patient's BG registry

Usually, the information regarding BG levels, carbs ingested, insulin boluses, and exercise can be entered in the insulin pump. But, sometimes, many patients forget to enter BG levels and carbs during a hypoglycemia event, and that information is lost when downloading the insulin pump information in the computer. If a hypoglycemia is not recorded, then when making adjustments, important information will be omitted. For that reason and for educational purposes, it is recommended that patients will make their own manual BG registry log (Figs. 38.7, 38.8, and 38.9). When a person does his own BG registry manually, he is more conscious of his own decisions, which can promote engagement.

Suggested BG registry format:

Step 3 Basal rate fine-tuning

Although some patients may achieve good BG control using one constant basal rate, most will need different basal rates during the day to achieve a tight BG control. Once the initial doses are set, the healthcare team should help the patient to evaluate and fine-tune the basal rate. There are some guidelines to follow during the evaluation period [4].

- The first time-frame to be evaluated should be overnight.
- It is preferred to see similar results for 2 days in a row to consider it a pattern and make adjustments. If the blood glucose is dropping during the evaluation, you can consider to change the rate without confirming a pattern.
- The blood glucose should be 100–150 mg/day (5.5–8.3 mmol/L) before starting the evaluation.
- On the day of the evaluation, the patient should avoid exercising, eating high fat meals, or drinking alcohol. Do not plan an evaluation if the patient is sick, under unusual stress, or if the patient experienced a severe hypoglycemia that day.
- The last meal before the beginning of the evaluation should be easy to count, preferably with low fat foods.
- Stop the evaluation if the blood glucose drops or rises out of the target range and treat it.
- Basal evaluation should begin 3–5 h after the last bolus.
- Check blood glucose every 1–2 h. For the overnight time frame: before bedtime, midnight, between 2–3 a.m., and upon awakening.

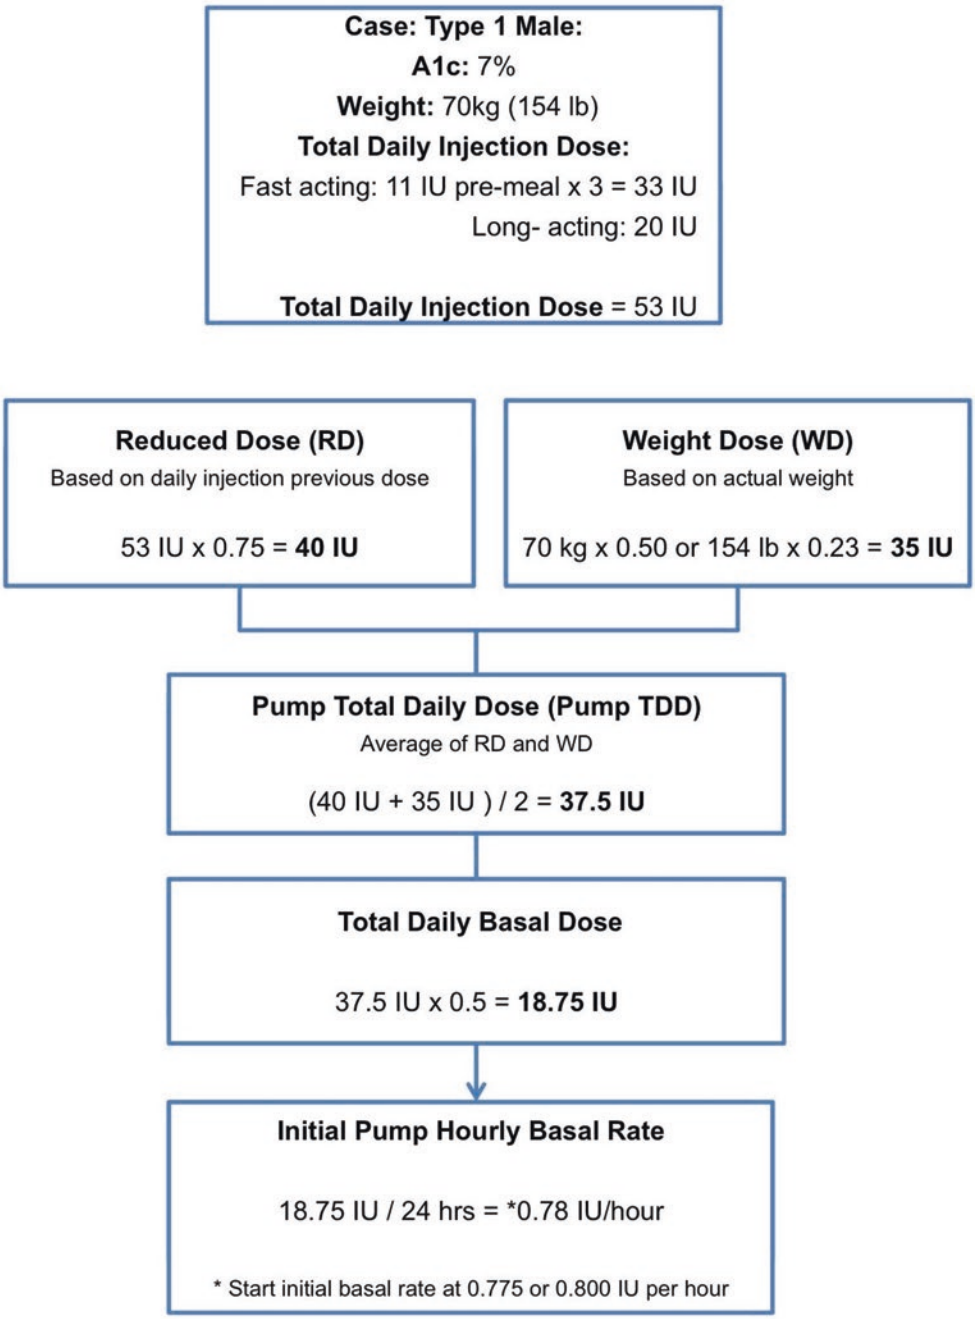

Fig. 38.4 Initial basal hourly rate doses calculation example. (Adapted from [3])

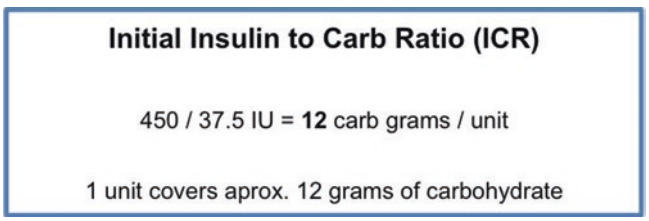

Fig. 38.5 Initial ICR calculation example. (Adapted from [3])

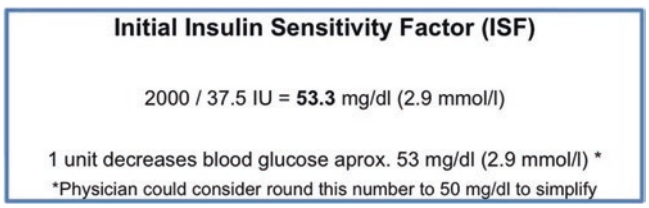

Fig. 38.6 Initial ISF calculation example. (Adapted from [3])

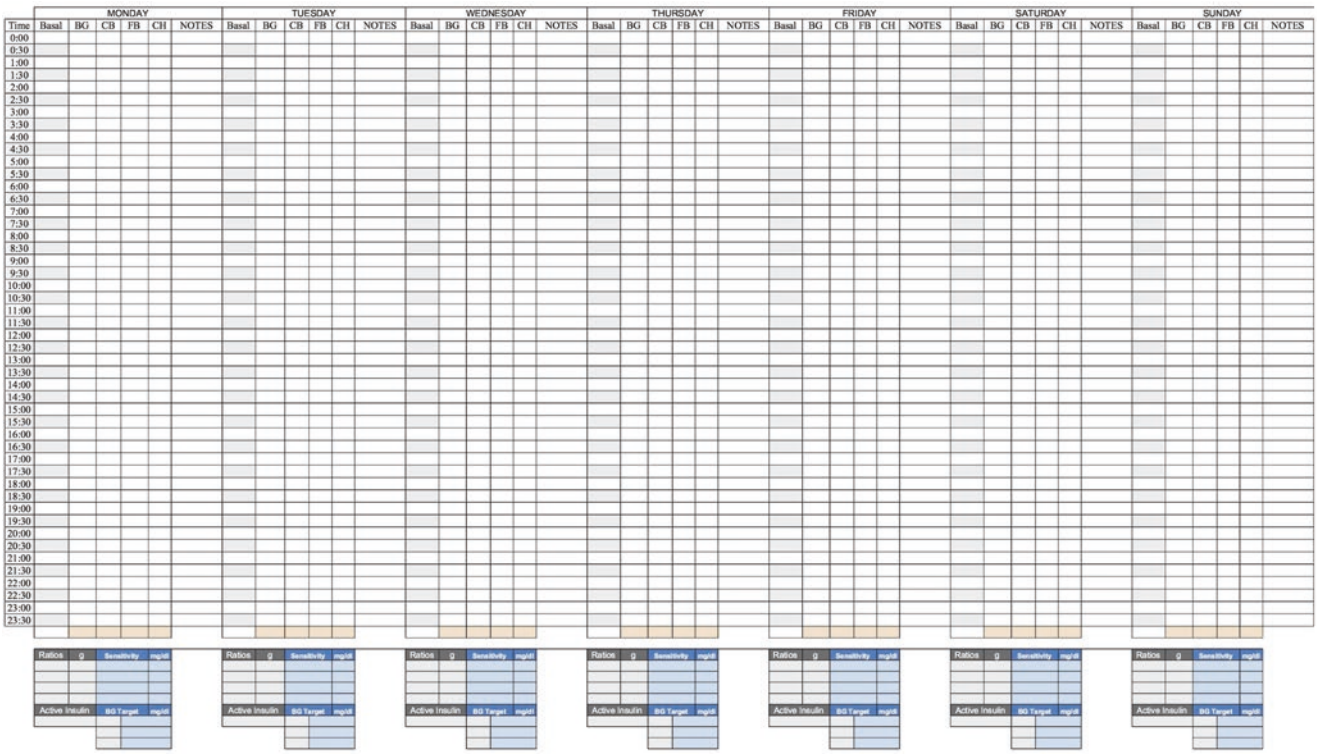

Fig. 38.7 Example of BG registry format. (Faradji R, Sainz E, Clinica EnDi, unpublished)

Time frame/guidelines	Check blood glucose	Evaluation
Overnight Eat dinner earlier: easy to count, low fat Don't eat afterward	• 3 h after dinner bolus • Midnight • 3:00 a.m. • Upon awakening	Basal rates are correct if BG does not increase or decrease more than 30–40 mg/dL (1.7 a 2.2 mmol/L) during the evaluation period If BG increases, basal rate needs to be increased for this time period If BG decreases, basal rate needs to be decreased for this time period
Breakfast time Check your BG upon awakening If BG is between 100–150 mg/dL (5.5–8.5 mmol/L) approximately begin evaluation Skip breakfast Eat no food until noon	Every 1–2 h until noon/ lunch time	
Lunch time Eat breakfast at usual time: easy to count, low fat Skip lunch Eat no food until dinner	• 3 h After breakfast bolus • Every 1–2 h until dinner	
Dinner time Eat lunch at usual time: Easy to count, low fat Skip dinner Eat no food until bedtime Eat a late dinner or bedtime snack if you desire	• 3 h. After lunch bolus • Every 1–2 h until bedtime snack/late dinner	
• Consider that meal time frames are different in different cultures; maybe you will have to adjust these guidelines • Each time frame evaluation must be done on different days • Keep in mind that basal insulin delivered has its maximum effect 2–3 h later. For example, if blood glucose is elevated at 3:00 in the morning, the basal rate must be changed starting at 0:00 h		

Adapted from [4]

Basal rate fine-tuning step-by-step didactic example (Fig. 38.10).

Day 1 Basal evaluation overnight: Monday to Tuesday
18:00 h—BG before dinner—120 mg/dL (6.7 mmol/L).
22:00 h—BG 4 h after dinner—150 mg/dL (8.3 mmol/L).
00:00 h—BG midnight—170 mg/dL (9.4 mmol/L).
03:00 h—BG 3 am- 240 mg/dL (13.3 mmol/L).

BG rises more than 30–40 mg/dL (2 mmol/L approx.) from midnight to 3:00 h. The patient should adjust basal rate from 0.800 to 0.850 IU/h on that time frame.

Day 2 Basal evaluation overnight: Tuesday to Wednesday
18:00 h—BG before dinner—110 mg/dL (6.1 mmol/L).
22:00 h—BG 4 h after dinner—155 mg/dL (8.6 mmol/L).

BG – Blood glucose (mg/dl)
CB – Correction Bolus (insulin units)
FB – Food Bolus (insulin units)
CH – Carbohydrates (grams)
NOTES – Food detail, excercise, cannula change, etc.

	MONDAY					
Time	Basal	BG	CB	FB	CH	NOTES

Fig. 38.8 Detailed example BG Registry Format. (Faradji R, Sainz E, Clinica EnDi, unpublished)

Ratios	g	Sensitivity	mg/dl
0:00	12	0:00	50
Active Insulin		**BG Target**	**mg/dl**
3 hrs		0:00	100-110
		6:00	90-100
		20:00	100-110

Fig. 38.9 Detailed example of pump settings summary

00:00 h—BG midnight—170 mg/dL (9.4 mmol/L).
03:00 h—BG 3 am—210 mg/dL (11.6 mmol/L).

BG rises more than 30–40 mg/dL (2 mmol/L approx.) from midnight to 3:00 h, even with the last adjustment, patient could adjust basal rate from 0.850 to 0.900 IU/h on that time frame.

We also observe a 2-day pattern of BG rising moderately from 22:00 to 00:00 h. The patient and his healthcare team could consider adjusting the basal rate from 0.800 to 0.850 u/h on that time frame.

Day 3 Basal evaluation overnight: Wednesday to Thursday
18:00 h—BG before dinner—120 mg/dL (6.7 mmol/L).
22:00 h—BG 4 h after dinner—155 mg/dL (8.6 mmol/L).
00:00 h—BG midnight—130 mg/dL (7.2 mmol/L).
03:00 h—BG 3 am—120 mg/dL (6.7 mmol/L).
06:00 h—BG wakeup—110 mg/dL (6.1 mmol/L).

BG remained without big changes during the night.

We can observe another pattern during the day on days 1, 2, and 3: from 9:00 h to 12:00 h BG decreases more than 30-40 mg/dL (2 mmol/L approx.): The patient could consider decreasing the basal rate from 0.800 to 0.750 IU/h during that time frame.

Day 4 Basal evaluation morning and overnight: Thursday morning and Thursday to Friday

Thursday morning:
09:00 h—BG 3 h after breakfast 160 mg/dL (8.9 mmol/L).
12:00 h—BG 3 h before lunch 150 mg/dL (8.3 mmol/L).

BG remained without big changes during the morning, the basal reduction to 0.750 u/h worked. After analyzing the breakfast postprandial results, the patient with his healthcare team could consider adjusting the breakfast ICR in order to achieve a better postprandial glucose result from 12 g of carbs to 10 g of carbs per 1 unit of insulin, just for breakfast.

Thursday to Friday:
18:00 h—BG before dinner—110 mg/dL (6.1 mmol/L).
20:00 h—BG 2 h after dinner—170 mg/dL (9.4 mmol/L).
23.00 h—BG 5 h after Dinner—120 mg/dL(6.7 mmol/L)
03:00 h—BG 3 a.m.—110 mg/dL (6.1 mmol/L).
06:00 h—BG wakeup—110 mg/dL (6.1 mmol/L).

BG remained without big changes during that night. We already have 2 days without big changes overnight. For now, overnight basal rate is working as expected.

Day 5 Bolus breakfast ratio evaluation: Friday.
06:00 h—BG before breakfast—110 mg/dL (6.1 mmol/L).
09:00 h—BG 3 h after breakfast—120 mg/dL (6.7 mmol/L).
12:00 h—BG before lunch—90 mg/dL (5 mmol/L).

BG remained without big changes during the morning. After breakfast, postprandial BG result is on a better range, without big changes and without hypoglycemia until lunch.

Fig. 38.10 Didactic sample of BG Registry: days 1–5

Step 4 Insulin-to-carb ratio (ICR) fine-tuning.

Once the basal rate has been evaluated and adjusted, we can continue with ICR and insulin sensitivity factor (ISF) evaluation and adjustments. There are some recommendations:

- ICR evaluation should take place when BG before a meal is in target. If the user needs to add a correction bolus to get the BG down, it won't be the best time to evaluate the ICR.
- The person must choose a low-fat meal, moderate in carbs (30–45 g) and prefer a meal that is easy to count.
- The person should estimate the carbs, apply the food bolus according to the pump settings, and eat.
- Then, the user should check his BG every 1–2 h for the next 4 h after that meal.
- Four to five hours after the meal, the BG should return to the target range, if the ICR is correct.
- It is recommended to reevaluate the ICR on different days and at different times of the day.
- Consider that the ICR can be different for different times of the day.

An example can be seen on days 4 and 5 as explained before.

Step 5 Sensitivity factor (ISF) fine-tuning.

Usually, the insulin sensitivity factor (ISF) evaluation occurs naturally when we observe on the patient BG registry log book, an isolated correction bolus. This correction bolus should have no food, exercise, or other interfering factors at that time. We can then manually calculate how many mg/dL

or mmol/L the BG drops with the bolus infusion of one unit of insulin.

The insulin pump user can identify an opportunity to evaluate his own ISF when he needs to take a correction bolus, and at least 3 h have passed since his last food bolus. The person must take a correction bolus based on his pump settings and then check his BG after 2 h and then again at 3–4 h without eating during that time frame.

ISF fine-tuning, step-by-step didactic example (Fig. 38.11).

Day 6 Sensitivity factor evaluation. Saturday morning.

7:00 h—BG wake up—220 mg/dL (12.2 mmol/L)—2.2u insulin correction bolus according to the pump settings: target BG 110 mg/dL (6.1 mmol/L) and ISF 50 mg/dL (2.7 mmol/L).

9:00 h—BG 90 mg/dL (5 mmol/L).

10:00 h—BG 3 h after correction bolus—65 mg/dL (3.6 mmol/L).

We can estimate the adjusted sensitivity factor based on the evaluation results as follows (Figs. 38.12 and 38.13):

As we can see, even though the ISF is 50 mg/dL (2.7 mmol/L), the BG drops 70 mg/dL (3.8 mmol/L). Therefore, we can adjust the ISF to 70 mg/dL (3.8 mmol/L), in that time frame.

Keep in mind that the ISF can be different on different time frames during the day. Usually, a patient may need an ISF for the night and another one during the day.

Comparison of initial pump settings with pump settings after fine tuning adjustments

Initial pump settings	Pump settings after first adjustments

Special Situations

Exercise

The normal physiologic response to exercise is the reduction in insulin production and the increase in the secretion of glucagon and sympathetic hormones, as well as other counterregulatory hormones [5–7].

The response to exercise is different depending on the type of exercise:

- Anaerobic exercise (weights, high intensity sprints): There is more catecholamine secretion and therefore increased likelihood in BG rise.
- Aerobic (running, swimming, biking): There is more energy expenditure, and therefore, the risk of hypoglycemia is higher.

In a person living with T1D, where insulin administration is exogenous and subcutaneous, insulin secretion cannot be decreased. In addition, the increase in glucagon associated with exercise may be lost in the first few years after diagnosis. Finally, if the patient has autonomic insufficiency (either organic or because of hypoglycemia associated autonomic failure-HAAF), the sympathetic response will be attenuated, leaving the person at risk of severe hypoglycemia and hypoglycemia unaware. As explained in Chap. 51, exercise can worsen this situation [5–7].

The risk of hypoglycemia is not only present during exercise but also in the hours following it, because of muscle glycogen stores replenishment that normally occur after exercise. This phenomenon can occur 7 h after doing exercise and may last for up to 24 h [8–10]. If exercise is performed on a daily basis, insulin sensitivity increases, and the insulin requirements may decrease.

In a patient with T1D, three responses to exercise may occur, depending on the insulin concentrations and on the level of the counterregulatory hormones [5–7].

(a) Euglycemia: If circulating insulin is decreased prior to exercise and the response to catecholamines is adequate, there will be appropriate glucose utilization by the muscle.
(b) Hypoglycemia: If there is excess or normal insulin concentrations and a normal or attenuated catecholamine response, the habitual response will be hypoglycemia.
(c) Hyperglycemia: This can occur in patients with uncontrolled diabetes, or in patients with good control, if there is relative insulin deficiency.

If there is insulin deficiency and an excessive catecholamine response, there can be the development of diabetic ketoacidosis.

In those patients treated with CSII, several studies have been carried out to evaluate what to do when exercising and using the pump.

Dr. Moshe Phillip's group published a study in 2005 [11], where the use of the insulin pump at a basal rate of 50% was compared to insulin pump disconnection during exercise in ten kids. There was no significant difference in the rate of hypoglycemia during exercise in the two groups, but there was an increased risk of hypoglycemia several hours after exercise in both groups. A trend toward more hypoglycemia several hours after exercise was seen in the group that used the temporary basal rate, compared to those that disconnected. Their recommendation is to disconnect the pump during exercise and to check BG levels frequently during and after exercise.

DirecNet (2006) [12] studied 49 children, where insulin pump use or not was compared during exercise at 4:00 p.m. They found that hypoglycemia during exercise was lower in the group that disconnected (16 vs. 43%), but post-exercise hyperglycemia was higher (27 vs. 4%).

Dr. Ana María Gomez published a study in 2015 [9], where the effect of exercise in BG levels was compared in exercise performed at the fasting state versus exercise performed 4 h after the main meal, in 35 insulin pump adult users. Both groups did aerobic exercise for 1 h, in a running machine. The insulin pump was disconnected immediately before, during and 45 min after finishing the exercise. They found that if exercise is performed in the morning, the rate of hypoglycemia is lower than if performed in the afternoon. Most hypoglycemic events occurred 15–24 h post-exercise. Those patients that performed fasting exercise increased 20% their euglycemia time, the day after exercise. They concluded that early morning exercise decreases the rate of hypoglycemia and improves glucose control.

McAuley et al. in 2016 [13] studied the effect of using a temporary basal rate of 50% 1 h before and during exercise (30 min), versus rest in 14 adult subjects with T1D. They found that even with the basal rate reduction, insulin concentrations rise during exercise, compared to being at rest. Three of the 14 subjects presented hypoglycemia, even with the temporary basal rate reduction, and required supplemental carbohydrates. Their recommendation is to give supplementary carbohydrates to those patients with BG levels below 126 mg/dL (7 mmol) and to consider basal rate reductions higher than 50% before and during exercise.

Strategies to decrease hypoglycemia during and after exercise in insulin pump users include the following [14]:

1. Having supplementary carbohydrates before exercise
2. Reducing basal rate before and during exercise (50% or more)
3. Consider disconnecting insulin pump during and 45 min after exercise
4. Reducing meal bolus if exercise will occur 2 or 3 h after exercise
5. Reducing basal rate post exercise, to decrease the incidence of late hypoglycemia or nocturnal hypoglycemia (e.g., a 20% reduction, i.e., an 80% basal rate, during the night of the exercise day)
6. Reducing meal bolus after dinner, to reduce the incidence of late hypoglycemia or nocturnal hypoglycemia
7. Performing high resistance and intensity exercise prior and after aerobic exercise
8. Using CGM to help guide insulin doses and additional carbohydrate intake.

Each patient will need to study his own response to exercise and to the different types of exercise so that he can make the best decisions, together with his healthcare team, to try to prevent exercise-induced hypoglycemia.

Sick Days

It is important that the patient and the healthcare team have a set plan in case of sick days. The patient should understand that during sick days his BG levels may rise, even if he is not eating as much, because of the counterregulatory hormones. For that reason, he must maintain well hydrated, check his BG levels often, and give himself a correction bolus when needed. He also needs to have urine or glucose ketone test strips and check if the BG is higher than 240 mg/dL (13.3 mmol/L). If positive, he should contact the healthcare team.

In addition, if the BG levels remain higher than normal, he may need to set a temporarily basal rate such as 120–150% for several hours during the day and the reassess.

The patient must understand that if the BG is higher than 240 mg/dL (13.3 mmol/L) in two occasions in a row, even if he has given himself a correction bolus, he must do the following:

1. Check ketones
2. Look for a possible cause (i.e., cannula occlusion or dislodgement, insulin bubbles in the catheter, spoiled insulin)
3. Correct with an insulin injection (with insulin syringe or pen)
4. Change the insulin, insulin reservoir, and infusion set

Patients should be trained to always carry with themselves an extra infusion set change and an insulin delivery device like insulin pen or syringes and an insulin vial.

In case there are ketones present, the patient will need to increase his correction dose. He may need up to 15–20% of his total insulin daily dose as correction and check BG and ketones in 1 h.

Another important consideration is that sometimes the patient will be prescribed corticosteroids, as part of the treatment of his inter-current disease (i.e., asthma attack, vestibular neuronitis, etc.). In that case, BG levels will rise significantly around 6 h after the initial dose. He must keep well hydrated and check BG often, and he must make insulin adjustments as needed. He may need a temporary basal rate of 150% or more and may need to change the ICR and ISF to as much as 1:5 g and 1:15 mg/dL (~1:1 mmol/L), respectively.

Finally, if there is nausea and vomiting that cannot be treated with an antiemetic at home, regardless if there are or not ketones present, the patient should be seen in the emergency room for hydration, anti-emetic treatment, and diagnosis of the cause of the nausea and vomiting. He may need to be hospitalized.

Fasting

If a patient living with T1D has his basal rate set correctly, fasting should not be a problem. If it is set too high, he may then be at risk of hypoglycemia. To know if a basal rate is set correctly, a basal rate evaluation can be performed as explained above.

Fasting may be required before medical or surgical procedures or may be a personal or religious choice (such as in Yom Kippur or in Ramadan) [15]. Careful monitoring of glucose levels (either capillary, flash or continuous), avoiding bolus insulin, or if needed, correcting to a higher BGTR (150 mg/dL—approx. 8 mmol/L instead of 100 mg/dL- approx. 5.5 mmol/L) and temporary reductions in basal insulin may be required to maintain safe glucose levels.

Hospitalizations

T1D patients using an insulin pump, who are conscious, should be able to maintain the use of their pump while in the hospital [1, 2], especially if they have not been admitted for an acute hypo or hyperglycemic crisis. Ideally, their specialist in insulin pump therapy should be consulted during their hospital stay.

With the increased utilization of insulin pumps by patients, hospitals should be encouraged to have pump experts on staff, especially the anesthesiologists and the ward physicians. As stated in the American Diabetes Association's 2014 Standards of Medical Care [16], "Patients who use CSII pump therapy in the outpatient setting can be candidates for diabetes self-management in the hospital, provided that they have the mental and physical capacity to do so. [The] availability of hospital personnel with expertise in CSII therapy is essential. It is important that nursing personnel document basal rates and bolus doses on a regular basis (at least daily)."

It is important to note that if going to an MRI machine, the pump should be disconnected, and the sensor should be removed during the study.

Surgery [1, 2, 15]

During surgery two key situations occur:

1. The patient is fasting and therefore is at risk of hypoglycemia.
2. The increase in stress hormones from surgery could raise BG levels.

For these reasons, it is important to monitor BG levels before surgery, every hour during surgery and recovery room, and every 3 h while fasting.

For the most part, patients should be able to continue using their insulin pump during surgery. It is important to note the localization of the cannula (and the sensor, if in place) and to avoid dislodging them.

Since the patient will be anesthetized, it is important to have someone that knows how to manage the pump during that time. It could either be the anesthesiologist, the insulin pump therapy specialist (endocrinologist or registered nurse/diabetes educator) or, if not possible and if allowed in the operating room, a family member (i.e., spouse or parent), who knows how to operate the pump and is in contact with the insulin pump specialist.

During surgery, a temporary basal rate may be required, either a lower rate to prevent hypoglycemia, or a higher rate if BG levels start to rise secondary to the stress. Also, correction bolus may be given to a target BG level of around 150 mg/dL (approx. 8 mmol/L).

It is not recommended, but if decided by the medical team, the insulin pump could be stopped, and an intravenous insulin infusion should be initiated.

Menstruation [15]

For some women living with T1D, important changes occur during the menstrual cycle. During the premenstrual period, they may experience higher BG levels and increased insulin requirements. In addition, when menstruation starts and progesterone concentrations fall steeply, insulin requirements may fall sharply, and there may be a higher risk of hypoglycemia. For these reasons, different basal rate patterns could be set in the insulin pump for these situations. Or a temporary basal rate could be set.

Some women will report increased insulin requirements when using birth control pills; therefore, insulin dose adjustments will need to be made.

Pregnancy [1, 15]

CSII has not yet proven to be superior to MDI for BG control and pregnancy outcomes (macrosomia). A large randomized control trial is necessary to study this. Even then, CSII facilitates BG control on those patients that are already on it when getting pregnant. And on those that are on MDI and are not well controlled, they can be changed to CSII to improve their BG control.

Pregnancy is a state where several changes occur, and one must be familiarized with them, to optimally control BG levels during each trimester.

If teratogenicity occurs, this will occur in the *first 8 weeks of gestation*; therefore, it is very important to have the best possible BG control preconception, with a HbA1c target of <6%, if possible. After words, if there is poor glycemic control, the risk is macrosomia, due to glucose passage through the placenta, and increase in insulin secretion by the fetus. If the BG levels are elevated during delivery, the risk is of neonatal hypoglycemia.

In the *first trimester*, there is an estate of increased insulin sensitivity, and the normal BG levels range from 60–90 mg/dL, and the post-prandial levels are usually below 120 mg/dL. In this trimester, the risk of hypoglycemia increases due to the nausea and vomiting. During this phase, using temporary basal rates, or doing basal insulin adjustments if a pattern is seen, can be easily done with insulin pump therapy. In addition, giving the insulin bolus after eating can be especially useful if nausea and vomiting are occurring frequently.

In addition, pregnancy is a state of accelerated ketosis [17]; just a few hours of insulin interruption can lead to hyperglycemia and ketosis. Therefore, the patient must be extremely careful with insulin infusion site changes.

During the *second trimester*, the insulin requirements slowly start to increase.

After the second trimester, as the abdominal wall starts stretching and the subcutaneous space starts to thin out, special care should be taken with choosing the insulin infusion sites; the arms and thigh can be an option.

After the 24th week (*third trimester*), there is an increase in human placental lactogen and other counterregulatory hormones, leading to a significant increase in insulin requirements that can occur even twice per week. These can occur up until the 36th week. Using an insulin pump can facilitate doing the changes twice a week.

During labor, there is significant glucose utilization by the uterine muscular contractions that is comparable to intense exercise (2.55 mg/kg/min); therefore, an intravenous infusion of 10% glucose will be required at 100 cc/h. Usually, the basal rate is left constant.

Right after the placental delivery, the insulin requirements fall significantly, leading to risk of hypoglycemia for the next 48 h. In these time, the patient will:

1. Stop the pump until BG levels are above 100 mg/dL (5.5 mmol/L)
2. Require to return to the pre-gestational insulin pump settings
3. May not require insulin meal bolus
4. Require the infusion of dextrose at 5% with normal saline at 100 cc/h

In case of a *cesarean section*, the BG levels may temporarily increase due to the surgical stress, and the basal rate should be temporarily increased.

During *breastfeeding*, insulin requirements fall significantly (by up to 25%), as available carbohydrate is used to provide lactose in milk. This, added to the post-delivery decreased insulin requirements, can increase the risk of hypoglycemia. At the beginning, the patient can take 15 g of carbohydrates before lactation and can also use temporary basal rates to reduce the risk of hypoglycemia.

Alcohol [15]

Alcohol inhibits hepatic gluconeogenesis and therefore increases the risk of nocturnal hypoglycemia. Strategies to avoid hypoglycemia after alcohol intake include limiting alcohol intake to one serving for females and two servings for males, eating carbohydrate while drinking alcohol, using a temporary basal rate overnight, and eating carbohydrate before bed.

Travel [15]

When planning a trip, the first thing to consider is if the best option is to go to that particular trip using the insulin pump. If the trip is to the beach and the patient will be in contact with the sand and swimming a lot, the patient may decide to disconnect from the pump for those days. If deciding to do so, please review the next section.

When traveling with the pump, it is important to be prepared. One should instruct the patient to: Adapted from [15]–Chap. 4.
- Ensure you have all your supplies: Not just pump supplies and insulin but blood glucose and ketone monitoring, rapid-acting glucose supplies, glucagon kit, back-up syringes. and long-acting insulin.
- Keep supplies in a bag that stays with you at all times (cabin baggage). Extra pump reservoirs, infusion sets, and batteries can be kept in check-in luggage. If possible, give a smaller backup supply to someone travelling with you in case luggage is misplaced.
- For long-distance travel or travel in hot countries, keep insulin in an insulation bag, such as an evaporative cooling case.
- Ensure you keep documentation from your doctor confirming you have T1D and need to carry supplies with you and need to wear your pump at all times—this may be needed for airport security.
- Know where to obtain medical help if needed and keep key contact numbers.
- Locating and obtaining pump supplies can be a problem in some countries.
- Medical travel insurance is advised and ensures it covers your diabetes and pump use.
- If travelling in a group, make sure group members are aware that you have diabetes and what they may need to do in an emergency.
- Keep any reminders you may need, such as your pump settings, sick-day rules, and multiple dose injection doses.
- Change the time in the insulin pump and in the blood glucose meter when arriving to the destination.

Insulin Adjustments When Travelling

When traveling through time zones, the circadian rhythm will take time to adjust, and therefore, there can be an increased risk of hypo- or hyperglycemia. For this reason, while waiting for the body to adjust, it might be wise to set a flat basal rate at a slightly lower level (10–20% lower) than the usual basal rate for 24 h and return to the usual basal rate, once the body has adjusted.

In addition, if the trip will entail a lot of walking, temporary basal rates may be needed or setting a pattern for travel with lower rates. At the beginning, it will be important to have frequent BG measurements (every 3 h).

Insulin Pump Therapy on Vacation [15]

On occasions, people with T1D may want to rest from the insulin pump. This can be done when taking a beach vacation, as explained above, or when it is psychologically needed, but it can also occur as an unplanned situation because of pump malfunction. It is important that every patient that is on the pump knows how to go off and back on the pump.

Going Off the Pump

The first thing that needs to be done is to calculate the basal insulin dose that will be required.

In general, it may be safer to switch the total basal CSII dose to the basal insulin analogue dose on a 1:1 ratio and then make adjustments as needed [18].

If changing from the pump to glargine U100, the patient may require the same or an increase of up to 20% of the total basal insulin dose. This may be given in one or two doses.

If changing from the pump to degludec insulin, the patient may require the same amount of basal insulin, or a 5–10% increase. And this is usually given once a day.

It is important to note that the pump should be discontinued 2 h after the first long-acting insulin injection is given. If possible, it is best to do this in the morning to minimize the risk of problems at night.

The patient will need to check the BG and give himself the bolus insulin using his ICR and ISF, as usual. He can use the insulin pump as a bolus calculator, or learn how to do the calculations manually. If a bolus calculator app is available in the specific country, then he can use it with the pump settings.

Going Back on the Pump

When resuming pump treatment, the patient should usually return to his previous pump settings, unless significant changes in insulin dose have occurred. The best time to restart the pump is just before the long-acting insulin has worn off (approximately 2 h prior to the next due dose of long-acting insulin). If possible, it is advisable to do this in the morning. It is important to note that with the new ultra-long-acting insulins (degludec), it may be needed to use a lower temporary basal rate, until all of the ultra-long-acting insulin has been absorbed and metabolized (it may take up to five half-lives, though usually this is only necessary for the first 24 h).

CGM

There are three main ways in which once can monitor glucose levels:

- Blood glucose meters: These measure capillary BG levels at a specific time. The glucose meters that are on the market use an enzymatic method to measure BG levels, and it can be either hexokinase or glucose oxidase. There are several BG meters on the market. The patient should ideally measure before each meal, 2 h after each meal, before bedtime, and occasionally at 3:00 in the morning.
- Continuous glucose monitors: These continuously (approximately every 5 min) measure interstitial glucose levels. These depend on a sensor (also uses an enzymatic method that is converted to electrons), a transmitter, and a reading device. The ones that are coupled to insulin pump therapy display the CGM graph on the pump. Some glucose monitors can also have their information displayed on a smart phone. There are two main brands in the Market: Dexcom and Medtronic. So far, both need to be calibrated, twice a day, on steady-state conditions, with BG reading obtained via a BG meter. Both show a CGM glucose graph and arrows showing the glucose rate of change.
- Flash glucose monitor (Free Style Libre, Abbott): This system measures interstitial glucose levels every minute. It consists of a sensor and a reading device. The sensor is factory calibrated and uses also an enzymatic method (glucose oxidase), to continuously measure the interstitial glucose levels. It can store up to 8 h of information, if not scanned by the reading device. When scanned, it displays the glucose reading at that time, a graph of the glucose values in the last 8 h, and an arrow, showing the glucose rate of change.

Integrated Systems

To close the loop is the holy grail of the integrated systems for insulin delivery for the treatment of T1D. Many years ago, this was tried with the biostator and the back-pack insulin pump. But these technologies measured intravenous glucose and gave intravenous insulin infusions. Since these were complicated and large in size, they never made it into the market. Medtronic has been a pioneer in integrated systems for insulin delivery that have reached the market. The first system started using a CGM that was able to communicate with the pump and give an alarm in case of hypoglycemia. The second system, also called a sensor augmented pump, had the CGM communicate with the pump and stop the infusion at a target low glucose reading, this feature is called “low glucose suspend”-LGS. This feature has shown to reduce the time spent in hypoglycemia [19]. The third system that reached the market is the PREDICTIVE control, in which the insulin infusion is stopped when it predicts a hypoglycemic event in the next 30 min. It also restarts when

the glucose levels stabilize [20] (Medtronic 640G). In 2016, the FDA approved the first hybrid close loop system (Medtronic 670G) that has an algorithm for the basal rate and corrects for hyper- or hypoglycemia automatically. The patient still has to check his BG levels and count carbohydrates, in order to give a meal bolus or a correction bolus. In the 3-month study for its approval, no patient had severe hypoglycemia, nor DKA.

Medtronic's 780G® advanced hybrid closed loop system, which is now available in the United States, Europe, and some Latin American countries, also has a basal algorithm that allows to choose the goal at 100 mg/dL, 110 mg/dL, or 120 mg/dL and has the autocorrect function. This system uses the artificial pancreas algorithm developed by DreaMed Diabetes based on Physicians' Fuzzy Logic (Fuzzy Logic, MD), co-authored by Drs. Thomas Dane, Tadej Battelino, and Moshe Phillip [21].

There are currently a number of companies that are developing closed-loop systems. Most using the highly accurate Dexcom G6® Continuous Glucose Monitor. Examples are the Tandem T-Slim® pump with Control IQ® (Tandem Inc., USA), the CAM-APS FX [22] (Cambridge, UK), which works with an App on Android phones, and is only under development in Europe, the Omnipod Horizon®, which is a disposable micro-pump without a tube, and Diabeloop®. The results of pivotal studies in children and adults with the Omnipod Horizon System, which can lead to goals of 110–150 mg/dL, in 10 mg/dL increments, were recently published. Most adults achieved excellent overnight glucose control, with time in range > 70% in adults and 65% in children [23]. All of these systems still require the user to announce the food to calculate the meal bolus.

Several groups are working in the development of the close loop system. One particularly interesting is the one by the group of Damiano and Russell, from Boston University, Massachusetts General Hospital, Harvard Medical School. They are developing a bi-hormonal (insulin and glucagon) close loop system with great promise [24–28].

Since many patients are not waiting for the institutional regulatory approvals, some (mostly engineers and technology savvy) have created their home made CGM-insulin pump integrated systems, with great success, increasing their time in blood glucose target range [29, 30].

Conclusions

Insulin pump therapy is an excellent tool to improve glycemic control and quality of life. To obtain the full potential of this therapy, an experienced multidisciplinary team approach should be established. It must be stressed out that continuous close professional advice should be available, especially at the beginning in order to make the adequate adjustments as soon as possible. It may take up to a month or more to adjust all the settings. In addition, when having significant life changes (childhood, puberty, pregnancy, menopause, aging, travelling, exercise), adjustments will need to be made in the therapy.

There have been significant advances in insulin pump therapy technology in recent years. This chapter focuses mostly in starting insulin pump therapy using capillary BG measurements for the initial adjustments and does not deepen into the use of integrated systems. Although CGM technology can help significantly in doing adjustments and reducing hypoglycemia, these technologies are not available in all the countries. Therefore, it is beyond the scope of this chapter to train in how to take full advantage of CGM technology and integrated systems. If a healthcare professional is interested in further deepening his knowledge, he should reach out to the insulin pump providers in their country.

Multiple Choice Questions

1. What type of insulin can be used on an insulin pump?
   (a) **rapid human insulin and fast acting insulin analogues**
   (b) basal insulin analogues
   (c) NPH insulin
   (d) basal- and fast-acting insulin analogues
2. How is the total daily insulin dose calculated?
   (a) Weight in kg × 0.5
   (b) Previous total daily dose × 0.75
   (c) Taking the average of a and b
   (d) **All of the** above **are correct**
3. How is the basal rate calculated?
   (a) Total daily dose × 0.5, divided by 24 h
   (b) Weight in kg × 0.5
   (c) C. Total daily dose divided by 24 h
   (d) D. 2000/total daily dose
4. How is the food insulin bolus calculated?
   (a) **By the insulin to carbohydrate ratio**
   (b) By the insulin sensitivity factor

(c) By the basal rate
(d) Using temporary basal rates

5. What is the formula to calculate the insulin to carbohydrate ratio?
   (a) **450/total daily dose**
   (b) 2000/total daily dose
   (c) Weight in kg × 0.5
   (d) Weight in kg × 0.8
6. How is the correction bolus calculated?
   (a) By the insulin-to-carbohydrate ratio
   (b) **By the insulin sensitivity factor**
   (c) By the basal rate
   (d) Using temporary basal rates
7. What is the formula to calculate insulin sensitivity factor?
   (a) 450/total daily dose
   (b) **2000/total daily dose**
   (c) Weight in kg × 0.5
   (d) Weight in kg × 0.8
8. What kind of delivery bolus options exist?
   (a) **Normal, dual, and square**
   (b) Manual and dual
   (c) Normal and temporary
   (d) Manual, dual, square, and temporary
9. What does the patient need to do in case of having two blood glucose values above 240 mg/dL despite correction?
   (a) **Measure ketones; look for a possible cause (i.e., cannula occlusion or dislodgement); correct with an insulin injection (with insulin syringe or pen); change the insulin, insulin reservoir and infusion set**
   (b) Give a correction bolus
   (c) Wait for insulin to act
   (d) Set an increase in temporary basal rate
10. Do the math for initial basal rate, insulin-to-carb ratio and insulin sensitivity factor: Forty-year-old, female patient, A1c 7%, weight 60 kg, actual insulin regimen 22 IU glargine and 8 IU lispro before each meal (3 meals).
    (a) Basal rate: 0.625 IU/h; ICR: 15 g; ISF: 70 mg/dL (calculated by weight)
    (b) Basal rate: 0.700 IU/h; ICR: 13 g; ISF: 60 mg/dL (calculated by previous dose)
    (c) Basal rate: 0.650 IU/h; ICR: 14 g; ISF: 60 mg/dL (average of a and b)
    (d) **All are valid options to consider to start, if risk of hypoglycemia is a particular concern, start with option a**

Part VII

Cardiovascular Risk Factors

Diabetes and Hypertension

39

Hasan Syed, Sowjanya Naha, Dharshan Khangura, Michael Gardner, L. Romayne Kurukulasuriya, and James R. Sowers

Objectives

- To explore the contemporary understanding of the pathophysiology of HTN complicating diabetes
- To review large scale clinical trials assessing HTN treatment goals and outcomes in diabetes
- Identify the indications for ambulatory BP monitoring
- Interpret HTN guidelines from different organizations
- To review glycemic lowering drugs that can reduce BP

Introduction

According to the United States (US) Centers for Disease Control and Prevention 2020 National Diabetes Statistics Report, 68.4% of patients over the age of 18 diagnosed with diabetes mellitus (DM) also have hypertension (HTN). A total of 34.2 million people or 10.5% of the US population has diabetes. DM has been diagnosed in 8.2% or 26.9 million. This is an underestimate due to under diagnosis of DM. Therefore, 7.3 million people or 21.4% were undiagnosed. Thus, a significant portion of the population has both DM and HTN, which predisposes them to

cardiovascular disease (CVD) and chronic kidney disease (CKD) [1]. In patients with DM and HTN, CVD is the key cause of premature morbidity and mortality and is the greatest contributor to health care costs. Therefore, the importance of screening for HTN is paramount and should be done at every routine office visit [2]. Indeed, the 2020 Canadian HTN guidelines also recommend that newly diagnosed patients with HTN be screened for diabetes using a fasting glucose and/or hemoglobin A1c. They also consider recommending an intensive systolic blood pressure (BP) target of <120 in appropriate patients with CKD. In the Centers for Disease Control and Prevention National Diabetes Statistics Report, HTN was defined as BP greater than or equal to 140/90 mmHg or taking prescription medications for treatment of HTN [3]. Independent of other CVD risk factors, HTN shows a significant increase in CVD that is incremental with each 20 mmHg rise of systolic BP and 10 mmHg rise of diastolic BP across the range from 115/75 to 185/115 mmHg. Patients with DM typically have additional risk factors apart from DM itself such as dyslipidemia, obesity, physical inactivity, vascular stiffness, and microalbuminuria, which further elevate CVD and CKD risk [4].

Pathophysiology

The pathophysiology of HTN in DM is multifactorial, involving multiple organ systems, metabolic signaling pathways, and environmental and genetic factors. Adipose tissue, when located disproportionately in the abdomen (visceral adiposity), is associated with insulin resistance, HTN, hyperglycemia, and a pro-inflammatory state [4]. Bioactive molecules and hormones referred to as adipokines have altered secretion in obesity, which contributes to obesity-related insulin resistance and HTN. Angiotensinogen, aldosterone-stimulating factor, dipeptidyl peptidase, leptin, adiponectin, resistin, tumor necrosis factor (TNF), interleukin 6, and complement-C1q TNF-related protein 1 (CTRP1) are examples of such pro-inflammatory adipokines that are increased with increased visceral adiposity [5, 6].

Insulin resistance is strongly associated with endothelial dysfunction, which results in impaired vascular relaxation and arterial stiffness, which is a biomarker for increased CVD. Impaired insulin metabolic signaling in insulin-resistant states such as obesity and type 2 DM is characterized by impaired serine phosphorylation of insulin receptor substrate-1 (IRS-1) and downstream phosphionositide 3-kinase, protein kinase B activation leading to reduced endothelial nitric oxide (NO) synthase activation and NO bioavailability in the vasculature. In insulin resistance, there is impairment of insulin growth factor signaling with activation of extracellular signal-regulated kinase (ERK1/2) and upregulation of endothelin-1, which contributes to increased vascular contraction and maladaptive growth and remodeling [5, 6].

The systemic and tissue renin-angiotensin-aldosterone system (RAAS) is often inappropriately activated in insulin-resistant states. In part, this is related to increased angiotensin II (Ang II) and aldosterone production by omental adipose tissue. Ang II and aldosterone may also inhibit insulin metabolic signaling in endothelial cells and vascular smooth muscle cells, as well as classical insulin sensitive tissues such as skeletal muscle, adipose, and liver tissue. There is increasing evidence that the inappropriate activation of RAAS is a major contributor to progression of CVD and chronic kidney disease (CKD) as it relates to endothelial dysfunction and arterial stiffness in insulin-resistant states [7].

Angiotensinogen and Ang II are produced in increased amounts in adipose tissue under oxidative stress and chronic low-grade inflammation. CTRP1 in rodent models of obesity and insulin resistance promotes the production of aldosterone [5]. Ang II and aldosterone activate nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, a major source of reactive oxygen species, which promotes oxidative stress and impaired NO-mediated vasodilation. Furthermore, aldosterone has been shown to increase epithelial sodium channel (eNaC) expression on the endothelial cell surface, thereby promoting endothelial cell cytoskeleton cortical stiffness. Increased uric acid, as a result of consumption of diets rich in fructose, also appears to contribute to immune and inflammatory responses leading to RAAS activation, endothelial dysfunction, and increased vascular stiffness [5, 7].

At the level of the nephron, the sodium-glucose cotransporter-2 (SGLT2) is a low-affinity, high-capacity transporter that is primarily responsible for plasma glucose reabsorption in the proximal convoluted tubule. In DM, glucose reabsorption is increased due to increased expression of SGLT2 associated with glomerular hyperfiltration causing glucose toxicity along with sodium reabsorption and retention [6]. Hyperinsulinemia may also cause sodium retention via increased expression of sodium transporters like eNaC in the distal nephron and increased activation of the sodium hydrogen exchanger in the proximal tubule (Fig. 39.1) [5].

Large-Scale Trials Assessing HTN

- United Kingdom Prospective Diabetes Study (UKPDS)
- Hypertension Optimal Treatment (HOT)
- The Action in Diabetes and Vascular disease, PreterAx and DiamicroN MR Controlled Evaluation (ADVANCE)
- Appropriate Blood Pressure Control in Diabetes (ABCD)
- Systolic Hypertension in Europe (Syst-Eur)
- The Action to Control Cardiovascular Risk in Diabetes (ACCORD)
- The International Verapamil SR—Trandolapril (INVEST)
- The Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET)
- Veterans Affairs Diabetes Trial (VADT)
- Systolic Hypertension in the Elderly Program (SHEP)
- Systolic Blood Pressure Intervention Trial (SPRINT)

Review of the Evidence

Evidence of the management of HTN in diabetic patients was sparse prior to the Hypertension in Diabetes Study (HDS) in 1998. Since then, there have been many large-scale trials that have examined BP control and CVD outcomes. The United Kingdom Prospective Diabetes Study (UKPDS) aimed to study the intensity of BP control and its effect on clinical outcomes in a subset of the group. Comparisons

were made of intensive control with a goal of <150/85 mmHg versus less intensive control with a goal of <180/105 mmHg. The median follow-up was 8.4 years, and mean BP in the intensive group was 144/82 mmHg compared to 154/87 mmHg in the less intensive group. A significant reduction in diabetes-related death, stroke, heart failure, and microvascular disease such as retinopathy was seen in the intensive group [8]. The ADVANCE study showed that reducing systolic BP by 5.6 mmHg and diastolic BP by 2.2 mmHg compared to placebo conferred a risk reduction of 8% for macrovascular events, 9% for microvascular events, and 18% for CVD death. The intervention in this study was adding a fixed dose perindopril/indapamide to existing standard therapy. The ABCD study treated DM patients with HTN and high normal BP with goal systolic BP of <130 mmHg. The HTN group's mean BP was 132 mmHg, and the high normal group achieved a mean BP of 128 mmHg. The HTN group had reduced total mortality, and the high normal group had reduced incidence of stroke and decreased progression of nephropathy. The Syst-Eur study showed a decrease in overall mortality and morbidity related to CVD events in diabetic and nondiabetic populations by lowering systolic BP [9].

The ACCORD study compared intensive BP control (<120 mmHg systolic) versus standard BP control (<140 mmHg systolic) and found no statistically significant difference in CVD but did see a reduction in stroke in the intensive group. However, the intensive group was associated with increased risk of hypotension, bradycardia, hyperkalemia, and renal impairment [10]. After observational analysis, the INVEST study showed that the group with goal systolic BP <130 mmHg compared to goal 130–139 mmHg had marginally increased all-cause mortality, and the group with systolic BP of <110 mmHg had significant increase in all-cause mortality (hazard ratio 2.18) [11]. The ONTARGET study examined CVD risk reduction with particular attention to baseline BP. They found significant reduction in CVD with a baseline systolic BP >140 mmHg [12], less reduction if baseline was <130 mmHg, but continued benefit for stroke reduction with lower baseline BP. The VADT study along with the ONTARGET study showed an increased risk of myocardial infarction and CVD events with low diastolic BP. In the VADT study group, diastolic BP was <70 mmHg with a systolic BP 130–139 mmHg [13]. The SPRINT trial aimed for a target systolic BP of 120 mmHg in adults 50 years of age or older with HTN and saw a significant reduction in CVD. This trial showed an associated 33% reduction of heart attack, heart failure, and stroke and a 25% reduction of death compared to a target systolic BP of 140 mmHg. Diabetic patients and patients with a history of previous stroke were excluded from this trial [14].

Guidelines and BP Targets

The most recent National Committee on Prevention, Detection, Evaluation, and Treatment of High BP (JNC 8) was released in 2014. They based their recommendations on evidence from randomized control trials (RCT), expert opinion, and the quality of evidence, which differed from the JNC 7 panel that included observational trials. JNC 8 recommends initiating pharmacological therapy to lower BP to a goal of <140/90 mmHg in patients age > 18 with DM. The ACCORD-BP study supported this lower systolic BP goal of <140 mmHg in the diabetic population compared to <150 mmHg in the nondiabetic population. Major trials such as Syst-Eur, UKPDS, and SHEP studies supported the conclusion that treatment to a systolic BP of <150 mmHg lowers mortality and improves CVD and cerebrovascular health outcomes. The HOT trial found that a diastolic BP reduced to <80 mmHg was associated with a reduction in major cardiovascular events when compared to <90 mmHg and < 85 mmHg by 51% and 24%, respectively. However, JNC 8 determined that this study was not of sufficient quality to recommend a lower diastolic goal, as it was a post hoc analysis of a small subgroup of the study population [9].

The European Society of Cardiology and European Association for the Study of Diabetes recommends systolic BP(SBP) of 130 or below for diabetics treated for hypertension if tolerated. In patients 65 or older, the SBP target range of 130–140 mmHg is recommended if tolerated. In all patients with DM, SBP should not be lowered to <120 mmHg. Diastolic blood pressure (DBP) should be lowered to <80 mmHg but not <70 mmHg. If office SBP is ≥140 mmHg and/or DBP is ≥90 mmHg, drug therapy is recommended in combination with non-pharmacological therapy [15].

The European Society of Hypertension and European Society of Cardiology as part of their 2018 guidelines recommend that antihypertensives should be started in diabetics, when office BP is ≥140/80 mmHg, aiming at an SBP of 130 mmHg. If treatment is well tolerated, treated SBP values of <130 mmHg should be considered because of the benefits on stroke prevention. SBP values of <120 mmHg should be avoided. In patients over 65 years of age, treating to a target SBP range of 130–139 mmHg is recommended. They recommend targeting DBP < 80 mmHg, but not <70 mmHg. In diabetic or nondiabetic patients with CKD, it is recommended to lower SBP to a range of 130–139 mmHg [16].

The International Society of Hypertension Global Hypertension Practice Guidelines recommend that blood pressure should be lowered if BP is ≥140/90 mmHg and treated to a target of <130/80 mmHg (< 140/80 in elderly patients) in diabetics [17].

The American Diabetes Association (ADA 2021 guidelines) recommends a BP goal of less than 130/80 for indi-

viduals with diabetes and hypertension at higher cardiovascular risk (existing atherosclerotic cardiovascular disease [ASCVD] or 10-year ASCVD risk ≥15%) if it can be safely attained. In diabetics with hypertension at lower risk for cardiovascular disease (10-year atherosclerotic cardiovascular disease risk <15%), ADA guidelines recommend a blood pressure target of <140/90 mmHg. In pregnant patients with diabetes and preexisting hypertension, a blood pressure target of 110–135/85 mmHg is suggested to reduce the risk for accelerated maternal hypertension and minimizing impaired fetal growth [2]. The American Association of Clinical Endocrinology (AACE) and American College of Endocrinology (ACE), in their 2015 clinical practice guidelines, recommend a goal of approximately 130/80 mmHg in pre-DM and DM patients with HTN. They also indicate that the goal should be individualized based on patient age, duration of disease, and comorbidities. If patients have complex comorbidities, are frail, or experience adverse effects of medications, a more relaxed goal is supported. If this can be achieved safely without adverse medication effects, a more intensive goal of 120/80 can be used [18].

The appropriate target goal for BP In the diabetic population has been the subject of much debate, as control is related to reduction in CVD and kidney disease. There have been many large-scale trials with discrepant results, which have led to confusion. The JNC 7 advocated a target of 130/80 mmHg; however, the trials that used these parameters rarely achieved the target systolic BP and were limited to only a few studies. Consideration of more recent trials such as SPRINT, post hoc analysis of ACCORD, and meta-analysis suggest that a more aggressive systolic BP target of <130 mmHg may be more appropriate than the systolic target of 140 mmHg that was recommended by JNC 8. Wu et al. analyzed a large Chinese cohort of 101,510 individuals with data from 2006 to 2014. The study involved patients with established DM and excluded those who had a BP >140/90 mmHg, were taking antihypertensives, were previously diagnosed with HTN, or had baseline CVD or cancer, in an effort to reduce confounding of mortality outcomes. This left them with 2311 diabetic, normotensive patients whom they examined whether BP of <120/80 mmHg had increased mortality. Their data suggested an increase in CVD events in patients with BP <120/80 mmHg [19]. It is important to note that in this study the participants were predominantly male and had early-stage DM without complications, whereas the ACCORD and SPRINT trials included high-risk hypertensive patients treated to a goal. Based on the collective data from all of the above trials, it appears that there may be a sweet spot to target between 120 and 135 mmHg systolic BP and that a more aggressive target of <120/80 mmHg may be considered for select diabetic patients at the highest risk for stroke [20]. An individual patient tolerance of medications and comorbidities must be considered when managing HTN.

Lifestyle Modification

Approach to weight loss and maintenance based on National Institutes of Health (NIH) clinical guidelines for treatment of obesity [21, 22]:

- Low calorie diet (800–1200 kcal/day): 8% weight loss over 6 months, reduces abdominal fat.
- Very low calorie diet (250–800 kcal/day): similar long-term weight loss, greater initial weight loss compared to low calorie diet.
- Aerobic exercises: Modest weight loss, improve cardiorespiratory fitness, may reduce abdominal fat.
- Physical activity + reduced caloric intake: greater weight loss than either alone.
- Add behavioral therapy to weight loss approach: additional short-term benefits.
- Initial weight loss goal: 10% reduction from baseline weight.
- Target weight loss: 1–2 pounds/week for 6 months.
- Start with moderate physical activity: 30–45 min at least 3–5 days/week.
- Bariatric surgery: BMI > 40 kg/m^2 or > 35 kg/m^2 with high-risk obesity-related morbidity and failed less invasive measures.

The most important therapy whether initial or in combination with pharmacotherapy is lifestyle modification. This involves reduced dietary sodium intake (<2 g/day), weight loss, physical activity, and moderation of alcohol intake. Moderation of alcohol intake is defined as less than two drinks or less in a day for men and one drink or less for women [23]. In the United States, one standard drink contains roughly 14 g of pure alcohol, which is found in 12 oz. of regular beer, 5 oz. of wine, 8–9 oz. of malt liquor, and 1.5 oz. of distilled spirits such as vodka, rum, gin, tequila, and whiskey [24]. In the NIH-funded Look AHEAD (Action for Health in Diabetes) trial, the impact of intensive lifestyle modification (ILI) including diet, physical activity, and behavioral modification on adults with DM type 2 was evaluated [25]. They compared their intervention to that of usual care of DM using diabetes support and education. At 1 year, the ILI group lost 8.6% of their initial body weight compared to 0.7%, decreased mean hemoglobin A1c −0.64 compared to −0.14, decreased systolic BP –6.8 mmHg compared to −2.8 mmHg and had a larger decrease in metabolic syndrome 93.6–78.9% compared to 94.4–87.3%, all of which were statistically significant [26].

Evidence demonstrates that excess dietary consumption of sodium impacts not only one's BP but also several other BP-independent effects. Sodium can affect multiple organ systems in the body, including neurologic, cardiac, renal, and vascular. It has been shown that high sodium intake is also

associated with increased glucocorticoid production, insulin resistance, and metabolic syndrome [27]. In many countries, public health recommendations include sodium restriction to less than 5–6 g per day. However, the Cochrane systemic review and multi-study meta-analysis demonstrated that a further reduction in sodium will lower BP even further [28]. The Dash-Sodium study, a multicenter, 14-week randomized feeding trial, followed three different dietary intakes of sodium for 1 month: (3.3 g, 2.4 g, and 1.5 g). The greatest BP drop was noticeable within the group with the greatest sodium restriction [29]. The US Department of Agriculture and Department of Health and Human Services currently recommend consumption of 2.3 g or less of sodium per day in adults.

In addition to sodium restriction, diet modification can have a positive impact on not only BP but also in the treatment of obesity. Two specific diets that have shown to be particularly effective are the Dietary Approaches to Stop HTN (DASH) diet and the Mediterranean diet. The DASH diet is based on the premise of a diet high in whole grains, fish, poultry, fruits, vegetables, low-fat dairy products, and reduced saturated and total fats. In essence, the diet is rich in potassium, magnesium, calcium, protein, and fiber. In the original DASH studies, carbohydrates supplied 55% of calories, total fats 27% of calories, proteins 18%, and saturated fats 6% [30]. The diet should consist of at least six to eight daily servings of grains, less than six servings of lean meats (poultry and fish), four to five daily servings of fruits and vegetables, two to three servings of low-fat milk products and fats and oils, and five or less servings per week of sweets, nuts, seeds, and legumes [31].

The first DASH feeding trials resulted in participants having lower BP and LDL cholesterol endpoints with statistical significance. Systolic BP was reduced on average by 11.4 mmHg ($P < 0.001$), and diastolic BP was reduced on average by 5.5 mmHg ($P < 0.001$). Seventy percent of participants had normal BP (goal SBP <140 and DBP <90 mmHg) at the end of the trial compared to 23% on the control diet [32]. Compared to controls, the DASH diet also reduced the estimated 10-year CVD risk by 18%. The relative risk ratio compared to controls at 8 weeks with baseline 10-year CVD risk was 0.82 (95% CI, 0.75–0.90, $P < 0.001$). In other studies, the DASH diet also decreased pulse wave velocity (PWV) over time ($p = 0.014$) reaching significance after 2 weeks ($p = 0.026$) [33]. Additional information on PWV will be provided later in this chapter.

The Mediterranean diet embodies the Mediterranean culture and lifestyle. Although there are now many variants of this diet, the traditional premise comprises low amounts of saturated fats, meat and meat products, and consumption of high amounts of olive oil, fruits, vegetables, cereals, legumes, nuts, moderate amounts of fish and dairy products, and wine in moderation [34]. Unlike the DASH diet, the Mediterranean diet has an increased consumption of the total amount of fats, up to 40% of caloric intake, with less than 7–8% of caloric intake consisting of saturated fats [35]. In the Greek European Prospective Investigation into Cancer and Nutrition (EPIC) prospective cohort study, lower consumption of meat and meat products, higher consumption of vegetables and fruits, and minimization of saturated fats with more monounsaturated fats were considered most beneficial with a higher predictive score of lower mortality [36]. In addition to diet, regular physical activity and culture-specific psychosocial support played an integral part in the Mediterranean diet. Meals were often consumed with others with frequent rest after meals that presumably reduced overall stress. In addition, mealtime interactions can also be correlated with dietary adherence (Fig. 39.2) [37].

The Mediterranean diet is associated with reduced all-cause mortality and reduced cardiovascular mortality in addition to improved health. A systematic review of 2824 studies with eight meta-analyses and five randomized controlled trials (RCTs) was done in 2015 that compared the Mediterranean diet to a control diet in patients with DM2 and prediabetic states. These studies demonstrated remission of metabolic syndrome, favorable effects on body weight, total and LDL cholesterol, and overall reduced risk of future diabetes by 19–23% [38]. The Prevencion con Dieta Mediterranea trial (PREDIMED) was a parallel-group, multicenter, randomized trial that studied primary cardiovascular prevention when comparing Mediterranean diets to a low-fat control diet. Although there was not a noted effect on all-cause mortality, results were suggestive of a protective effect with noted unadjusted hazard ratios of 0.7 ($p = 0.015$) when compared to the control diet. There was an absolute risk reduction in approximately three major cardiovascular events per 1000 person-years [39].

Combining the Mediterranean diet with a healthy lifestyle, avoidance of tobacco products and regular exercise has shown to have a positive outcome with reduced mortality rate. The Healthy Ageing Longitudinal study in Europe (HALE) project was conducted between 1988 and 2000 that showed a 50% lower rate of all-cause and cause-specific mortality in individuals aged 70–90 years of age who adhered to the Mediterranean diet with a heathy lifestyle [40]. In the exercise and nutrition intervention for cardiovascular health (ENCORE) study, combining the DASH diet with weight management resulted in larger BP reductions with improved secondary outcomes in vascular and autonomic function and reduced left ventricular mass. Up to 12.5 mmHg systolic and 5.9 mmHg diastolic reduction in BP was observed in the DASH diet combined with a behavioral weight management program [41].

Aerobic exercise is not only effective in weight loss but also thought to lower BP independent of weight loss [42]. According to the recommendations from American College

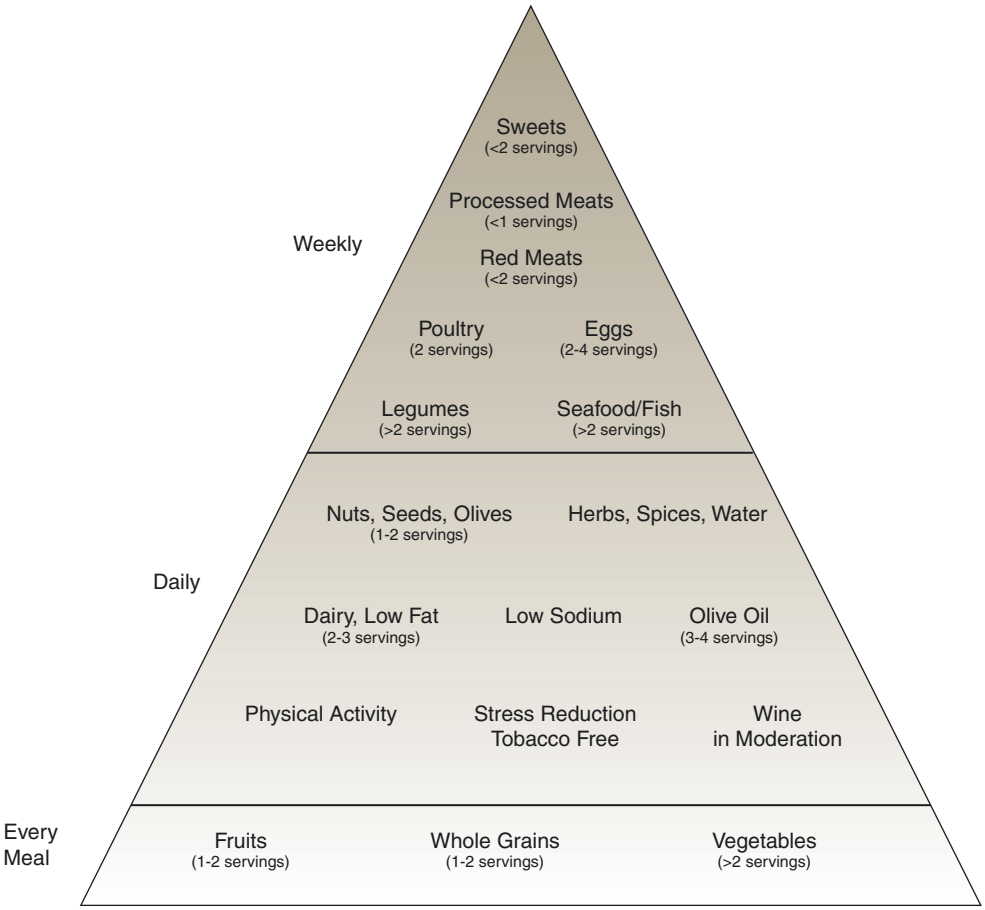

Fig. 39.2 Mediterranean diet pyramid

of Sports Medicine and American Heart Association, all healthy adults should engage in moderate-intensity aerobic physical exercise for minimum of 30 min for 5 days per week, vigorous-intensity activity minimum of 20 min for 3 days per week or combination of moderate, and vigorous-intensity activity [43]. Moderate-intensity physical activity should target a heart rate of 50–70% of his or her maximum heart rate (MHR). The MHR (calculated as 220 minus your age) is the upper limit of what your cardiovascular system can handle during exercise. For example, a 40-year-old patient should sustain heart rate between 90 and 126 for 30 min (0.5 or 0.7 × [220–40]). Vigorous-intensity physical activity should target 70–85% of his or her MHR. However, a 2011 review suggests that the MHR prediction in adults that are overweight or obese can be more accurately determined using a MHR equation: 208–0.7 × age [44]. Per the American College of Sports Medicine Position Stand, a minimum of 150 min of moderate-intensity activity per week with an energy deficit of 500–1000 kcal per day is recommended for continued weight loss. With a structured and supervised exercise program, weight loss can be maximized [45].

There are multiple ways in which lifestyle modification can be implemented; however, the common ingredient is significant determination and effort on the part of the patient with the support of a multidisciplinary team. Not only is it effective, as was evidenced by the Look AHEAD trial, but it could also reduce financial burden and adverse events as a result of fewer medications needed for treatment. At 9.6 years of follow-up, the ILI group used less insulin, antihypertensives, and statins compared to the control group [26].

DM Medications

The following are diabetes medications/classes shown to reduce BP:

- Thiazolidinedione
- Glucagon-like peptide-1 (GLP-1) receptor agonist
- Dipeptidyl diphosphatase 4 (DPP-4) inhibitor
- Sodium–glucose cotransport 2 (SGLT2) inhibitor
- Bromocriptine mesylate

GLP-1 receptor agonist exenatide had a significant effect on BP reduction [46]. When studied in 120 patients, after 52 weeks, there was a decrease in BP with a greater effect

observed when the baseline BP was higher. In patients with a baseline systolic BP >130 mmHg, there was a reduction of 11.4 mmHg in systolic BP and a reduction of 3.6 mmHg in diastolic BP. In patients with a mean BP of 128/78, there was a reduction of 6.2 mmHg in systolic BP and a reduction of 2.8 mmHg in diastolic BP. These reductions were independent of both weight loss and medication changes. Exenatide has the benefit of once weekly dosing and causes weight loss in a dose-dependent fashion. It has been shown to cause weight loss in 75% of patients at 30 weeks with average loss of 4 kg, and like its effect on BP, greater effect is seen with patients with a higher BMI (>30 kg/m^2) at baseline [47]. Exenatide is thought to have both natriuretic and vasodilator properties [48, 49]. In a case series of 12 patients who took exenatide over a 12-week period, noticeable increases in plasma concentrations of vasodilators, cyclic guanosine monophosphate (cGMP), cyclic adenosine monophosphate (cAMP), and atrial natriuretic peptide (ANP) while suppressing the RAAS suggest vasodilator and natriuretic properties [50]. Further evidence suggests that exenatide may also have diuretic and renal vasodilator effects. Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial demonstrated a sustained decrease in BP (SBP/DBP –1.2/−0.6 mmHg) with a slight increase in heart rate (3 bpm.) [51]. In a meta-analysis of 25 trials with once a week exenatide and daily liraglutide, it was shown that GLP-1 receptor agonists had beneficial effects on systolic and diastolic BP [52].

Insulin resistance intervention after strole (IRIS) III study showed that addition of 30 mg of pioglitazone for 20 weeks to the existing medication regimen of 2092 diabetics with A1c between 6.6% and 9.9% reduced systolic BP from 141 to 137 mmHg and diastolic BP from 83 to 81 mmHg. Interestingly, fewer or even no antihypertensives were needed in 25% of previously hypertension-treated patients at the end of the study [53]. Thiazolidinedione's mechanism of action is through activation of peroxisome proliferator-activated nuclear receptors (primarily PPARγ receptor) and subsequent upregulation of genes decreasing insulin resistance. Studies have shown that lowering the expression of PPARγ receptors increased BP [54]. Some evidence suggests vasodilatory effects through inhibition of arginine vasopressin and norepinephrine responses and direct vascular effect through inhibition of calcium uptake of vascular smooth muscle [55, 56].

The DPP4 inhibitors, in addition to hyperglycemic control, have been shown to have a modest effect on BP, as well as a favorable effect on atherosclerosis, stroke and CVD. Sitagliptin, a DPP4 inhibitor, was used in a small study and showed a statistically significant reduction of −2.0 mmHg to −2.2 mmHg in systolic BP and −1.6 mmHg to −1.8 mmHg in diastolic BP [57]. One proposed mechanism includes upregulation of GLP-1, increasing NO bioavailability and therefore improving overall endothelial function in HTN [58, 59].

SGLT2 inhibitors have been reported to be associated with weight loss and to act as osmotic diuretics, resulting in lowering of BP [60]. One meta-analysis indicated a significant reduction in systolic and diastolic BP with a weighted mean difference of −2.46 mmHg in SBP and weighted mean differences of −1.46 mmHg for DBP. The weighted mean difference for the effect of SGLT2 inhibitors on body weight was −1.88 kg across all studies. There were no heart rate changes [61]. Another metanalysis with clinical trials with a duration of at least 12 weeks comparing SGLT-2 inhibitors with placebo or active drugs showed that patients on SGLT-2 inhibitors had statistically significant −1.2 reduction in systolic BP and −1.9 reduction in diastolic BP [62]. Clar et al. reported that dapagliflozin treatment was associated with a reduction in SBP ranging from −1.3 to −7.2 mmHg in the patients treated with doses of 10 mg [63]. Rosenstock et al. reported a reduction in SBP in response to canagliflozin treatment ranging from −0.9 mmHg with 50 mg once daily to −4.9 mmHg with 300 mg once daily (compared to −1.3 mmHg with placebo and −0.8 mmHg with sitagliptin) [64]. Inhibitors of sodium-glucose co-transporter-2 reduce BP beyond the projected impact of weight reduction on BP. A large-scale multicenter RCT has demonstrated that treatment with an SGLT-2 inhibitor, empagloflozin, was associated with small reductions in systolic/diastolic BP, weight, waist circumference, and uric acid levels compared to placebo. Results also indicated reduced risk of death from CVD, nonfatal myocardial infarction, nonfatal stroke, and death from all causes [65].

Large randomized controlled trials have reported statistically significant reductions in cardiovascular events for three of the SGLT-2 inhibitors (empagliflozin, canagliflozin, and dapagliflozin) and four GLP-1 receptor agonists (liraglutide, dulaglutide, semaglutide, and albiglutide) [2]. We now have data from several trials that indicate CV benefits from the use of glucose-lowering drugs in patients with CVD or at very high/high CV risk. The results obtained from these trials strongly suggest using both GLP1-RAs (LEADER, SUSTAIN-6, Harmony Outcomes, REWIND, and PIONEER 6) and SGLT2 inhibitors (EMPA-REG OUTCOME, CANVAS, DECLARE-TIMI 58, and CREDENCE), in patients with T2DM with prevalent CVD or very high/high CV risk [15]. Meta-analyses of the trials reported to date suggest that in type 2 diabetes with established ASCVD, GLP-1 receptor agonists, and SGLT2 inhibitors reduce risk of atherosclerotic major adverse cardiovascular events to a comparable degree [66]. SGLT2 inhibitors also appear to reduce risk of heart failure hospitalization and progression of kidney disease in patients with established ASCVD, multiple risk factors for ASCVD, or diabetic kidney disease [67]. It is unknown whether the use of both classes of drugs will provide an additive cardiovascular outcomes benefit [2].

Bromocriptine Mesylate quick release (Cycloset) is a quick release dopamine receptor agonist indicated for treatment of type 2 diabetes. This is a micronized formulation. Proposed mechanism of actions is reestablishing morning brain dopamine D2 receptor activity, reducing sympathetic tone, and

increasing insulin sensitivity. These actions lead to improved post prandial hyperglycemia. Study with 15 poorly controlled diabetics on metformin and GLP-1 agonist showed that bromocriptine mesylate caused a significant reduction in blood pressure compared to placebo. Systolic (134 ± 4 vs. 126 ± 6 mmHg), diastolic (78 ± 3 vs. 73 ± 4 mmHg), and mean arterial blood pressure (97 ± 5 vs. 90 ± 4 mmHg) all decreased significantly ($P < 0.05$) [68]. Some patients may end up with orthostatic hypotension. Another study with 1791 patient on metformin addition of bromocriptine Mesylate has shown to reduce cardiovascular risk compared to placebo [69].

Addition of hypoglycemic agents with antihypertensive effects should be done cautiously in hypertensive diabetics well controlled on antihypertensives. The need may arise to reduce the doses of antihypertensive drugs. Patients should be warned about the blood pressure lowering effects of these drugs.

Antihypertensive Medications

Medication classes used to treat HTN:

- ACEI (ACE inhibitor)
- ARB (angiotensin receptor blocker)
- CCB (calcium channel blocker)
- Diuretics
- Alpha/beta-adrenergic blockers
- Beta-adrenergic blockers
- Alpha blockers
- Alpha-2 agonists
- Mineralocorticoid receptor (MR) blockers
- Vasodilators
- Renin inhibitors

When initiating pharmacotherapy for the treatment of HTN, it is important to consider patient characteristics, medication tolerability, and desirable protective effects. The preferred initial medication according to the ADA and AACE/ACE is a RAAS blocker (ACEI or ARB) in patients with DM due to the beneficial effect on cardiovascular outcomes. If BP is not controlled, other classes of medications should be added until goal BP is obtained [4]. Evidence including systematic reviews and meta-analysis has shown that RAAS blockers not only are comparable to other classes of medications in efficacy for treatment of HTN but also reduce the risk of microalbuminuria and creatinine doubling. This suggests that RAAS blockers may be preferred to other antihypertensive agents, as it is well documented that both HTN and DM are associated with the development of CKD [70, 71]. The combination of an ACEI and ARB is not recommended, as they were associated with increased risk of hypotension, syncope, and renal failure in Ongoing Telmisartan Alone and in combination with Ramipril Global enspoint Trial (ONTARGET) [56]. In the JNC 8 guidelines, there was no preference given to a particular agent, and it was recommended that a thiazide-type diuretic, CCB, ACEI, or ARB be used as the initial antihypertensive medication. These guidelines were derived solely from RTCs, which are considered the gold standard for evidence-based medicine [9].

Amlodipine, a CCB, has been compared to other medications in large-scale clinical trials in patients with DM and HTN. The Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial compared the combination of benazepril/amlodipine to benazepril/hydrochlorothiazide and found a 21% relative risk reduction in cardiovascular events with the amlodipine-containing combination. The Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) found a 14% reduction in cardiovascular events with amlodipine compared to atenolol. CCBs are well tolerated, do not have unfavorable effects on metabolism, and may be the best medication to add to a RAAS blocker if combination therapy is required to reach BP goals in the diabetic population [72].

Diuretics, in particular the thiazide-type diuretics, are a common first choice for the treatment of HTN; however, there are some disadvantages to their use in the diabetic population. They can cause metabolic derangements such as hyperuricemia, dyslipidemia, insulin resistance, and hyperglycemia. Despite these side effects, diuretics have been shown to be as effective as CCBs and ACEIs in decreasing the risk of CVD events and have a significant role in the treatment of HTN in DM [72].

Beta-blockers have been associated with metabolic derangements including dyslipidemia, increased insulin resistance, and weight gain. Beta-blockers can mask hypoglycemia symptoms. Like diuretics, beta-blockers have a significant role in the treatment of HTN in DM, particularly when patients have had a previous myocardial infarction, rhythm disorder, or heart failure. The Glycemic Effects in Diabetes Mellitus: Carvedilol-Metoprolol Comparison in Hypertensives (GEMINI) trial studied patients already on a RAAS blocking agent. Results suggested that if a beta-blocker is indicated, carvedilol might be superior to metoprolol as it was not associated with the increase in hemoglobin A1c or dyslipidemia that was seen with metoprolol [72, 73].

Combination therapy is often necessary in diabetics with HTN and lead to more patients achieving goals when compared to monotherapy, regardless of the baseline BP. In the UKPDS study, three or more medications were required to achieve goals in up to one third of patients [74]. It was the recommendation of the JNC 7 that if BP was more than 20 systolic and more than 10 mmHg diastolic above goal that combination therapy be initiated [75].

When patients are not at goal on optimal doses of three antihypertensive agents including a diuretic, it is referred to as resistant HTN. Resistant HTN is common in patients with diabetes and obesity. Secondary causes of HTN should be

excluded and referral to a HTN specialist should be considered in resistant cases. There is a hypothesis that resistant hypertension occurs due to excess sodium retention. Thus, additional diuretic action by adding a mineralocorticoid receptor (MR) blocker may be beneficial. Spironolactone and eplerenone are steroidal MR blockers, and the newer Finerenone is a nonsteroidal MR antagonist. Since Eplerenone and Finerenone are more selective mineralocorticoid receptor blockers, they are not associated with gynecomastia and menstrual irregularities seen with spironolactone. A study showed that spironolactone was superior to placebo, doxazosin, and bisoprolol in patients with resistant HTN; however, this was not done in a solely diabetic population, and patients with CKD with a GFR <45 mL/min were excluded. MR blockers should be used cautiously, as they can lead to hyperkalemia, especially in the DM population, in which CKD is more common [76]. In the Finerenone trial for reducing kidney failure and disease progression in diabetic kidney disease (FIDELIO- DKD) showed that when finerenone is added to treatment of patients with CKD and type 2 diabetes already on maximum tolerable doses of renin angiotensin system blockers it resulted in lower risks of CKD progression and cardiovascular events than placebo [77]. Finerenone is indicated to reduce the risk of sustained eGFR decline, end-stage kidney disease, cardiovascular death, nonfatal myocardial infarction, and hospitalization for heart failure in adult patients with chronic kidney disease (CKD) associated with type 2 DM.

Aliskiren is the only renin inhibitor out in the market. It is an effective antihypertensive agent that is well tolerated. In the air versus oxygen in myocardial infraction trial (AVOID), Aliskerin plus losartan showed a 20% greater reduction in proteinuria compared to losartan and placebo. This study showed that the reno protective effect of Aliskerin was independent of the BP lowering effect in diabetic and hypertensive patients with nephropathy on losartan [78]. The Aliskiren Trial in Type 2 Diabetes using Cardiorenal end points (ALTITUDE) was done to determine the safety and effectiveness of direct renin inhibitors compared with placebo with respect to fatal and nonfatal renal and cardiovascular events in patient with type 2 diabetes who were on an ACE inhibitors or ARB. This study did not show a statistically significant difference in cardiovascular events with addition of Aliskerin, but the addition of Aliskerin caused a higher incidence of hyperkalemia and hypotension [79]. At his point, addition of Aliskiren to ACE inhibitor and ARB therapy is not recommended (Fig. 39.3).

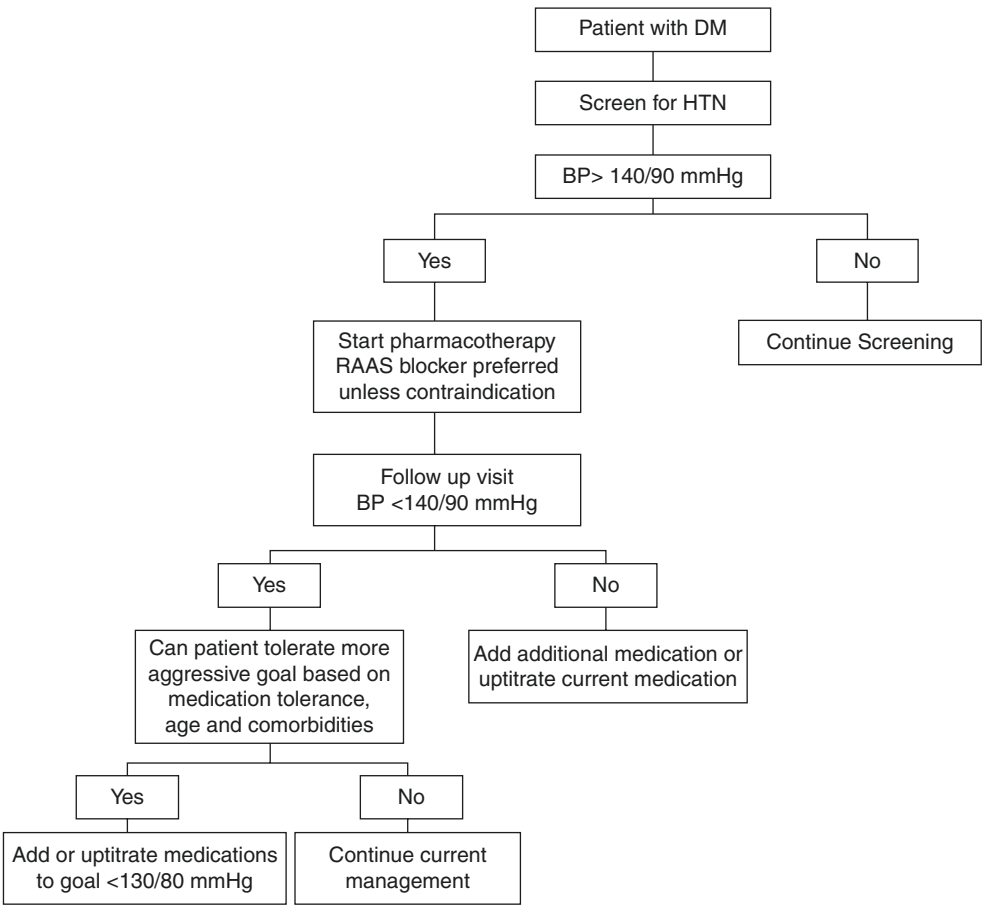

Fig. 39.3 Flow chart for the treatment of HTN in diabetes

Other Monitoring Modalities

Screening and monitoring of treatment for HTN has traditionally been based on evaluation in the healthcare setting. Out-of-office BP monitoring has been used in European guidelines; as of April 2021, the US Preventive Services Task Force (USPSTF) has endorsed its use for diagnosis and management of HTN. Ambulatory BP monitoring (ABPM) involves placement of a BP cuff on the nondominant arm that measures BP over the course of a 24-h period by taking measurements every 15–30 min. Compared to in-office BP measurement, ABPM is of higher prognostic value for CKD, CVD, and mortality risks [80].

Suspected white coat HTN, evaluation of resistant HTN, episodic HTN, suspected episodes of hypotension, and evaluation of treatment efficacy are indications for ABPM. Patients with DM who have BP excursions on 24-h monitoring are at increased risk of complications even before the diagnosis of HTN. Both Type 1 DM and Type 2 DM in comparison with controls without DM have been found to have higher mean BP values. These elevated means were associated with higher rates of nephropathy, albuminuria, retinopathy, and increased left ventricular mass. BP normally has a physiologic circadian rhythm in which BP drops >10% during the night relative to daytime BP. Patients in which BP decreases by <10% are said to have a non-dipping pattern, which was observed to be more prevalent in those with DM. This non-dipping pattern has been associated with cardiovascular autonomic neuropathy; its contribution to progression of chronic DM complications however is more controversial. Studies thus far have shown some mixed results and may be more relevant and add information to other BP values when related to outcomes with retinopathy. Hyperglycemia has exhibited a role in normal nocturnal BP fall, likely related to its effect on modifying circulating plasma volume, interfering with blood flow distribution and renal hemodynamics. Decreased BP means and increased BP fall during the night have been seen after 1 week of improved glycemic control in type 1 DM. Patients with normal office BP measurements (<140/90 mmHg) with elevated ABPM measurements (>135/85 mmHg) are referred to as having masked HTN. Type 2 DM patients have been shown to have a higher prevalence of masked HTN at 30% versus 10–20% in those without DM. Masked HTN has been associated with increased cardiovascular risk and when studied in Type 2 DM patients was associated with albuminuria and increased left ventricular wall thickness. ABPM appears to add significant information that can be used in risk stratification in the DM population and should be utilized more frequently. However, additional clinical study is needed to further explore the parameters obtained with ABPM and their effects on the complications of DM and to develop treatment strategies to benefit such patients [81].

PWV is a noninvasive measure of arterial stiffness with carotid-femoral PWV considered the reference standard measurement of aortic stiffness. It is not used clinically in the United States; however, it is suggested in Europe by expert consensus that carotid-femoral PWV greater than 10 m/s is a cardiovascular risk factor for middle-aged adults with HTN. Studies have shown an association between DM and aortic stiffness measured by PWV, which did not vary by gender but was significantly stronger in Caucasians as compared to African Americans. In more advanced DM, present for more than 10 years, albuminuria and elevated glycosylated hemoglobin were all associated with higher aortic stiffness measured by PWV. This suggests that PWV measurement may contribute to the currently available methods to risk stratify patients who have more risk of developing cardiovascular events and mortality related to complications of DM. However, further clinical studies are needed to help delineate how this modality for the measurement of arterial stiffness can specifically be used in the diabetic population and if treatment targeting arterial stiffness can improve outcomes [82].

COVID-19 and Antihypertensive Therapy in Individuals with Diabetes

The ongoing novel SARS-CoV-2 coronavirus (COVID-19) pandemic has had a disproportionate impact on individuals with multiple medical comorbidities. For instance, a large observational study from China revealed that up to 23.7% of patients with severe infection had a history of hypertension and 16.2% were known diabetics compared to patients with nonsevere infection of whom just 13.4% and 5.7% had a history of hypertension and diabetes, respectively [83]. Likewise, studies in the United States have shown as much as 78% of patients admitted to ICU with COVID-19 have diabetes and that diabetics are more than twice as likely as nondiabetics to get admitted to a hospital with COVID-19 after adjusting for other comorbidities [84]. It is now believed that diabetic individuals have an exaggerated immune response to infection with COVID-19 leading to increased production of inflammatory cytokines and reactive oxygen species. This cascade ultimately results in greater end organ injury and excess mortality [85]. These individuals also have a higher prevalence of heart failure and chronic kidney disease that predispose to complications from COVID-19. Moreover, it has been observed that many patients with hypertension and diabetes share common underlying socioeconomic themes such as lack of access to quality healthcare and healthy foods that increases their risk for adverse outcomes [86].

Extensive research into COVID-19 infection in this subset of patients has led to questions on the role of ACE inhibi-

tors and ARBs in its pathogenesis. Specifically, the observation that the novel coronavirus binds to human cells via the angiotensin-converting enzyme 2 raised concerns that medications such as ACE inhibitors and ARBs might accelerate infection with the novel coronavirus by increasing the levels of this enzyme. However, currently, there is no clinical evidence to support this hypothesis. The European Society of Cardiology Council on Hypertension, the American College of Cardiology (ACC)/American Heart Association (AHA)/Heart Failure Society of America (HFSA) and the American Society of Hypertension have all released policy statements strongly recommending that patients continue treatment with their usual antihypertensive regimen [87]. Therefore, at this time, recognizing the multiple benefits obtained with these classes of medications in patients with diabetes and hypertension, it is not advisable to discontinue therapy simply because of COVID-19 infection [88].

Future Considerations

There should be more awareness about HTN complicating diabetes. Healthcare systems should have more aggressive screening to diagnose these conditions. Every new hypertensive patient should be screened for diabetes. Lifestyle modifications are the cornerstone for management of these two interrelated medical conditions and should be emphasized at a younger age. Schools should have more programs that advocate healthy living.

Most of current HTN studies are based on office BP monitoring. ABPM and home BP monitoring should be used more frequently. This technique is a very useful tool in white coat HTN (high BP in clinic but normal in other settings) and masked HTN (normal BP in clinic and high BP at other settings). Additionally, it is also helpful in resistant HTN, episodic HTN, autonomic dysfunction, and hypotension while taking antihypertensive medications. ABPM also identifies patients who have nocturnal HTN dipper versus non-dippers. This has important implications since non-dippers are at higher cardiovascular risk. Some experts believe that home BP monitoring should be done several times a day and dosage of BP medications adjusted based on BP at a given time similar to finger stick blood glucose monitoring and adjustment of insulin dosing.

There should be more American Society of Hypertension certified HTN centers that are focused on treating patients who have more complex issues with HTN and related complications so that patients can be referred to these centers for more comprehensive care. Internal medicine and related residency and fellowship training programs should encourage more trainees to become hypertension specialists. More research should be done on genetic analysis to provide more individualized medicine, which will help determine the appropriate medication/medications for any given patient. The low efficacy of some therapies could be related to interindividual genetic variability. Genetic studies of families have suggested that heritability accounts for 30–50% of interindividual variation in blood pressure (BP). Genome-wide studies have confirmed that genetic factors are related not only to BP elevation but also to interindividual variability in response to antihypertensive treatment. Due to the polygenic nature of hypertension, a single locus cannot be used as a relevant clinical target for all individuals. Therefore, the analysis of complex traits, such as drug response phenotypes, should involve the assessment of interactions among multiple loci. Genome-wide association studies (GWASs) have led to the discovery of variants associated with drug efficacy and adverse drug reactions. However, due to the multigenic and multifactorial nature of the drug response phenotypes, further research in this area is required to establish reliable recommendations [89].

Conclusion

Over 20 million people in the United States have both HTN and DM. Diagnosis and treatment of these conditions is very important to decrease the risk of CVD, which is a major cause of morbidity, mortality, and healthcare cost. The pathophysiology of HTN in DM is complex with the inappropriate activation of the RAAS system, the endocrine action of adipose tissue, oxidative stress, and maladaptive effects on the vascular endothelium being involved. The western diet and obesity play an important role in inducing a pro-inflammatory state contributing to metabolic derangement. There have been multiple large-scale clinical trials that have examined BP control in DM and its effect on CVD outcomes. The data from these studies suggests that targeting a systolic BP between 120 mmHg and 135 mmHg would be most appropriate, reserving a more aggressive target of <120/80 mmHg in select patients that are at highest risk of stroke and can tolerate the target without adverse effects. Lifestyle modification remains the most important intervention including a reduced sodium diet, weight loss, exercise, and moderation of alcohol intake. When treating DM in patients with HTN, it is important to note that the choice of DM medications can have an impact on BP control. ACEI or ARB should be considered preferred initial therapy for diabetics with HTN due to beneficial effect on CVD and renal outcomes. Adding medications or titrating existing medications should be done until BP goals are met. ABPM should be used for further evaluation in cases of resistant HTN, episodic HTN, and suspected white coat HTN or episodes of hypotension. PWV may be an additional tool that can be used to identify patients at risk for developing CVD and complications of DM. There continues to be further studies contributing to the knowledge of these interrelated conditions.

Concluding Remarks: Diabetes and hypertension are frequent co-existing risk factors that are promoted by obesity and increase the risk for both CVD and CKD. There is increasing evidence that treatment of both conditions should be individualized based on various factors such as age and duration of diabetes. Emerging evidence suggests that an optimal goal for blood pressure control is less than 130/85 mmHg for most patients with diabetes.

Multiple Choice Questions

1. Which one of the following studies showed that combination of angiotensin converting enzyme inhibitor and angiotensin receptor blockers were associated with and increased risk of renal failure?
   (a) UKPD
   (b) **ONTARGET**
   (c) ADVANCE
   (d) VADT
   (e) SPRINT

   The ONTARGET trial-Ongoing Telmisartan Alone and in combination with Ramipril global endpoint trial showed that the combination was associated with increased risk of hypotension, syncope, and renal failure.
2. Ambulatory BP monitoring will be helpful in all the following conditions except:
   (a) 45 year with uncontrolled HTN on maximum dose of three medications including a diuretic
   (b) **60 year old with well-controlled HTN on 2 BP medications**
   (c) 35 year with good BP at home and local store but high at the physician office
   (d) 45-year-old diabetic who complains of orthostatic symptoms
   (e) To evaluate masked HTN (normal office BP with elevated Home BP)

   Ambulatory BP monitoring should be considered in suspected white coat HTN, resistant HTN, episodic HTN (i.e., pheochromocytoma), autonomic dysfunction, or suspected episodes of hypotension.
3. All of the following antidiabetic medications will lower BP except:
   (a) Exanetide
   (b) Sitagliptin
   (c) Pioglitazone
   (d) Empagloflozin
   (e) **Insulin.**

   Antidiabetic medications GLP-1 agonists, DPP4 inhibitors, SGLT-2 inhibitors, Bromocriptine mesylate QR, and thiazolidinediones have shown to reduce BP.
4. All of the following are true about DASH diet except:
   (a) Has as a positive impact on BP
   (b) DASH diet is high in whole grains, fish, poultry, fruits, and vegetables
   (c) Has shown to reduce cardiovascular risk
   (d) **Has been shown to increase pulse wave velocity**
   (e) DASH diet will lower LDL cholesterol

   DASH diet has shown a positive impact on BP, obesity, and LDL cholesterol. DASH diet has also been shown to reduce cardiovascular risk and reduce pulse wave velocity.
5. When treating diabetics with HTN, which of the following is correct?
   (a) **American Diabetic Association and American Association of Clinical Endocrinologists recommend RAAS blockers as first line treatment.**
   (b) JNC 8 recommends a BP goal of less than 120/80 for all diabetics.
   (c) Use of thiazide diuretics are not recommended due to associated metabolic derangements.
   (d) Metoprolol is preferred over carvedilol.
   (e) There is no additional benefit of using RAAS blockers over other antihypertensives.

   AACE and ADA recommend RAAS blockers as the first line of treatment for diabetics due to beneficial effects on cardiovascular outcome. In addition, it reduces microalbuminuria and the risk of creatinine doubling. JNC 8 recommends a BP goal of <140/90. Despite metabolic derangements associated with thiazide diuretics, they are still used to treat diabetics. Diuretics have shown to reduce cardiovascular risk. Unlike metoprolol, carvedilol will not increase blood sugar or lipids.
6. The 2020 Canadian HTN guidelines recommend that newly diagnosed patients with HTN be screened for which of the following cardiovascular risk factors?
   (a) Kidney disease
   (b) Dyslipidemia
   (c) Diabetes mellitus
   (d) b and c
   (e) a, b and c.

   The 2020 Canadian HTN guidelines recommend that newly diagnosed patients with HTN be screened for diabetes with a fasting glucose and/or hemoglobin A1c, as well as hyperlipidemia with labs for serum total cholesterol, LDL, HDL, non-HDL cholesterol, and triglycerides, as well as kidney disease with urinalysis, assessment of albumin excretion in diabetics.
7. What is the initial weight loss goal from baseline weight in the National Institutes of Health clinical guidelines for treatment of obesity?
   (a) 5%
   (b) 20%
   (c) 30%
   (d) **10%**
   (e) 25%

Approach to weight loss and maintenance based on National Institutes of Health clinical guidelines for treatment of obesity recommends an initial weight loss goal of a 10% reduction from baseline weight.

8. All of the following are nondesirable side effects of beta blockers in diabetics except:
   (a) Masking of hypoglycemia symptoms
   (b) **Lowering of heart rate**
   (c) Dyslipidemia
   (d) Weight gain
   (e) Insulin resistance

   Beta-blockers have been associated with metabolic derangements including dyslipidemia, increased insulin resistance, and weight gain and can mask hypoglycemia symptoms.
9. The following have been postulated to be involved in the pathophysiology of HTN in DM except:
   (a) Sodium retention due to hyperfiltration
   (b) Reduced nitric oxide bioavailability
   (c) Deranged metabolic signaling of insulin.
   (d) **Reduced sympathetic nervous system activation**
   (e) Inappropriate activation of the RAAS system

   The pathophysiology of HTN in DM is multifactorial, involving multiple tissues, organ systems, metabolic signaling pathways, and environmental and genetic factors.
10. Lowering systolic BP to less than what number was shown in multiple major trials to lower mortality and improves CVD outcomes?
    (a) 160
    (b) **150**
    (c) 140
    (d) 130
    (e) 120

    Major trials such as Syst-Eur, UKPDS, and SHEP studies supported the conclusion that treatment to a systolic BP of <150 mmHg lowers mortality and improves CVD and cerebrovascular health outcomes.
11. All of the following statements are true of finerenone except
    (a) It is a non-steroidal mineralocorticoid receptor antagonist
    (b) Contraindicated in patients with adrenal insufficiency
    (c) **Best taken on an empty stomach**
    (d) Only Mineralocorticoid receptor antagonist indicated to reduce the risk of sustained eGFR decline, end stage kidney disease, cardiovascular death, nonfatal myocardial infarction, and hospitalization for heart failure in adult patients with chronic kidney disease (CKD) associated with type 2 diabetes
    (e) No relevant affinity to androgen, progesterone, and estrogen receptors

Finerenone is a nonsteroidal mineralocorticoid receptor blocker that can be taken with or without food. It is contraindicated in adrenal insufficiency and with concomitant use with strong CYP3A inhibitors. It is the only MR blocker indicated to reduce the risk of sustained eGFR decline, end-stage kidney disease, cardiovascular death, nonfatal myocardial infarction, and hospitalization for heart failure in adult patients with chronic kidney disease (CKD) associated with type 2 diabetes. No relevant affinity to androgen, progesterone, and estrogen receptors. It can be taken with or without food.

Diabetes and Atherogenic Dyslipidemia

40

Arshag D. Mooradian

Introduction

Despite the recent decline in the incidence of cardiovascular mortality in people with diabetes, cardiovascular disease (CVD) continues to be the leading cause of morbidity and mortality in this patient population [1–5]. The cause of accelerated atherosclerosis and premature emergence of coronary artery disease (CAD) is multifactorial. Nevertheless, dyslipidemia is an important risk factor in diabetes that is modifiable with lifestyle changes and institution of effective pharmacologic agents [6, 7].

People with diabetes can have all the variants of dyslipidemias observed in nondiabetic people [7–9]. However, in type 2 diabetes where obesity and insulin resistance are common, a typical dyslipidemia is manifested as high plasma triglyceride and low high-density lipoprotein (HDL) cholesterol concentrations and increased small dense low-density lipoprotein (LDL) cholesterol particles [8, 9].

Prevalence of Dyslipidemia in Diabetes

In the Framingham Heart Study, the prevalence of high LDL cholesterol concentrations in men and women with diabetes mellitus (9% and 15%, respectively) did not differ significantly from the rates in men and women who did not have diabetes (11% and 16%, respectively) [10]. However, people with diabetes had more often high plasma triglyceride concentrations (19% in men and 17% in women) than people without diabetes mellitus (9% of men and 8% of women). In this survey, high levels of total cholesterol, LDL cholesterol, and triglyceride were defined as values above the corresponding 90th percentile for the US population [10]. The prevalence of low plasma HDL cholesterol concentrations (defined as a value below the 10th percentile for the US population) was 21% in men and 25% in women with diabetes, while only 12% nondiabetic men and 10% of nondiabetic women had low HDL cholesterol levels [10]. A similar increase in the prevalence of hypertriglyceridemia and low HDL cholesterol level was observed in the UK Prospective Diabetes Study (UKPDS) [11].

Pathophysiology of Dyslipidemia in Diabetes

One of the major drivers of increased plasma triglyceride concentrations in people with type 2 diabetes is the increased free fatty-acid release from insulin-resistant fat cells [7–9]. The increased flux of free fatty acids into the liver promotes triglyceride production. Subsequently, there is increased secretion of apolipoprotein B (apoB) and very low-density lipoprotein (VLDL) cholesterol.

Insulin resistance is also associated with low HDL cholesterol levels [7–9] and increased concentration of small dense LDL-cholesterol particles as VLDL-transported triglyceride is exchanged for HDL or LDL-transported cholesteryl ester through the action of the cholesteryl ester transfer protein (CETP) (Fig. 40.1). This exchange results in increased amounts of both atherogenic cholesterol-rich VLDL remnant particles and triglyceride-rich, cholesterol-depleted HDL and LDL particles. The latter triglyceride-enriched particles are hydrolyzed by hepatic lipase or lipoprotein lipase resulting in dissociated apolipoprotein A-I (apo A-I) that is filtered by the renal glomeruli and degraded in renal tubular cells (Fig. 40.1) [7–9]. The increased concentration of small dense LDL-cholesterol particles occurs by a similar lipid exchange that results in lipid depletion of the LDL particles (Fig. 40.1).

The lipid exchange pathway cannot entirely explain why low HDL cholesterol levels can also occur in people who do not have hypertriglyceridemia. In these patients, inability of insulin to upregulate the apo A-I production owing either to insulin resistance or increased inflammatory cytokines notably tumor necrosis factor (TNF) alpha might contribute to low HDL cholesterol levels [12–14].

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_40

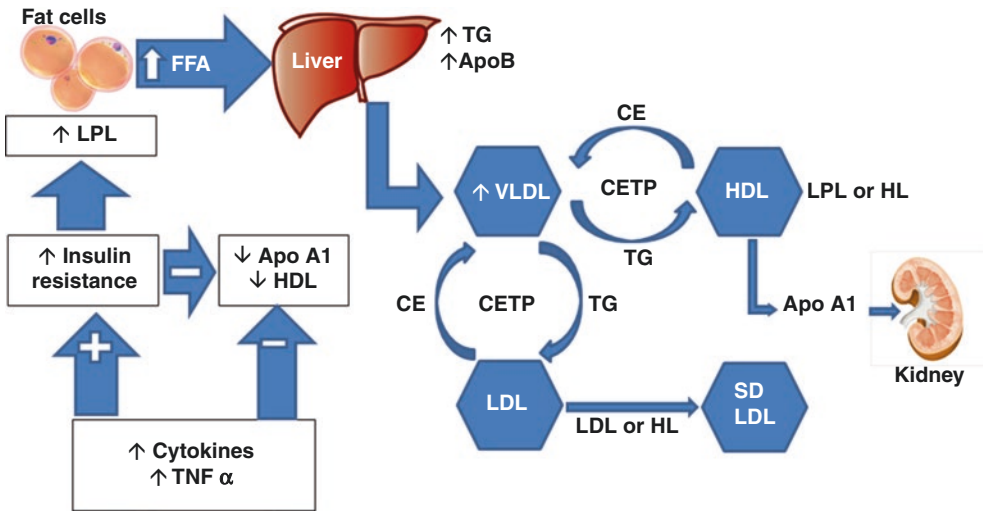

Fig. 40.1 Pathogenesis of diabetic dyslipidemia. Insulin resistance initiates the characteristic triad of high triglyceride level, low HDL cholesterol level, and high small dense LDL level. If the concentration of VLDL transported triglyceride is high, CETP promotes the transfer of LDL cholesteryl ester or HDL cholesteryl ester in exchange for triglyceride. Triglyceride-rich HDL or LDL can undergo hydrolysis by hepatic lipase or lipoprotein lipase. ↑ increased level, *TNF α* tumor necrosis factor α, *ApoA-1* apolipoprotein A-1, *ApoB* apolipoprotein B, *CE* cholesteryl ester, *CETP* cholesteryl ester transfer protein, *FFA* free fatty acid, *HL* hepatic lipase, *LPL* lipoprotein lipase, *SD LDL* small dense LDL cholesterol, *TG* triglyceride, *HDL* high-density lipoprotein, *LDL* low-density lipoprotein, *VLDL* very low-density lipoprotein. Reprinted from reference [8] with permission of the authors and the publisher

Insulin resistance is also associated with a decreased ratio of lipoprotein lipase to hepatic lipase in heparin-treated plasma, which contributes to the low HDL-cholesterol level [8, 9]. In addition, the esterification of cholesterol (mediated by lecithin-cholesterol acyl transferase) is either modestly increased or unaltered, whereas increased CETP activity depletes HDL of its cholesteryl ester and therefore contributes to the lowering of HDL cholesterol levels [8, 9].

It is noteworthy that the combination of high triglyceride and low HDL cholesterol levels is observed in familial and sporadic syndromes (e.g., familial combined hyperlipidemia and familial hypertriglyceridemia) and the onset of obesity and insulin resistance would augment the lipid abnormality phenotype in these people [9].

Atherogenicity of Dyslipidemia in Diabetes

Interventional trials with statins have proven the efficacy of these drugs in reducing cardiovascular events in people with diabetes. In these trials, the linear relationships between LDL cholesterol levels and the incidence of cardiovascular events were similar in individuals both with and without diabetes mellitus [15]. However, the role of low HDL cholesterol and increased triglyceride levels in CVD is still unproven. The association between hypertriglyceridemia and the increased risk of CVD is not as strong as the association between LDL cholesterol level and CVD risk.

Patients with elevated triglyceride levels especially in the context of familial combined hyperlipidemia or low HDL level might have increased risk for CVD. In addition, severe hypertriglyceridemia (greater than or equal to 5.65 mmol/L (500 mg/dL) increases the risk of pancreatitis.

Interventional trials that used fibrate therapy to lower triglyceride and increase HDL cholesterol levels have failed to show a reproducible reduction in cardiovascular events. In the HDL Intervention Trial (HIT), gemfibrozil treatment was associated with a 22% reduction in the risk of coronary heart disease (CHD) and a 25% reduction in the risk of stroke [16]. In the latter study, a quarter of the subjects studied had diabetes. The favorable effect of gemfibrozil in the primary prevention of CHD was also demonstrated in previous trials [17].

The Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study did not show that fenofibrate had a statistically significant effect on the primary outcome (CHD-related death or nonfatal myocardial infarction) [18, 19]. However, fenofibrate reduced the prevalence of nonfatal myocardial infarction and coronary revascularization, but it did not reduce the risk of fatal events [18, 19].

The Action to Control Cardiovascular Risk in Diabetes (ACCORD) study examined whether treatment with a statin plus a fibrate, as compared with statin alone, would decrease the risk of cardiovascular events in a population of 5518 patients with type 2 diabetes [20]. After a mean follow-up period of 4.7 years, fenofibrate with simvastatin group compared with simvastatin alone did not have reduced cardiovascular events. Further analyses suggested a possible benefit for patients with the combination of a high baseline triglyceride level and low HDL cholesterol [20]. This observation

was in agreement with the previous findings in the FIELD trial [19].

The HDL has a central role in reverse cholesterol transport and possesses a number of other cardioprotective properties. However, most trials with agents known to increase HDL levels have not shown any reduction in cardiovascular events except possibly in a subgroup of patients with high serum triglycerides and low HDL cholesterol levels [21–26].

The Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides Impact on Global Health Outcomes (AIM-HIGH) [21] and the Heart Protection Study 2: Treatment of HDL to Reduce the Incidence of Vascular Events (HPS2-THRIVE) [22] used niacin as the HDL cholesterol-boosting agent. Four clinical trials used CETP inhibitors to increase HDL cholesterol level [23–26]. Only the Randomized Evaluation of the Effects of anacetrapib through Lipid Modification (REVEAL) trial showed favorable effects on cardiovascular outcomes, but most of the benefit was attributed to its ability to reduce non-HDL cholesterol levels [26]. It is possible that when HDL levels are increased with enhanced de novo production rather than impaired turnover secondary to CETP inhibition, the quality and functionality of HDL improve to become a more effective cardioprotective moiety [27].

Management of Dyslipidemia in Diabetes Mellitus

An integral component of the management of dyslipidemia is to exclude secondary aggravating causes notably hypothyroidism and use of hormone replacement therapy. Although most people with diabetes would require pharmacologic agents, lifestyle modifications are still important cornerstone of therapy. These include dietary restrictions, increased physical activity, and smoking cessation [7]. Glycemic control usually improves the dyslipidemia by either providing insulin or enhancing insulin action, but it may not increase the reduced HDL cholesterol levels [28]. In addition, some agents such as pioglitazone may have direct effects on lipid metabolism [8].

Medical Nutrition Therapy

Dietary interventions should be individualized based on patient's own dietary preferences [8, 9]. While the low fat diet has been the cornerstone of the dietary guidelines in the past, more recent guidelines emphasize the importance of limiting added sugars to less than 10% of total energy intake. This recommendation is based on a large body of evidence for the association between the consumption of added sugars, especially fructose from corn syrup and atherogenic lipid profile [29–32]. In addition, clinical trials using a diet enriched with monounsaturated fat such as the Mediterranean diet have shown favorable effects on cardiovascular risk [33]. When weight loss is the goal of dieting, there is not clinically meaningful difference between carbohydrate-restricted diets and fat-restricted diets. It is best to limit portion size as all calories count irrespective of their source [32, 34]. The American Diabetes Association (ADA) recommends modest weight loss for overweight individuals [35]. As little as 5% weight loss can have favorable metabolic effects, and clinical studies have shown that 7% or less of weight loss can prevent or delay the onset of diabetes in high-risk individuals [36].

Low-carbohydrate diets (LCD) can enhance weight loss in the short term although its effect is small and not sustainable [32]. In people with diabetes and insulin resistance, LCD is helpful in achieving glycemic control. However, there are untoward side effects especially when carbohydrates are severely restricted (<50 g/day) to induce ketosis. The latter curbs appetite but also may cause nausea, fatigue, and water and electrolyte losses and limits exercise capacity [32]. In addition, observational studies suggest that low-carbohydrate diets (<40% energy from carbohydrates) as well as very high carbohydrate diets (>70% energy from carbohydrate) are associated with increased mortality [32]. The available scientific evidence supports the current dietary recommendations to replace highly processed carbohydrates with unprocessed carbohydrates as well as limiting added sugars in the diet [32].

The type of fat consumed is more important than total amount of fat. A reduction in dietary saturated fat to less than 10% of total daily calories is recommended along with preferential consumption of monounsaturated fat, elimination of trans-fat intake, and limiting daily sodium consumption to less than 2300 mg [35]. Overall, Mediterranean [33] or Dietary Approaches to Stop Hypertension (DASH) [37] style diets are prudent advice to people with diabetes. Of note is that the previous recommendation of restricting dietary cholesterol intake to less than 300 mg/day has been removed from the 2015 and 2020 Dietary Guidelines for Americans [29]. People with diabetes should follow the dietary guidelines issued for the general population [35].

It is noteworthy that replacing saturated fat intake with carbohydrate lowers total cholesterol, LDL and HDL cholesterol, and may increase triglyceride level [38, 39]. On the other hand, substituting saturated fat with monounsaturated or polyunsaturated fat has favorable effect on HDL cholesterol and triglyceride levels. Dietary protein or various amino acids do not have clinically significant effects on lipoprotein profile [38, 39].

Effects of Exercise

Staying active and exercising have multiple benefits notably enhanced cardiovascular health. Increased physical activity also helps to maintain the weight loss attained with caloric restriction [40]. In addition, independent of weight loss, exercise can improve insulin sensitivity and increase HDL cholesterol levels [41, 42]. Both aerobic or resistance training improve glycemic control in type 2 diabetes, and larger improvement in glycemic control can be achieved with combined resistance and aerobic training [43].

There is a paucity of trials examining the effect of exercise on lipid changes in diabetes. In a study of postmenopausal women with type 2 diabetes, exercise without weight loss was associated with a reduction in waist circumference and improve visceral adipose tissue [44]. In another study of people with type 2 diabetes, a supervised aerobic exercise program reduced VLDL–apo B pool size [45]. Despite the limitations in these studies, it is a prudent clinical practice to encourage people with diabetes to engage in exercise to the extent possible. Overall, 30 min of walking five times a week is effective in improving insulin sensitivity and reducing the risk of diabetes in those at risk for developing diabetes [36].

Pharmacologic Interventions

Various classes of lipid-modifying agents are summarized in Table 40.1. Of these agents, statins have been consistently associated with cardiovascular event reduction [15]. Although the efficacy of statins correlates well with their ability in reducing LDL cholesterol, the potential contribution of pleiotropic effects of statin to CVD risk reduction was supported by the observation that therapeutic targeting hsCRP (highly sensitive C-reactive protein) with rosuvastatin was associated significant improvement in event-free survival, and the effect was independent of LDL cholesterol level achieved [46].

The cholesterol hypothesis in contrast to the statin hypothesis is supported by the observation that ezetimibe, a selective cholesterol absorption inhibitor, was also associated with reduction in CVD events when used in addition to statins [47]. This latter study is in contrast to earlier studies with ezetimibe, one in patients with aortic stenosis [48] and the other in those with chronic kidney disease [49]. In the latter studies, ezetimibe and statin combination did not alter mortality but had some favorable effects on secondary endpoints such as fewer coronary bypass procedures, reductions in non-hemorrhagic stroke, and arterial revascularization procedures [48, 49]. Thus, ezetimibe should be considered when maximal doses of high potency statins are not tolerated [35]. Similarly, two interventional trials with PCSK9 (proprotein convertase subtilisin/kexin 9) inhibitors, evolocumab and alirocumab, showed a reduction in cardiovascular events in a high-risk population with LDL cholesterol levels of 1.8 mmol/L (70 mg/dL) or higher who were receiving statin therapy [50, 51]. Another related drug soon to be available is inclisiran (Leqvio®). This investigational drug would be the first LDL cholesterol-lowering siRNA medicine. Its twice-yearly dosing by subcutaneous injection is a significant advantage in enhancing adherence to cholesterol lowering drugs [52].

An additional option is ATP citrate lyase inhibitor bempedoic acid (Nexletol®). This drug is approved for the treatment of adults with heterozygous familial hypercholesterolemia or established atherosclerotic cardiovascular disease who require additional lowering of LDL cholesterol. A single-pill combination of bempedoic acid and ezetimibe (Nexlizet®) is also available [53].

The bile acid sequestrants (BAS) have a limited role in reducing LDL cholesterol except possibly in women of reproductive age and children where safety of statins and ezetimibe is of concern. Gastrointestinal side effects, increased risk of cholelithiasis, and aggravation of hypertriglyceridemia limit the clinical utility of these agents. In general, colesevelam has a better gastrointestinal side effects profile and has favorable effects on glucose metabolism. In the glucose-lowering effect of WelChol Study (GLOWS) in patients with type 2 diabetes, colesevelam added to existing therapy with metformin- and/or sulfonylurea-lowered LDL cholesterol by 11.7% and HbA1c by 0.5% [54]. The increase in triglyceride level was not significant in the GLOWS, although in other trials, when colesevelam was added to sulfonylurea or insulin, the triglyceride levels increased by 17.7% and 21.5%, respectively ($P < 0.05$) [55–57].

Niacin lowers triglyceride, LDL cholesterol, and small dense LDL levels and raises HDL cholesterol. Thus, its pharmacologic effect is well suited to target the triad of diabetic dyslipidemia. However, the use of niacin has been limited by its side effects such as flushing, itching, gastrointestinal upset, tachycardia, hypotension, and aggravation of insulin resistance. More importantly, two large clinical trials, one the HPS-2 THRIVE and the second AIM-HIGH, failed to show any clinical benefit of adding niacin to statin therapy, and there was a possible increase in ischemic strokes with the combination therapy [21, 22]. The combination should rarely be used in patients with high risk of hypertriglyceridemia-related pancreatitis.

The role of fibrates is limited because of lack of reproducible cardiovascular benefits. However, results from the available clinical trials suggest that in the subgroup of patients with moderate dyslipidemia (high triglycerides ≥2.24 mmol/L (200 mg/dL) and low HDL cholesterol <0.9–1.0 mmol/L (35–40 mg/dL), fenofibrate treatment compared

Table 40.1 A select list of therapeutic agents available for the management of dyslipidemia

Drug or drug class	Pharmacologic effects	Side effects	Specific agents (trade name) and dosage
1. Single agent formulations			
HMG-CoA reductase inhibitors (statins)	LDL-c ↓ 18–55%	Hepatotoxicity, myopathy, risk of diabetes	Lovastatin (Mevacor®) 10–80 mg orally nightly or two divided doses
	HDL-c ↑ 5–15%		Lovastatin extended-release (Altoprev®) 10–60 mg orally nightly
	TG ↓ 7–30%		Lovastatin extended-release (Altocor®) 10–60 mg orally nightly
			Simvastatin (Zocor®) 5–80 mg orally nightly[a]
			Pravastatin (Pravachol®) 10–80 mg orally once daily
			Fluvastatin (Lescol®) 20–40 mg orally nightly
			Fluvastatin extended release (Lescol XL®) 80 mg orally up to a maximum daily dose 40 mg twice daily
			Atorvastatin (Lipitor®) 10–80 mg orally once daily
			Rosuvastatin (Crestor®) 5–40 mg orally once daily
			Pitavastatin (Livalo®) 1, 2, and 4 mg orally nightly
ATP citrate lyase inhibitor	LDL-c ↓ 17–24%	No major side effects	Bempedoic acid (Nexletol®, Nilemdo®) 180 mg orally once daily
	LDL-c ↓ 15–20%		
Ezetimibe	HDL-c ↑ 1%	No major side effects, rare myopathy	Zetia®, Ezetrol® 10 mg orally once daily
	TG ↓ 8%		
PCSK9 inhibitors	LDL-c ↓ 60%	Neurocognitive changes	Evolocumab (Repatha®) 140 mg SC Q 2 weeks or 420 mg Q month
	HDL-c ↑ 5%	Cost	Alirocumab (Praluent®) 75 mg SC Q 2 weeks or 150 mg Q month
	TG ↓ 15%		
Nicotinic acid (niacin)	LDL-c ↓ 5–25%	Flushing, hyperglycemia, hyperuricemia, hepatotoxicity	Nicotinic acid 1–2 g orally two or three times daily
	HDL-c ↑ 15–35%		Extended-release nicotinic acid (Niaspan®)
	TG ↓ 20–50%		1000–2000 mg orally nightly
	Small, dense LDL↓		Sustained-release nicotinic acid (Slo-Niacin®) 250–750 mg orally once or twice daily
			Other trade names include *B-3-50, B3-500-Gr, Niacin SR, Niacor, Niaspan ER, Neasyn-SR, Nialip, Nicocin ER*
Fibrates (fibric acid derivatives)	LDL-c ↓ 5–20%	Dyspepsia, gallstones, hepatotoxicity, myopathy	Fenofibrate, micronised (Antara™) 43 and 130 mg orally once daily
			Fenofibrate, micronised (Lofibra™) 67, 134 and 200 mg orally once daily
	HDL-c ↑ 10–35%		Fenofibrate (Tricor®) 48 and 145 mg orally once daily
			Fenofibric acid delayed release capsules (Trilipix®) 45 and 135 mg orally once daily
	TG ↓ 20–50%		Other trade names for fenofibrate include Fenoglide, Lipidil EZ, Lipidil Micro, Lipidil Supra, Lipofen, Triglide, Lipanthyl, Tricheck, Golip
			Gemfibrozil (Lopid®, Apo-Gemfibrozil®, Gen-Gemfibrozil®, PMS-Gemfibrozil®) 600mg orally twice daily Bezafibrate (Bezalip®, Bezagen®, Fibrazate®, Liparol™, Zimbacol®) 200 mg orally twice daily
	Small, dense ↓ LDL-c		Bezalip® Mono 400 mg orally once daily
			Pemafibrate (Parmodia®) 0.1–0.2 mg orally twice a day
Bile acid binding agents (or sequestrants)	LDL-c ↓ 10–20%	Gastrointestinal distress, constipation	Cholestyramine (Questran®, Prevalite®) 4–24 g orally two or three times daily
	HDL-c ↓ 1–2%		Colestipol (Colestid®) 5–30 g orally once or twice daily
	TG ↓ possible ↓ 10%		Colesevelam (Welchol®) 1.875–3.75 g orally once or twice daily

(continued)

Table 40.1 (continued)

Drug or drug class	Pharmacologic effects	Side effects	Specific agents (trade name) and dosage
Omega-3 fatty acid	TG ↓ 25–30%	Fishy aftertaste, gastrointestinal disturbances, possible association with frequent recurrences of atrial fibrillation or flutter	Lovaza® 2 g orally twice daily or 4 g once daily
	LDL-c ↓ 5–10%		OTC: e.g., fish oil, Promega, Cardio-Omega 3, Marine Lipid Concentrate, MAX EPA®, SuperEPA 1200, 2–4 g/day of EPA + DHA
	HDL-c ↑ 1–3%		*Epanova*® (*omega-3*-carboxylic acids) 2–4 g orally daily
			Vascepa® (icosapent ethyl) 4 g orally daily
2. Double agent formulations			
Simvastatin and Ezetimibe	LDL-c ↓ 45–60%	As above for individual agents	Ezetimibe/Simvastatin (Vytorin™) 10/10 mg,10/20 mg, 10/40 mg, and 10/80 mg orally once daily[b]
	HDL-c ↑ 6–10%		
	TG ↓ 23–31%		
Lovastatin and nicotinic acid	LDL-c ↓ 30–42%	As above for individual agents	Nicotinic acid/lovastatatin (Advicor®) 500/20 mg, 750/20 mg, 1000/20 mg, 1000/40 mg orally nightly
	HDL-c ↑ 20–30%		
	TG ↓ 32–44%		
Niacin extended-release/simvastatin	LDL-c ↓ 25%	As above for individual agents	Niacin extended-release/simvastatin (Simcor®) 500/20 mg to 2000/40 mg orally nightly
	HDL-c ↑ 24%		
	TG ↓ 36%		
	Non-HDL-c ↓ 27%		
Simvastatin and sitagliptin	LDL-c ↓ 20–40%	As above for statins	Simvastatin/sitagliptin (Juvisync®) 100/10 mg, 100/20 mg, 100/40 mg orally once daily
	HDL-c ↑ 5–10%		
	TG ↓ 10–20%		
	Hba1c ↓ 0.5–0.07%		
Atorvastatin and amlodipine	LDL-c ↓ 30–60%	As above for statins	Atorvastatin/amlodipine (Caduet®) 2.5, 5, or 10/10, 20, 40, or 80 mg orally once daily
	HDL-c ↑ or ↓ 5–10%		
	TG ↓ 30%		
	Anti-hypertensive		
Bempedoic acid and ezetimibe	LDL-c ↓ 30%	As above for individual agents	Bempedoic acid/ezetimibe (Nexlizet®) 180 mg/10 mg orally once daily

DHA docosahexaenoic acid, *EPA* eicosapentaenoic acid, *HDL-c* high-density lipoprotein-cholesterol, *LDL-c* low-density lipoprotein-cholesterol, *OTC* over the counter, *TG* triglyceride
[a]The use of the 80 mg dose should be restricted to patients who have been taking simvastatin 80 mg chronically (e.g., for 12 months or more) without evidence of muscle toxicity
[b]The use of the Vytorin™ 10/80-mg dose should be restricted to patients who have been on this strength chronically (e.g., for 12 months or more) without evidence of muscle toxicity

to placebo is associated with fewer cardiovascular events [19, 20]. Fibrate use can be considered in people with elevated triglyceride level >5.6 mmol/L (500 mg/dL) along with dietary modification and improving glycemic control to prevent chylomicronemia and the associated risk of pancreatitis. When used in combination with statins, fenofibrate or bezafibrate seems to convey a minimal risk of rhabdomyolysis, while the combination with gemfibrozil should be avoided. Pemafibrate (Parmodia®) is a novel selective peroxisome proliferator-activated receptor alpha (PPARα) modulator (or fibrate) that is currently available in Japan. The ongoing clinical trial, Pemafibrate to Reduce Cardiovascular OutcoMes by Reducing Triglycerides IN patiENts With diabeTes (PROMINENT) (ClinicalTrials.gov Identifier: NCT03071692), will address the role of this fibrate in reducing cardiovascular events in people with diabetes [58].

Fish oil supplements are another option to reduce triglyceride levels. In general, daily supplements of 3–5 g of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) reduce serum triglyceride levels by an average of 28%. The Combination of Prescription Omega-3 Plus Simvastatin (COMBOS) trial in statin-treated patients who have persis-

tent triglyceride levels between 200 and 499 mg/dL found that omega-3 fatty acid supplementation reduced non-HDL-c by 9% compared with 2.2% with placebo, triglycerides by 30% compared to 6% with placebo, and increased the HDL cholesterol by 3.4% [59]. Two open-label trials suggested some clinical benefits of omega-3 fatty acids. In the Gruppo Italiano per lo Studio della Infarto Miocardico (GISSI-Prevenzione) trial, mortality was reduced by 28% in people with diabetes and by 18% in nondiabetics randomized to omega-3 fatty acid supplementation [60]. Similarly, in a study of Japanese hypercholesterolemic patients, daily supplementation with 1800 mg EPA was associated with a significant reduction in nonfatal coronary events [61]. However, in subsequent large cohorts of diabetic patients, fish oil supplementation was not associated with any beneficial outcomes [62–64]. These trials used 1 g of *n*-3 fatty acids. The subsequent Reduction of Cardiovascular Events with Icosapent Ethyl-Intervention Trial (REDUCE-IT) found an approximately 25% relative risk reduction ($p < 0.001$) in major adverse cardiovascular events with an ethyl ester form of eicosapentaenoic acid (EPA) (Vascepa®) 4 g/day compared with placebo after a median follow-up of 4.9 years [65]. These favorable cardioprotective effects were not duplicated in the trial with omega-3 carboxylic acids (Epanova®) as the STRENGTH (a long-term outcomes study to assess STatin Residual risk reduction with EpaNova in hiGh cardiovascular risk paTients with Hypertriglyceridemia) trial was terminated early for low likelihood of demonstrating a benefit. Nevertheless, it is approved for lowering triglycerides in patients with very high levels of triglycerides. This approval was based on data from a clinical development program that included positive results from the Phase III EVOLVE (EpanoVa fOr Lowering Very high triglyceridEs) trial [66].

In rare genetic disorders with sever hypercholesterolemia such as homozygous familial hypercholesterolemia, a novel antisense oligonucleotide inhibitor of apo B100 synthesis, mipomersen (Kynamro®), was developed, but its marketing and use has been discontinued because of significant risk of liver damage [67, 68].

Lomitapide (Juxtapid®), a microsomal triglyceride transfer protein (MTP) inhibitor reduces the synthesis of chylomicrons and very low-density lipoprotein, resulting in a reduction in plasma LDL levels. The drug was approved with a boxed warning for increased the risk of hepatotoxicity. Other precautions with lomitapide include reduced absorption of fat-soluble vitamins, gastrointestinal adverse events, and numerous drug–drug interactions [69].

Another medication for the treatment of homozygous familial hypercholesterolemia is evinacumab (Evkeeza®). This monoclonal antibody against angiopoietin-like 3 (ANGPTL3) acts as an inhibitor of lipoprotein lipase and endothelial lipase. In ELIPSE HoFH trial, individuals were treated with other lipid-lowering therapies, including maximally tolerated statins, PCSK9 inhibitors, ezetimibe, LDL apheresis, and lomitapide, adding evinacumab to other lipid-lowering therapies decreased LDL cholesterol by 49% on average, compared to lipid-lowering therapies alone. The drug's prohibitive cost will limit its utility [70, 71].

Another novel medication currently in clinical trials for the treatment of familial chylomicronemia syndrome is volanesorsen (Waylivra®). This is an antisense oligonucleotide inhibitor of apo C-III mRNA. In phase 2 trials, this agent resulted in 71% decrease in triglycerides, 46% increase in HDL cholesterol, and improved blood glucose levels in type 2 diabetes [72, 73].

There is emerging evidence that diabetes is associated with increased cellular stress notably, oxidative, inflammatory, and endoplasmic reticulum stress [74, 75]. These stressors promote atherosclerosis, and in two clinical trials with anti-inflammatory drugs, canakinumab [76] and colchicine [77] reduced major adverse cardiovascular events. Targeting cellular stress with novel and safe drugs may increase the opportunities for reducing cardiovascular events in people with diabetes.

A Rational Approach to Drug Therapy

The current consensus is to recommend high-intensity statin to all patients with diabetes and atherosclerotic cardiovascular disease (i.e., secondary prevention). For those younger than 40 years of age with additional cardiovascular risk, moderate-intensity statins are recommended after the healthcare provider and the patient discuss the risks and benefits of such intervention, as there is paucity of date for individuals below age 40 or above age 75 years. For those aged over 40 years without any additional risk, moderate-intensity statin is suggested in addition to lifestyle modifications, while those with any additional risk should be on high-intensity statin (i.e., primary prevention) [35]. Various statins are categorized according to their intensity in Table 40.2. The dose and

Table 40.2 Classification of statins according to their efficacy in reducing LDL cholesterol

	High intensity	Moderate intensity
Average effect on LDL cholesterol with daily dose	Lowering of LDL cholesterol ≥50%	Lowering of LDL cholesterol 30 to <50%
Examples	(a) Atorvastatin 40–80 mg (b) Rosuvastatin 20–40 mg	(a) Atorvastatin 10–20 mg (b) Fluvastatin 40 mg twice a day or extended release 80 mg once a day (c) Lovastatin 40 mg (d) Pitavastatin 2–4 mg (e) Pravastatin 40–80 mg (f) Rosuvastatin 5–10 mg (g) Simvastatin 20–40 mg

choice of statin can be adjusted based on patient's response, side effects, and tolerability. Addition of ezetimibe to moderate-intensity statin may provide additional benefits especially in patients with acute coronary syndrome and LDL cholesterol of 1.29 mmol/L (50 mg/dL) or over or for those who cannot tolerate high-intensity statin. Combination of statin and fenofibrate may be considered in men with triglyceride levels of 2.3 mmol/L (204 mg/dL) or more and HDL cholesterol level of 0.9 mmol/L (34 mg/dL) or less. Combination of statin and niacin has no benefit beyond statin therapy, may increase the risk of stroke, and generally should be avoided. Statins are contraindicated in pregnancy [35].

Lipid profile should be measured before starting statin therapy, 4–12 week after the initiation of therapy and periodically thereafter to monitor compliance and efficacy [35]. Based on the currently available literature, an evidence-based algorithm for the drug therapy of dyslipidemia in patients with diabetes is shown in Fig. 40.2. As lowering LDL cholesterol levels are irrefutably linked to reducing cardiovascular events, the first priority for most patients with CVD should be to start statin therapy irrespective of baseline lipid levels (Fig. 40.2). High-intensity statins are recommended for those with established coronary artery disease or those who have 10-year risk of ≥20%. If the LDL cholesterol response to therapy is less than 50% in a very high-risk individual, or if the patient cannot tolerate statins, then addition of ezetimibe, bempedoic acid, and PCSK9 inhibitors such as evolocumab and alirocumab should be considered especially if LDL cholesterol level is above 1.8 mmol/L (70 mg/dL) [35, 70, 71].

In general, cholesterol-binding resins are an option only if the patient's serum triglyceride concentration is less than 2.83 mmol/L (250 mg/dL) or less than 2.26 mmol/L (200 mg/dL) for those on sulfonylurea or insulin, as this class of agents might exacerbate hypertriglyceridemia. An attractive option is colesevelam as it has blood glucose-lowering effect in addition to its inhibition of cholesterol absorption [56]. In patients with established cardiovascular disease or for those with multiple cardiovascular risk factors, if triglyceride levels are 1.5–5.6 mmol/L (135–499 mg/dL), 4 g of icosapent ethyl can be added to reduce adverse cardiovascular events [65].

Currently, the principal rationale for targeting the triglyceride levels is to reduce the risk of pancreatitis. This serious complication rarely occurs when the serum triglyceride levels are less than 1000 mg/dL. However, individual variability in triglyceride-related risk should be taken into consideration when determining the threshold level below which the risk of pancreatitis is negligible.

When serum triglyceride level is over 5.65–11.3 mmol/L (500–1000 mg/dL) (the range is to account for differences in individual susceptibility to pancreatitis), fibrate with and without omega-3 fatty acids is recommended. An exception would be patients who have chylomicronemia associated with a profound lipolytic deficiency. It is noteworthy that the

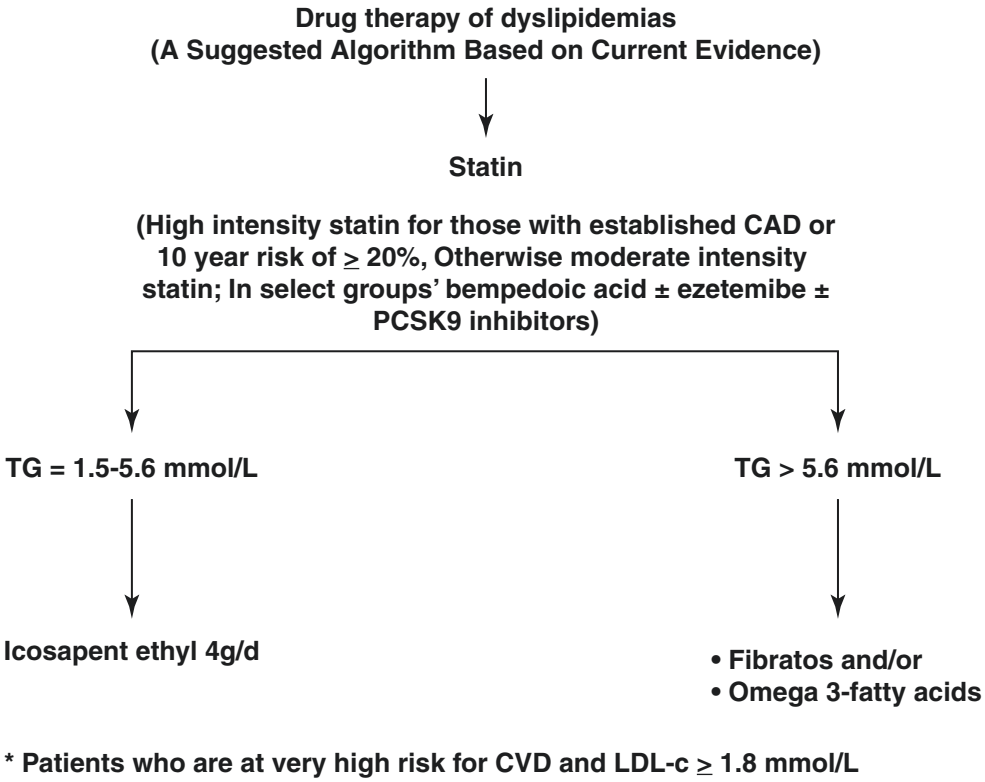

Fig. 40.2 A suggested evidence-based algorithm for drug therapy of dyslipidemia in patients with diabetes mellitus. *LDL-c* low-density lipoprotein cholesterol, *TG* triglycerides, *CVD* cardiovascular disease. Reprinted from reference [8] with some modifications and with permission of the authors and the publisher

combination of a statin and a fibrate or nicotinic acid can potentiate the risk of rhabdomyolysis, and as such, these combinations should be used cautiously.

Conclusions

Type 2 diabetes is commonly associated with atherogenic dyslipidemic profile that includes high triglycerides, low HDL, and large number of small LDL particles. Lowering LDL cholesterol with statins, ezetimibe, and PCSK9 inhibitors has proven clinical benefits. In patients with established cardiovascular disease or for those with multiple cardiovascular risk factors, LDL cholesterol goal is <1.8 mmol/L (70 mg/dL). Most patients at 40–75 years of age regardless of their basal plasma cholesterol levels require statin therapy, and high-intensity statins are recommended for high-risk patients especially those with clinically established coronary artery disease. Some individuals may benefit from combination therapy with icosapent ethyl if triglyceride levels are 1.5–5.6 mmol/L (135–499 mg/dL) [65]. Use of ezetimibe and bempedoic acid in those who cannot tolerate high-intensity statins may be prudent. In select patients, PCSK9 inhibitors are an option.

In addition to proper management of the hyperlipidemia, other risk factors frequently associated with diabetes, such as hypertension, obesity, and smoking, should be addressed.

Multiple Choice Questions

1. One of the major drivers of increased plasma triglyceride concentrations in people with type 2 diabetes is
   (a) High intake of saturated fat from animal foodstuffs
   (b) **Increased free fatty-acid release from insulin-resistant fat cells**
   (c) Inhibition of lipoprotein lipase activity
   (d) Ectopic fat distribution
   (e) All of the above
2. Diabetic dyslipidemia is characterized by
   (a) Moderate/high plasma LDL cholesterol
   (b) High plasma triglyceride levels
   (c) Low plasma HDL cholesterol levels
   (d) **All of the above**
   (e) A and B are correct
3. The increased flux of free fatty acids into the liver promotes
   (a) **Increased triglyceride, apoB, and VLDL production**
   (b) Increased total cholesterol, apo A, and LDL production
   (c) Increased triglyceride, apoA, and LDL production
   (d) Decreased triglyceride, apoB, and LDL production
   (e) Increased triglyceride, apoB, and no changes in VLDL production
4. Severe hypertriglyceridemia (greater than or equal to 5.65 mmol/L (500 mg/dL) increases the risk of
   (a) Acute myocardial infarction
   (b) Stroke
   (c) **Acute pancreatitis**
   (d) Peripheral artery disease
   (e) Acute gastritis
5. Glycemic control can be improved with:
   (a) Low carbohydrate diet
   (b) Aerobic exercise
   (c) Resistance training
   (d) Thirty minutes of walking five times a week
   (e) **All of the above**
6. Most people with diabetes would require pharmacologic agents, but lifestyle modifications are still important cornerstone of therapy when they
   (a) Include high-intensity aerobic exercise
   (b) **Achieve modest body weight loss (7%), increase physical activity and smoking cessation**
   (c) Include ketogenic diets
   (d) Increase the intake of vitamins and minerals
   (e) Are focused on dietary restrictions
7. Lowering LDL cholesterol levels is irrefutably linked to reducing cardiovascular events, the priority for most patients should be
   (a) Early insulin therapy with the goal to reduce lipolysis
   (b) **Start statin therapy irrespective of baseline lipid levels**
   (c) Additional therapy with metformin at low doses
   (d) The use of anti-platelet adhesion agents
   (e) Preparations for cardiovascular management
8. Combination therapy of statin and the following drug may increase the risk of stroke
   (a) Fenofibrate
   (b) **Nicotinic acid**
   (c) Bempedoic acid
   (d) PCSK9 inhibitors
   (e) Ezetimibe
9. In patients with established cardiovascular disease or for those with multiple cardiovascular risk factors, if triglyceride levels are 1.5–5.6 mmol/L (135–499 mg/dL)
   (a) Icosapent ethyl, 1 g/day should be added
   (b) Fenofibrate should be added
   (c) **Icosapent ethyl, 4 g/day can be added to reduce adverse cardiovascular events**
   (d) Omega-3 carboxylic acids 4 g/day can be added to reduce adverse cardiovascular events.
   (e) Recommend low carbohydrate diet
10. While statins have well established cardiovascular benefits, the following agents are also shown to be associated with reduced cardiovascular adverse events
    (a) Bempedoic acid

(b) **PCSK9 inhibitors**
(c) **Niacin**
(d) Omega-3 fatty acids
(e) Antioxidant vitamins such as vitamin E and C

Obesity and Diabetes: Clinical Aspects

41

Sean Wharton, Rebecca A. G. Christensen, Christy Costanian, Talia Gershon, and Joel Rodriguez-Saldana

Objectives

1. To contrast the utility of assessments of obesity and their accuracy in determining health risk
2. To discuss genetic, social, and environmental causes of obesity and diabetes
3. To summarize different treatment methods for obesity and diabetes

Introduction

The worldwide prevalence of obesity has been increasing since the 1980s, and by 2014, 600 million adults had obesity [1]. There are region-specific variations in these rates; nonetheless, rates of obesity have been increasing in both developing and developed nations [1]. Furthermore, it has been estimated that the rates of obesity will continue to rise and reach over 40% of adults in the United Kingdom and over 50% of adults in the United States by 2030 [2].

Obesity has been recognized as a major public health concern owing to the considerable increases in health risks associated with excess weight. Having obesity is associated with an increased risk of having chronic [3] and communicable diseases [4]. Furthermore, having obesity is associated with 4.7 to 13 years of life lost [5, 6], with the greatest decrease in life expectancy for individuals with a body mass index ≥45 kg/m^2 [5]. This places a considerable burden on healthcare systems.

It has been estimated that more than $100 billion is spent annually in the United States for direct healthcare costs associated with obesity [7, 8]. These costs can affect people both individually and systemically. For example, a study observed that patients with overweight and obesity paid considerably more (22–41%) for an emergency department visit precipitated by shortness of breath and chest pains than those with normal weight, with cost increasing per BMI category [9]. Furthermore, obesity can have considerable costs in relation to loss of productivity. Results from a large observational study in the United States observed that individuals with excess weight are 32–118% more likely to report missing work in the past year with the likelihood increasing with each BMI category [10].

Type 1 diabetes was traditionally associated with individuals with lower weight. However, with improvements in glycemic control and increasing use of insulin, a weight-promoting hormone, now many patients with type 1 diabetes also have obesity [11]. Weight management has been challenging in this group, as insulin is the primary treatment [12], and the fear of hypoglycemic can promote excessive calorie intake [13]. Type 1 diabetes and obesity are not well studied at this stage; therefore, this chapter will focus on type 2 diabetes (T2D).

Assessment of Obesity

Body Mass Index (BMI)

Body mass index (BMI) is the most commonly used method for classifying individuals as having obesity and is calculated by dividing weight in kilograms by height in meters squared. The World Health Organization (WHO) has pro-

Table 41.1 World Health Organization's weight categories according to body mass index

Category	Body Mass Index
Normal weight	18.5–24.9 kg/m^2
Overweight	25.0–29.9 kg/m^2
Obesity class I	30.0–34.9 kg/m^2
Obesity class II	35.0–39.9 kg/m^2
Obesity class III	≥40 kg/m^2

vided guidelines for using BMI to categorize individuals as having underweight, normal weight, overweight, or obesity (Table 41.1). BMI is meant to be a measure of health, and research has suggested that increasing levels of BMI are associated with poorer health outcomes [1]. As such, obesity can be further subcategorized as: Class I: 30.0–34.9 kg/m^2, Class II: 35–39.9 kg/m^2, and Class III: ≥40 kg/m^2.

Although BMI is currently used to track trends in obesity, there are criticisms for its lack of utility in determining body composition, as well as in predicting morbidity and mortality. Additionally, due to differences in the accumulation of central adiposity, BMI thresholds may not be appropriate for all ethnicities. Indeed, a WHO expert committee [14] and other international organizations [15, 16] have recognized this issue and recommend lowering thresholds by 2.5 kg/m^2 for individuals of Asian descent. However, there is considerably variability in the health risk associated with a given BMI in all ethnic groups. For example, individuals who identify as White in the United States have a lower body fat percentage for a given BMI than those in Europe [17]. Thus, to avoid confusion and due to the lack of sufficient concise evidence, WHO guidelines still use the cutoff of a BMI ≥30 kg/m^2 for obesity [14]. Moreover, BMI does not consider a subject's body composition when classifying their health risk [18] and therefore may not be an accurate predictor of cardiovascular disease and other conditions that correlated with adipose percentage, adipose type, and location. Morbidity and mortality staging systems, such as Edmonton obesity staging system (EOSS), have been proposed for use instead of or along with BMI.

Body Circumference(s)

Waist Circumference

Excess abdominal adiposity is associated with a greater risk of death [19] and having chronic conditions such as T2D [20, 21] irrespective of BMI. As such, waist circumference can be used to assess health. However, there is considerable disagreement regarding the most optimal site to measure waist circumference. WHO recommends measuring a person's waist circumference at the midpoint between the lower margin of the last palpable rib and the top of the iliac crest [22].

The National Institutes of Health (NIH) has identified waist circumferences ≥102 cm for men and ≥88 cm for women as an indication of increased risk of morbidity and mortality [22]. However, these thresholds have been criticized due to known ethnic differences in abdominal fat distribution [23]; therefore, ethnic-specific thresholds have been proposed to address this limitation. For example, the use of lower thresholds (87–90 cm for men, 54–77 cm for women) is recommended for South Asians as it was observed that these thresholds were more strongly associated with ill-health in this population [24]. There has also been criticism regarding the use of universal waist circumference thresholds for all BMI categories, since the NIH waist circumference thresholds were developed by taking the average waist circumference for a large sample of White men and women with a BMI of 30 kg/m^2 [25]. Therefore, the NIH thresholds may be more of a surrogate measure for BMI rather than an assessment of health risk. To address this limitation, Ardern et al. [26] developed BMI-specific waist circumference thresholds that are more strongly related to poor health. These new thresholds range from 87 cm (normal weight) to 124 cm (class II obese) in men and 79 cm (normal weight) to 115 cm (class II obese) in women.

Waist-to-Hip Ratio

Waist-to-hip ratio is another tool used to measure body fat distribution and evaluate health risks associated with excess weight [27]. Waist-to-hip ratio is calculated by dividing an individual's waist circumference by their hip circumference [18]. While there is no agreement regarding the most optimal site to measure waist circumference, in general protocols recommend that hip circumference be measured around the widest portion of the buttocks. Waist-to-hip ratios are meant to build on solely waist circumference measurements as hip circumferences are thought to provide information regarding key measures of body composition like muscle mass, while waist circumference is used to assess abdominal adiposity [28]. The WHO recommends that waist-to-hip ratios of ≥0.9 for men and ≥0.85 women be used to identify a substantially increased risk of ill-health [27].

Several criticisms regarding the utility of waist-to-hip ratio in assessing body composition and health have been made. To begin, changes in weight are not consistently correlated with changes in waist-to-hip circumferences. For example, when individuals gain or lose weight, their waist-to-hip ratio tends to increase and decrease, respectively. However, patients can have increases in their waist-to-hip ratio, while their weight remaining weight stable [29]. Research has also suggested that changes in waist-to-hip ratios independent of changes of weight are not associated with improvements in cardiovascular health risk [30]. Thus, it may be the change in weight that contributes to the changes

in waist-to-hip ratio that is associated with a risk of ill-health rather than changes in the ratio itself [31].

Body Fat

Two types of body fat are present: subcutaneous and visceral. Subcutaneous fat is located directly under the skin and is not associated with poor health [30]. On the other hand, visceral fat, also known as organ fat, surrounds the organs, and when in excess, it is closely associated with metabolic complications [32]. The total of both subcutaneous and visceral fat is considered when measuring an individual's body fat content, which is usually given as a percentage of total body mass. Many methods exist for evaluating body fat, and these methods include, but are not limited to, skinfold thickness, bioelectrical impedance analysis (BIA), dual energy X-ray absorptiometry (DEXA), and the 4-compartmental model. While there is criticism regarding the use of universal cutoffs due to ethnic differences in body composition [33, 34], cutoffs of ≥25% and ≥35% are proposed for men and women, respectively [35]. Various methods of measuring body fat are described in further detail below.

Skinfold Thickness

Skinfold thickness is measured using a caliper. The caliper is used to measure the thickness of subcutaneous adipose tissue. Measurements should be taken when an individual is standing in a relaxed position. The caliper is then used to take skinfold measurements, typically along the right side of the body, at various points such as the bicep, tricep, subscapular, and supra-iliac areas. These values are then entered into prediction equations that convert skinfold measures to body fat percentages. However, there can be considerable variability in body fat distribution based on differences in sex [36, 37], ethnicity [23], and age [37]. Thus, rather than universal thresholds, such as those recommended for BMI categorization, various population-specific equations have been suggested [38–41], such as the sex-specific equations proposed by Jackson and Pollock.

Bioelectrical Impedance Analysis (BIA)

Lean tissue is highly conductive due to its increased electrolyte and water content compared to fat, which is more of an insulator. BIA uses these differences in the flow of electric current through body tissues to estimate body fat. An electrical current is sent through your body, and based on the rate it returns, an individual's total body water can be calculated. This total body water value is then used to estimate fat free (muscle, bone, tissue) and fat mass [42].

BIA is an easy, inexpensive, and quick way to assess body fat. However, many factors can affect the accuracy of this measurement and should be controlled for when using BIA to assess body fat. Dehydration and moderate exercise increases the body's electrical resistance leading to an overestimation of body fat, and consumption of a meal decreases electrical resistance, therefore resulting in lower estimates of body fat [43]. Additionally, having excess weight is associated with greater amounts of extracellular fluids. Thus, BIA may not be an appropriate tool to assess body fat in individuals with overweight or obesity as extracellular fluids will contribute to an underestimation of body fat [43].

Dual Energy X-Ray Absorptiometry (DEXA)

DEXA was initially developed for the measurement of total bone mineral since it uses X-rays to distinguish between and measure three major bodily components: bone mineral, fat mass, and non-bone lean tissue. The advantages of using DEXA are that it operates with a safe radiation level for a whole-body scan [44] and provides a more accurate assessment of body fat than the other methods outlined above [45, 46]. However, the cost associated with the equipment and expertise to run the test often makes the use of DEXA to assess body fat prohibitive. There are also machine specifications that limit the use of DEXA for assessing body fat in individuals with severe obesity. For example, the maximum weight that most machines can hold is 300 pounds with a width of 60 cm [47]. Additionally, DEXA determines an individual's body fat based on underlying assumptions regarding the distribution of bone mineral, fat, and non-bone lean tissue, which may be inaccurate due to person-to-person variability. Similar to other tools used to assess body fat, factors such as level of hydration and age can lead to an altered body composition distribution.

The Four-Compartmental Model

To assess an individual's body fat using the four-compartment model, four measurements must be taken: (1) body weight, (2) body density, (3) total body water, and (4) total body mineral [48, 49]. Various tools can be used to measure these four factors such as water displacement tests or DEXA. Each factor is then put into a prediction equation to estimate body fat. While this method is considered more accurate than other methods for assessing body fat discussed in this chapter and is frequently used to validate more simplistic measures [49], similar to DEXA, specialized laboratory equipment costs and technician expertise mean that this method is often not practical or feasible for the rapid assessment of body fat [49].

Causes of Obesity

In the most basic terms, obesity develops as a result of an energy imbalance, in which an individual consumes a greater amount of calories than they expend. However, obesity is a complex, multifactorial disease, and there are many avenues that contribute to this energy imbalance, without one definitive cause. A system map referred to as the "spaghetti map" was constructed to describe the interplay of factors that result in the development of obesity [50]. Sixteen thematic clusters are represented on this map, which include categories such as the influence media, social, and psychological factors. Each cluster has various sub-factors, which make up this diagram, the description of which is far beyond the scope of this textbook and chapter. As such, this section will focus on the factors that are most salient to the development of obesity and T2D.

Hereditable Factors

While obesity is often viewed as a condition resulting from disordered eating or other patient choice-related cause(s), genetics play a key role in the development of obesity. Genome studies have identified over 200 genes that are associated with body weight and adiposity in mice [51]. In humans, a single-gene mutation in 11 genes was found to be responsible for the development of over 150 cases of obesity. A deficiency of the melanocortin 4 receptor (MC4) gene [52] and Prader Willi chromosomal abnormalities [53] is the most common congenital single gene mutations leading to obesity. Furthermore, genes associated with hyperphagia, a characteristic typically defined as a behavioral cause of obesity, have been identified [54]. Taken together, this evidence suggests there is likely a variety of genes and genetic mutations that have contributed to the development of obesity [51, 55].

Population studies have provided additional evidence that supports the notion of a strong hereditable component to obesity. For example, research suggests that children who have one or both parents with a BMI greater than 30 kg/m^2 are at a 2.5 to 10.4 times greater risk of having childhood obesity [56]. Moreover, studies conducted on monozygotic twins further support the influence of genes on obesity development. Studies have observed a strong correlation in the BMI of separately reared monozygotic twins ranging from 0.61 to 0.70 [57, 58]. However, this is not to discount the effects of environmental factors on the development of obesity. Indeed, when comparing the BMIs of monozygotic and dizygotic twins reared in the same environment, their BMIs were more strongly correlated than those reared apart [57].

Environmental Factors

Diet

Obesity has been referred to as over nutrition in comparison to the energy expenditure, which alludes to the importance of dietary factors in the development of this chronic disease. As energy expenditure is challenging to modify, diet frequently becomes the key modifiable risk factor. An increase in caloric consumption has been observed in most high-income countries from the 1980s through the mid-1990s that appears concomitant with increases in the prevalence of obesity [59]. There were country-specific trends in caloric consumption that further support this notion. For example, the United States had one of the largest increases in BMI over the 10-year period (1.5 kg/m^2 on average) as well as the largest increase in caloric consumption per capita (314 kcal/day). Nonetheless, researchers state that changes in absolute caloric intake alone cannot explain the increase in the rates of obesity that has been occurring over the past four decades [60]. Thus, other factors, such as the macronutrient content of an individual's diet, may also contribute to changes in weight.

The influences of individual macronutrients, such as sugar and fats, have previously been explored with equivocal results. For example, when controlling for differences in total caloric and sugar consumption, each 100 kcal increase in dietary fat has been associated with a 0.21 kg/m^2 increase in BMI [59]. Additionally, research suggests that high dietary fat intake in women with overweight or obesity who have a familial history of obesity is associated with significant increases in their BMI [61]. Conversely, a large meta-analysis observed that increased sugar intake was associated with a 0.75 kg/m^2 increase in BMI. These results are in line with the WHO recommendations to decrease the intake of free sugars to <10% of total caloric intake to decrease an individual's likelihood of having overweight or obesity and to decrease sugar intake to <5% for greater health benefits [62]. Thus, while it still remains unclear exactly how macronutrients contribute to the development of obesity, both the quantity and type of caloric intake appear to play a role.

Physical Activity

When energy expenditure is lower than caloric intake, the balance leans toward increased weight. Theoretically, increases in energy expenditure through the participation in physical activity could result in sufficient caloric deficits to delay or prevent disease onset. Indeed, increased physical activity is often associated with decreases in weight [63] and greater weight loss maintenance over the long term [64]. However, research suggests that individuals with overweight and obesity complete significantly less steps per day than their normal weight counterparts [65]. Moreover, individuals

with obesity are unlikely to meet basic public health physical activity recommendations of 30 min/day of moderate to vigorous physical activity a minimum of 5 days/week, completing only an average of 17.3 min of moderate and 3.2 min of vigorous physical activity a day.

Physical inactivity is becoming a major health concern worldwide. While individuals with overweight and obesity participate in less physical activity on average than those with normal weight, overall less than 5% of adults in the United States meet public health physical activity recommendations [65]. While purposeful physical activity, also referred to as exercise, plays a role in weight management, nonpurposeful physical activity may also be contributing to the increased rates of obesity. Indeed, adults spend more than half of their day being sedentary [65]. This is likely in part due to shifts in occupational demands during the twentieth century, which led to a decrease in physically intensive jobs, such as labor jobs, and increase in the rate of jobs with significant sedentary time, such as office managers [66]. These trends had the unintended side effect of decreasing the amount of structured nonpurposeful physical activity and therefore decreasing caloric expenditure throughout the course of a work day. Moreover, it is important to consider changes to the built environment, which has also occurred over this time period that may further contribute to physical inactivity. Research suggests that individuals who live in more walkable neighbors participate in more physical activity and are less likely to have overweight or obesity [67]. Thus, it appears that other factors, beyond personal choices, have contribute to low physical activity levels, and by extension, increase in the rates of obesity.

Type 2 Diabetes (T2D)

Obesity and a genetic predisposition are well-known risk factors for T2D [68]. The relationship between obesity and T2D is mostly described as being interdependent with obesity significantly increasing the risk of T2D, since over 90% of patients with T2D are obese [69]. Four prospective cohort studies examining the role of obesity in cardiovascular risk factors and disease concluded that children with overweight or obesity and who also had overweight or obesity as adults had increased risks of developing T2D, hypertension, dyslipidemia, and carotid-artery atherosclerosis. The risks of these outcomes among children with obesity who became nonobese by adulthood were similar to those among children who were never obese [70].

A strong association between increasing BMI and glucose intolerance exists [71]. It has been established that insulin action declines as a function of BMI. This relationship is approximately linear in both men and women, and so obesity can be considered as being in an insulin-resistant state. Moreover, a long duration of obesity is associated with lower fasting insulin levels, indicating pancreatic β-cell exhaustion. Those who had class III obesity and insulin resistance need a very large amount of insulin to maintain glucose tolerance. It is clear that individuals with obesity and insulin-resistance impose a large stress on pancreatic β-cells, and this is maintained for prolonged periods of time [71].

It must be noted that the strong associations between excess body fat and T2D do not necessarily indicate that being overweight or obese will cause T2D, since not all individuals with obesity develop diabetes and not all individuals with T2D have obesity [69]. Therefore, obesity alone is not sufficient to cause T2D. Furthermore, obesity, insulin resistance, and eventually T2D share common risk factors, as they are included in the continuum of risk factors for cardiometabolic disease. Thus, the fundamental shared risk factors for obesity and T2D at the individual level may be poor diet and physical inactivity [72]. The relationship between obesity and T2D is affected by several modifying factors, such as duration of obesity, distribution of body fat, physical activity, diet, and genetics/ethnicity [73]. In the last half century, lifestyles, including dietary habits, have changed across the world, accompanied by the global obesity epidemic. While physical activity has decreased in many regions, especially in low-income countries, in high-income countries such as the United States, overall physical activity has remained stable or even increased over the last 30 years as the obesity epidemic has mounted [72, 74]. This suggests that the main driver of the obesity epidemic in the United States may be a worsening diet, while in most low-income countries, it is likely a combination of decreased physical activity and worsening diet [72, 75, 76].

The excess adiposity accompanying T2D, particularly in a central or visceral location, is thought to be part of the pathogenic process [73]. The pathophysiological mechanism between obesity and T2D relates primarily to the adipose tissue, which has been recognized as an endocrine organ that secretes hormones and communicates with the central nervous system to regulate appetite and metabolism [73]. The increased adipocyte mass leads to increased levels of circulating free fatty acids (FFA) and other fat cell products, called adipokines. Adipocytes secrete a number of biologic products (nonesterified free fatty acids, retinol-binding protein 4, leptin, TNF-, resistin, and adiponectin). Again, studies have generally suggested that circulating levels of these products are elevated in individuals with T2D [73]. In addition to regulating body weight, appetite, and energy expenditure, adipokines also modulate insulin sensitivity. The increased production of free fatty acids and some adipokines may cause insulin resistance in skeletal muscle and liver [73] . For example, free fatty acids impair glucose utilization in skeletal muscle, promote glucose production by the liver, and impair beta cell function. In con-

trast, the production by adipocytes of adiponectin, an insulin-sensitizing peptide, is reduced in obesity, and this may contribute to hepatic insulin resistance [73]. Adipocyte products and adipokines also produce an inflammatory state and may explain why markers of inflammation such as IL-6 and C-reactive protein are often elevated in T2D [73]. Adipose tissue also can cause insulin resistance by elevating leptin levels [77]. Leptin is a protein produced by adipocytes. The main role of leptin is to regulate food intake and energy expenditure by reducing food intake and increasing sympathetic nervous system outflow, therefore inducing weight loss. Recent evidence showed that leptin levels fall during weight loss and increase brain activity in areas involved in emotional, cognitive, and sensory control of food intake [78]. Restoration of leptin levels maintains weight loss and reverses the changes in brain activity. Thus, leptin is a critical factor linking reduced energy stores to eating behavior. In obesity, the actions of both leptin and insulin within the liver are resistant. Therefore, in individuals with obesity, leptin levels are elevated, and this has been found to positively correlate with insulin resistance [78]. Leptin can impair the production of insulin and reduce the effects of insulin on the liver.

Treatment for Obesity and T2D

A modest weight loss of 5–10% has been shown to result in improvements in morbidity and mortality risks among individuals with overweight and obesity [79]. Thus, weight loss is typically prescribed to individuals with overweight and obesity. Obesity and T2D are comorbid conditions with approximately 85% of patients with T2D having overweight or obesity [69]. Moreover, excess weight has been associated with elevated blood glucose levels [80, 81]. Weight loss has been shown to result in improvements in glucose levels [82–86] and even complete remission of T2D [83, 84]. Therefore, treatments for obesity are often also prescribed for T2D. Treatment options for obesity and T2D are categorized into three domains: lifestyle, pharmacological, and surgical interventions.

Lifestyle Intervention

As with T2D, lifestyle intervention is the first-line treatment option for weight management. Lifestyle interventions for weight management consist of dietary, physical activity, or combined interventions with variable success (range: 2–13% of initial body weight loss [87, 88]). While in the short-term (<6 months), dietary and combined interventions appear to be equally more effective than those that are purely physical in nature, over the long term (≥1 year), combined interventions seem to have greater weight loss success [88–90].

The benefits of combined lifestyle interventions for glycemic control in individuals with impaired glucose tolerance (IGT) [91, 92] and T2D [93, 94] have been well established in large-scale randomized control trials. Specifically, the *Diabetes Prevention Program* (DPP) in the United States and *Finnish Diabetes Prevention study* (DPS) enrolled IGT patients and randomized them to an intensive combined lifestyle intervention program, or control, with the DPP program including a third arm prescribed metformin. Patients participating in the intensive lifestyle intervention had greater improvements in key glycemic indicators such as fasting plasma glucose [91, 92] and glycated hemoglobin [92] than controls. Moreover, a smaller proportion of patients progressed to T2D in intensive lifestyle intervention group than controls [91, 92] or those prescribed metformin [91]. In patients who already have T2D, combined lifestyle intervention can also result in significant improvements in glycemic control. The Look AHEAD study randomized patients with T2D to receive an intensive combined lifestyle intervention or a diabetes support and education group and also observed greater decreases in weight and glycated hemoglobin after 1 [93, 94] and 4 year(s) [94] of treatment in the intensive combined intervention group. Unfortunately, these improvements due to the lifestyle intervention decreased overtime [93, 94].

Currently, there is considerable disagreement regarding what is the most optimal diet, or physical activity type for weight management. For example, dietary recommendations for weight management once focused on decreasing not only caloric intake but also the intake of dietary fat as this macronutrient was thought to be associated with ill-health. However, results from several meta-analyses suggest that at 1 year there is no significant difference in the weight loss achieved by patients prescribed a low fat versus low carbohydrate diet [95–97]. When taking into consideration the management of T2D, certain types of diets may be more optimal as they are associated with not only weight loss but also improvements in glycemic control. Specifically, individuals who consumed a low carbohydrate diet had greater decreases in their glycated hemoglobin [95] than participants consuming a low fat diet.

Physical activity can be categorized as aerobic or anaerobic. Aerobic, also referred to as cardio, includes activities like running and dancing. Anaerobic, also referred to as resistance, is a type of activities that can only be performed in short bursts due to the muscle oxygen demand, such as weight lifting or sprinting. Research suggests that either aerobic or anaerobic exercise interventions can result in improvements in glycated hemoglobin; however, combined exercise interventions resulted in greater improvements than solely aerobic or anaerobic interventions [98]. Owing to the

health benefits associated with physical activity, the American College of Sports Medicine and the American Diabetes Association has released a joint statement that advocates for individuals with T2D participate in both aerobic and anaerobic physical activity weekly. Specifically, they recommend individuals with T2D participate in a minimum of 3 days/week of aerobic and 2–3 days/week of anaerobic activities for improvement in blood sugar [99]. For weight management, participating in both anaerobic and aerobic physical activity is also more beneficial than aerobic or resistance alone [100, 101]. Furthermore, a greater amount (>250 min/week vs. 150 min/week) of moderate to vigorous physical activity is recommended for significant weight loss [101].

Patients are able to achieve clinically significant improvements in their T2D and weight when implementing behavioral changes. Yet, these improvements are often transient in nature as patients are prone to regaining weight, or returning to previous habits [88, 102, 103]. This can be especially detrimental for patients with T2D as weight (re)gain is associated with a concomitant increases in glycated hemoglobin in populations with [104] and without T2D [105, 106]. Thus, the use of other interventions that can directly counteract physiological changes that make individuals prone to regaining weight, such as pharmacological or surgical interventions, may be advantageous.

Pharmacological Interventions

Pharmacological intervention is recommended for individuals who have attempted and previously failed at losing weight and have a BMI ≥30, or BMI ≥27 with at least one other medical condition [107]. Pharmaceuticals have a distinct advantage over lifestyle interventions as they directly target physiological changes that occur with and may inhibit weight loss and weight maintenance. Pharmaceutical intervention for weight can also provide additional benefits in the management of T2D beyond weight loss. Research suggest that taking weight management pharmaceuticals is associated with greater improvements in blood glucose levels and other metabolic parameters such as waist circumference and blood pressure than lifestyle intervention alone [108–110]. Moreover, patients who take weight management pharmaceuticals are also less likely to develop T2D [110], and patients with T2D have a greater rate of remission [85, 86]. Thus, effective interventions for weight management should commence as soon as T2D, or impaired glucose tolerance or abdominal obesity, is diagnosed.

Options for weight management for pharmaceuticals remain limited with only two agents available worldwide. Orlistat (Xenical), which has been available for over two decades, is the most widely approved weight management pharmaceutical. Its side effects include oily stools and fecal incontinence, which contribute to the high attrition rates (33–77% [111, 112]) observed among patients taking this agent. Patients prescribed orlistat lose significantly more weight than those just participating in lifestyle interventions, with T2D patients losing on average 4.6–6.2% of their initial body weight and significantly greater improvements in key diabetes indicators such as glycated hemoglobin and fasting blood glucose [113]. However, it is unclear whether these improvements in T2D indicators are due to the medication's effects, or to the amount of weight loss achieved.

A GLP1 analogue, liraglutide 3.0 mg (Saxenda), has been approved for use within the United States, Canada, Mexico, the United Arab Emirates, and most European countries. Several large randomized control trials, referred to as the *Satiety and Clinical Adiposity–Liraglutide Evidence in Non-Diabetic and Diabetic People* (SCALE), have examined the efficacy of this pharmaceutical for weight management. The only SCALE study that examined individuals with T2D observed that after 56 weeks of treatment, individuals taking the medication had a greater weight loss (6% vs. 2% weight loss) and improvements in glycemic control than those taking the placebo [114]. It is important to note that liraglutide 3.0 mg was initially prescribed and still remains on the market as a T2D medication (Victoza) at the maximum therapeutic dose of 1.8 mg, which may allude to greater beneficial effects in respective to the management of T2D compared to other weight management pharmaceuticals. Only one study has directly compared the efficacy of orlistat, liraglutide, and lifestyle modification for weight management, but it excluded individuals with T2D [109]. Nevertheless, patients in this study who were prescribed liraglutide 3.0 mg lost more weight and had greater improvements in their blood glucose than patients prescribed orlistat or just a lifestyle intervention after 20 and 56 weeks of treatment [109].

Other pharmaceuticals available for weight management include a phentermine and topiramate combination (Qsymia), a bupropion and naltrexone combination (Contrave), and lorcaserin (Belviq). However, these pharmaceuticals are only approved for weight management in the United States and are under review in Canada, Europe, and other countries. Several studies have examined the efficacy of these medications for glycemic control and weight management in individuals with T2D. All three of these medications resulted in significantly greater weight loss (lorcaserin: −9.3 vs. −7.5 kg [82], phentermine/topiramate: −9.1 vs. −2.6 kg [85], and bupropion/naltrexone: −5.3 vs. −1.9 kg [86]) than placebo. Moreover, patients with T2D had greater improvements in their glycated hemoglobin and required the addition of less T2D medication to control their blood sugars than those just participating in the lifestyle intervention [82, 85, 86].

The prescription of pharmaceuticals is much more common in the treatment of T2D than weight. This may be due

to the more acute detrimental effects that high blood glucose can have on a patient when the effects of excessive weight tend to occur over the long term. Diabetes medications can have a beneficial (i.e., metformin, liraglutide) or detrimental (i.e., insulin, secretagogues) effect on a patient's ability to lose weight [107, 115, 116]. Thus, it is important to consider the effects that these medications can have on a patient's weight prior to prescribing them. This is in line with recommendations from The Endocrine Society, which recommended weight-losing and weight-neutral medications as first- and second-line agents for T2D management in patients with overweight or obesity [107]. Further, if insulin therapy is necessary, it is recommended to co-prescribed a diabetes medication with weight negative properties to mitigate the weight gain typically associated with insulin [107]. Given the association between weight gain and elevated blood glucose levels [80, 81], it may be advantageous to prescribe weight neutral and weight negative T2D medications as first- and second-line treatment of diabetes in lean populations as well as overweight and obese.

Surgical Intervention

Compared to lifestyle and pharmaceutical interventions, patients who undergo bariatric surgery lose more weight and maintain a greater proportion of this loss over the long term, making bariatric surgery the most effective treatment for obesity [117]. However, there are lifelong dietary changes and potential complications that accompany this intervention [117–119], which had meant that until recently, bariatric surgery was reserved for individuals with severe obesity. Multiple international organizations [15, 16] recommend bariatric surgery for individuals who had previously failed at weight loss and have a BMI $\geq$40 kg/m^2 or a BMI $\geq$35 kg/m^2 with at least one comorbidity. However, with bariatric surgery being recognized as a metabolic surgery due to the reduction in cardiometabolic risk factor levels observed post-surgery, as well as due to the differences for disease risk attributed to excess weight by ethnicity, these organizations now recommend consideration of patients with lower (i.e., <35 kg/m^2) BMIs for this surgery.

The International Federation for the Surgery of Obesity and Metabolic Disorders surveyed national organizations in 56 countries to determine trends in bariatric surgery. This survey contained 16 possible procedures. Sleeve gastrectomy was the most common procedure (45.9%), followed by roux-en-y gastric bypass (39.6%), and then gastric banding (7.4%), with no other procedure accounting for greater than 2% of procedures performed worldwide [120]. Below is a brief description of the three most common surgical procedures:

- Roux-En-Y gastric bypass: A small portion of the upper stomach is made into a pouch and is attached to the jejunum, bypassing a portion of the digestive system and making a y shape, which gives this procedure its name [117]. This procedure is referred to as both a restrictive and malabsportive weight loss procedure. It is considered restrictive as the resizing of the stomach restricts the amount of food that a patient can consume and malabsorptive, as bypassing part of the stomach and intestine results in decreased absorption of nutrients.
- Sleeve gastrectomy: A large portion of the stomach is removed, and the remainder is stapled closed resulting in a smaller tubular shaped stomach [119]. This is a purely restrictive as the new smaller size of the stomach decreases the amount of calories the patient can consume [121], but no bypassing of the digestive system takes place to result in malabsoprtion.
- Gastric banding: A small, thin band, typically made of a flexible material such as silicon, is placed around the upper stomach to create a pouch [117]. Similar to the sleeve gastrectomy, this is a purely restrictive procedure. For the majority of patients, frequent adjustments to the band are necessary within the first 2 years to promote and maintain weight loss [122].

Bariatric surgery is a relatively safe procedure, with 30-day mortality rates ranging from 0.05% to 0.5% [119, 123] and 30-day complication rates of 1.4–5.9% [119]. One-year post-surgery, patients who underwent sleeve gastrectomy (range: 68.2–69.7% excess weight [123, 124]) and roux-en-y (60.5–62.6% excess weight [118, 123, 124] appear to lose comparable amounts of weight, and patients who underwent gastric banding (42.6–47.5% excess weight [118, 123]) have considerably less weight loss.

Bariatric surgery may be one of the best tools for the management and treatment of T2D. Patients with T2D typically lose less weight than nondiabetic populations in lifestyle and pharmaceutical interventions. However, a meta-analysis observed that patients in the T2D sub-sample lost more weight than the full sample of patients with and without T2D. This may suggest the lower mean weight loss in the full sample was due to less optimal weight outcomes in patients without T2D [84]. Moreover 86.6% of patients with T2D experience improved or complete resolution of their diabetes post-surgery [84]. Over half of patients with T2D that undergo bariatric surgery have complete resolution of their diabetes regardless of the procedure; however, the proportion of patients who go into remission is significantly greater for those with sleeve gastrectomy (79.7%) and roux-en-y (80.3%) than those with gastric banding (56.7%) [84]. Lastly, patients who undergo bariatric surgery can have additional benefits beyond significant weight loss and improvements or resolution of their T2D or IGT, such as

a decrease in mortality risk [125–127] and risk of T2D complications [126, 127].

Gastric banding is now being recognized as an inferior bariatric surgery procedure, likely due to the decreased weight loss and improvements in comorbidities. Furthermore, due to complications and insufficient weight loss, over half of patients who undergo gastric banding will need band removal and conversion to another type of bariatric procedure [128]. Owing to these suboptimal outcomes, the Canadian Diabetes Association has recommended against the use of the gastric band [12]. This may mean that other procedures will increase in popularity as gastric banding falls into disuse. For example, a less common surgery that is gaining traction is the bilio-pancreatic diversion with the duodenal switch. This procedure is more invasive than the other three procedures discussed but has better results in terms of diabetes remission and long-term weight loss than the more common alternatives (i.e., roux-en-y bypass and gastric banding) [84].

Conclusion

Obesity is a chronic disease categorized by excessive weight with ill-health effects. BMI is the most common tool to categorize obesity, with a recommended threshold of ≥30 kg/m^2. There are many different methods to assess obesity; however, due to considerable differences in the associations of excess weight and ill-health based on age, sex, and ethnicity, heavy criticism exists regarding the use of universal thresholds. Nonetheless, these measurements remain in use due to their ability to assess the potential health impacts of excess weight.

Obesity is a chronic, multifactorial disease. Multiple factors have been identified that are associated with developing obesity, with genetics, diet, and physical activity being the factors that are most salient to obesity and T2D. Mechanistic studies have determined the presence of several genes associated with having obesity, and epidemiological studies have further supported this evidence. Increased caloric intake, macronutrient content, and lack of physical activity also play a role in the development of obesity, but these are modifiable risk factors, which can be manipulated in the treatment of these conditions.

Treatment options for obesity, as with T2D, can be categorized as lifestyle,

Pharmacological, or surgical. Lifestyle intervention is a first line of treatment; however, treatment benefits are often not maintained over the long term. Thus, medications and surgery provide additional opportunities for weight management and have been shown to have greater efficacy for weight loss and improvements in comorbidities than lifestyle interventions alone.

Concluding Remarks

1. Obesity is a chronic medical characterized by excess weight associated with ill-health effects. For trend analysis and owing to the ease of measurement, a BMI ≥ 30 kg/m^2 is the most frequently used definition.
2. A multitude of factors contribute to the development of obesity; however, genetics, diet, and physical activity are the most important. T2D is closely linked to obesity and share similar biological processes and epidemiology.
3. Lifestyle, pharmaceutical, and surgical treatment options all have the potential to improve and eliminate the negative health effects of T2D or excess weight; however, surgical interventions are the most successful.

Multiple Choice Questions

1. Body mass index is a tool commonly used to classify an individual as having obesity. What threshold is used to define obesity?
   (a) Greater than or equal to 27.5 kg/m^2
   (b) **Greater than or equal to 30 kg/m^2**
   Although there is variability in the ill-health effects associated with a given BMI based on ethnicity, the World Health Organization still recommends a threshold of 30 kg/m^2 to define obesity.
   (c) Greater than or equal to 35 kg/m^2
   (d) Greater than or equal to 40 kg/m^2
   (e) No threshold exists
2. Which of the following are methods used to assess obesity?
   (a) Skinfold measures
   (b) Dual Energy X-ray Absorptiometry (DEXA)
   (c) Forehead circumference
   (d) **A & B**
   Many circumference measurements are used to assess obesity such as waist, hip, and neck circumferences, but forehead circumference is not one of them.
   (e) All of the above
3. What are some common demographics that make the use of absolute thresholds for the assessment of obesity and its ill-health effects difficult?
   (a) Age
   (b) Sex
   (c) Ethnicity
   (d) **All of the above**
   Age, sex, and ethnicity can all change the association that excess weight can have with ill-health.

For example, some excess weight may actually be beneficial to elderly populations as it has been shown to decrease frailty. Women are able to have higher body fat percentages than men without ill-health effects. Furthermore, certain ethnicities, for example, people of Asian descent, start to have exhibit ill-health effects at lower levels of body fat than White counterparts.

(e) None of the above

4. Which of the following is true regarding the notion that there is hereditary component to the development of obesity?
   (a) Children who have one parent with obesity are at a greater risk for developing obesity than those with two
   (b) BMIs of monozygotic and dizygotic twins raised together are more similar than those raised apart
   (c) Genes have been found that are associated with hypophagia
   (d) All of the above
   (e) **None of the above**

   Children who have two parents with obesity are at a greater risk of having obesity, and genes have been identified associated with hyperphagia (excessive eating). Furthermore, while it is true that the BMI of twins reared together are more similar than those raised apart, there is still a strong association in the BMIs of twins reared apart.
5. Which of the following are patient modifiable risk factors associated with the development of obesity?
   (a) **Physical activity**

   Physical activity is the only factor that listed that individuals have control over. While it is possible for the built environment to be modified to encourage more physical activity, this is not something that an individual would be able to change by themselves.

   (b) The built environment
   (c) Genetics
   (d) Type 2 diabetes
   (e) A & B
6. Which of the following diet and physical activity factors contribute to the development of obesity?
   (a) Excessive caloric intake
   (b) Being sedentary
   (c) Macronutrient content of diet
   (d) Employment
   (e) **All of the above**

   Beyond the typical modifiable factors that are addressed in the treatment of obesity, such as diet and physical activity, other factors, such as your employment, can contribute to weight gain. This is due to occupational shifts that have occurred during the twentieth century that have resulted in an increase in management and decrease in labor type jobs.
7. Adipokines secreted by adipocytes, regulate body weight, appetite, and energy expenditure. They also contribute to increasing insulin resistance by?
   (a) Increasing lipid production
   (b) Decreasing leptin levels
   (c) **Modulating insulin sensitivity**

   In addition to regulating body weight, appetite, and energy expenditure, adipokines also modulate insulin sensitivity. The increased production of free fatty acids and some adipokines may cause insulin resistance in skeletal muscle and liver.

   (d) Promoting beta cell function
   (e) Reducing markers of inflammation
8. Which of the following statements is true regarding low fat and low carbohydrate diets?
   (a) Low fat diets are more beneficial for weight loss, but low fat and low carbohydrate diets are equally effective for managing diabetes management.
   (b) Low carbohydrate diets are more beneficial for weight loss, but low fat and low carbohydrate diets are equally effective for diabetes management.
   (c) Low fat and low carbohydrates are equally beneficial for weight loss, but low fat diets are more beneficial for diabetes management.
   (d) **Low fat and low carbohydrates are equally beneficial for weight loss, but low carbohydrate diets are more beneficial for diabetes management**.

   While low fat and low carbohydrates do appear to be equally effective for weight management, diets low in carbohydrates appears to be more beneficial for patients with T2D. Indeed, research has suggested that T2D consuming diets lower in carbohydrates will have greater improvements in glycemic control than consuming a low fat diet.

   (e) Low fat and low carbohydrate diets are equally effective in the management of obesity and diabetes.
9. Which of the following statements is false regarding weight management medications:
   (a) **Weight management medications decrease weight, but do not provide any benefits for the management of diabetes**

   Each of the available weight management medications have been tested in populations with T2D, and all have been shown to improvement glycemic control. Furthermore, these patients typically require the addition of less glycemic medication than those given a placebo.

   (b) Liraglutide 3.0 mg is more effective for glycemic control than orlistat.

(c) All approved weight management medications are associated with greater improvements in glycated hemoglobin than lifestyle intervention alone.
(d) Patients prescribed weight management medications lose significantly more weight than those participating in only lifestyle interventions.
(e) Liraglutide, a weight management medication, is also available as a T2D medication at a lower therapeutic dose.

10. Which of the following correctly lists the three treatment options for obesity and T2D in order from most to least effective?
(a) Medication, lifestyle, and surgical
(b) Lifestyle, medication, and surgical
(c) **Surgical, medication, lifestyle**
Patients who undergo surgical intervention lose more weight and have greater rates in T2D remission than patients taking weight management medications or just lifestyle intervention. Furthermore, patients taking weight management medications have greater improvements than lifestyle alone.
(d) Surgical, lifestyle, medication
(e) They are all equally effective treatments for weight and diabetes management.

Glossary

Bariatric Surgery It is a type of surgical procedure that decreases the amount of calories a patient can consume and/or digests to result in significant weight loss. Types of bariatric surgery include roux-en-y gastric bypass, sleeve gastrectomy, and gastric banding.

Body Fat It is the amount of subcutaneous and visceral fat in a person's body that can be presented as an absolute value or percentage.

Body Mass Index It is the most common tool to assess obesity. It is calculated by dividing weight in kilograms by height in meters squared.

Malabsorptive Bariatric Surgery It is a bariatric surgery procedure that alters a patient's digestive tract to decrease the amount of nutrients they can absorb from calories consumed. Examples of types of bariatric surgery that use this technique include the roux-en-y gastric bypass and bilio-pancreatic diversion with the duodenal switch.

Metabolic Surgery It is a newer term used to refer to bariatric surgery owing to the drastic improvements in metabolic conditions that have been observed post-surgery.

Obesity It is excess body weight associated with ill-health. Multiple objective methods exist to classify obesity, with a BMI greater than or equal to 30 kg/m^2 the most common.

Restrictive Bariatric Surgery It is a bariatric surgery procedure that decreases the amount of calories a patient can consume by decreasing the size of the stomach. Examples of types of bariatric surgery that use this technique include the sleeve gastrectomy and gastric banding.

Subcutaneous Fat It is the type of body fat located just beneath the skin and can be felt by pinching the skin.

Visceral Fat It is the type of body fat located internally around the organs. As such, visceral fat is also called organ fat.

Metabolic and Bariatric Surgery in Diabetes Management

42

Luis Zurita Macías Valadez, María E. Frigolet, Raúl Marín Dominguez, Radu Pescarus, Carlos Zerrweck, Vanessa Boudreau, Aristithes Doumouras, Tyler Cookson, and Mehran Anvari

Objectives

1. To describe the types and principles of the distinct bariatric surgical techniques
2. To define the clinical outcomes of most performed bariatric procedures
3. To illustrate the molecular and other mechanisms that explain metabolic outcomes of bariatric surgery
4. To explain the evolving bariatric techniques

Introduction

Bariatric surgery is the conjunct of surgical techniques to induce weight loss and metabolic health in morbidly obese patients. The recommendations for bariatric surgery are BMI ≥ 40 kg/m^2 or BMI 35–39.9 kg/m^2 with at least one comorbidity associated to obesity or clinical condition with impaired quality of life [1] (Table 42.1).

Bariatric surgery is currently the most effective treatment for severe obesity. Its effects are defined according to the amount of weight loss (surgery success has been defined as ≥50% excess weight loss [2]), mortality, quality of life, and social function, which are all positively modified as observed in several studies [3].

Bariatric surgery first evolved from a bowel resection [4], and the first Roux-en-Y gastric bypass (RYGB) [5] was intended for the treatment of obesity [4, 5]. Since then, numerous techniques have been introduced, and technology has migrated the open-surgery approach to the endoscopic, laparoscopic, and robotic approaches. Such minimally invasive methodologies and the enhanced recovery aim after bariatric surgery have significantly reduced risks and complications driven by the surgery.

Throughout time, metabolic improvements after bariatric surgery were responsible for shifting bariatric surgery to metabolic surgery, a concept first proposed by Buchwald and Varco in 1978 [6, 7]. For instance, type 2 diabetes (T2D) and other various metabolic abnormalities were resolved or remitted shortly after surgery. Metabolic surgery has been proved by randomized controlled trials to be safe and a more effective treatment for obesity and T2D compared with conventional medical multidisciplinary approach (lifestyle changes or pharmacotherapy) [8–10].

In fact, metabolic surgery could be considered in obesity class 1 (BMI 30–34.9 kg/m^2) and diabetic subjects when hyperglycemia is inadequately controlled despite medical treatment [11]. Thus, since 2016, the American Diabetes Association (ADA) includes metabolic/bariatric surgery in their Standards of Care for Diabetes algorithm [12].

Different recommendations in this regard are still valid, and consensus should be gained in years to come. Finally, bariatric surgery and its metabolic effects represent, to date, the most effectual tool for obesity treatment. Importantly, the investigation of the mechanisms associated with massive weight loss and metabolic improvements will enlighten the medical community toward the understanding of processes involved in the development of obesity and related diseases.

Table 42.1 Obesity-related comorbidities to indicate bariatric surgery in patients with a BMI of 35–39.9 kg/m^2

T2D	Obesity-hypoventilation syndrome
High risk of T2D-insulin resistance, prediabetes, and/or metabolic syndrome	Pickwickian syndrome
Nonalcoholic fatty liver disease (NALFD)	Idiopathic intracranial hypertension
Nonalcoholic steatohepatitis (NASH)	Gastroesophageal reflux disease (GERD)
Obstructive sleep apnea (OSA)	Severe venous stasis disease
Osteoarthritis (knee/hip)	Impaired motility due to obesity
Urinary stress incontinence	Considerably impaired quality of life

Types of Bariatric Surgery

Traditionally, bariatric procedures have been characterized as restrictive [laparoscopic adjustable gastric banding (LAGB), sleeve gastrectomy (SG)]; malabsorptive [biliopancreatic diversion with duodenal switch (BPD-DS), single anastomosis duodeno-ileal bypass with sleeve gastrectomy (SADI-S)]; and mixed procedures [Roux-en-Y gastric bypass (RYGB)] [1]. However, now we know that not only energy restriction and nutrient absorption explain profound weight loss, but other mechanisms are involved. Here, we describe the most common techniques and their mechanisms of action as well as their influence on improved metabolism.

Laparoscopic Adjustable Gastric Band (LAGB)

In this procedure, a silicone band is placed around the gastric cardias, creating a small gastric pouch (approximately 30 mL) and restricting food intake. The band is connected to a port that is fixed at the abdominal wall [13]. Through this port, sterile saline is injected to adjust the inner diameter of the band. The reduction of this diameter decreases the gastric pouch emptying and consequent food intake. The adjustment of the band can be changed over time depending on the evolution of the patient (Fig. 42.1a).

Sleeve Gastrectomy (SG)

SG was initially performed as the first step of the laparoscopic biliopancreatic diversion to reduce the high morbidity in super-obese and/or high-risk patients [14]. Because of adequate weight loss in this group of patients, SG was accepted in 2012 by the American Society for Metabolic and Bariatric Surgery (ASMBS) as an independent bariatric procedure [15]. SG is currently the most common procedure performed in the United States [16] and worldwide [17, 18]. The latter is because while it offers adequate success rates, it is also a less technically challenging procedure, representing lower morbidity and mortality compared with the RYGB [19].

The SG technique consists of the dissection of the greater curvature of the stomach. This is performed from 2 to 6 cm proximal to the pylorus toward the angle of His. Then, an orogastric bougie (32–36 Fr) is placed and used as a guide for vertical gastric transection. Approximately 80% of the body and gastric fundus is resected and removed, leaving a tubular pouch or sleeve-shaped stomach [19, 20] (Fig. 42.1b).

Roux-en-Y Gastric Bypass (RYGB)

Currently, RYGB is considered the "gold-standard" weight loss surgery and was, until recent years, the most frequently performed bariatric surgery [17]. The procedure has several components: gastric remnant, gastric pouch, gastrojejunal and jejunojejunal anastomosis, alimentary limb, biliopancreatic limb, and common limb. A small gastric pouch (30–50 mL) is constructed by dividing the gastric cardias from the rest of the stomach. Then, the jejunum is divided 40–150 cm distally to the ligament of Treitz, creating two limbs. The proximal limb is called biliopancreatic limb (BPL) (from the excluded stomach to the proximal division of the jejunum) and distal limb, which will be connected to the gastric pouch (gastrojejunal anastomosis). The biliopancreatic limb is anastomosed to the jejunum (from 75 to 150 cm distally to the gastrojejunal anastomosis). This anastomosis will divide the distal limb into alimentary limb (from GJA to JJA) and common limb. The distal intestine is called common limb (from JJA to terminal ileum) [21] (Fig. 42.1c).

Biliopancreatic Diversion with Duodenal Switch (BPD-DS)

BPD-DS is the most effective surgical treatment for severe obesity and T2D [8, 22]. Nevertheless, because it is a technically challenging surgery with the highest postoperative complication rate, this is the most infrequent procedure [23]. The technique consists of two stages, which may be performed in one or two surgeries depending on the presence of super-obesity and, thus, the patients' risk. During the first stage, an SG is performed. In the second stage, the duodenum is transected, and its proximal part is anastomosed at 250 cm proximal to the ileocecal valve (alimentary limb). The excluded limb (biliopancreatic limb) is connected, creating an ileal-ileal anasto-

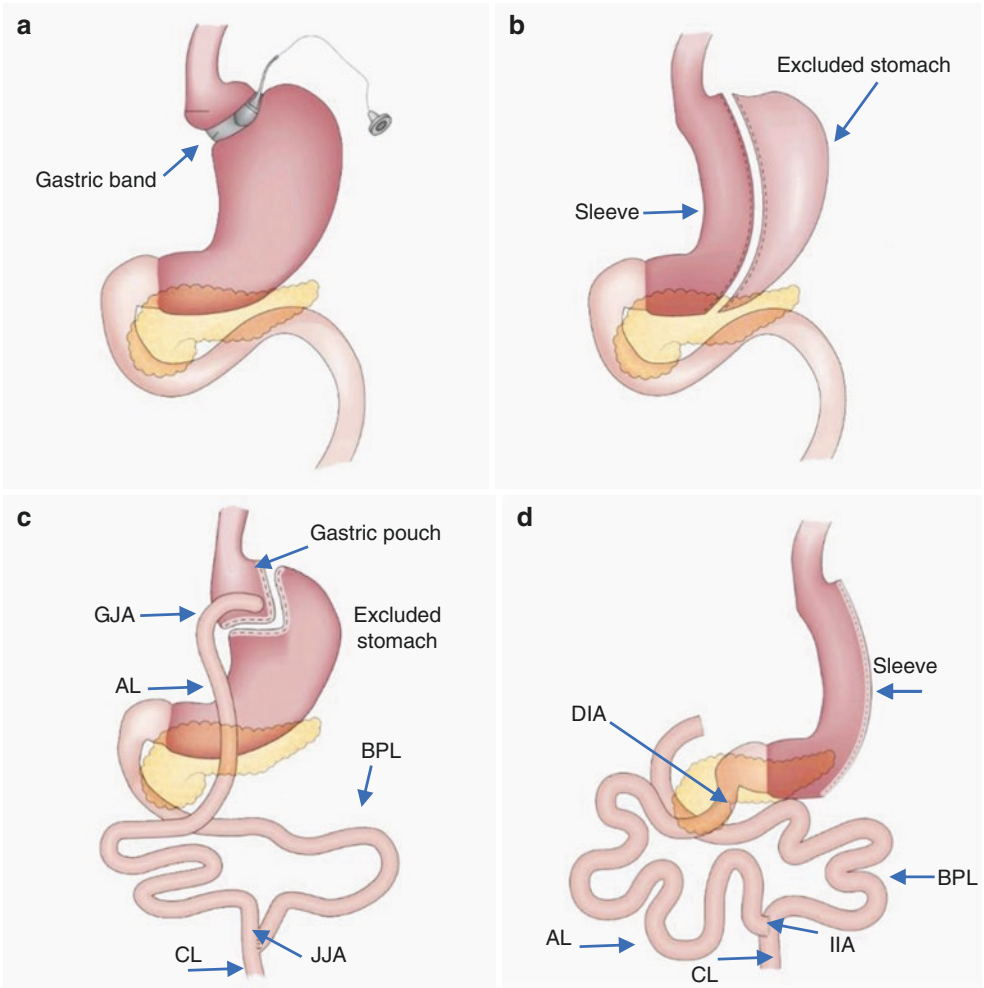

Fig. 42.1 (**a**) Laparoscopic adjustable gastric band (LAGB). (**b**) Sleeve gastrectomy (SG). (**c**) Roux-en-Y gastric bypass (RYGB). (**d**) Biliopancreatic diversion with duodenal switch (BPD-DS). *GJA* gastrojejunal anastomosis, *JJA* jejunojejunal anastomosis, *AL* alimentary limb, *BPL* biliopancreatic limb, *CL* common limb, *DIA* duodeno-ileal anastomosis, *IIA* ileoileal anastomosis

mosis, 100 cm proximal to the ileocecal valve, generating a common limb in a *Roux-en-Y* configuration. The main difference between a BPD-DS and an RYGB is the length of the small intestine bypassed, which, in the case of BPD-DS, is substantially greater than RYGB, resulting in increased malabsorption of nutrients (Fig. 42.1d).

One Anastomosis Gastric Bypass (OAGB)

OAGB, initially named mini-gastric bypass, was introduced in 2001 by Rutledge et al. as a simple and effective treatment for morbid obesity [24]. In 2005, Carbajo et al. proposed a modification of this technique and changed the name to one anastomosis gastric bypass [25]. There is currently an increasing number of OAGB performed worldwide [26–29]. OAGB is not yet accepted as a treatment for morbid obesity in the United States due to a lack of prospective and long-term follow-up studies [29].

The OAGB technique begins with the construction of a long sleeve-like gastric pouch using a 36 Fr bougie as a guide. Then, this gastric pouch is anastomosed to the jejunum (from 200 to 300 cm distally to the ligament of Treitz) in a Billroth II-like style [30, 31].

Single Anastomosis Duodeno-ileal Bypass with Sleeve Gastrectomy (SADI-S)

SADI-S is a relatively new surgical technique, introduced in 2007 by Sanchez Pernaute et al., described as a modification of BPD-DS in an effort to simplify the technique and reduce the complications associated to a long anesthetic procedure [32]. In 2020, the ASMBS accepted the SADI-S technique as an appropriate metabolic bariatric surgery [24].

The SADI-S technique comprises two stages. First, a tubular gastric pouch is created, wider than an SG, using a 54 Fr bougie. Second, the duodenum is sectioned, and its distal part is anastomosed with the ileum (200–300 cm proximal to the ileocecal valve). This Billroth II-like configuration in comparison to the *Roux-en-Y* decreases by half the number of anastomosis and has no mesentery opening, reducing operative time and the risk of intestinal obstruction [32].

Mechanisms of Action of Bariatric Surgery

Despite the effectiveness of bariatric surgery for the treatment of morbid obesity and associated metabolic diseases [9, 33, 34], its underlying mechanisms of action remain unclear. Several mechanisms have been related to bariatric/metabolic surgery, from food intake restriction and malabsorption, hormone release, and gut microbiota composition modifications, all of which influence metabolism.

Gastric Volume Restriction

Over the years different gastric restriction techniques have been performed, varying from 15 to 200 mL gastric capacity; nevertheless, no correlation has been found between stomach volume and weight loss [35]. Other mechanisms like gastric emptying speed, increase of intragastric pressure, as well as changes in gastrointestinal hormones may be involved in weight loss in the gastric restrictive bariatric procedures.

Malabsorption

The malabsorption of nutrients is achieved after bypassing distinct lengths of the small intestine. In 2010, Odstrcil et al. reported that malabsorption accounted for approximately 6% and 11% of the total reduction in combustible energy absorption at 5 and 14 months after RYGB, secondary to fat malabsorption with little or no malabsorption of proteins and carbohydrates [36].

Enteroendocrine Modifications

Since several hormones that control appetite and satiety processes are derived from the gastrointestinal tract, and bariatric surgery modifies the size and capacity of the stomach and/or the gut, then metabolic changes driven by the surgery have been found associated with altered pancreatic and gut peptide profiles [37]. Here, we will review the peptides that have been investigated and related to the metabolic outcomes of bariatric surgery.

Ghrelin

Ghrelin is secreted by the gastric and duodenal enteroendocrine cells and is not fully activated until acetylated. Once acetylated due to the action of ghrelin-O-acyltransferase (GOAT), it exerts an orexigenic action at the central nervous system (CNS), increasing food intake. In fasting conditions, ghrelin is acetylated, which is able to activate the growth hormone secretagogue receptor (GHSR) found in the hypothalamus and pituitary glands [38]. During obesity, the acetylated levels of ghrelin are apparently higher compared to those levels of ghrelin in lean subjects [39].

After bariatric surgery, mixed results regarding the circulating levels of ghrelin have been found, depending on the surgical technique. While gastric banding has been associated with increased ghrelin concentrations [40], RYGB and SG have been related to decreased levels of the hormone [41–43]. This could be attributed to the fact that RYGB excludes the gastric fundus, reducing the contact between ghrelin-producing cells and ingested food. However, further research is needed to elucidate the involvement of ghrelin in the short- and long-term effects of bariatric and metabolic surgery.

Incretins

Interestingly, weight loss or regain following combined restrictive-malabsorptive bariatric surgery is not predictive of diabetes remission, and glycemic control has been observed to improve soon after surgery, before clinically significant weight loss [44–47]. Due to the timing of these observations following surgery, other mechanisms related to the anatomical reconstruction of the GI tract are likely present to account for this. One explanation for such rapid responses relies on the variable concentrations of incretins after surgery.

Incretins are intestinal peptides known for stimulating insulin production after food intake. The main incretins are GIP (glucose-dependent insulinotropic polypeptide) and GLP-1 (glucagon-like peptide-1), which are specifically secreted from K cells in the small intestine and L cells in the ileum and colon, respectively [48]. Some clinical reports have described reduced fasting and postprandial concentrations of GIP after bariatric surgery [49, 50]. However, other groups have not found the same, and it is possible that these controversies rely on the type of procedure and diabetes diagnosis before surgery [51–53].

On the other hand, GLP-1 has shown, more consistently, that its concentrations are modified shortly after bariatric surgery and that this peptide represents a possible and partial explanation for some metabolic consequences of the surgery. Although using a small cohort, a prospective study found that total GLP-1 levels and the incretin effect were dramatically increased within 1 month of RYGB surgery and prior to clinically significant weight loss [52].

Indeed, analogs of GLP-1 (i.e., liraglutide, semaglutide) have been used for the treatment of both obesity and diabetes, establishing weight loss reductions of 5–10% and improved glucose tolerance in patients with T2D [54]. Acute and marked increases of circulating GLP-1 after LAGB, RYGB, and SG have been reported by several [55–57], and such increases are not achieved by patients that lose similar amounts of weight due to energy restriction [52]. Furthermore, it has also been suggested that higher serum concentrations of GLP-1 are associated with better weight loss results 1 year after the surgery [42].

Mechanisms that possibly explain rises in GLP-1 after surgery highlight the “hindgut hypothesis” versus the “foregut hypothesis [58, 59]. The former states that improved glucose homeostasis is caused by the delivery of nutrients to the

distal part of the small intestine to enhance the secretion of factors involved in glucose metabolism, and the latter adjudicates the lower glucose concentrations to the exclusion of the duodenum and jejunum from their interaction with nutrients. The main candidate molecule supporting the hindgut hypothesis is GLP-1, which exerts its effects via several pathways. First, the peptide decreases appetite and gastrointestinal motility in humans, reducing food consumption [60]. Also, the insulinotropic properties of GLP-1 are associated with increased insulin gene transcription and biosynthesis, as well as increased *glucokinase* and *Glut2* gene expression [61, 62]. Finally, GLP-1 has been associated with increased beta cell proliferation and decreased apoptosis [63].

Although the effects of GLP-1 account for some of the observed consequences of bariatric surgery, additional mechanisms are involved. For instance, humans using the specific GLP-1 receptor antagonist exendin 9-39 and animal models that lack GLP-1 receptor expression and, thus, have GLP-1 ablated response show similar weight loss after RYGB and SG [64], evidencing the influence of other factors in the process.

Other gut hormones that have been found implicated in the metabolic changes after bariatric surgery are cholecystokinin (CCK), pancreatic peptide YY (PYY), pancreatic polypeptide (PP), and secretin, among others. CCK is a hunger suppressant and a stimulator of digestion, which apparently increases after SG more than after RYGB [65, 66]. PYY delays gastric emptying, alters colon motility, and regulates appetite centrally [67–69]. Seemingly, PYY increases postprandially after bariatric surgery independent of the type of procedure [55]. Despite the extensive research and recent findings, further research is needed to better understand the role of these gut hormones in bariatric surgery.

Adipokines

Several adipokines (molecules that are released from adipose tissue) have been explored regarding their concentrations and influence over metabolic surgery. The most well-known adipokines are leptin and adiponectin. Leptin represents the communicator between adipose tissue and the CNS to suppress food intake during energy sufficiency [70]. During obesity conditions, resistance to the action of leptin concurs with hyperleptinemia. Adiponectin acts on peripheral tissues, exerts anti-inflammatory and insulin-sensitizing actions, and is decreased in serum of obese subjects [71]. In fact, the secretion of this adipokine is considered to be a hallmark of healthy adipocyte function [72]. After bariatric surgery, leptin decreases and adiponectin increases, which suggests gain of adequate function of the adipose tissue [73–77]. Interestingly, some groups found that adiponectin production was significantly increased 2 weeks after the surgery when weight loss has not occurred yet, meaning that adipokine promotion is independent of massive weight loss [78]. Along with adipokine secretion modifications, adipocyte size and adipose tissue structure have also been reported different after surgery [79]. The surgery-derived modifications in adipose tissue could be contributing to decreased chronic inflammation, which is thought to be one of the most important mediators of metabolic improvement after surgery. However, the global contribution of adipose tissue and derived hormones on metabolic improvements mediated by bariatric surgery needs to be revealed yet.

Gut Microbiota

The human intestinal tract contains an extraordinary conjunct of microorganisms, namely, the bacterial component of the human gut microbiota. The number of genes in the human gut microbiota exceeds the human genome by 150-fold [80], and it confers metabolic advantages such as vitamin and fatty acid generation, carbohydrate fermentation, and bile acid metabolism.

It has been shown that in addition to weight loss and glucose tolerance, RYGB modifies gut microbiota composition and diversity within 3 months and later, during a long-term period [81]. Compared with controls, and at the phylum level, RYGB increased the abundance of Proteobacteria and Bacteroidetes and decreased Firmicutes [82–84].

Although SG has also been related to microbiota modifications, RYGB has more robust effect on the composition of gut microbiota. One possible reason for this difference is that compared with RYGB, SG induces relatively mild physical manipulations of the intestinal tract. Additionally, with exposure of the luminal contents of the intestine to an aerobic environment during prolonged surgery or increased concentrations of swallowed air reaching the gut with RYGB compared to SG, the survival of obligate anaerobic bacteria is threatened, and it may contribute to the expansion of aerobic bacteria populations in the gut microbiota following bariatric/metabolic surgery.

Bile Acids

Bile acids play a role in glucose and lipid homeostasis. The bile acid receptor FXR not only regulates bile acid synthesis but also stimulates glycogen synthesis, decreases gluconeogenesis, and increases glycolysis [85]. Bile acid receptor TGR5 activation has been associated with gallbladder filling, modulation of energy expenditure, GLP-1 release from L cells, reduction of inflammatory mediators, and suppression of hepatic glycogenolysis [72, 86–89]. Multiple studies have reported increased fasting and postprandial bile acid concentrations following RYGB [90–92]. The mechanisms involved have not been identified. Several physiologic processes altered by metabolic surgery are associated to elevated concentrations of bile acids. Whether these processes are modified by the change in bile acid concentrations remains unclear.

Histological and Anatomical Changes

Alterations in pancreatic and hepatic tissue and blood flow can be seen after bariatric surgery. Immonen et al. reported that diabetic patients subjected to bariatric surgery experienced a normalization of hepatic fat content and a decrease in liver volume, as well as an increase in insulin-mediated hepatic glucose uptake, which was negatively correlated with liver fat content without any changes in BMI, suggesting a direct impact in hepatic glucose regulation [93]. Honka et al. reported that patients that underwent bariatric surgery had a decreased pancreatic lipid content and pancreatic blood flow. Glucose tolerance was found to be inversely correlated to pancreatic fat and decreased pancreatic blood flow associated to improvement of β-cell function [94].

In summary, the improvements in systemic metabolism and mainly in T2D after bariatric surgery are due to histological changes, modifications in several hormonal factors, gut microbiota composition, and their interaction. This is still under investigation, and so far, we can point out to some gut and adipose molecules as well as the microbiome, which have been associated with the amelioration of metabolic syndrome that accompanies bariatric surgery. Finally, the complex interaction between bariatric surgery, weight loss, and metabolic improvements reveals that the restriction or malabsorption components are no longer applicable to explain by themselves the effects of the surgery.

Outcomes After Metabolic Surgery

Bariatric surgery's main indication is for weight loss in individuals with obesity. Through manipulating the GI tract, bariatric surgery causes a plethora of effects that achieve substantial weight loss in a high proportion of patients. Importantly, this GI tract manipulation has effects beyond weight loss and has effects on several important metabolic disorders. In this way, bariatric surgery is a potential option for treatment for individuals with diabetes of all weights. Accordingly, this section will discuss the weight and diabetes outcomes following metabolic surgery and the implications of bariatric and metabolic surgery on other obesity-related comorbidities using an evidence-based approach.

Weight Loss After Metabolic Surgery

The weight loss component of metabolic surgery remains its most widespread indication and is the clear gold standard in the treatment of severe obesity. Patients that undergo metabolic surgery show both statistically and clinically significant weight loss soon after surgery that is maintained for several years [9, 33, 44, 95–99]. Specifically, total body weight loss at 1 year after metabolic surgery is about 25–30%, compared to 5–10% weight loss with medical therapy, and is accompanied by large reductions in body mass index (BMI) and waist circumference [33, 44, 96, 98]. At 1 year, reductions in BMI range from 19.6% to 27.6% for surgical patients compared to 1.81% to 10.14% for medical therapy patients; at 2–3 years, reductions range from 19.1% to 33.8% for surgical patients and 4.4% to 4.7% for medical therapy patients; and at 5 years, reductions range from 18.6% to 21.9% for surgical patients compared to 6.59% for medical therapy patients [9, 33, 44, 95–99]. Similarly, reductions in waist circumference at 1 year range from 17.5% to 22.8% for surgical patients and 3.6% to 7.2% for medical therapy patients; at 2–3 years, reductions range from 12.8% to 20.7% for surgical patients compared to 1.5% to 7.7% for medical therapy patients; and at 5 years, reductions range from 12.2% to 14.7% for surgical patients and 1.3% for medical therapy alone [9, 33, 44, 95, 96, 98, 99]. One of the most eminent trials in this area is the STAMPEDE trial, which randomized 150 obese patients with uncontrolled T2D to receive either intensive medical therapy alone or intensive medical therapy plus RYGB or SG [33]. A 5-year follow-up to the STAMPEDE trial showed a total body weight loss of 18% for SG and 22% for RYGB compared to 6% for medical therapy alone [9]. Moreover, metabolic surgery is much more successful than medical therapy at initiating and maintaining weight loss in morbidly obese patients with long-standing T2D.

Diabetes Remission and Main Diabetes-Associated Abnormalities Following Metabolic Surgery

Although bariatric surgical techniques have been established for the treatment of obesity by promoting weight loss and reshaping intestinal hormone signals responsible for postprandial satiety, nutrient absorption, and insulin sensitivity, the use of these techniques for the primary purpose of treating obesity-related comorbidities is still not as widely accepted compared to use primarily for weight loss. There is, however, evidence to support the use of bariatric surgical techniques in patients with T2D. With data showing that diabetic patients with obesity had increased remission rates following bariatric surgery, investigations focused on bariatric surgery to specifically manage T2D. Compiling this data in 2009, a large meta-analysis ultimately consisting of 3188 T2D patients showed that diabetes completely resolved in 78.1% of patients and either improved or resolved in 86.6% of patients following bariatric surgery [100].

Evidence from Randomized Controlled Trials

Currently, it is difficult to compare remission rates between studies as they often use different definitions of diabetes

remission and different methodologies, such as variable follow-up periods. These studies are further limited by relatively small sample sizes. While studies struggle to agree on the definitions of diabetes remission, most studies would agree that a percent glycated hemoglobin (%HbA1c) level less than 6.5% without the use of antidiabetic medication represents a T2D patient in remission. Several randomized controlled trials (RCTs) have described statistically and clinically significant differences in diabetes markers, including HbA1c, fasting plasma glucose, and homeostatic model assessment for insulin resistance (HOMA-IR) scores, between patients that receive metabolic surgery and those that receive intensive medical therapy [8, 33, 96, 101]. These studies primarily examined RYGB, biliopancreatic diversion with duodenal switch (BPD-DS), or SG in which their 1-year diabetes remission rates range from 35% to 44% for surgical patients compared to 0% to 9% for medical therapy patients, their 2-year remission rates range from 21.6% to 89.5% for surgical patients compared to 0% to 5.9% for medical therapy patients, and their 5-year remission values were also extremely variable with rates ranging from 18.8% to 50% for surgical patients compared to 0% for medical therapy patients [8, 9, 33, 95, 96, 101]. However, in spite of the large variation in remission rates, metabolic surgery consistently outperforms intensive medical therapy alone for the management of T2D in these RCTs.

Renal Changes and Micro-/Macrovascular Complications

When looking at diabetes-related complications, the STAMPEDE trial showed that there were either minimal or no changes to the measures of renal function, such as glomerular filtration rate (GFR), albuminuria, or creatinine-to-albumin ratio [95]. Conversely, Du et al. found that in patients with class 2 or 3 obesity, hyperuricemia was either resolved or improved in about 73% of patients following metabolic surgery, compared to 4% of class 1 obese patients [102]. These results would suggest that higher BMI subjects could benefit more from metabolic surgery in terms of positive renal changes; however, there is little evidence to validate this finding.

Microvascular complications, including retinopathy, nephropathy, and neuropathy, and macrovascular complications, including coronary artery disease, cerebrovascular disease, and peripheral artery disease, can occur in T2D patients with long-standing disease. Prospectively collected data on the attenuation or reduced risk of micro- and macrovascular complications is limited. However, among the 603 patients with T2D in the Swedish Obese Subjects (SOS) study, there were a 56% and a 32% decreased incidence of micro- and macrovascular complications, respectively, following bariatric surgery compared to the medical therapy group at a 15-year follow up [103]. Similarly, the incidence of microvascular complications was 59% lower in bariatric surgery patients compared to nonsurgical controls in a retrospective matched cohort study including 4024 surgical patients with a median follow-up of 4.3 years [104]. Further, a 2021 meta-analysis found that bariatric surgery reduced macrovascular complications by 50% with a mean follow-up time of 10.96 years [105].

Outcomes of Other Comorbidities Associated with Obesity and Metabolic Syndrome Following Metabolic Surgery

In addition to diabetes, there is evidence that metabolic surgery improves other obesity-related comorbidities, such as hypertension, dyslipidemia, and cardiovascular diseases. The research into the effect of bariatric surgery on these other comorbidities is often secondary to diabetes outcomes. As such, one cannot state conclusively whether metabolic surgery improves these conditions and whether the amelioration of these conditions is strictly due to weight loss or is also dependent on weight loss-independent mechanisms. We can, however, comment on the current state of knowledge regarding the impact of metabolic surgery on various test parameters, including blood pressure and serum lipid levels, to preliminarily assess the potential of metabolic surgery in attenuating obesity-related comorbidities.

Hypertension

Hypertension is one of the components that comprise "metabolic syndrome." As a major risk factor for cardiovascular and renal diseases, blood pressure management is imperative to prevent the development of other complications. Prevention or management of high blood pressure can be achieved by also managing weight. Metabolic surgery generally decreased systolic blood pressure (SBP) with reductions ranging from 12 mmHg to 34 mmHg [44, 96, 97, 99], while diastolic blood pressure (DBP) had reductions ranging from 5 mmHg to 10 mmHg [44, 96, 99]. A retrospective study found that metabolic surgery resolved or improved hypertension in 60% of class 2 or 3 obese subjects and 20% of class 1 obese subjects at 3 years postoperatively [102]; however, due to the small sample size, these results were not significant. In the STAMPEDE trial, neither SBP nor DBP was reduced by metabolic surgery at 1, 3, or 5 years, but there was a significant decrease in the number of antihypertensive medications required to manage the disease [9, 33, 95]. Similar results were found in a small RCT with no changes in SBP or DBP at 1 year following metabolic surgery [98], and another RCT showed reductions in antihypertensive medications following RYGB [97]. Any changes in blood pressure following

metabolic surgery are still controversial, yet it appears that those who receive metabolic surgery require less medical management of hypertension.

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) is an obesity-related disorder that increases the risk of hypertension development. Several studies have found that a large proportion of bariatric surgery patients show improvement in the number of sleep disturbances, sleep efficiency, and the severity of OSA [106–109] while others show no change in polysomnographic variables in the years after bariatric surgery [10]. A systematic review of OSA outcomes following bariatric surgery including 69 studies and 13,900 patients saw that BPD-DS, followed by SG, RYGB, and finally LAGB, had the most improvement in OSA postoperatively [107]. In fact, 99% of BPD-DS patients saw improvement in their OSA, compared to 85.7% for SG, 79.2% for RYGB, and 77.5% for LAGB [107]. Bariatric surgery has quite promising results in attenuating OSA symptoms. While unlikely to be the primary objective for performing bariatric surgery, improvement of OSA is a favorable secondary effect.

Dyslipidemia

Abnormal serum lipid levels are also a condition of metabolic syndrome. Typically, we see higher low-density lipoprotein (LDL) cholesterol and triglycerides (TG) and lower high-density lipoprotein (HDL) cholesterol in metabolic syndrome. In articles that categorically assessed dyslipidemia incidence before and after metabolic surgery, dyslipidemia was resolved in about 50% of patients at 1 year and 59% at 3 years [98, 102]. Within the first 1–5 years following metabolic surgery, there are consistent results of elevated HDL cholesterol to acceptable levels (≥45 mg/dL or 1.17 mmol/L) and decreased TGs to optimal levels (<150 mg/dL or 1.7 mmol/L), which is not observed in the medical therapy group [9, 33, 44, 96, 97, 110]. In regard to LDL cholesterol, the results are discrepant between studies. Several studies did not observe any changes in LDL cholesterol from baseline to their respective follow-up period in either the metabolic surgery recipients or those receiving medical therapy [9, 95, 96]. However, appropriate LDL reductions have also been observed following metabolic surgery in other studies [44, 97]. Particularly, one study showed that BPD-DS reduced LDL cholesterol and TGs to clinically optimal levels (<2.6 mmol/L or 100 mg/dL for LDL cholesterol), but this was not observed in the patients that received RYGB surgery. Reductions in LDL cholesterol following BPD-DS have also been reported in other studies [110, 111]. While some techniques, including RYGB, may normalize serum lipid levels apart from LDL cholesterol, it is possible that BPD-DS can achieve optimal LDL cholesterol reductions. At the 1-, 3-, and 5-year follow-ups in the STAMPEDE trial, the use of lipid-lowering medications by metabolic surgery recipients decreased by 60%, 56%, and 43% from baseline, respectively, with no changes in lipid-lowering medications by the patients receiving medical therapy only [9, 33, 95].

Cardiovascular Disease

Cardiovascular disease (CVD) is the leading cause of death worldwide, and both obesity and T2D can greatly increase the risk for CVD development. A group from the United States sought to determine if metabolic surgery can protect obese T2D patients from CVD with their retrospective cohort study of over 2200 diabetic patients with obesity undergoing metabolic surgery compared to over 11,000 matched controls. Looking specifically at major adverse cardiovascular events (MACE) over an 8-year period, this group found that metabolic surgery recipients had a hazard ratio of 0.61 compared to controls [112]. This suggests that metabolic surgery patients with both obesity and diabetes were about 40% less likely to experience a MACE in the first 8 years after surgery. A 2021 propensity score matched study of 2638 patients assessing bariatric surgical patients and nonsurgical controls with severe obesity and cardiovascular disease showed similar success with a hazard ratio of 0.58 for surgical patients compared to the nonsurgical controls [113]. In subgroup analyses of patients with a history of heart failure or ischemic heart disease, bariatric surgery reduced the incidence of MACE by 56% and 40%, respectively [113]. In addition to this, in terms of individual cardiovascular events, metabolic surgery patients had a much lower incidence of heart failure, coronary artery disease, cerebrovascular disease, nephropathy, and atrial fibrillation [112]. Moreover, the use of antidiabetic, antihypertensive, and lipid-lowering medications was significantly reduced in metabolic surgery patients [112], further corroborating the observations of the STAMPEDE trial.

Special Topics

Apart from the conventional use for metabolic surgery in T2D patients with a BMI ≥ 35 kg/m^2, physicians have started to apply these surgical techniques to different populations, such as in T2D patients with a BMI < 35 kg/m^2 or in type 1 diabetic (T1D) patients. Moreover, current studies are aiming to identify which type of bariatric surgery is the most effective for diabetes remission and to determine the long-term outcomes following metabolic surgery. These special topics serve as the future of metabolic surgery research and application to target populations.

The Use of Metabolic Surgery in Type 2 Diabetes Patients with a BMI < 35 kg/m²

Bariatric/metabolic surgery is typically only performed in patients with a BMI ≥ 35 kg/m² and long-standing diabetes. While the use of metabolic surgery is still controversial in overweight and class 1 obese patients, the idea that metabolic surgeries may be used to manage uncontrolled T2D in these patients is becoming more popular. In metabolic surgery patients with a BMI < 35 kg/m², clinically significant reduction in BMI, weight, and waist circumference has been observed as early as 6 months after surgery [114]. This effect is seen following various metabolic surgery techniques, including RYGB [98, 102, 114–120], BPD [121], SG [114, 122], one anastomosis gastric bypass (OAGB), [122] and LAGB [98, 114, 123]. Additionally, a reduced BMI is often maintained for several years following metabolic surgery in class 1 obese patients [102, 117, 121, 122]. Most studies that compare metabolic surgery to other anti-obesity or antidiabetic standard-of-care treatments, such as GLP-1 analogs, intensive medical therapy, lifestyle interventions, and SGLT2 inhibitors, also show marked reductions in anthropometric variables with metabolic surgery compared to the pharmacological or lifestyle interventions [98, 114, 116, 123].

What should be noted, however, are the comparisons between class 1 obesity and class 2/3 obesity weight outcomes following metabolic surgery. The changes in weight loss are not absolute in obesity patients. Instead, all three classes of obesity tend to exhibit comparable BMIs for several years following surgery [102]. While remaining clinically significant, it appears that patients with a higher preoperative BMI achieve greater anthropometric effects postoperatively compared to overweight or class 1 obese metabolic surgery patients. Thus, to assess and compare the benefits of metabolic surgery between different classes of obesity, we must explore the outcomes of diabetes following surgery in this population.

A retrospective review found no difference in diabetes remission rates between class 1 and class 2/3 obese patients at 1- or 3-year follow-up [102]. However, while some may argue that metabolic surgery is more efficacious for the management of diabetes in patients with a higher preoperative BMI, it needs to be determined whether metabolic surgery is also reasonably more effective than standard medical and lifestyle interventions in patients with a BMI lower than 35 kg/m². From data in RCTs and prospective studies in this population, diabetes remission rates within 1 year of surgery range from 51 to 65% and somewhere around 26 and 84% between 18 months and 5 years after surgery [102, 114, 115, 118, 120–122]. In the few studies that compared remission rates after metabolic surgery to medical therapy, the diabetes remission rates in the medically treated groups were either nonexistent or significantly lower at 0–6% [114, 118, 120]. Notably, these studies are limited by small sample sizes and poor follow-up. Regardless, although there is debate on whether higher classes of obesity may or may not exhibit greater benefits from metabolic surgery than lower classes, these preliminary results show that the benefits that are observed in T2D patients with a BMI < 35 kg/m² remain superior to medical therapies. Instead of comparing between classes of obesity, a "cut-off point," which defines a certain weight category that no longer attains higher diabetes remission rates than medical therapies, should be determined.

Metabolic Surgery in Type 1 Diabetics

Obesity is common in T2D patients and increases the risk for the development of diabetes [124]. However, obesity is rarer in T1D patients, although a subset of T1D patients is overweight [125]. Moreover, intense insulin treatment may make patients more susceptible to weight gain [126, 127]. By examining the outcomes of bariatric surgery in obese patients with T1D, we can begin to assess the viability of metabolic surgery in this population. A systematic review and meta-analysis of outcomes following bariatric surgery in obese T1D patients show clinically significant weight loss [128]. In addition to this, although bariatric surgery reduced daily insulin requirements, insulin therapy was still required [128]. This can be explained since T1D patients have little to no β-islet cell activity to produce their own insulin. Bariatric surgery also decreased HbA1c levels, but only to 7.9 ± 1.1% [128]; these levels remain quite elevated and are not indicative of diabetes remission, in spite of the statistically significant improvement. Further investigation into the efficacy of metabolic surgery in T1D patients is warranted, but based on these preliminary results, the efficacy of surgery is unclear and may be considered draconian relative to the extent of diabetes remission.

The suggested mechanisms for improved glycemic control and reduced insulin requirements are similar to those in T2D metabolic surgery patients. Weight may ameliorate obesity-related insulin resistance via reduced lipotoxicity and inflammation [128]. Although studies in this area are small and limited, there is some evidence to suggest that insulin requirements following bariatric surgery are not directly correlated to weight loss, indicating that there are other mechanisms for improved glycemic control independent of weight loss [129]. Reduced insulin requirements may be simply due to decreased caloric intake and glycemic load. Further, increased incretin release due to the hindgut hypothesis may inhibit the actions of glucagon and even potentiate insulin activity in patients with residual β-islet cell function [130]. Regardless, mechanisms that reduce insulin sensitivity and potentiate the actions of insulin will allow for the mitigation of excessive exogenous insulin use. Kirwan et al.

report that bariatric surgery results in the remission or improvement of many obesity-related comorbidities, including hypertension and dyslipidemia [128]. A single, small retrospective study comparing BPD-DS and SG recipients found that T1D and T2D patients had similar remission rates of hypertension and dyslipidemia [131]. Therefore, although the use of metabolic surgery to induce remission of diabetes in T1D patients is contentious, there is currently no contraindication for the use of these techniques in obese patients with T1D or obesity-related comorbidities.

Diabetes Remission and Relapse Using Different Types of Metabolic Surgery

With such a wide array of different bariatric surgical techniques, it is difficult to parse out which may be the most effective in terms of diabetes remission based on the hundreds of studies with consistent or contradictory findings. The 2009 meta-analysis by Buchwald et al. showed that diabetes remission rates are maintained at a 2-year follow-up with BPD-DS at 95.1%, RYGB at 80.3%, then gastroplasty at 79.7%, and finally LAGB at 56.7% [100]. The relationships between different techniques are echoed in a 2020 network meta-analysis of RCTs evaluating diabetes remission following metabolic surgery in patients with follow-ups greater than 3 years with rank probabilities of remission at 91.3% for BPD-DS, 84.2% for OAGB, 58.4% for RYGB, 39.9% for SG, and 24.9% for LAGB [132]. Notably, the remission rates for RYGB and LAGB were substantially lower in the 2020 study compared to the study conducted in 2009.

Using RCTs, we can also evaluate the relapse rates of diabetes for the various techniques. BPD-DS had a 37% relapse rate between postoperative years 2 and 5 [8]. RYGB had moderate relapse rates with 25% relapse between years 1 and 2 [101], 53% relapse between years 2 and 5 [8], and 47.6% relapse between years 1 and 5 [9, 33]. On the other hand, SG had 60% diabetes relapse between postoperative years 1 and 2 [101] and about 46% relapse between years 1 and 5 [9, 33].

Even though LAGB is not performed as widely as it was a decade ago, this technique can be compared to the more modern surgeries. While diabetes remission does not typically correlate directly to weight loss following metabolic surgery as stated earlier in this chapter, RCTs using LAGB to attenuate diabetes have shown weight loss is the major force promoting diabetes remission [123, 132, 133], likely due to a lack of considerable anatomical reconstruction of the GI tract. This may also explain why surgeries like BPD-DS, RYGB, and SG typically perform better than LAGB.

Patients appear to exhibit the highest diabetes remission rates and the lowest relapse following BPD-DS compared to the other surgical techniques. In a 2005 review of 312 obese T2D BPD-DS patients, over 99% of patients achieved diabetes remission at 1 year, and there was only a 2% relapse rate over 10 years [110]. These values are drastically higher than those reported in the RCTs and meta-analyses; regardless, BPD-DS is consistently the most effective in terms of both weight loss and diabetes remission rates; however, this technique is not used as frequently worldwide due to its inherent technical challenges and there is also a higher risk of complications including nutritional deficiencies when the proximal small intestine is bypassed [134]. While more research into this area is definitely needed, there is a strong potential for successful treatment of diabetes using bariatric surgical techniques.

Long-Term Outcomes of Metabolic Surgery

One of the strongest available long-term studies on T2D remission is the SOS study [103]. This prospective matched cohort study examined diabetes remission for non-adjustable gastric banding (NGB), vertical banded gastroplasty (VBG), and RYGB versus standard diabetes and obesity care over a 15-year period. T2D remission rates at 2 years after surgery were 16.4% for medical therapy patients and 72.3% for bariatric surgery patients. At 15 years, diabetes remission rates decreased to 6.5% for medical therapy patients and to 30.4% for bariatric surgery patients. There is a high relapse in diabetes remission from 2 to 5 years; however, remission rates were still much greater in the bariatric surgery group compared to the medical therapy group. In addition to this, the risk of both macro- and microvascular complications was significantly reduced in those that had bariatric surgery.

A recent retrospective study of insulin-treated T2D patients that received BPD-DS showed substantial diabetes remission rates 10 years after metabolic surgery with up to 68% of patients in complete remission [135]. Importantly, those with a shorter disease duration at the time of surgery were more likely to achieve complete diabetes remission compared to those with longer disease duration [135]. As metabolic surgery is seldom going to be a primary management strategy for diabetes, earlier diagnosis and treatment will be an important factor in order for patients to have the best chances of achieving remission with metabolic surgery.

Complications After Bariatric/Metabolic Surgery

Bariatric/metabolic surgery is considered extremely safe nowadays, even as safe as a laparoscopic cholecystectomy [136]. Morbidity and mortality rates have decreased dramatically since the introduction of the laparoscopic approach, as well as the evolution of technology, understanding of

associated diseases, and perioperative management of patients [137]. In order to standardize the way in which complications in bariatric surgery should be reported, their classification by temporality and severity has been established [138]. Early complications are those that occur within the first 30 days, and after that, they are considered late complications. By severity, they are divided into minor and major, with the major generally being those that cause early reintervention, bleeding that requires blood transfusions, need for ICU, and hospital stay longer than 7 days. The most common complications appear during this period, being mainly bleeding (intra-abdominal or gastrointestinal), leak/fistula, and stenosis, which is observed in approximately 2–19% of cases (there is variability depending on the type of procedure [139, 140]). Deep vein thrombosis (DVT) and pulmonary embolism (PE) can also occur within this period but are less frequent. Mortality should not exceed 0.1–0.5% [136]. In terms of late complications, the RYGB has been associated with a greater cause of readmissions and a greater number of complications compared to SG [141]. The most observed pathologies during follow-up are cholelithiasis, marginal ulcers, internal hernias, reflux, and nutritional deficiencies. Some of the factors associated to higher morbidity are open procedures, extreme obesity, previous DVT/PE, sleep apnea, revisional surgery, and surgeries performed at low-volume hospitals [142].

Even though bariatric surgery, with the upcoming technologies, has proved to be a safer procedure, less invasive and novel patient-targeted approaches are being developed in order to decrease current rates of complications, morbidity, and mortality.

Evolving Technologies for Metabolic Treatment

The prevalence of obesity is continuously increasing worldwide with an accentuation during the current COVID-19 pandemic. Currently, bariatric surgery represents the best option for the treatment of obesity and its related metabolic comorbidities. Importantly, only a small fraction of the eligible population undergoes bariatric surgeries even in those countries with well-established bariatric surgery centers.

Recently, various endoscopic treatments have evolved with the goal of offering minimally invasive options for a greater number of patients suffering from obesity as well as diabetes [143]. Although not currently FDA approved, these interventions might represent viable options in the future somewhere in the continuum of care between bariatric surgery and pharmacotherapy and lifestyle interventions. These metabolic endoscopic interventions may offer a different therapeutic perspective than the well-established gastric space-occupying devices and endoscopic gastric suturing procedures.

Currently, there are three main types of endoscopic small bowel interventions that could have a significant impact in patients with metabolic syndrome: endoscopic anastomosis systems, duodenal mucosal resurfacing systems, and finally endoluminal bypass liner systems.

Endoscopic Magnetic Compression Anastomotic Devices

Endoscopic therapies trying to replicate the weight loss and metabolic results of the SADI-S procedure have been described. The Incisionless Magnetic Anastomosis System (IMAS-GI Windows, West Bridgewater, MA, United States) relies on a magnet that is introduced through the working channel of the endoscope and takes its final octagonal form when deployed into the lumen. A recent case series of eight patients with a BMI of 35–47 and T2D illustrated the feasibility of a combined laparo-endoscopic procedure [144]. The proximal magnet was inserted endoscopically and positioned 2 cm distal to the pylorus, while the distal magnet was inserted laparoscopically through a 5 mm enterotomy 300 cm proximal to the ileocecal valve. The magnets were expelled per rectum at a median of 29.5 days post procedure with no complications. All anastomoses were patent at 1 year. The baseline HbA1c was reduced below 7% in 75% of patients, and greater than 5% of total body weight loss was seen in 87.5% of patients at 12 months [144].

The Magnamosis device (Magnamosis Inc.) is a pair of rare earth magnets encased in a polycarbonate shell [145]. Following multiple successful animal studies, a first-in-human trial was published in 2017. This case series included five patients. The surgical procedures were performed through laparotomy in complex urology cases requiring the creation of an ileal conduit. One small bowel side-to-side anastomosis was created in each case with a central hole being performed surgically to obtain immediate patency. No complications such as anastomotic leaks, bleeding, or stenosis were noted during the 13-month median follow-up (range: 6–18 months). Although no metabolic interventions were attempted to date using this device, Magnamosis Inc. has recently been awarded an NIH grant to study the effect of a Magnetic Duodeno-Ileal Bypass (DIPASS) on T2D in a primate model [146].

Finally, a third device, EasyByPass (EasyNOTES) [147], uses neodymium rare earth magnets that are placed endoscopically to create a gastrojejunal anastomosis under fluoroscopy and with the help of a large external magnet [143]. A few weeks following the creation of the new anastomosis, a pyloric plug is inserted endoscopically to divert the gastric contents through the new gastrojejunostomy [147]. There is

currently no published data on the use of this device in animal or human studies.

Duodenal Mucosal Resurfacing

The Revita duodenal mucosal resurfacing (DMR) procedure is a minimally invasive endoscopic procedure in which the mucosa distal to the ampulla of Vater is thermally ablated using a specially designed catheter (Fractyl Laboratories, Lexington, MA, United States) that is advanced over a guidewire under endoscopic guidance. Following a mucosal saline lift, a sequential ablation of the duodenal mucosa is performed for about 10 cm distal to the ampulla [148]. In a recent international multicenter study, the effect of DMR was studied in patients with T2D treated with at least one oral hypoglycemic medication and with a BMI ranging from 24 to 40 kg/m^2 [149]. The procedure was completed in 80% of patients. There was only one significant adverse event: fever with spontaneous resolution. Mean HbA1c was 10 mmol/mol (0.9%) lower at 1 year post DMR compared to baseline. There was some weight loss at 4 weeks post procedure with weight stabilization afterward. No correlation between the weight loss and glycemic control was noted.

Another DMR device, DiaGone (Digma Medical, Petah Tikva, Israel), uses a precisely controlled laser technology to target the duodenal submucosal neural plexi [150]. The results of a small multicenter feasibility study were published in an abstract in 2019 [151]. Nine patients with a BMI of 34.0 ± 4.6 kg/m^2 and T2D with insufficient glycemic control on metformin were enrolled. A significant decrease ($p < 0.01$) in fasting glucose (12.4 mmol/L baseline to 9.5 and 9.7) and HbA1c (7.83% mmol/mol baseline to 6.4% and 6.48%) was noted at 3 and 6 months following the procedure. No adverse events nor change in weight was noted during the 6-month follow-up [151].

Endoluminal Bypass Liners

Currently, there are two types of endoluminal "sleeve" systems that share the same mechanism of prevention of contact between the gastric contents and the proximal small bowel and possibly alterations in gut microbiota [143, 152] (Table 42.2).

Duodenal-Jejunal Bypass Liner

The first system is the duodenal-jejunal bypass liner EndoBarrier (DJBL – GI Dynamics, Lexington, MA, USA). EndoBarrier is a 60 cm fluoropolymer liner that is placed under endoscopic and fluoroscopic control. The proximal nitinol anchor is deployed in the duodenal bulb with the liner released distally into the small bowel [150]. It is removed endoscopically after 3–12 months. A meta-analysis published in 2018 that included 17 studies evaluating EndoBarrier has shown an overall 18.9% total body weight loss and a 1.3% reduction in HbA1c. The weight loss was shown to be still significant at the 12-month follow-up post device explantation [153].

Table 42.2 Current endoscopic metabolic interventions targeting the small intestine [143]

Endoscopic small bowel interventions	Clinical options
Endoscopic anastomotic devices	IMAS: Incisionless Magnetic Anastomosis System (GI Windows) Magnamosis (Magnamosis Inc.) EasyByPass incisionless anastomosis device (EasyNOTES)
Duodenal mucosal resurfacing systems	Revita (Fractyl Laboratories) DiaGone (Digma Medical)
Endoluminal bypass liner systems	Duodenal-jejunal bypass liner (DJBL – GI Dynamics) Gastro-duodenal bypass liner (ValenTx Endoluminal Bypass)

Notwithstanding the excellent results published in the previous studies, a multicenter controlled trial in the United States had to be terminated early when 3.5% of patients developed hepatic abscesses [154]. Recently, the largest multicenter randomized controlled study of DJBL was published [155]. The study enrolled 170 patients with inadequately controlled T2D and obesity that were subsequently randomized to intensive medical care with or without DJBL. Interestingly, there was no significant difference in the percentage of patients achieving a HbA1c reduction of ≥20% at 12 months (primary outcome). There was, however, greater weight loss in the DJBL group (24% of patients achieved ≥15% weight loss in the DJBL group compared to only 4% in the intensive medical care group at 12 months). Better reduction in systolic blood pressure, cholesterol levels, and alanine transaminase was noted at 12 months. There were 19 early explantations of the DJBL, and these were caused by seven cases of migration of the device, abdominal pain in five patients, upper gastrointestinal bleeding in two patients, cholecystitis in two patients, and a single case of liver abscess, anticoagulation, or withdrawal of consent. The hepatic abscess resolved following explantation of the device and percutaneous drainage of the abscess. One explantation had to be performed laparoscopically as the endoscopic removal failed [155]. Although there was no improved glycemic control, the improvement in weight and other comorbidities together with the lower rate of hepatic abscess (1.3%) is encouraging. The large US STEP-1 FDA-approved trial is currently actively recruiting patients, and this will hopefully generate valuable information about the efficacy and safety profile of DJBL.

Gastro-duodenal Bypass Liner

The second system is the gastro-duodenal bypass liner system (ValenTx Endoluminal Bypass, Maple Grove, MN, USA). This device has twice the size of the DJBL (120 cm) with the proximal part being anchored at the gastroesophageal junction. It is designed to reproduce some of the restrictive and hypoabsorptive characteristics of a classic laparoscopic gastric bypass. The initial human experience reported in 13 patients showcased impressive results with a 54% excess weight loss and >70% improvement in associated comorbidities after 12 months [156]. Only four of these patients had T2D; 3/4 had more than 1% improvement in Hb1Ac, and 1/4 had significant improvement *with cessation of hypoglycemic treatment* [156]. Despite these encouraging results, early device removal was necessary due to odynophagia and intolerance in 17% and 23% of cases, respectively [156, 157]. In a more recent multicenter international study, 32 patients with a mean BMI of 42.3 kg/m^2 were enrolled into a single-arm feasibility trial [158]. Eighty-eight percent of devices remained implanted after 12 months, with notable adverse events including knotting of the sleeve in two patients, distal migration of the device requiring removal through laparotomy in one patient, and esophageal food impaction in one patient. Although no metabolic data was published, subjects lost on average 17.6% total body weight and 44.8% excess body weight at 12 months. Ongoing device development and further clinical investigations are currently underway.

Multiple Choice Questions

1. What is the gold standard bariatric/metabolic surgery?
   (a) LAGB
   (b) SG
   (c) **RYGB**
   (d) BPD-DS
2. What is the most commonly performed bariatric surgery worldwide?
   (a) LAGB
   (b) **SG**
   (c) RYGB
   (d) BPD-DS
3. What are the main surgeries that promote decreased ghrelin and an increase of GLP-1 and YY?
   (a) LAGB and SG
   (b) SG and RYGB
   (c) **RYGB and BPD-DS**
   (d) BPD-DS and LAGB
4. What is the main orexigenic hormone that is suppressed after sleeve gastrectomy?
   (a) Adiponectin
   (b) Leptin
   (c) **Ghrelin**
   (d) PYY-GLP-1
5. What hormone, which increases after RYGB, is associated with insulin resistance and appetite?
   (a) Adiponectin
   (b) Leptin
   (c) Ghrelin
   (d) **GLP-1**
6. Which of the following is an indication for bariatric surgery?
   (a) Obesity class 1
   (b) Obesity class 2 without comorbidities associated
   (c) **Obesity class 3 even when no comorbidities are associated**
   (d) BMI > 30 kg/m^2 and metabolic syndrome
7. According to the Standards of Care for Diabetes algorithm, when can metabolic surgery be considered?
   (a) Obesity class 1
   (b) **Diabetic subjects with inadequately controlled hyperglycemia despite medical treatment in subjects with a BMI ranging from 30 to 34.9 kg/m^2**
   (c) Overweight patients with uncontrolled diabetes
   (d) Metabolic surgery is not currently considered as an option for treatment
8. What changes in the composition of gut microbiota are associated after RYGB?
   (a) **Increased presence of Proteobacteria and Bacteroidetes**
   (b) Increase in Bacteroidetes and Firmicutes
   (c) Decrease in Firmicutes and Proteobacteria
   (d) Increase in *Lactobacillus* and Firmicutes
9. What is the adipokine that communicates between adipose tissue and the CNS to suppress food intake during energy sufficiency and decreases after bariatric surgery?
   (a) Adiponectin
   (b) GLP-1
   (c) **Leptin**
   (d) PYY

Glossary

Adipokines Hormones that are released from adipose tissue. The most well-known adipokines are leptin and adiponectin.

Bariatric Surgery Type of surgery that involves changes in the digestive system (restriction or redirection) in order to achieve weight loss and metabolic improvement

Incretins Intestinal peptides known for stimulating insulin production after food intake. The main incretins are PYY and GLP-1.

Laparoscopic surgery Minimal invasive surgery where trough small incisions (5–10 mm), ports are placed, CO_2 is insufflated, a camera (that transmit imagen from abdominal cavity to a monitor) and specialized instruments are inserted to perform a surgery. This type of surgery has the

advantage to be faster and less invasive compared to open approach and facilitates a faster recovery.

Obesity Abnormal or excessive fat accumulation that presents a risk to health. It is considered when BMI is ≥30 kg/m^2.

Obesity Class 1 Patients with a BMI ranging from 30 to 34.9 kg/m^2

Obesity Class 2 Patients with a BMI ranging from 35 to 39.9 kg/m^2

Obesity Class 3 Patients with a BMI of 40 kg/m^2 or greater

Roux-en-Y Gastric Bypass Gold standard bariatric surgery that involves a re-routing of the passage of food. A small gastric pouch is created and connected to the jejunum, "bypassing" the stomach, the duodenum, and the first portion of the jejunum. After the surgery, a decrement in ghrelin and GIP and an increase of GLP-1 and PYY are observed.

Sleeve Gastrectomy Vertical transection of the stomach, starting at the greater curvature at 6 cm proximal to the pylorus toward the angle of His. It is performed with a laparoscopic stapler, guided over a 32Fr orogastric tube. It decreases the amount of food intake, ghrelin concentrations, and appetite and increases intragastric pressure.

Diabetes and Smoking: The Burden of Evidence

43

Sameer Aggarwal, Deepak Khandelwal, Deep Dutta, Sanjay Kalra, and Yatan Pal Singh Balhara

Introduction

Smoking has been identified as the leading preventable risk factor for premature mortality and morbidity. Large volumes of literature are now available linking smoking with cardiovascular morbidity and mortality, diabetes, vascular damage, cancers, and neurocognitive dysfunction, among others. It will not be erroneous to state that every system of the body is affected by smoking. Smokers die on average 8–10 years younger than nonsmokers. This chapter intends to highlight the complex relationship between smoking and the occurrence and the associated morbidity related to diabetes.

Smoking and Diabetes: Incidence and Mechanism

The impact of smoking on glycemia is complex. Smoking is strongly linked with both increased incidence and severity of diabetes. Smoking cessation, at least in the short term, is associated with weight gain, which is also associated with increased incidence of diabetes.

The risk of developing diabetes in smokers has been found to be dose dependent. A meta-analysis of 25 studies reported that heavy smokers (smoking ≥20 cigarettes/day) were more likely to develop diabetes (relative risk (RR) = 1.61; 95% CI = 1.43–1.80) as compared to light smokers (RR = 1.29; 95% CI = 1.13–1.48) and former smokers (RR = 1.23; 95% CI = 1.14–1.33). A study on industrial workers in a large cohort of individuals in Taiwan showed that compared to never-smokers, both current smokers and ex-smokers in their first 2 years of abstinence had higher odds ratios (ORs) for newly diagnosed diabetes mellitus (never-smokers 3.6%, OR = 1; current smokers 5.5%, OR = 1.499, 95% CI = 1.147–1.960, and $p = 0.003$; ex-smokers in their first year of abstinence 7.5%, OR = 1.829, 95% CI = 0.906–3.694, and $p = 0.092$; and ex-smokers in their second year of abstinence 9.0%, OR = 2.020, 95% CI = 1.031–3.955, and $p = 0.040$) [1]. This higher incidence of diabetes in ex-smokers was independent of the associated weight gain [1].

Smoking is found to cause diabetes by insulin resistance as well as decreased insulin release due to pancreatic β-cell damage by inflammatory and oxidative pathway mechanisms. Another concerning fact is that fetal exposure to smoking (maternal smoking during pregnancy) is associated with increased risk of diabetes later in life [2]. The silver lining is the observation that a healthy lifestyle intervention can go a long way in reducing this risk of diabetes among these persons [2].

Smoking is associated with increased and differential DNA methylation of type 2 diabetes genes, especially the ANPEP, KCNQ1, and ZMIZ1 genes, which may explain how smoking is associated with long-term increased diabetes risk [3].

Smoking and Non-microvascular or Non-macrovascular Complications

Smoking is an independent predictor of atherosclerosis. It has a stronger association with postprandial dyslipidemia and not fasting lipid values. It has been linked with postprandial hypertriglyceridemia [4].

Smoking and Microvascular Complications of Diabetes

Smoking increases the risk for microvascular complications of diabetes, probably via its metabolic effects in combination with increased inflammation and endothelial dysfunction [5]. This association is strong in type 1 diabetes patients and seen for all microvascular complications. However, the association of smoking with microvascular complications in type 2 diabetes is comparatively weaker except for nephropathy. Studies have clearly supported the negative impact of smoking on diabetic kidney disease in type 2 diabetes too, but its independent influence on retinopathy and neuropathy in type 2 diabetes remains unclear [5].

Smoking and Diabetic Nephropathy

Several studies have demonstrated that smoking promotes the development and progression of diabetic nephropathy in persons with both type 1 and type 2 diabetes, and smoking is an independent risk factor for diabetic kidney disease. Also, smoking is associated with an increased risk for end-stage renal disease and decreased survival on commencement of dialysis. In a 13-year follow-up study by Biesenbach et al., the progression of diabetic nephropathy was clearly increased in smokers. Other prospective studies have also confirmed more frequent diabetic nephropathy in smokers than nonsmokers. Continued smoking has shown to be associated with further poor renal outcome as compared to persons who quit smoking. Smoking adversely affects renal hemodynamics and protein excretion even in subjects without apparent renal disease. In addition, it impairs the prognosis for renal function in patients with nondiabetic renal disease. Factors implicated in the pathogenesis of smoking-induced renal function impairment are the sympathetic activation, increased endothelin production, increased oxidative stress, and impaired endothelial cell-dependent vasodilation [6]. Cessation of smoking has been associated with slower progression of the nephropathy and, as an alone measure, may reduce the risk of progression by 30% in patients with type 2 diabetes.

Smoking and Diabetic Retinopathy (DR)

Smoking has a profound negative impact on overall eye health in diabetes [5]. Smoking has been implicated in the development and progression of numerous ocular diseases, including age-related macular degeneration, glaucoma, and cataracts. Chronic smoking has been shown to be associated with decreased retinal circulation as well as abnormalities in the retinal vessel parameters. Smoking leads to a higher incidence of and accelerated progression of diabetic retinopathy (DR) in patients with type 1 diabetes. However, in type 2 diabetes, evidence is controversial in context of smoking and DR. The Hoorn study demonstrated a nonsignificant trend for increased DR incidence in cigarette smokers as well as ex-smokers. Another, 25-year follow-up study showed a nonsignificant trend of developing more proliferative DR in current smokers. However, there was no statistically significant association between smoking status or pack-years of smoking and proliferative DR. In the same study, mild NPDR was more common among current smokers than former smokers, which may suggest that smoking is indeed related to early forms of diabetic retinopathy. However, many studies have reported no association with smoking and retinopathy in type 2 diabetes. Rather the United Kingdom Prospective Diabetes Study (UKPDS) study demonstrated a protective effect of smoking on both new development and progression of DR. Thus in type 2 patients, the effects of smoking on DR is more complex and yet to be fully elucidated [6].

Smoking and Diabetic Neuropathy

Like the association of smoking and retinopathy, there is evidence that smoking is an independent risk factor of peripheral neuropathy in patients with type 1 diabetes [7]. However, the association of smoking with neuropathy in type 2 diabetes is not clear. Surprisingly, a protective effect of smoking has been reported in few studies. In other studies with patients with type 2 diabetes, smoking was not a risk factor for the polyneuropathy or sensory neuropathy as diagnosed by symptoms and signs. A meta-analysis including 10 prospective and 28 cross-sectional studies has found that smoking had an unadjusted odds ratio of 1.26 for prospectively developing diabetic sensory polyneuropathy. In the cross-sectional studies, the pooled odds ratio for diabetic sensory polyneuropathy due to smoking was 1.42. However, for both analyses, evidence was graded as low strength. More studies are needed to evaluate the association between smoking and neuropathy [7].

Smoking and Macrovascular Complications of Diabetes

Smoking has been shown to be a significant risk factor for all-cause mortality, and for mortality due to cardiovascular disease (CVD) and coronary heart disease (CHD) in patients with diabetes.

Coronary Artery Disease

Smoking is a major risk factor for CVD in nondiabetic subjects, as well as diabetic subjects. In the London cohort of the 8-year prospective, World Health Organization Multinational Study of Vascular Disease in Diabetes, it was shown that smoking is significantly associated with an increased risk for coronary heart disease (CHD) in type 1 and type 2 diabetes patients [8]. In the Diabetes Control and Complications Trial (DCCT), designed to study the role of intensive insulin treatment and optimized glycemic control in type 1 diabetes, smoking was not a significant risk factor for macrovascular complications [9, 10]. The subjects participating in this study were young, and, thus, the DCCT was not optimally designed to study the role of tobacco use in macrovascular complications [9, 10]. Other studies in slightly older type 1 subjects with diabetes have shown that smoking does increase the risk for CHD. In type 2 subjects with diabetes, the UKPDS clearly showed that cigarette smoking is a significant and independent risk factor for CHD, stroke, as well as peripheral vascular disease [11]. In the Nurses' Health Study, in women with type 2 diabetes, it was demonstrated that smoking was associated in a dose-dependent manner with an increased mortality and CHD. The risk for mortality from all causes was 1.64 in diabetic women who smoked 15 to 34 cigarettes per day and 2.19 in women who smoked more than 34 cigarettes per day [12]. Ten years after having stopped smoking, the risk for mortality has normalized when compared with nonsmoking diabetic women. Another data has shown that compared with never-smokers, the relative risks for CHD were 1.66 for current smokers of 1 to 14 cigarettes per day and 2.68 for current smokers of 15 or more cigarettes per day [12].

A meta-analysis in the Asia-Pacific region, in men with diabetes, the hazard ratio for CHD comparing current smokers with nonsmokers was 1.42 [13]. Cigarette cessation strategies can be beneficial in terms of reducing the burden of CVD in men with diabetes [14].

A large prospective study by Chaturvedi et al. studied the effects of smoking cessation on cardiovascular risk in diabetic patients [15]. Mortality risks in previous smokers with diabetes were compared with risks for subjects who have never smoked. All-cause mortality risks were around 50% higher for patients who stopped smoking during the past 1–9 years and 25% higher in individuals who quit smoking before that, when compared with subjects who have never smoked [15]. The results from this study show that stopping smoking reduces mortality risk in diabetes, but risks still remain high several years after quitting smoking. The mortality risk with smoking in diabetes is dependent on the duration of smoking.

Smoking and Cerebrovascular Accident/ Stroke

Smoking also increases the risk of stroke in patients with diabetes, but the association may not be as strong as CHD. Smoking and HbA1c are predictors of stroke among the type 2 diabetes patients without a history of a previous stroke. In the London cohort of the 8-year prospective World Health Organization Multinational Study of Vascular Disease in Diabetes, it was shown that smoking was not significantly associated with stroke [16]. In a study using the general practice research database in the United Kingdom, smoking was an additional risk factor for stroke in type 2 diabetes patients [17]. In the Nurses' Health Study, in smokers who smoked 1 to 14 cigarettes per day, the risk was significant for CHD but not for stroke [12]. In those who smoked 15 cigarettes or more per day, the relative risks for CHD and stroke were 2.68 and 1.84, respectively [12]. Similar trends were shown in a Swedish study, in which the relative risk of smoking was higher in myocardial infarction (2.33) than for stroke (1.12) in 30- to 59-year-old patients [18].

Smoking cessation should be a main target for the prevention of CVDs in patients with type 2 diabetes and is also very cost-effective. Smoking cessation should be integrated in a multiple-risk-factor control program [19]. This was shown in the Steno-2 trial, where a decrease in smoking rate was combined with a successful decrease in other risk factors in the intensively treated group [20].

Smoking and Peripheral Artery Disease

Smoking is associated with exacerbation of peripheral artery disease in diabetes. Smoking per se is a risk factor for peripheral artery disease (Buerger's disease). The peripheral artery disease associated with smoking per se primarily affects the medium-sized arteries. In contrast, diabetes per se affects the more distal arteries and arterioles. The presence of smoking in the background of diabetes has a synergistic effect on the peripheral artery disease occurrence and progression [21]. Smoking at least one pack of cigarettes per day ([OR] 2.5; 95% CI 1.1, 6.0) was associated with a

significant increase in the occurrence of symptomatic peripheral artery disease [22]. The presence of diabetes was the strongest predictor of peripheral artery disease in smokers in that study [22]. Ankle brachial index (ABI) assessment has an important role in disease severity assessment as well as prognostication (predicting cardiovascular and all-cause mortality) [21].

Smoking Cessation, Diabetes, and Technology

One of the aims of the comprehensive management plan for diabetes is to include smoking cessation plan for the patients with support from the family, friends, diabetic educator. and physician. The "5 A's"—ask, assess, advise, assist, and arrange—are five intervention steps suggested to help patients quit smoking (Box 43.1). Also, interventions to prevent relapse should be undertaken with patients who have quit smoking. Counseling and behavior therapy remain most important in helping patients quit smoking. Pharmacotherapy is often helpful with the use of nicotine replacement therapy (including nicotine patches, gum, and lozenges) and sustained-release bupropion. Patients receiving bupropion must be closely monitored for seizures and hyperglycemia. There is evidence supporting the safety and efficacy of varenicline in smokers with diabetes. However, the glycemic status must be monitored carefully in patients receiving varenicline as case reports of severe hypoglycemia in patients with type 1 diabetes exist. A meta-analysis reported that delivering structured smoking cessation interventions or medication for smoking cessation was found to have significantly better smoking abstinence rates compared to counselling or optional medication.

Box 43.1 Five Intervention Steps to Help Patients Quit Smoking

Ask: Identify active smoker/ex-smoker at each visit.
Assess: Determine person's willingness to quit smoking.
Advise: Strongly advise all tobacco users to quit.
Assist: Assist patients in quitting smoking.
Arrange: Arrange follow-up visits.

It must be highlighted that the weight gain and the associated transient mild increase in the risk of diabetes in patients who quit smoking should not be a deterrent for stopping smoking. It must be clearly highlighted to the smokers that quitting overall has a beneficial effect of quality of life and survival. In a large community-based cohort (Framingham Offspring Study data collected from 1984 through 2011), smoking cessation was associated with a lower risk of coronary artery disease events among participants without diabetes, and weight gain that occurred following smoking cessation did not modify this association, which supports a net cardiovascular benefit of smoking cessation, despite subsequent weight gain [23].

The diagnosis and treatment of diabetes or any of its complication are potential "teachable moments" for smoking cessation as at the time of diagnosis, patients were found to have significantly higher motivation to quit.

Recent reports have suggested that the use of Internet and mobile phone-based technology (mHealth) can go a long way in promoting healthy lifestyle habits and institute positive feedback mechanism, which can help in smoking cessation as well as ensuring better glycemic control in patients with diabetes [24].

Multiple-Choice Questions

1. Which of the following is the correct statement regarding the relationship of smoking and glycemia?
   (a) Smoking is linked with increased incidence of diabetes.
   (b) Smoking is linked with increased severity of diabetes.
   (c) The risk of developing diabetes in smokers has been found to be dose dependent.
   (d) All of the above.
2. Smoking is associated most evidently with which microvascular complications in type 2 diabetes?
   (a) Retinopathy
   (b) Nephropathy
   (c) Neuropathy
   (d) Gastroparesis
3. Other than retinopathy, smoking has been implicated in the development and progression of which other ocular diseases?
   (a) Age-related macular degeneration
   (b) Glaucoma
   (c) Cataract
   (d) All of the above
4. Which of the following is a false statement regarding mortality risks in smokers with diabetes?
   (a) Remains high even several years even after quitting smoking
   (b) Dependent on duration of smoking
   (c) Increases only in type 2 diabetes persons, not in type 1 diabetes persons
   (d) Dose dependent
5. What parts are primarily affected by the peripheral artery disease associated with smoking per se?
   (a) Medium-sized arteries

(b) Distal arteries and arterioles
(c) Large arteries
(d) Capillaries

6. What parts are primarily affected by the peripheral artery disease associated with diabetes per se?
   (a) Medium-sized arteries
   (b) Distal arteries and arterioles
   (c) Large arteries
   (d) Capillaries
7. What pharmacological agents are helpful in quitting smoking?
   (a) Nicotine gums/patches
   (b) Sustained-release bupropion
   (c) Varenicline
   (d) All of the above
8. Varenicline use for smoking cessation in type 1 diabetes persons has been reported with which adverse event?
   (a) Hypoglycemia
   (b) Hyperglycemia
   (c) Hypokalemia
   (d) Hyponatremia
9. What might be associated with smoking cessation in short term?
   (a) Weight gain
   (b) Weight loss
   (c) Increased risk of diabetes
   (d) A and C
10. Which of the following statement is incorrect regarding cessation of smoking?
   (a) Smoking cessation may lead to transient increase in body weight.
   (b) Smoking cessation may be associated with transient mild increase in the risk of diabetes.
   (c) Smoking cessation may lead to transient increased risk of coronary artery disease.
   (d) B and C.

Part VIII

Acute Complications

Hyperglycemic Crises: Diabetic Ketoacidosis

44

Bobak Moazzami, Zohyra E. Zabala, and Guillermo E. Umpierrez

Diabetic ketoacidosis (DKA) most often occurs in patients with type 1 diabetes, but many patients with type 2 diabetes may develop ketoacidosis under stressful medical and surgical conditions [1]. In contrast to popular belief, DKA is more common in adults than in children. Data from the T1D Exchange Clinic Network including 2561 patients shows that young adults (18–25 years) have the highest occurrence of DKA (~5%) defined as ≥1 event in the prior 3 months [2]. In community-based studies [1, 2], more than 40% of patients with DKA are older than 40 years, and more than 20% are older than 55 years. Worldwide, infection is the most common precipitating cause for DKA, occurring in 30–50% of cases. Other precipitating causes are intercurrent illnesses (i.e., surgery, trauma, myocardial ischemia, pancreatitis), psychological stress, and noncompliance with insulin therapy.

Treatment of patients with DKA and hyperosmolar hyperglycemic syndrome (HHS) is associated with substantial mortality and healthcare costs. DKA is the leading cause of mortality among children and young adults with T1D, accounting for ~50% of all deaths in diabetic patients younger than 24 years of age [3]. In the United States, the overall inpatient DKA mortality is <1% [3, 4], but a higher rate is reported among elderly patients with life-threatening illnesses [3–6]. Mortality increases substantially with aging, with mortality rates for those over 65–75 years reaching 20–40%. The cause of death in patients with DKA rarely results from the metabolic complications of hyperglycemia or metabolic acidosis but relates to the underlying medical illness (i.e., trauma, infection) that precipitated the ketoacidosis.

In up to 25% of patients, the initial presentation consists of combined features of DKA and HHS. Over 30% of patients have features of both DKA and HHS with most recent evidence confirming that about one out of four patients will have both conditions at the time of presentation with hyperglycemic crisis [7]. Patients presenting with this phenotype have shown to have a worse prognosis and have a higher risk of mortality (8%) compared to those with isolated hyperglycemic crises (3% for isolated DKA and 5% for isolated HHS) [8].

Pathogenesis

DKA is characterized by uncontrolled hyperglycemia, metabolic acidosis, and increased circulating total body ketone concentration. Ketoacidosis results from the lack of, or ineffectiveness of, insulin with concomitant elevation of counter-regulatory hormones (glucagon, catecholamines, cortisol, and growth hormone) [9, 10]. In individuals with and without diabetes, insulin controls hepatic glucose production by suppressing hepatic gluconeogenesis and glycogenolysis. In insulin-sensitive tissues such as muscle, insulin promotes protein anabolism, glucose uptake, and glycogen synthesis and inhibits glycogenolysis and protein breakdown. In addition, insulin inhibits lipolysis, ketogenesis, and free fatty acid (FFA) [1, 10]. In contrast, counter-regulatory hormones (glucagon, catecholamines, cortisol, and growth hormone) promote metabolic pathways opposite to insulin action, both in the liver and peripheral tissues, leading to altered glucose production and disposal and increased lipolysis and the production of ketone bodies.

The pathophysiologic basis for hyperglycemia and ketoacidosis in DKA is shown in Fig. 44.1 [11]. Hyperglycemia results from increased hepatic glucose production and impaired glucose utilization in peripheral tissues. Increased gluconeogenesis results from the high availability of gluco-

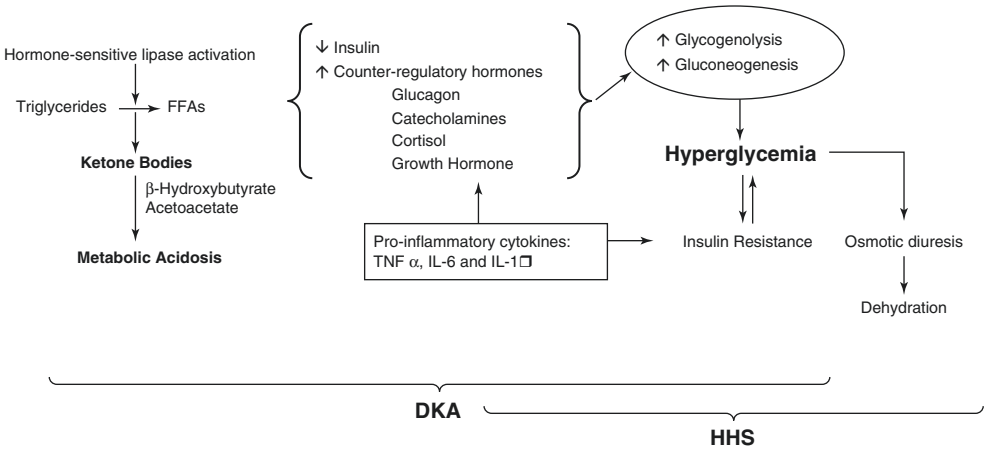

Fig. 44.1 Pathogenesis of hyperglycemic emergencies [11]. Hyperglycemia and the accumulation of ketone bodies result from a relative or absolute insulin deficiency and excess counter-regulatory hormones (glucagon, cortisol, catecholamines, and growth hormone). *Increased ketone bodies and ketoacidosis*. Decrease in insulin levels combined with increase in counter-regulatory hormones, particularly epinephrine, causes the activation of hormone-sensitive lipase in adipose tissue and breakdown of triglyceride into glycerol and free fatty acids (FFAs). In the liver, FFAs are oxidized to ketone bodies, a process predominantly stimulated by glucagon. The two major ketone bodies are β-hydroxybutyrate and acetoacetic acid. Accumulation of ketone bodies leads to a decrease in serum bicarbonate concentration and metabolic acidosis. Higher insulin levels present in HHS inhibit ketogenesis and limit metabolic acidosis. *Increased glucose production in DKA and HHS*. When insulin is deficient, hyperglycemia develops because of three processes: increased gluconeogenesis, accelerated glycogenolysis, and impaired glucose utilization by peripheral tissues. Hyperglycemia causes osmotic diuresis that leads to hypovolemia, decreased glomerular filtration rate, and worsening hyperglycemia

neogenic precursors (alanine, lactate, and glycerol) and from the increased activity of gluconeogenic enzymes (phosphoenolpyruvate carboxykinase (PEPCK), fructose-1,6-bisphosphatase, and pyruvate carboxylase) [10]. In addition, both hyperglycemia and high ketone levels cause an osmotic diuresis leading to hypovolemia and decreased glomerular filtration rate; the latter further aggravates hyperglycemia [11].

The mechanisms that underlie the increased production of ketones have been recently discussed in several reviews [1, 11]. The association of insulin deficiency and increased concentration of catecholamine, cortisol, and growth hormone causes the activation of hormone-sensitive lipase in adipose tissue. This enzyme causes endogenous triglyceride breakdown with subsequent release of large amounts of fatty acids into the circulation. Elevated FFAs are transported into the hepatic mitochondria, where they are oxidized to ketone bodies, a process predominantly stimulated by glucagon. Glucagon lowers the hepatic levels of malonyl coenzyme A (CoA), the first committed intermediate in the synthesis of long-chain fatty acids (lipogenesis) and a potent inhibitor of fatty acid oxidation. Malonyl CoA inhibits carnitine palmitoyl acyltransferase (CPTI), an enzyme that regulates the movement of FFA into the mitochondria. Therefore, reduction in malonyl CoA leads to stimulation of CPTI and effectively increases ketoacid production. In addition to increased ketone body production, there is also evidence that decreased clearance of ketoacids also contributes to the development of DKA.

Precipitating Causes

DKA is the initial manifestation of diabetes in 20–30% of patients with type 1 diabetes. In known diabetic patients, precipitating factors for DKA include infections, intercurrent illnesses, psychological stress, and noncompliance with therapy (Table 44.1). Infection is the most common precipitating factor for DKA, occurring in 30–50% of cases [1]. Urinary tract infection and pneumonia account for most infections. Other acute conditions that may precipitate DKA include cerebrovascular accident, alcohol abuse, pancreatitis, pulmonary embolism, myocardial infarction, and trauma. Drugs that affect carbohydrate metabolism such as corticosteroids, thiazides, and sympathomimetic agents may also precipitate the development of DKA.

One large retrospective review from the UK reported that hyperglycemic emergencies occurred at a rate of 1–2 per 1000 person-years following initiation of antipsychotics [13]. Of the antipsychotics, olanzapine and risperidone were associated with the highest risk [13]. Anticancer medications including immune checkpoint inhibitors such as ipilimumab, nivolumab, and pembrolizumab have been associated with newly diagnosed diabetes and DKA. Around 1% of patients taking these medications develop diabetes with half of them presenting with DKA as the first manifestation of diabetes. Patients with beta-cell autoimmunity are more susceptible to develop diabetes while taking anticancer medications [14–16].

Recently, the use of sodium glucose co-transporter 2 (SGLT2) inhibitors, a new class of oral antidiabetic agents that

lowers plasma glucose by inhibiting proximal tubular reabsorption of glucose in the kidney, has been associated with DKA in patients with T1D and T2D [17–21]. An atypical presentation of DKA, which can lead to delayed recognition and treatment, has been referred to as "euglycemic DKA" due to only mild to moderate elevations in blood glucose reported in many cases. Compiled data from randomized studies with the use of SGLT2 inhibitors reported a very low incidence of DKA in patients with T2D (~0.07%) [22, 23]; however, the risk of ketosis and DKA is higher in patients with T1D. About 10% of patients with T1D treated with SGLT2 inhibitors develop ketosis, and 5% require hospital admission for DKA. Potential mechanisms have been proposed, including higher glucagon levels, reduction of daily insulin requirement leading to a decrease in the suppression of lipolysis and ketogenesis, and decreased urinary excretion of ketones [1].

The importance of noncompliance and psychological factors in the incidence of DKA has been emphasized in recent studies [24–26]. In a survey of 341 female patients with type 1 diabetes, Polonsky et al. reported that psychological problems complicated by eating disorders were a contributing factor in 20% of recurrent ketoacidosis in young women. In addition, eating disorders are reported in up to one-third of young women with type 1 diabetes. Factors that may lead to insulin omission in young subjects included fear of gaining weight with good metabolic control, fear of hypoglycemia, rebellion from authority, and diabetes-related stress. Lack of insulin treatment adherence is reported as a major precipitating cause for DKA in urban black and medically indigent patients. Many studies have reported that in urban black patients, poor compliance with insulin accounted for more than 50% of DKA cases admitted to a major urban hospital [1, 27]. Limited resources and lack of health insurance increase hospitalization rates for DKA by two- to threefold higher than comparable rates among diabetic persons with private insurance.

Although the use of continuous subcutaneous insulin infusion by an insulin pump was associated with an increased risk of DKA, recent mechanical improvements in such devices and the use of frequent home glucose monitoring have reduced this complication considerably [1]. In one of the largest prospective studies for therapy and follow-up of type 1 diabetes, the Diabetes Control and Complications Trial, the incidence of DKA was quite low in patients treated with continuous insulin infusion devices.

Ketosis-Prone Diabetes

A growing number of ketoacidosis cases have been identified in adult individuals with clinical features of type 2 diabetes that are not accompanied by precipitating factors [28]. This variant of type 2 diabetes has been referred to as ketosis-prone diabetes [29]. Patients with ketosis-prone diabetes are usually obese, have a strong family history of diabetes, and have a low prevalence of autoimmune markers [28]. The age of onset of ketosis-prone diabetes is usually in the fourth or fifth decade of life; however, the incidence has been increasing in the pediatric population. The prevalence is two- to threefold higher in men compared to women. While this entity has been reported across different ethnicities worldwide, people of African origin and Hispanics appear to have the highest risk [30]. Most patients present with a few weeks of polyuria, polydipsia, and weight loss and are found to have severe hyperglycemia accompanied with urinary ketonuria or frank DKA [31]. The clinical course of patients with ketosis-prone diabetes is different than those with chronic insulin dependence from type 1 diabetes with DKA. Many obese subjects with ketosis-prone diabetes experience near-normoglycemic remission off insulin therapy within the first few months of treatment. While at the beginning, these patients show impairments in both insulin secretion and insulin action, aggressive diabetes management results in significant improvement in β-cell function and insulin sensitivity that is usually sufficient to allow discontinuation of insulin therapy in almost 70% of individuals within a few months of treatment [32, 33].

COVID-19 and DKA

With the recent coronavirus disease 2019 (COVID-19) pandemic, there is now accumulating evidence that suggests a higher frequency and severity of DKA among those with COVID-19. A higher number of DKA admissions occurred during the COVID-19 pandemic, which was mostly seen among those with type 2 diabetes and newly diagnosed diabetes and less frequently in patients with type 1 diabetes [12]. Possible reasons for this increased DKA incidence dur-

ing the pandemic include social restrictions, less access to medical care, and an increased prevalence in a sedentary lifestyle. Results from a large cohort of patients with DKA during the COVID-19 pandemic showed that patients with COVID-19 had a higher body mass index, higher insulin requirements, prolonged time to resolution of DKA, and a sixfold higher rate of mortality compared with patients without COVID-19 [34].

Diagnosis

Symptoms and Signs

Symptoms of hyperglycemia including polyuria, polydipsia, and weight loss are usually present for several days prior to the development of DKA [3, 11]. Two-thirds of patients present with weakness, nausea, vomiting, and abdominal pain [35]. Abdominal pain, sometimes mimicking an acute abdomen, is especially common in children; although the cause has not been elucidated, delayed gastric emptying and ileus induced by electrolyte disturbance and metabolic acidosis have been implicated as possible causes of abdominal pain.

Physical examination reveals signs of dehydration, including loss of skin turgor, dry mucous membranes, tachycardia, and hypotension. Mental status can vary from full alertness to profound lethargy; however, fewer than 20% of patients are hospitalized with loss of consciousness [10]. Acetone on breath and labored Kussmaul respiration may also be present on admission, particularly in patients with severe metabolic acidosis.

Laboratory Findings

The syndrome of DKA consists of the triad of hyperglycemia, ketosis, and acidemia (Table 44.2) [10]. Diagnostic criteria for DKA accepted by the American Diabetes Association are a blood glucose greater than 250 mg/dL, pH lower than 7.3, serum bicarbonate lower than 15 mEq/L, and a moderate degree of ketonemia (hydroxybutyrate and acetoacetic acid greater than 3 mmol) [3]. The key diagnostic feature is the elevation in circulating total blood ketone concentration.

Table 44.2 Diagnostic criteria for DKA

	DKA		
	Mild	Moderate	Severe
Plasma glucose (mg/dL)	>250	>250	>250
Arterial pH	7.25–7.30	7.00–<7.24	<7.00
Serum bicarbonate (mEq/L)	15–18	10–<15	<10
Urine ketone[a]	Positive	Positive	Positive
Serum ketone	Positive	Positive	Positive
Effective serum osmolality[b]	Variable	Variable	Variable mOsm/kg
Anion gap	>10	>12	>12
Alteration in sensorium	Alert	Alert/drowsy	Stupor/coma

[a] Nitroprusside reaction

[b] Effective serum osmolality: 2[measured Na^+ (mEq/L)] + glucose (mg/dL)/18

Table 44.3 Useful formulas for the evaluation of DKA

1. Calculation of anion gap (AG):
$$AG = [Na^+] - [Cl^- + HCO3^-]$$
2. Total and effective serum osmolality:
$$\text{Total} = 2[Na^+] + \frac{\text{glucose}(\text{mg/dL})}{18} + \frac{\text{BUN}(\text{mg/dL})}{2.8}$$
$$\text{Effective} = 2[Na^+] + \frac{\text{glucose}(\text{mg/dL})}{18}$$
3. Corrected serum sodium:
$$\text{Corrected [Na+]} = \frac{1.6 \times \text{glucose}(\text{mg/dL}) - 100}{100} + [\text{measured Na+}]$$
4. Total body water (TBW) deficit:
$$\text{TBW deficit} = [\text{wt (kg)} \times 0.6] - \left[\frac{\text{corrected } Na^+}{140}\right] - 1$$

Assessment of ketonemia can be performed by the nitroprusside reaction, which provides a semiquantitative estimation of acetoacetate and acetone levels, or by direct measurement of beta-hydroxybutyrate, the main ketoacid in DKA.

Accumulation of ketoacids results in an increased anion gap metabolic acidosis. The anion gap is calculated by subtracting the sum of chloride and bicarbonate from the sodium concentration [Na-(Cl + HCO_3)]. The normal anion gap is 12 ± 2 mEq/L (Table 44.3).

Not all patients who present with ketoacidosis have DKA. Patients with chronic ethanol abuse with a recent binge culminating in vomiting and acute starvation may develop alcoholic ketoacidosis (AKA). The key difference between AKA and DKA is the concentration of blood glucose. DKA is characterized by severe hyperglycemia; the presence of ketoacidosis without hyperglycemia in an alcoholic patient suggests AKA. In addition, some patients with decreased food intake lower than 500 calories/day may present with starvation ketosis. The diagnosis of starvation ketosis is suggested by a history of poor intake and the fact that it rarely presents with a serum bicarbonate concentration less than 18 mEq/L [10].

The following laboratory findings should be kept in mind in patients admitted with suspected or confirmed DKA. Leukocytosis is present in most patients with DKA; however, a leukocyte count greater than 25,000 mm^3 or the presence of greater than 10% neutrophil bands is seldom seen in the absence of bacterial infection [10]. The admission serum sodium is usually low because of the osmotic flux of water from the intracellular to the extracellular space in the presence of hyperglycemia. An increase in serum sodium concentration in the presence of hyperglycemia indicates a rather profound degree of water loss. To assess the severity of sodium and water deficit, serum sodium may be corrected by adding 1.6 mg/dL to the measured serum sodium for each 100 mg/dL of glucose above 100 mg/dL [36]. The admission serum potassium concentration is usually elevated in patients with DKA. These high levels occur because of a shift of potassium from the intracellular to the extracellular space due to acidemia, insulin deficiency, and hypertonicity.

Treatment

The American Diabetes Association algorithm for the management of hyperglycemic emergencies is shown in Fig. 44.2 [3]. Successful treatment of DKA requires frequent monitoring of patients, correction of hypovolemia and metabolic disorder, and careful search for the precipitating cause for DKA. Most patients with uncomplicated DKA can be treated in the emergency department or in step-down units, if close nursing supervision and monitoring are available. Several studies have failed to demonstrate clear benefits in treating DKA patients in the intensive care unit (ICU) compared to step-down units [37–39]. The mortality rate, length of hospital stay, and time to resolve ketoacidosis are similar between patients treated in ICU and non-ICU settings. In addition, ICU admission has been associated with more laboratory testing and higher hospitalization cost in patients with DKA [37, 40].

Patients with mild to moderate DKA can be safely managed in the emergency department or in step-down units, and only patients with severe DKA or those with a critical illness as precipitating cause (i.e., myocardial infarction, gastrointestinal bleeding, sepsis) [3, 41] should be treated in the ICU. Patients with altered mental status and comatose state have higher mortality than alert patients and should be managed in the ICU.

Fluid Therapy

All patients with DKA are volume depleted (fluid deficit ~5–8 L) requiring aggressive fluid resuscitation to restore intravascular volume and renal perfusion. Isotonic saline (0.9% NaCl) is infused at a rate of 500–1000 mL/h during the first 2 h, but larger volume may be required in patients with hypovolemic shock to restore normal blood pressure and tissue perfusion. After intravascular volume depletion has been corrected, the rate of normal saline infusion should be reduced to 250 mL/h or changed to 0.45% saline depending upon the serum sodium concentration. The free water deficit can be estimated, based on corrected serum sodium concentration, using the following equation: water deficit = (0.6)(body weight in kilograms) × (1 − [corrected sodium/140]) [10]. The goal is to replace half the estimated water deficit over a period of 12–24 h.

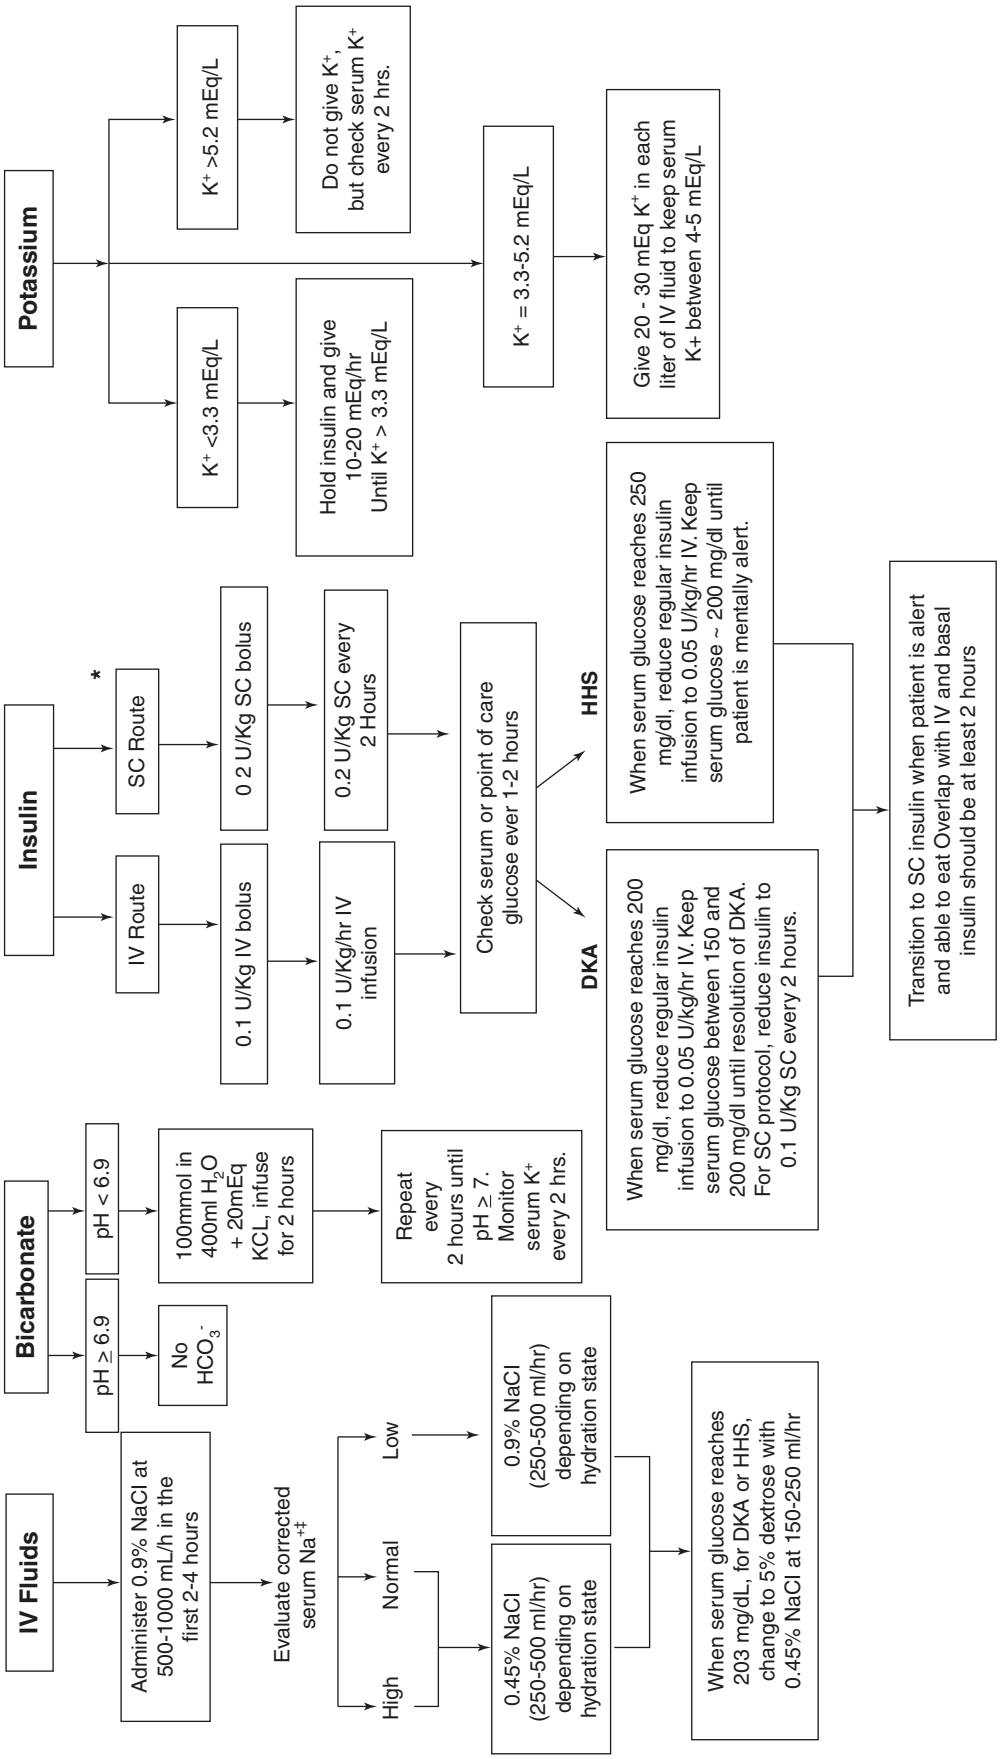

Fig. 44.2 Management of hyperglycemic emergencies [3]. *Subcutaneous Insulin Protocol has not been validated for HHS (Modified with permission from Diabetes Care from the American Diabetes Association Consensus Statement on Hyperglycemic Crises, 2009 [3])

Once the plasma glucose reaches 250 mg/dL, replacement fluids should contain 5–10% dextrose to allow continued insulin administration until ketonemia is controlled while avoiding hypoglycemia [3]. An important aspect of fluid management in patients with DKA is to replace the volume of urinary losses. Failure to adjust fluid replacement for urinary losses may delay the correction of electrolytes and water deficit.

Capillary blood glucose testing should be determined during treatment every 1–2 h at the bedside using a glucose oxidase reagent strip; and blood should be drawn every 4 h for determination of serum electrolytes, glucose, blood urea nitrogen, creatinine, magnesium, phosphorus, and venous pH until resolution of ketoacidosis.

Insulin Therapy

Insulin therapy is the cornerstone of DKA management. Insulin lowers blood glucose concentration by increasing peripheral glucose utilization and reducing hepatic glucose production. In addition, insulin therapy inhibits lipolysis and the release of free fatty acid from adipose tissue and decreases ketogenesis.

Regular insulin given intravenously by continuous infusion remains the drug of choice. Intermittent infusion or hourly boluses of low-dose intravenous insulin should be avoided because of regular insulin's [3] short half-life. The American Diabetes Association recommends an initial intravenous bolus of regular insulin of 0.1 units/kg of body weight, followed by a continuous infusion of regular insulin at a dose of 0.1 units/kg per hour until blood glucose levels reach 250 mg/dL [1]. Once glucose is lower than 250 mg/dL, dextrose should be added to intravenous fluids, and the insulin infusion rate is reduced to 0.05 units/kg per hour. Thereafter, the rate of insulin administration should be adjusted to maintain glucose levels at approximately 150–200 mg/dL and continued until ketoacidosis is resolved. Resolution of hyperglycemia takes about 4–6 h, but resolution of ketoacidosis takes longer (~10–14 h); thus, dextrose is needed to allow insulin infusion and the prevention of hypoglycemia [10].

Several studies and a meta-analysis have reported that the administration of hourly or every 2 h doses of subcutaneous rapid-insulin analogs (lispro and aspart) represents an effective alternative to the intravenous infusion of regular insulin [42–44]. The administration of an insulin subcutaneous bolus of 0.2–0.3 U/kg followed by 0.1–0.2 U/kg every 1–2 h, respectively, until glucose is <250 mg/dL. The dose is then reduced by half to 0.05 U/kg every 1 h or 0.01 U/kg every 2 h until resolution of DKA [42, 45]. Using scheduled subcutaneous insulin allows for safe and effective treatment in the emergency room and step-down units without the need for ICU care in patients with mild or moderate DKA. The use of intramuscular injections of rapid-acting insulin is also effective in the treatment of DKA, but this route tends to be more painful than subcutaneous injection and might increase the risk of bleeding among patients receiving anticoagulation therapy [1, 46]. The use of rapid-acting subcutaneous insulin analogs is not recommended for patients with severe and complicated DKA.

Potassium

An estimated total body potassium deficit of ~3–5 mEq/kg of body weight has been reported in adult patients with DKA [10]; however, most patients present with normal or high serum potassium. With initiation of insulin and fluid therapy, the extracellular potassium concentration invariable falls. Insulin therapy and correction of acidosis decrease serum potassium levels by stimulating cellular potassium uptake in peripheral tissues. Therefore, all patients require intravenous potassium to prevent hypokalemia.

The American Diabetes Association recommends the administration of intravenous potassium chloride (20–30 mEq/L) as soon as the serum potassium concentration is below 5.5 mEq/L. The treatment goal is to maintain serum potassium levels within the normal range of 4–5 mEq/L. A presentation with severe hypokalemia may be aggravated during insulin administration, which can induce life-threatening arrhythmias and respiratory muscle weakness. Thus, if the initial serum potassium is equal or lower than 3.0 mEq/L, potassium replacement should be given for 1–2 h at a rate of 10–20 mEq per hour, before insulin infusion is started.

Bicarbonate

Bicarbonate administration in patients with DKA is rarely indicated. Several controlled studies have failed to show any benefit from bicarbonate therapy in patients with DKA and arterial pH between 6.9 and 7.1 [3, 10]. Despite the lack of evidence, most experts in the field recommend that in patients with severe metabolic acidosis (pH < 6.9–7.0), 44.6 mEq of sodium bicarbonate should be added to a liter of hypotonic saline until pH rises to at least 7.0. In patients with arterial pH ≥ 7.0, no bicarbonate therapy is necessary.

Phosphate

Total body phosphate deficiency is present in most patients with DKA. Similar to studies with bicarbonate replacement, several studies have failed to show any beneficial effect of phosphate replacement on clinical outcome [3, 10]. Aggressive phosphate therapy may be potentially hazardous, as indicated in case reports of children with DKA who developed hypocalcemia and tetany secondary to intravenous phosphate administration. Careful phosphate replacement may be indicated in patients with cardiac dysfunction, anemia, respiratory depression, and in those with serum phosphate concentration lower than 1.0–1.5 mg/dL. If phosphate replacement is needed, it should be administered as a potassium salt, by giving half as potassium phosphate and half as potassium chloride. In such patients, because of the risk of hypocalcemia, serum calcium and phosphate levels must be monitored during phosphate infusion.

Transition to Subcutaneous Insulin

Patients with DKA should be treated with continuous intravenous or frequent subcutaneous insulin administration until ketoacidosis is resolved. Criteria for resolution of DKA include a blood glucose lower than 200 mg/dL, a serum bicarbonate level equal to or greater than 18 mEq/L, a venous pH greater than 7.3, and a calculated anion gap equal to or lower than 14 mEq/L [3, 10].

The half-life of insulin is <10 min [47]; thus, abrupt cessation of the insulin may result in rebound hyperglycemia, ketogenesis, and recurrent metabolic acidosis. Subcutaneous insulin should be given at least 2 h before discontinuing the intravenous insulin infusion [3]. The initial dose of NPH should be given 2 h before stopping insulin infusion. Earlier initiation 3–4 h before discontinuation of insulin drip should be considered when using basal insulin analogs (glargine, detemir, degludec), which have a longer delay in onset of action than NPH insulin. One randomized controlled trial evaluated the effect of co-administration of IV insulin with subcutaneous glargine shortly after the onset of treatment of DKA compared to IV insulin alone [48]. Patients who received glargine had slightly shorter time to resolution of DKA and shorter hospital stay; however, these differences were not statistically significant [48]. Another study found that the administration of basal insulin analogs early during treatment (more than 4 h) could reduce the frequency of rebound hyperglycemia after transition off insulin drip [49].

Patients with known diabetes may be given insulin at the dosage they were receiving before the onset of DKA. In patients with newly diagnosed diabetes, an initial insulin total insulin dose of 0.6 units/kg/day is usually sufficient to achieve and maintain metabolic control.

The use of insulin analogs in a basal-bolus regimen is the preferred insulin regimen and has been shown to reduce the risk of hypoglycemia compared to human insulin (NPH and regular) regimen [50]. If insulin analogs are used, the total daily dose is given 50% as basal (glargine, detemir, degludec) once daily at the same time of the day and 50% as prandial insulin 150–15 min before meals. If a patient is to be treated with NPH/regular insulin combination, the total daily dose should be given two-thirds in the morning and one-third in the evening as a split-mixed dose consisting of two-thirds of NPH and one-third of regular insulin.

Prevention

Patient education and the implementation of protocols aiming to acute and maintenance insulin administration after discharge may reduce lapses in treatment and are cost-effective ways to reduce the future risk of hospitalization for hyperglycemic emergencies [11]. Systems-based methods to reduce preventable causes of hyperglycemic emergencies may represent an important next step in reducing costs and improving patient care.

The frequency of hospitalizations for DKA has been reduced following diabetes education programs, improved follow-up care, and access to medical advice. The alarming frequency of insulin discontinuation due to economic reasons as the precipitating cause for DKA in low economic populations illustrates the need for health care legislation for reimbursement for medications to treat diabetes.

Home blood ketone monitoring, which measures beta-hydroxybutyrate levels on a fingerstick blood specimen, is commercially available ketones. Clinical studies have shown that elevation of beta-hydroxybutyrate levels is common in patients with poorly controlled diabetes and may allow early recognition of impending ketoacidosis, which may help to guide insulin therapy at home, and, possibly, may prevent hospitalization for DKA.

Multiple Choice Questions

1. Triad that is characteristic of diabetic ketoacidosis:
   (a) *Hyperglycemia, ketosis, and acidemia*.
   (b) Frequent urination, thirst, hunger.
   (c) Hyperglycemia, weight loss, fatigue.
   (d) High levels of hyperglycemia, dehydration, hyper-osmolality.
   (e) Hyperglycemia, depression of alert, unresponsiveness.
2. The key diagnostic feature of diabetic ketoacidosis:
   (a) Hyperglycemia.
   (b) Dehydration.
   (c) Confusion, stupor, and coma.
   (d) Polyuria.

(e) *Ketonemia*.

3. Which is the most common precipitating cause for diabetic ketoacidosis?
   (a) Insufficient insulin dose.
   (b) *Infection*.
   (c) Excessive food intake.
   (d) Psychological stress.
   (e) Noncompliance with therapy.
4. Ketoacidosis results from:
   (a) *Lack of or ineffectiveness of insulin and elevation of counter-regulatory hormones*.
   (b) Accelerated immune attack on beta-cells.
   (c) Increasing demands of insulin.
   (d) Low C-peptide levels.
   (e) Low compliance of patients.
5. Antidiabetic agents associated with diabetic ketoacidosis:
   (a) Metformin.
   (b) Sulfonylureas.
   (c) Glitazones.
   (d) DPP-4 inhibitors.
   (e) *SGLT2 inhibitors*.
6. Clinical symptoms of diabetic ketoacidosis include:
   (a) *Polyuria.*
   (b) *Polydipsia.*
   (c) *Weight loss.*
   (d) *Abdominal pain.*
   (e) *Labored Kussmaul respiration.*
7. The requirements for the successful treatment of diabetic ketoacidosis include:
   (a) Frequent monitoring.
   (b) Rehydration.
   (c) Insulin.
   (d) Investigating and correcting the cause.
   (e) *All of the above*.
8. The correct formula to estimate corrected serum sodium:

   (a) Corrected [Na+] = $\frac{6.1 \times \text{glucose}(\text{mg/dL}) + 100}{100}$ + [measured Na+].

   (b) Corrected [Na+] = $\frac{6.1 \times \text{glucose}(\text{mg/dL}) - 100}{100}$ + [measured Na+].

   (c) *Corrected [Na+]* = $\frac{1.6 \times \textit{glucose}(\textit{mg/dL}) - 100}{100}$ + *[measured Na+].*

   (d) Corrected [Na+] = $\frac{1.5 \times \text{glucose}(\text{mg/dL}) + 100}{100}$ + [measured Na+].

   (e) Corrected [Na+] = $\frac{6.1 \times \text{glucose}(\text{mg/dL}) + 200}{100}$ + [measured Na+].

9. Regarding insulin therapy, the American Diabetes Association recommends:
   (a) *An initial intravenous bolus of regular insulin of 0.1 units/kg of body weight, followed by a continuous infusion of regular insulin at a dose of 0.1 units/kg per hour until blood glucose levels reach 250 mg/dL.*
   (b) An initial intravenous bolus of intermediate-acting insulin of 0.1 units/kg of body weight, followed by a continuous infusion of long-acting insulin at a dose of 0.1 units/kg per hour until blood glucose levels reach 250 mg/dL.
   (c) An initial intravenous bolus of regular insulin of 1 units/kg of body weight, followed by a continuous infusion of regular insulin at a dose of 1 units/kg per hour until blood glucose levels reach 100 mg/dL.
   (d) An initial intravenous bolus of regular insulin of 10 units, followed by a continuous infusion of regular insulin at a dose of 1 units/kg per hour until blood glucose levels reach 150 mg/dL.
   (e) An initial intravenous bolus of insulin lispro of 1 units/kg of body weight, followed by a continuous infusion of regular insulin at a dose of 1 units/kg per hour until blood glucose levels reach 250 mg/dL.
10. Criteria for resolution of diabetic ketoacidosis include:
   (a) Blood glucose lower than 300 mg/dL, a serum bicarbonate level equal to or greater than 18 mEq/L, a venous pH greater than 3.7, and a calculated anion gap equal to or lower than 41 mEq/L.
   (b) *A blood glucose lower than 200 mg/dL, a serum bicarbonate level equal to or greater than 18 mEq/L, a venous pH greater than 7.3, and a calculated anion gap equal to or lower than 14 mEq/L.*
   (c) A blood glucose lower than 200 mg/dL, a serum bicarbonate level equal to or greater than 18 mEq/L, a venous pH greater than 7.4, and a calculated anion gap equal to or lower than 14 mEq/L.
   (d) A blood glucose lower than 150 mg/dL, a serum bicarbonate level equal to or greater than 18 mEq/L, a venous pH greater than 7.4, and a calculated anion gap equal to or lower than 14 mEq/L.
   (e) A blood glucose lower than 120 mg/dL, a serum bicarbonate level equal to or greater than 18 mEq/L, a venous pH greater than 7.4, and a calculated anion gap equal to or lower than 14 mEq/L.

Hypoglycemia: Diagnosis, Management, and Prevention

45

Raquel N. Faradji, Ana C. Uribe-Wiechers, and Elena Sainz de la Maza

Objectives

To know:

- The definition and classification of hypoglycemia
- The normal physiologic counterregulatory response to hypoglycemia and glycemic thresholds
- The altered counterregulatory responses to hypoglycemia
  - T1D
  - Long-standing T2D
  - Hypoglycemia unawareness
  - Hypoglycemia-associated autonomic failure
- The epidemiology of hypoglycemia
- The detection, diagnosis, and causes of hypoglycemia
- The risk factors of hypoglycemia
- The treatment of hypoglycemia
- The strategies to reduce or prevent hypoglycemia
- The technology in the reduction and prevention of hypoglycemia
- Beta cell replacement for the treatment of severe hypoglycemia

Introduction

Hypoglycemia is one of the most important barriers to achieve optimal glycemic management in the treatment of diabetes. It may cause potentially incapacitating and life-threatening events in patients with type 1 diabetes (T1D) and long-standing type 2 diabetes (T2D). It precludes patients from reaching euglycemia, limiting the benefits of tight control. Patients may develop unawareness of hypoglycemic symptoms due to blunted responses resulting from recurrent episodes of hypoglycemia posing them into grave danger.

Hypoglycemia Definition and Classification

The ADA (American Diabetes Association) defined hypoglycemia in patients with diabetes as "all episodes of abnormally low plasma glucose concentration that expose the individual to potential harm." The International Hypoglycemia Study Group, endorsed by the ADA, and the European Association for the Study of Diabetes define hypoglycemia in three levels (Table 45.1) [1, 3, 4].

Level 1 Measurable glucose concentration of <70 mg/dL (3.9 mmol/L) or less but >54 mg/dL (3.0 mml/L). A blood glucose level concentration of 70 mg/dL has been recognized as a threshold for neuroendocrine response to falling glucose in people without diabetes. It is considered clinically important

Table 45.1 Levels of hypoglycemia

Level	Description	Glycemic criteria	Description
1	Hypoglycemia alert	≤70 mg/dL	Sufficiently low for treatment with fast acting carbohydrates and dose adjustment of glucose-lowering therapy
2	Clinically relevant	≤54 mg/dL	Sufficiently low to indicate serious, clinically important hypoglycemia
3	Severe hypoglycemia		Hypoglycemia associated with severe impairment requiring external assistance for recovery

Adapted from [1, 2]

Table 45.2 Clinical classification of hypoglycemia in diabetes

Severe	Requiring assistance of another individual to administer carbohydrates, glucagon, or rescue therapy.
Symptomatic	Typical symptoms of hypoglycemia are accompanied by a measured plasma glucose concentration <70 mg/dL (3.9 mmol/dL)
Asymptomatic	Not accompanied by typical symptoms of hypoglycemia but the measured plasma glucose is <70 mg/dL (3.9 mmol/dL)
Probable	Symptoms typical of hypoglycemia are present but a measured plasma glucose of <70 mg/dL (3.9 mmol/dL) could not be determined
Pseudo-hypoglycemia	A person reports symptoms of hypoglycemia, but the plasma glucose concentration is >70 mg/dL (3.9 mmol/dL)

Adapted from [4]

(independent of the severity of acute hypoglycemic symptoms) and requires attention to prevent hypoglycemia [2].

Level 2 Defined as a glucose concentration <54 mg/dL (3.0 mml/L), it indicates serious clinically important hypoglycemia. It is the threshold at which neuroglycopenic symptoms begin to occur and requires immediate action to resolve the hypoglycemic event. These low levels may lead to defective hormonal counterregulation and impaired awareness of hypoglycemia. This clinical scenario warrants investigation and review of the medical regimen.

Level 3 Defined as a severe event characterized by altered mental status and/or physical functioning that requires assistance from another person for recovery. A subgroup of severe hypoglycemia is *severe hypoglycemic coma*, which is described as a severe hypoglycemic event resulting in coma or convulsions requiring parenteral therapy [2, 5].

The clinical classification of hypoglycemia includes severe, symptomatic, asymptomatic, probable, and pseudo-hypoglycemia (Table 45.2).

Physiology of Hypoglycemia

Glucose is the predominant metabolic source of energy for the brain, as it requires a constant and adequate supply of glucose. Under normal post-absorptive conditions, the brain accounts for 65% of whole-body glucose. The brain cannot synthesize nor store glucose under normal physiologic conditions but can adapt and utilize other substrates. Thus, during periods of fasting, ketone bodies, lactate, and alanine can be used as alternative brain fuels [6, 7].

Decreased Glucose Uptake by the Brain

- When blood glucose drops to 65–70 mg/dL (3.6–3.0 mmol/L), brain glucose uptake falls.
- At 54 mg/dL (3.0 mmol/L), the blood-to-brain glucose transport becomes rate limiting for brain glucose metabolism [7].

Normal Glucose Counterregulation

In defense against declining plasma glucose concentrations, several physiological mechanisms have evolved to prevent and correct hypoglycemia [6].

First Defense

Inhibition of endogenous insulin secretion. Insulin is the principal physiological factor that lowers plasma glucose. Insulin is secreted primarily in response to glucose, but amino acids, non-esterified fatty acids, adrenergic stimulation, and acetylcholine can also activate its secretion. Insulin secretion can be inhibited by hypoglycemia, insulin itself, somatostatin, and adrenergic activity [7].

Secondary Defense

Increased glucagon release. Glucagon is released from the alpha cells in the islet of Langerhans. The factors that stimulate its release include hypoglycemia, amino acids, catecholamines (epinephrine and norepinephrine), and free fatty acids. Inhibition of glucagon release includes insulin and somatostatin. Glucagon's physiologic actions are restricted almost exclusively by the liver, stimulating a rapid increase in hepatic production over a period of 10–15 min. The initial rise in glucose output is provided by an increase in hepatic glycogenolysis. If hypoglycemia continues, glucagon can stimulate hepatic gluconeogenesis; this can only be done if there are three carbon precursors present (glycerol, lactate, amino acids) [7].

Third Defense

Increased release of epinephrine. Similar to glucagon, epinephrine can act rapidly to increase hepatic glucose output by stimulating glycogenolysis. If hypoglycemia continues and three carbon precursors are present, epinephrine will stimulate gluconeogenesis. Epinephrine also decreases glucose utilization by directly inhibiting tissue glucose uptake and by inhibiting insulin release. Epinephrine is approximately ten times more potent than norepinephrine in producing these effects. Epinephrine stimulates glucose production directly by a beta-adrenergic mechanism and indirectly by inhibiting insulin secretion by an alpha-adrenergic mechanism. Glucose counterregulation from insulin-induced hypoglycemia is primarily by glycogenolysis during the first 2 h by gluconeogenesis thereafter. While the effect of both glucagon and epinephrine on glucose production is transient, the effect of epinephrine to limit glucose utilization is sustained [7].

Late Defense

Release of cortisol and growth hormone. Increased secretion of cortisol and growth hormone is involved in defense against prolonged hypoglycemia. Both can increase glucose through increases in gluconeogenesis. Both hormones can also inhibit insulin-stimulated peripheral glucose uptake and can increase proteolysis and lipolysis. However, prolonged hypoglycemia (3–5 h) is needed before the metabolic effects are measurable, and even at that time, they only represent 20–25% of the action of epinephrine. Thus, cortisol and growth hormone are not critical to recovery from even prolonged hypoglycemia or to the prevention of hypoglycemia after an overnight fast [7, 8].

Key Points

- The release of neuroendocrine counterregulatory hormones and the inhibition of endogenous insulin secretion occur before a healthy adult can feel any symptoms of hypoglycemia.
- In the acute phase of hypoglycemia, there is an increase in the concentrations of glucagon and epinephrine (within minutes); increases of cortisol and growth hormone occur later.
- Glucagon plays a primary role in the prevention and correction of hypoglycemia. Epinephrine is not normally critical but becomes critical when glucagon is deficient.
- Insulin, glucagon, and epinephrine play a major role in the prevention and correction of hypoglycemia. All of these three factors are impaired in diabetes (Fig. 45.1).

Glycemic Thresholds

Glycemic thresholds for the activation of counterregulatory hormones have been reported to be at or just below the lower limit of normal plasma glucose range and elicit a characteristic sequence of response (Fig. 45.1) with a defined hierarchy. Symptoms are generated at blood glucose concentrations around 50–58 mg/dL in young adults [7].

Glycemic Mechanisms

Falling plasma glucose concentrations are detected by glucose-responsive neurons in the hypothalamus and other regions of the brain. There is evidence that glucose sensors in the periphery, apart from pancreatic beta cells, have been found in the intestine, hepato-portal vein, and carotid body. Within the central nervous system (CNS), studies have identified a number of areas that contain neurons sensitive to local changes in glucose. One brain region in particular, the VMH (ventromedial hypothalamus), appears to play a crucial role during hypoglycemia. The specialized glucose-sensing neurons in the CNS have been broadly defined as either glucose exited, which increase their action potential frequency when glucose rises, or glucose inhibited, which increase their action potential frequency when glucose levels fall. These neurons are liable to react in a coordinated manner to alterations in the glucose level to which they are exposed. The neurons also respond to other metabolites such as lactate and beta hydroxybutyrate, as well as hormones such as insulin, leptin, and possibly glucagon-like peptide 1, reflecting the central role they play in responding to alterations in fuel supply and in maintaining glucose homeostasis [9].

Pathophysiology of Glucose Counterregulation in Diabetes

T1D

The physiology of glucose counterregulation is extensively impaired in patients with T1D. As endogenous insulin secretion becomes completely deficient, the first physiologic line of defense (modulation of endogenous insulin) becomes lost. As the plasma glucose concentration falls, insulin levels do not decrease. In addition, the rise in glucagon secretion (second line of defense) is lost as glucose levels decline. This is an acquired defect, but it develops early in the course of T1D. Glucagon responses to other stimuli are intact; therefore, it cannot be attributed to alpha cells and must represent a signal abnormality. The deficient glu-

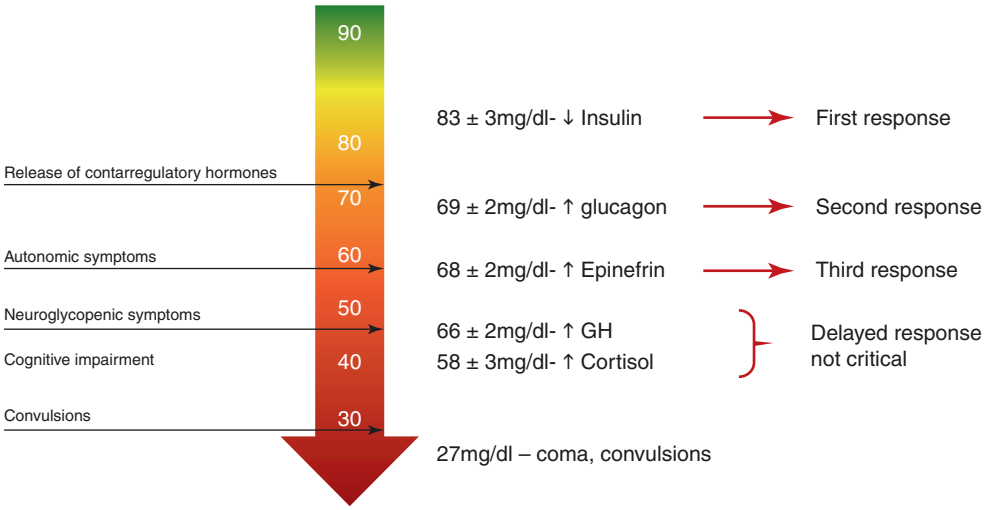

Fig. 45.1 Glycemic thresholds for hypoglycemia. (Adapted from [6–8])

cagon response is tightly related to absolute insulin deficiency. Insulin levels do not fall and glucagon levels do not rise as the plasma glucose concentration falls to hypoglycemic levels (Fig. 45.2).

The epinephrine response to failing glucose concentrations is commonly attenuated. This acquired abnormality is also selective in that epinephrine response to other stimuli is intact. However, while the deficient glucagon response to hypoglycemia appears to be absolute, the deficient epinephrine response appears to be a threshold abnormality. This epinephrine abnormality has been determined to be due to previous episodes of hypoglycemia [6].

Additional Facts

- Repeated hypoglycemia produces acute reductions (30–50%) in epinephrine, pancreatic polypeptide (a marker of parasympathetic nervous system activity), and muscle sympathetic nerve activity.
- Recent (within 24 h) antecedent hypoglycemia blunts the release of glucagon, growth hormone, adrenocorticotropic hormone (ACTH), and cortisol during subsequent hypoglycemia [7, 8].

T2D

The glucose counterregulatory mechanisms are generally intact during the initial course of T2D. Although there may be mild counterregulatory hormonal deficiencies, epinephrine secretion appears to be intact. Several studies have shown that counterregulatory hormonal release occurs at higher blood glucose levels in individuals with diabetes than in nondiabetic persons. This may confer greater protection against hypoglycemia. The glucagon response to hypoglycemia may be mildly decreased [10].

In many individuals with T2D who have insulin resistance, the lipolytic effects of epinephrine outweigh the effects of insulin on adipose tissue. Plasma free fatty acids increase in response to hypoglycemia in patients with T2D but not T1D. Epinephrine secretion in hypoglycemia may have a greater protective effect in insulin-resistant patients by promoting metabolic substrate release rather than storage. Epinephrine also stimulates the release of glucose from the kidney [10].

Nevertheless, as insulin progressively declines due to failing pancreatic endogenous secretion of insulin, glucagon response to hypoglycemia will progressively decline (Fig. 45.2).

It is important to consider the effects of aging in the response to hypoglycemia in patients with T2D as the majority of the population is elderly. With increasing age, the symptoms of hypoglycemia become less intense, and the symptom profile is modified. It has been reported that there is a modest attenuation of blood glucose recovery from hypoglycemia in the elderly nondiabetic population, in whom the rise of plasma epinephrine was slower than younger subjects. The elevation of glucagon and epinephrine occurred at lower plasma glucose levels in elderly nondiabetic patients compared to younger nondiabetic patients. The magnitude of the response is also lower in the elderly group. Also, the rate of insulin clearance from the circulation declines with increasing age, which may enhance the risk of hypoglycemia [10].

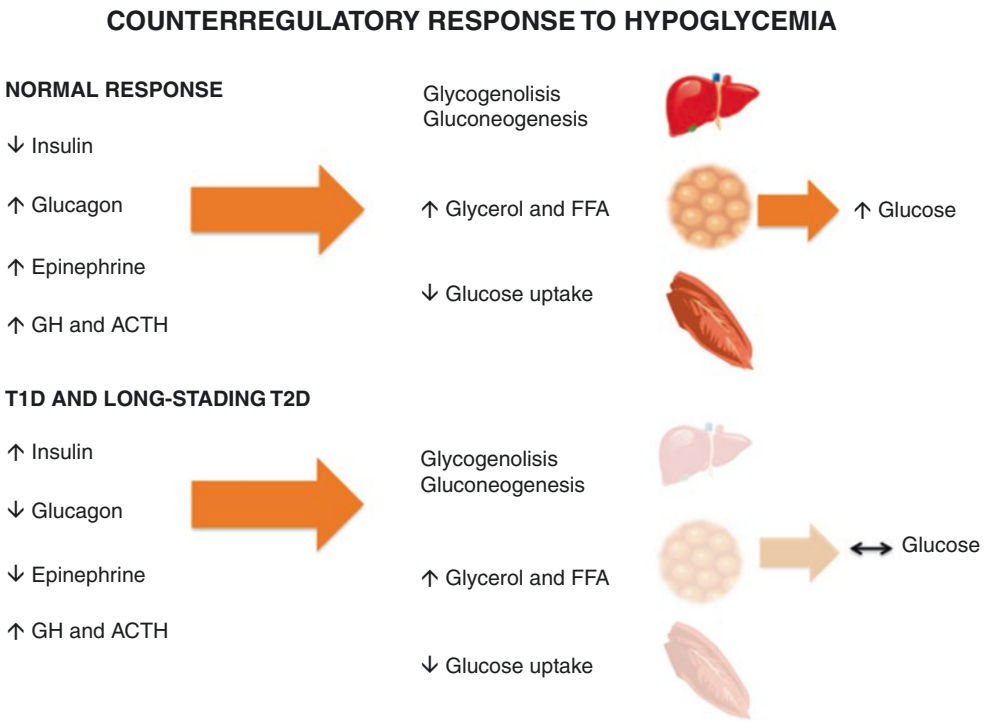

Fig. 45.2 Counterregulatory response to hypoglycemia

Hypoglycemia Unawareness

Individuals with intensive glucose control and multiple episodes of hypoglycemia find that activation of the physiologic responses to hypoglycemia is pushed to a lower plasma glucose level. This dangerous condition, called hypoglycemia unawareness, results in inability of patients to recognize falling plasma glucose until the value is <50 mg/dL (2.8 mmol/L). In some individuals, a falling plasma glucose level is not recognized at plasma glucose of 30 mg/dL (1.7 mmol/L). Thus, thresholds for the activation of physiologic defenses against hypoglycemia are labile and can change rapidly [7].

A major defect in the counterregulatory response to hypoglycemia in diabetes is a reduced autonomic response. Hypoglycemia unawareness occurs in 20% of patients with T1D and about half of the patients with long-standing T1D and is estimated to occur in about 25% of patients with long-standing T2D. As glucose declines, there is activation of the autonomic nervous system (ANS) that results in increased glucose production and decreased glucose uptake. The autonomic response is directly related to the generation of a symptomatic response to hypoglycemia. When this response becomes impaired, there is reduced awareness of the symptoms of hypoglycemia as well as reduced catecholamine release. The reduced autonomic response includes the sympathetic neural norepinephrine and acetylcholine, as well as the adrenomedullary epinephrine response (Fig. 45.3). As discussed previously, this reduced response becomes critical in patients with T1D and long-standing T2D, as there is no glucagon response, increasing the risk of hypoglycemia [9].

Key Points

- A defective autonomic response usually precedes prior episodes of hypoglycemia.
- This sets up a vicious cycle whereby hypoglycemia increases the likelihood of subsequent hypoglycemia.
- Hypoglycemia unawareness has been found to increase the frequency of hypoglycemia by a factor of 7 [7].

Hypoglycemia: Associated Autonomic Failure

The combination of defective glucose counterregulation (decreased glucagon release and attenuated epinephrine release) and hypoglycemia unawareness (reduced autonomic-sympathetic neural and adrenomedullary response) constitutes the clinical syndrome of hypoglycemia-associated autonomic failure (HAAF). It occurs in patients with T1D and long-standing T2D who have had recent antecedent hypoglycemia; it can also occur by sleep or prior exercise (Fig. 45.3) [11].

In patients with T1D, recent hypoglycemia has been shown to shift glycemic thresholds for autonomic and cognitive dysfunction responses to lower plasma glucose concentrations. It has been shown that avoidance of hypoglycemia

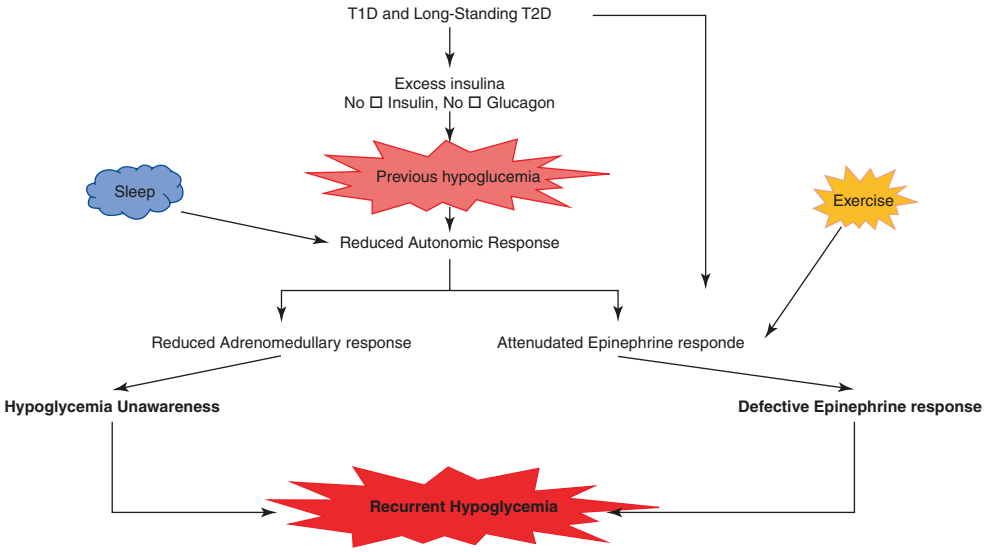

Fig. 45.3 Hypoglycemia-associated autonomic failure. (Adapted from [11])

for 2–3 weeks reverses hypoglycemia unawareness and improves the reduced epinephrine defective response; nevertheless, the glucagon response is not restored [8].

Additional Facts

- Repeated episodes of relative mild <70 mg/dL (3.9 mmol/L) and only brief durations (15–20 min) of hypoglycemia can independently blunt counterregulatory responses to subsequent hypoglycemia.
- One prolonged episode (2 h) of moderate hypoglycemia <50 mg/dL (2.8 mmol/L) is sufficient to induce HAAF within a few hours on the same day [7].

It has been proposed that repeated hypoglycemia increased cerebral glucose uptake in both healthy individuals and patients with T1D, thereby reducing the stimulus for neuroendocrine counterregulatory responses during subsequent hypoglycemia. Other mechanisms that have been proposed include activation of the hypothalamic-pituitary-adrenal axis, increases in neurotransmitters such as GABA, and changes in hypothalamic fuel sensors such as glucokinase or AMP kinase. Additionally, experimental evidence demonstrates that alcohol and opioids can downregulate subsequent ANS and neuroendocrine responses to hypoglycemia.

As mentioned above, sleep and exercise can induce HAAF. Compared to hypoglycemia during waking period, hypoglycemia during sleep (nocturnal hypoglycemia) elicits reduced counterregulatory response. Research has revealed a 60–70% reduction in epinephrine response during nocturnal hypoglycemia. Thus, exercise blunts ANS response (by 30–50%) to subsequent hypoglycemia and vice versa. This feed-forward vicious cycle of blunted ANS responses between exercise and hypoglycemia can occur after only a few hours and persists for at least 24 h following either stress [7].

Opioid receptor blockade, via treatment with naloxone, during hypoglycemia has been shown to prevent blunting responses (epinephrine and endogenous glucagon production) to next-day hypoglycemia in individuals with T1D [7].

Physiologic Stimuli to Blunted Hormonal Responses to Hypoglycemia

- Antecedent hypoglycemia
- Nocturnal hypoglycemia
- Sleep
- Alcohol
- Opioids [7]

Epidemiology

Iatrogenic hypoglycemia is more frequent in patients with profound endogenous insulin deficiency, T1D, and advanced T2D (as its incidence increases with the duration of diabetes). The frequency of hypoglycemia is about threefold greater in T1D than in T2D. Ninety percent of all patients who receive insulin have experienced hypoglycemic episodes [12].

During the Hypoglycemia Assessment Tool (HAT) global study, which was a non-interventional, multicenter, 6-month retrospective and 4-week prospective study involving 27,585 patients with either T1D or T2D treated with insulin, in 24 countries worldwide, it was found that during the prospective period, 83% of patients with T1D and 46.5% of patients with T2D reported hypoglycemia. Overall, there were 73.3

events/patient-year of hypoglycemia in T1D and 19.3 in patients with T2D. There were 11.3 events/patient-year of nocturnal hypoglycemia in T1D and 4.9 in T2D. And finally, there were 4.9 events/patient-year of severe hypoglycemia in T1D and 2.5 events/patient-year in T2D [13].

In the United States, from 1993 to 2005, around five million emergency department visits were due to hypoglycemic events, 25% of which led to hospitalization. This is especially common in elderly patients. Additionally, the NICE-SUGAR trial demonstrated that critically ill patients who are intensively controlled had an increased risk of moderate-to-severe hypoglycemia and increased risk of death [14].

A trial involving 33,675 hospitalized patients with and without diabetes found that hypoglycemia, with either insulin or spontaneous, was associated with increased short- and long-term mortality. In this cohort of hospitalized patients to medical wards, 9% of patients had at least one episode of hypoglycemia [15].

T1D

People with T1D are bound to have hypoglycemia; as they attempt to achieve euglycemia, they will suffer numerous episodes of asymptomatic hypoglycemia. Plasma glucose concentrations may be <50 mg/dL (2.8 mmol/L) 10% of the time. They have an average of two episodes of hypoglycemia per week, thousands of such episodes over a lifetime, and an episode of severe hypoglycemia approximately once a year [7]. Population data indicate that 30–40% of people with T1D experience an average of one to three episodes of severe hypoglycemia each year. Older estimates were that 2–4% of patients with T1D die from hypoglycemia. More recent estimates are that 6–7% or 10% of those with T1D die from hypoglycemia [16].

In the DCCT (Diabetes Control and Complications Trial), severe hypoglycemia occurred in 65% of patients with T1D treated intensively and 35% of patients with T1D on the conventional group over 6.5 years. There were no statistical differences in hospitalizations; however, there were two fatal motor vehicle accidents in the intensive therapy group, which may be attributed to hypoglycemia. The DCCT also confirmed that the presence of detectable endogenous insulin as measured by residual C-peptide secretion is associated with a reduced risk of hypoglycemia [17].

Ninety percent of the surviving cohort of DCCT joined the EDIC (Epidemiology of Diabetes Interventions and Complications), which was an observational follow-up study to examine the long-term effects of the original DCCT therapies. Around 50% of participants in each group reported an episode of severe hypoglycemia during the 20 years of EDIC. The main characteristics, HbA1c (glycated hemoglobin), and hypoglycemia events can be seen in Table 45.3 [18].

There was a group of participants who reported four or more episodes of hypoglycemia. During the DCCT, 54% of the intensive group and 30% of the conventional group experienced more than four episodes of severe hypoglycemia. In the EDIC, 37% of the intensive group and 33% of the conventional group experienced four or more episodes. A subset of participants (14%) experienced nearly one-half of all severe hypoglycemia in the DCCT, and 7% in the EDIC experienced almost one-third of all episodes of severe hypoglycemia. This observation exposes the possibility that there are certain individuals who are more susceptible to severe hypoglycemia [18].

In a retrospective epidemiological survey of an unselected population with T1D, the prevalence of severe hypoglycemia was reported to be 37% over a 1-year recall period, with 130 events occurring per 100 patient-years. In this report, 5% of the participants experienced 54% of all severe hypoglycemia [20].

T2D

Overall, the frequency of hypoglycemia is substantially lower in T2D than in T1D. Event rates for severe hypoglycemia are

[a] Events per 100 patient-years

approximately tenfold lower in T2D even during aggressive insulin therapy. They are even lower in those treated with oral hypoglycemic agents. Most episodes of hypoglycemia in T2D are considered to be mild to moderate [21].

Miller et al. performed a cross-sectional study on T2D African American population. Hypoglycemia had a prevalence of 24.5%, and severe hypoglycemia had a prevalence of 0.5%. The prevalence of hypoglycemia was highest on patients receiving triple therapy, followed by those receiving insulin alone or a single oral agent, and infrequent on those receiving hypoglycemic agents alone or diet therapy alone. In all treatment groups, the prevalence of hypoglycemia tended to increase as HbA1c decreased. The highest prevalence was seen in patients receiving insulin therapy who had HbA1c less than 7% [22].

Over 6 years in the UKPDS (United Kingdom Prospective Diabetes Study), major hypoglycemia was reported in 2.4% of T2D patients treated with metformin, 3.3% of patients treated with sulfonylurea, and 11.2% of those treated with insulin. They found a higher frequency of hypoglycemia in the intensive group compared with the conventional group. With intensive treatment, hypoglycemia occurred most frequently in the insulin-treated patients, and the prevalence of hypoglycemia was lower in the first decade of the study that in later years [8].

Oral and Injectable Agents

Hypoglycemia with oral agents medications occurs most frequently with sulfonylureas and meglitinides. Both classes of medications have increased the absolute risk of hypoglycemia by 4–9% compared to placebo or other agents. Sulfonylureas have an 11% higher risk of hypoglycemia than metformin [23].

Metformin

When used as monotherapy, metformin has minimal risk of hypoglycemia. When compared with placebo, hypoglycemia was reported in less than 5% of patients taking metformin alone. Since metformin enhances insulin sensitivity, when combined with other medications that increase circulating levels of insulin, the risk of hypoglycemia increases [24].

Alpha-Glucosidase Inhibitors

The risk of hypoglycemia is very low; however, should patients experience hypoglycemia, it cannot be treated with sucrose or fruit juice (which is hydrolyzed to glucose and fructose), since the absorption is inhibited by the mechanism of these medications. Hypoglycemic episodes must be treated with simple sugars such as oral glucose (dextrose), which can be in glucose tablets, or grapes [24].

Sulfonylureas

The risk of hypoglycemia is very common with sulfonylureas, even when administered as monotherapy. The rates of hypoglycemia differ with each sulfonylurea based on each agent's pharmacokinetic properties. Glyburide (glibenclamide) has been associated with a higher incidence of hypoglycemia when compared to glipizide. Glyburide should be avoided in patients with creatinine clearance of <50 mL/min.

In randomized clinical trials, sulfonylureas are associated with a significant greater risk of any or severe hypoglycemia when compared to insulin sensitizers or incretin-based therapies. A meta-analysis that included trials with a duration of >24 weeks, enrolling patients with T2D, comparing sulfonylurea with placebo or active drugs different from sulfonylureas, reported that hypoglycemia, including severe hypoglycemia, was frequent in patients treated with sulfonylureas. They also found that the risk of hypoglycemia with sulfonylureas is not different from that of insulin in head-to-head trials. The overall risk of severe hypoglycemia was increased more than threefold with sulfonylureas than with comparators. The cumulative incidence of hypoglycemia with sulfonylureas was 17% and for severe hypoglycemia 1.2% [25].

Amylin

Amylin analogues are associated with a high risk of hypoglycemia when they are combined with insulin therapy. Pramlintide carries a black box warning that when adding pramlintide to insulin, the prandial insulin dose must be reduced by 50% and titrated up to avoid severe hypoglycemia.

Dipeptidyl Peptidase-4 (DPP-4) Inhibitors

DPP-4 inhibitors generally do not cause hypoglycemia when used as monotherapy, are weight neutral, and are relatively well tolerated.

Sodium-Glucose Co-transporter 2 (SGLT2) Inhibitors

SGLT2 inhibitors have been shown to have a low risk of hypoglycemia with monotherapy [24].

Insulin

Glargine

Insulin glargine is a long-acting insulin analogue, which is less soluble at physiologic pH (potential of hydrogen) than human insulin. Insulin glargine reduces the risk of nocturnal hypoglycemia in T1D patients compared with insulin NPH (neutral protamine Hagedorn or isophane insulin) when taken either with prandial unmodified human insulin or rapid-acting insulin analogues [20, 26].

Detemir

This is a long-acting basal insulin that has extended duration due to molecular modifications leading to increased albumin binding. Detemir has also been associated with reduced nocturnal hypoglycemia in people with T1D compared with NPH insulin, as reported in numerous studies. In studies comparing twice-daily insulin detemir to NPH insulin, where both groups used a fast-acting insulin analogue prandially, significant reductions in hypoglycemia had been attained with detemir [20, 26].

Degludec

Insulin degludec is an ultra-long-acting insulin analogue, which forms a subcutaneous depot and is slowly released. Studies comparing insulin degludec with glargine have reported a reduced number of nocturnal hypoglycemic episodes in the degludec group.

Insulin degludec was compared with insulin glargine U100 in the SWITCH 1 and SWITCH 2 trials. Both studies used a randomized, double blind, treat-to-target, crossover design. Patients with T1D ($N = 501$; SWITCH 1) or patients with T2D ($N = 721$; SWITCH 2) who had one or more risk factors were enrolled. These patients were randomized to either insulin degludec or insulin glargine U100 for 32 weeks (16-week titration and then 16-week maintenance) and then crossed over to the alternate insulin treatment for an additional 32 weeks (16-week titration and 16 week maintenance). In SWITCH 1, the rate of overall symptomatic hypoglycemia was significantly lower with insulin degludec than insulin glargine U100 (2200.9 vs. 2462.7 episodes/100 patient-years of exposure). In SWITCH 2, the rates of severe hypoglycemia were also statistically significantly lower with insulin degludec than insulin glargine U100 (185.6 vs. 265.4 episodes/100 patient-years) [27–29].

Glargine U300

Another prolonged-acting insulin analogue is insulin glargine U300 [30, 31] (300 IU/mL). By being more concentrated, it forms a compact subcutaneous depot with a smaller surface area to produce a more gradual and prolonged release. Compared to glargine U100, it has shown lower event rates of nocturnal hypoglycemia. Glargine U300 can be injected with a 3 h flexible regimen.

There are pharmacokinetics studies [30] that compare degludec to glargine U300. The clinical studies have not shown a significant difference in the rate of hypoglycemia between the two types of insulin [32].

Fast-Acting Insulin Analogues

Fast-acting insulin analogues were developed in order to better stimulate the physiological postprandial insulin response. Data from subsequent clinical trials comparing lispro with human insulin suggest that the more physiologic pharmacokinetics are associated with a reduced risk of nocturnal hypoglycemia. A multicenter randomized, double blind, crossover study with 90 participants demonstrated a significantly reduced severe hypoglycemia as well as improved glycemic control with insulin aspart compared with human insulin. Fast-acting insulin analogues have shown to reduce nocturnal and late postprandial hypoglycemia [20].

Clinical Manifestations

For people with diabetes, the detection of hypoglycemic symptoms is a critical tool for the recognition and treatment of hypoglycemia. Recognition of hypoglycemia is possible through self-monitoring blood glucose (SMBG), continuous glucose monitoring (CGM), and detection of hypoglycemic symptoms. Numerous biological and psychological modifiers can either facilitate or interfere with the recognition of hypoglycemia. With experience, individuals develop beliefs concerning their symptoms of hypoglycemia. Nevertheless, beliefs have a high incidence of false alarm rates; individuals with poor control may believe that they have hypoglycemia when instead they have hyperglycemia, and individuals with tight control may have hypoglycemia unawareness and not be able to recognize an episode of hypoglycemia. When blood glucose falls too low, then consciousness becomes impaired, making it difficult to accurately interpret the meaning of any symptom. Some people may deny symptoms of hypoglycemia because symptoms represent failure in their self-management [33].

Symptoms of hypoglycemia are divided into two categories (Table 45.4):

- Autonomic (neurogenic) symptoms are the result of perception of physiological changes caused by the autonomic nervous system release triggered by hypoglycemia.

Table 45.4 Symptoms of hypoglycemia

Autonomic	Neuroglycopenic
Adrenal	Slowed thinking
• Trembling	Abnormal mentation
• Shakiness	Irritability
• Palpitations	Confusion
• Nervousness	Difficulty speaking
• Anxiety	Ataxia
• Pupil dilation	Paresthesias
• Pallor	Headaches
Cholinergic	Stupor
• Clamminess	Seizures
• Sweating	Coma
• Hunger	Death (if untreated)
• Tingling	

Adapted from [34]

- Neuroglycopenic symptoms occur as a result of brain neuronal glucose deprivation. The patient usually recognizes these symptoms first.

Physical signs that result from activation of the sympathoadrenal system include pallor and diaphoresis, which are often prominent, and increased heart rate and systolic blood pressure, which are often subtler. Hypothermia is often present. Transient focal neurological deficits (diplopia, hemiparesis) occur occasionally [7].

Symptoms of hypoglycemia vary greatly among patients and depend on the individual's personal experience and sensitivity. In mild hypoglycemia, symptoms result from an ANS response and usually consist of tremors, palpitations, sweating, blurred vision, mood variations, and excessive hunger. Major cognitive deficits usually do not accompany mild reactions, so patients are generally able to self-treat. These mild symptoms usually respond to an oral ingestion of 10–15 g of carbohydrates and resolve within 10–15 min. Moderate hypoglycemia includes neuroglycopenic as well as autonomic symptoms, which usually consist of headache, mood changes, irritability, decreased attentiveness, and drowsiness. Behavioral changes such as irritability, agitation, quietness, stubbornness, and tantrums may be the prominent symptoms for the preschool child and may result from a combination of neuroglycopenic and autonomic response [5]. People often need assistance in treating themselves, and these reactions produce longer-lasting and more severe symptoms usually requiring a second dose of carbohydrates. Severe hypoglycemic symptoms are characterized by unresponsiveness, combativeness, unconsciousness, or seizures and typically require assistance from another individual. Patients who experience seizures with severe hypoglycemia are at risk for recurrence [35, 36].

Diagnosis and Detection

People may recognize hypoglycemia based on their symptoms and experience, although as discussed earlier, individuals may not be aware of an episode of hypoglycemia or may misinterpret their symptoms. It has been reported that patients who are being typically aware of their hypoglycemia, on average, recognize 50% of their hypoglycemic episodes [36]. Therefore, documentation of a low plasma glucose concentration is very helpful. A hypoglycemic episode is most convincingly documented by the Whipple's triad: symptoms compatible with hypoglycemia, a low plasma or blood glucose concentration, and restoration of those symptoms after the glucose concentration is raised to normal [8].

There are two technologies available to measure glucose in an outpatient setting: capillary measurement with point-of-care glucose meters or self-monitoring blood glucose (SMBG) and interstitial measurement with CGM, both retrospective and real time [1].

Additional Facts

- Plasma glucose samples are up to 15% higher than mixed venous whole blood glucose samples.
- Mixed venous blood glucose values can be considerably lower than arterial or capillary levels.
- Glucose meters can be imprecise, especially at low blood glucose levels [14].

Causes

The need to identify underlying causes is an important aspect of hypoglycemia evaluation and management. Looking back over the events of several hours preceding the reactions can often identify the factors precipitating an event of hypoglycemia (Table 45.5).

Table 45.5 Conventional causes of hypoglycemia

Insulin (or secretagogues or insulin sensitizers) doses are excessive, ill-timed, or of wrong type
Exogenous glucose delivery is decreased
• Missed meal
• Low carbohydrate meal
• Overnight fast
• Vomiting
Endogenous glucose production is decreased
• Alcohol ingestion
Glucose utilization is increased
• Exercise
• Sepsis, trauma, burns
Sensitivity to insulin is increased
• Late after exercise
• Weight loss
• Improved fitness
Insulin clearance is decreased
• Renal failure
• Liver failure
• Hypothyroidism

Adapted from [8]

Risk Factors and Determinants

Many factors can put T1D and T2D patients at increased risk of experiencing hypoglycemia (Table 45.6). Severe hypoglycemia is mostly associated with the use of glucose-lowering drugs, especially insulin or insulin secretagogues.

In a large retrospective cohort study involving people with T2D, severe hypoglycemia was recorded in 12 cases per 10,000 patient-years. They observed approximately six times higher incidence rate in patients using insulin during follow-up than in non-insulin users. Patients with cardiovascular disease and renal failure had approximately 1.5 times higher incidence rate of severe hypoglycemia. In this study, the current use of insulin or sulfonylureas, age ≥75, renal failure, and cognitive impairment/dementia were associated with a substantially increased risk of developing severe hypoglycemia in the overall population [34].

The Fremantle Diabetes Study was a longitudinal observational cohort study aimed at defining the determinants of severe hypoglycemia complicating T2D. Insulin treatment or its duration, renal impairment, peripheral neuropathy, and higher education proved to be independent predictors of first and multiple episodes of hypoglycemia. The frequency of hypoglycemia was also associated with a lower fasting serum glucose but paradoxically higher HbA1c. A prominent predictor of the first episode of hypoglycemia in this cohort was duration of insulin treatment, with each year increasing the risk by 33%. They also found that a previous history of hospitalization for severe hypoglycemia was a strong independent predictor of the first episode of hypoglycemia [37].

Table 45.6 Risk factors for hypoglycemia

Insulin deficiency
Negative C peptide
Long-standing diabetes
History of severe hypoglycemia
Hypoglycemia unawareness
Extremes of age (young and elderly)
Cognitive impairment/dementia
Systemic illness
• Renal failure
• Liver failure
• Congestive heart failure
Ethanol use
Autonomic neuropathy
Glucose variability
Aggressive glycemic therapy
Peripheral neuropathy
Lower glycemic goals
Medications
• Fixed insulin regimens
• Sulfonylureas
• Salicylates
• Beta blockers
• Coumarin
• Fibrates
Nutritional factors
• Ethanol consumption
• Gastroparesis
• Fasting or missed meals
• Malnutrition
• Low-carb diets
Nocturnal hypoglycemia
Erratic schedules
Exercise (especially irregular)
Hormonal factors
• Adrenal insufficiency
• Hypothyroidism
• Hypopituitarism
• Pregnancy/breastfeeding
• Allopurinol
• Nonsteroidal anti-inflammatory drugs (NSAIDs)

Physical Activity and Exercise

Physical activity may increase glucose transport and utilization by skeletal muscles, acutely and chronically. Hypoglycemia can occur during 1–2 h after exercise, or up to 17 h after exercise. Aerobic exercise results in an increase in both insulin- and non-insulin-mediated glucose uptake [38, 39].

The blood glucose response to exercise is affected by many factors including duration, intensity and type of exercise, the time of day when exercise is performed, plasma glucose, insulin levels, and the availability of supplemental and stored carbohydrates [5].

During moderate intensity exercise in nondiabetic individuals, endogenous insulin secretion is reduced by 40–60% [40]. The increased fuel demands on the working muscle necessitate compensatory metabolic processes in the liver and kidney. Changes in hepatic glycogenolysis and gluconeogenesis have been found to be closely coupled to the increase in glucose uptake produced by the working muscle because of the actions of the pancreatic hormones. The exercise-induced increase in glucagon secretion and the concomitant decrease in insulin secretion interact to stimulate hepatic glycogenolysis, whereas the increase in hepatic gluconeogenesis is determined primarily by gluca-

gon's action to increase hepatic gluconeogenic precursor fractional extraction and the efficiency of intrahepatic conversion to glucose. Epinephrine and norepinephrine become important in increasing glucose production during prolonged or heavy exercise. Catecholamines can produce this effect by directly stimulating both hepatic and renal glucose production, by increasing the availability of gluconeogenic precursors (lactate, alanine, or glycerol), and by increasing lipolysis. Catecholamine-induced metabolic effects at the muscle and adipose tissue are rapid, increasing gluconeogenic precursor uptake at the liver within minutes [7].

Recent studies have demonstrated that there is a vicious cycle of counterregulatory failure between exercise and hypoglycemia. Thus, two episodes of prolonged, moderate-intensity exercise can reduce ANS and neuroendocrine responses by 50% during subsequent similar hypoglycemia. Similarly, two episodes of antecedent hypoglycemia can reduce counterregulatory responses during subsequent exercise by 40–50%. Therefore, individuals who have had a previous episode of hypoglycemia are at greater risk of hypoglycemia during exercise [40].

In a randomized crossover study involving subjects with T1D, participants were randomly assigned to morning exercise versus afternoon exercise. They found that morning exercise confers a lower risk of late-onset hypoglycemia than afternoon exercise and improves metabolic control on the subsequent day [39].

Alcohol

Ethanol induces hypoglycemia by inhibiting gluconeogenesis; as little as 50 g of alcohol might be sufficient. Alcohol excess, especially in the fasting state, is a major risk factor for severe hypoglycemia. Ethanol and its metabolism influence several pathways vital for the manufacture and production of glucose by the liver [41].

The gluconeogenesis pathway is disrupted with ethanol ingestion by

- Reduced nicotinamide adenine dinucleotide NADH/NAD ratio—as a result of the oxidation of alcohol to acetaldehyde and acetate, thus reducing the ability of the liver and kidney to oxidize lactate and glutamate to pyruvate and alpha-ketoglutarate.
- Inhibiting the release of alanine from the muscle (a vital precursor of gluconeogenesis)
- Inhibition of lactate, glycerol, and alanine uptake by the liver

Alcohol potentiates the hypoglycemic effect of insulin and sulfonylureas, and because of the inhibition of gluconeogenesis, glucagon and catecholamines are ineffective in raising glucose levels [7].

Moderate consumption of alcohol in the evening may predispose patients to hypoglycemia on the subsequent morning with reduced nocturnal growth hormone secretion [5].

Medications

Beta-Blockers

Propranolol and other nonselective beta-blockers decrease the ability of the liver and kidney to increase their release of glucose, enhance peripheral insulin sensitivity, and may mask the symptoms of hypoglycemia. The risk of hypoglycemia becomes even higher in the presence of renal dysfunction. The hypoglycemic effect of beta-blockers seems to be directly tied to the diminished adrenergic response to hypoglycemia and to the diminished concentration of circulating free fatty acids. Therefore, propranolol should be used with caution or, if possible, avoided in patients with renal failure. Recent studies indicate that beta-1 selective blockers do not present an increased risk for severe hypoglycemia and therefore should not be considered as being contraindicated in diabetic patients.

- Salicylates—Salicylates can act by binding hepatic glucose production and increasing insulin secretion.
- Sulfonamides—Have a chemical structure similar to sulfonylureas and have been known to have blood glucose-lowering properties.
- Angiotensin-converting enzyme inhibitors can increase insulin sensitivity and can decrease the degradation of bradykinin, which has certain insulin mimetic actions.
- Pentamidine is cytotoxic to pancreatic beta cells, and hypoglycemia occurs with the release of insulin from degenerating cells [7].

Renal Failure

Renal insufficiency is a very common predisposing condition for hypoglycemia. In fact, it is probably the second most common potentiating factor of hypoglycemia after insulin therapy. Nearly 50% of hospitalized patients who were recognized to have hypoglycemia had chronic renal failure. The mortality rate in patients with chronic renal failure may be related to the degree of hypoglycemia and to the number of risk factors for hypoglycemia. In renal failure, hypoglycemia may result from the use of insulin, antidiabetic agents, certain drugs, or a combination of the above [42].

Hypoglycemia resulting from an oral hypoglycemic agent in patients with renal failure is more likely to occur when other factors such as hepatic dysfunction, hypoalbuminemia, alcoholism, or an associated endocrine deficiency are pres-

ent. It is usually manifested by neuroglycopenic symptoms rather than neurogenic symptoms, and patients may display atypical symptoms. Hypoglycemia is usually of long duration, particularly when a sulfonylurea is the causal agent.

Congestive Heart Failure

The occurrence of congestive heart failure in patients with renal failure may also precipitate hypoglycemia. The pathogenesis of hypoglycemia in heart failure is varied and involves liver dysfunction resulting from congestion, poor nutrition, cachexia, and poor blood supply to muscles and liver. Insufficient production or delivery of substrates for adequate gluconeogenesis in the liver, severe depletion of glycogen stores, possibly caused by poor dietary intake, and gastrointestinal malabsorption caused by congestive heart failure are major potentiating factors of hypoglycemia. The coexistence of renal failure and congestive heart failure may place the patient at even higher risk for hypoglycemia.

Sepsis, Trauma, and Burns

Initially, the response to the stress of infection is an increase in glucose turnover, with glucose production often exceeding glucose utilization and resulting in mild hyperglycemia. This response involves increases in both glycogenolysis and gluconeogenesis and is largely mediated by glucagon. As the infection worsens, increased release of endotoxin and its derivatives, complement activation, endoperoxide activation, and release of endogenous inflammatory mediators (tumor necrosis factor-alpha, interleukins, and other monokines) compromise cardiovascular integrity and cause central venous pooling, inadequate tissue perfusion, and microvascular protein transudation. At this stage, a decrease in splanchnic and renal blood flow occurs. Despite concomitantly reduced peripheral tissue perfusion, glucose utilization is increased. Decreased tissue oxygenation causes increased anaerobic glycolysis, which perpetuates the increased glucose utilization [7].

The inability of glucose production to keep pace with increased tissue demands results in hypoglycemia. Hepatic glycogen stores are rapidly exhausted; consequently, glucose production becomes solely dependent on gluconeogenesis. However, gluconeogenesis fails because of a reduction in ANS and neuroendocrine effects.

Glucose Variability

It has been shown that glucose variability is associated with increased risk of hypoglycemia. In an observational study involving people with T2D, they found that hypoglycemia was positively associated with glucose variability and negatively associated with mean glucose concentration. The risk of hypoglycemia was completely or virtually eliminated when the glucose variability was <30 mg/dL (<1.7 mmol/L). Therefore, lowering glycemia without reducing glucose variability should be avoided as it places the individual at greater risk of hypoglycemia [43].

Nocturnal Hypoglycemia

It has been estimated that about one-half of hypoglycemia episodes occur during sleep. Hypoglycemia, including severe hypoglycemia, occurs most commonly during the night in people with T1D.

The counterregulatory responses to hypoglycemia are attenuated during sleep, leading to HAAF syndrome; also, insulin sensitivity is enhanced during the middle of the night. Furthermore, sleep often precludes recognition of warning symptoms of developing hypoglycemia and thus appropriate response [22, 38].

Pregnancy

Normal blood glucose levels in pregnant women are 20% lower than in nonpregnant women. A great number of metabolic changes occur during pregnancy to make women more vulnerable to hypoglycemia. Pregnancy itself is associated with suppression of glucose counterregulatory responses [7].

Maternal hypoglycemia during pregnancy is a risk factor for newborns small for gestational age, which in turn is associated with increased long-term risks such as development of diabetes, coronary artery disease, and hypertension [14].

For women with T1D, severe hypoglycemia occurs three to five times more frequently in the first trimester and at a lower rate in the third trimester when compared with the incidence in the year preceding pregnancy. Risk factors for severe hypoglycemia in pregnancy include history of severe hypoglycemia, hypoglycemia unawareness, long duration of diabetes, low HbA1c in early pregnancy, glucose variability, excessive use of insulin. When pregnant and nonpregnant women are compared with CGM, mild hypoglycemia (defined by the authors as <60 mg/dL or 3.3 mmol/L) is more common in all pregnant women. For women with preexisting diabetes, insulin requirements rise throughout the pregnancy and then drop precipitously at the time of delivery of the placenta, requiring an abrupt reduction in insulin dosing to avoid post-delivery hypoglycemia.

Breastfeeding may also be a risk factor for hypoglycemia in women with insulin-treated diabetes [1].

Elderly

Hypoglycemia is a common problem in old people with diabetes. Aging modifies the cognitive, symptomatic, and counterregulatory hormonal responses to hypoglycemia. The effect of aging on increased risk of unawareness or severe episodes of hypoglycemia has also been recognized. Older individuals may have multiple risk factors for hypoglycemia such as renal impairment, chronic heart disease, malnutrition, and polypharmacy.

In older individuals, episodes of hypoglycemia are more likely to be followed by changes in the blood-brain circulation, which may further increase the risk of neurological damages in this population [12].

Severe hypoglycemia has a considerable impact on the well-being, productivity, and quality of life of old people with diabetes.

Children and Adolescents

It is now well recognized that although many physiologic responses are similar across the age groups, there can be significant developmental and age-related differences in children and adolescents. The DCCT reported a higher rate of severe hypoglycemia in adolescents as compared to adults, 86 vs. 57 events requiring assistance per 100 patient-years, despite adolescents having poorer control with HbA1c levels approximately 1% higher. There are a number of physiologic and behavioral mechanisms that contribute to this difference. First, there are behavioral factors such as variable adherence that have been clearly associated with poor glycemic control in adolescents. Second, during puberty, adolescents with or without T1D are more insulin resistant than adults. During hypoglycemia, adolescents with or without diabetes release catecholamines, cortisol, and growth hormone at higher glucose levels than adults. However, intensively treated young adults with T1D counterregulate and experience hypoglycemia symptoms at a lower glucose level, suggesting a greater susceptibility to hypoglycemia in the young [5].

Young children with T1D are noted as particularly vulnerable to hypoglycemia because of their reduced ability to recognize hypoglycemic symptoms and effectively communicate their needs [2].

Children with early-onset diabetes, particularly those diagnosed before age 6, and severe episodes of hypoglycemia have an increased range of cognitive dysfunction and brain abnormalities. Repeated hypoglycemic seizures in young children may also cause structural brain damage [12].

Hypoglycemia Impact

There are several major concerns about the risks of hypoglycemia as it may cause severe morbidity and even death. One vulnerable organ is the brain, which is markedly dependent on glucose as a fuel for normal functioning. Brain dysfunction or damage may occur, and it may cause permanent damage. Among the severe manifestations of hypoglycemia is sudden death, which may not be directly linked to the effects of hypoglycemia. Cardiovascular consequences of hypoglycemia include alteration of ventricular repolarization. Hypoglycemia creates a prothrombotic state and may predispose to ischemic injury. Additional studies have established associations between hypoglycemia and the development of cardiac arrest and cerebral ischemia and cardiac arrhythmias [38, 44].

Hypoglycemia and Cardiovascular Disease

Patients with diabetes have an increased risk of cardiovascular disease, as it is the most common cause of diabetes-related deaths. Intensive glucose control increases the risk of hypoglycemia and severe hypoglycemia. Several epidemiological studies have linked hypoglycemia to increased cardiovascular risk, as it will be discussed further [42].

Acute hypoglycemia causes pronounced physiological responses as a consequence of autonomic activation, principally of the sympathoadrenal system, and results in end-organ stimulation and a profuse release of epinephrine. This profound autonomic response provokes hemodynamic changes. The magnitude of the counterregulation is directly proportional to the depth of hypoglycemia. Blood flow is increased to the myocardium, the splanchnic circulation, and the brain. There are also an increase in heart rate and peripheral systolic blood pressure, a fall in central blood pressure (reducing peripheral resistance), and an increase in myocardial contractility, stroke volume, and cardiac output. The workload of the heart is therefore markedly increased [45].

Increased plasma viscosity occurs during hypoglycemia due to an increase in erythrocyte concentration. Also, coagulation is promoted by platelet activation and increase in factor VIII and von Willebrand factor. Endothelial function may be compromised due to an increase in C-reactive protein. Soluble vascular cell adhesion molecule 1, soluble intracellular adhesion molecule 1, and soluble E-selectin are increased from baseline under hypoglycemic conditions. Soluble P-selectin, plasminogen activator inhibitor 1, tissue plasminogen activator, von Willebrand factor, and platelet-monocyte aggregation were measured by Joy and colleagues and found to be significantly increased during hypoglycemia and returned to baseline during normoglycemia [44, 45].

Hypoglycemia in ACCORD, ADVANCE, and VADT

These three studies randomized almost 24,000 patients with long-standing T2D to standard or intensive glycemic control for up to 5 years, ensuring HbA1c levels <7%. All three trials were carried out in participants with either known cardiovascular disease or multiple risk factors. Strict glycemic control did not incur a significant cardiovascular benefit, and none of the trials demonstrated a positive effect on cardiovascular events of mortality. In fact, the ACCORD study was interrupted prematurely because of an excess mortality in the intensive group. In all three trials,

Table 45.7 Clinical Characteristics, ACCORD/ADVANCE Clinical Trials

		ACCORD		ADVANCE		VADT	
Participants		10,251		11,140		1791	
Age (years)		62		66		60	
Men/women (%)		61/39		58/42		97/33	
BMI (kg/m^2)		32.2 ± 5.5		28 ± 5		6.9 ± 8.5	
Diabetes duration (years)		10		8		11.5	
History of CVD%		32		28		31	
Mean HbA1c%		8.1		7.2		9.4	
HbA1c%	HbA1c%	6.4	7.5	6.5	7.3	6.9	8.5
Intensive	Standard						
Hypoglycemia	Hypoglycemia	16.2	5.1	2.7	1.5	21.2	1.5
Intensive %	Standard %						
On insulin at baseline %		35		1.5		52	
Insulin	Insulin	77	55	40	24	89	74
Intensive %	Standard %						
Mean duration of follow-up		3.5 (terminated early)		5		5.6	
CVD		35%		34%		40%	
Primary CVD end point		↓ 10% ($p = 0.16$)		↓ 6% ($p = 0.37$)		↓ 13% ($p = 0.12$)	
Mortality (overall)		↑ 22% ($p = 0.012$)		↓ 7% (p = NS)		↑ 6.5% ($p = 0.12$)	
CV mortality		↑ 35% ($p = 0.02$)		↓ 12% (p = NS)		↑ 25% (p = NS)	

Based on [45, 46]

hypoglycemia was significantly higher in the intensive glucose-lowering arms compared with the standard arm. Symptomatic severe hypoglycemia was associated with an increased risk of death within each study arm. In the VADT study, a recent severe hypoglycemic event was an important predictor of cardiovascular death and all-cause mortality (Table 45.7) [45, 46].

It is possible that severe hypoglycemia could increase the risk of cardiovascular death in patients with underlying cardiovascular risk.

Cardiac Arrhythmias

Hypoglycemia has been known to cause electrocardiographic changes with lengthening of the corrected QT (QTc) interval and cardiac repolarization, exerting a pro-arrhythmogenic effect. Other electrocardiographic abnormalities observed during hypoglycemia include a decrease in PR interval and depressed T waves [44]. Abnormal cardiac repolarization appears to be related to the sympathoadrenal stimulation and release of catecholamines and to the hypokalemia that results from the insulin effect. In an observational study of patients with T1D, the effect of nocturnal and daytime hypoglycemia was assessed on EKG (electrocardiogram) with CGM. They found that hypoglycemia was common and had different distinct patterns in the EKG. Bradycardia was commonly seen while patients had nocturnal hypoglycemia, while with daytime hypoglycemia, they had more atrial ectopy. Prolonged QTc, T-peak to T-end interval duration, and decreased T wave symmetry were detected during nocturnal and daytime hypoglycemia [47]. Cardiovascular autonomic neuropathy or impairment is associated with increased mortality.

Cognitive Function and Dementia

Repeated severe hypoglycemia over time may impair cognitive function or damage the brain. Patients with T1D and a history of severe hypoglycemia have a slight but significant decline in intelligence scores in comparison with matched controls. Magnetic resonance imaging (MRI) in small studies of patients with T1D with no history of severe hypoglycemia when compared with patients with T1D with a history of five or more episodes of severe hypoglycemia has found cortical atrophy in nearly half of those who had a history of severe hypoglycemia. Severe hypoglycemia has been known to induce focal neurological deficits and transient ischemic attacks, which are reversible with the correction of blood glucose. Recent studies suggest that recurrent and severe hypoglycemia may predispose to long-term cognitive dysfunction and dementia [42, 44].

A number of studies have observed a relationship between dementing illness and diabetes. Both hyperglycemia and hypoglycemia potentially are implicated in the increased risk of dementing illness most commonly observed in elderly patients [12].

Dead-in-Bed Syndrome and Sudden Death

The "dead-in-bed" syndrome is an uncommon fatal event thought to be responsible for 6% of deaths of patients with

T1D who are younger than 40 years old. In 1991, Tattarsall and Gill described 22 cases of unexplained death that they labeled as dead-in-bed syndrome. Possible contributors to dead-in-bed syndrome are hypoglycemic brain damage, autonomic neuropathy, cardiac events such as arrhythmias, and electrolyte abnormalities. Nocturnal hypoglycemia is of substantial concern because patients may be "unaware" and susceptible to serious sequelae. Tanenberg reported a 23-year-old patient with T1D who died in his undisturbed bed from hypoglycemia. Postmortem download of the data in the CGM demonstrated glucose below 30 mg/dL around the time of his death and a vitreous humor glucose of 25 mg/dL [48].

Prolonged, profound hypoglycemia can cause brain death. The mechanism is thought to be sustained increased plasma glutamate release and receptor activation when plasma glucose concentrations are <18 mg/dL (1.0 mmol/L), the electroencephalogram is isoelectric, and brain glucose and glycogen levels are immeasurably low.

Quality of Life

Hypoglycemia can have a significant impact on patients' health-related quality of life, treatment satisfaction, and cost of diabetic management. The well-being of patients may be affected both directly from the effects of hypoglycemia and indirectly from fear of recurrence. Nocturnal hypoglycemia may impact one's sense of well-being on the following day because of its impact on sleep quality and quantity. Patients with recurrent hypoglycemia have been found to have chronic mood disorders including depression and anxiety. Interpersonal relationships may suffer as a result of hypoglycemia in patients with diabetes. Hypoglycemia also impairs one's ability to drive a car [1, 12].

In the UKPDS, patients reporting more frequent hypoglycemic episodes also reported increased tension, mood disturbances (anger, fatigue), and less work satisfaction. In the RECAP-DM study, participants with hypoglycemia reported significantly lower scores on scales for effectiveness, convenience, and global satisfaction than patients who did not have hypoglycemia, with concomitant barriers to treatment adherence. In this study, patients reporting symptoms of hypoglycemia were in general more markedly affected by their illness, had significantly lower self-rated general health, and had more worries about hypoglycemia than participants without hypoglycemia [49].

Fear of Hypoglycemia

When people experience hypoglycemia and its unpleasant symptoms, this has been shown to result in fear of future hypoglycemia. This concept may compromise overall glycemic control and impair quality of life. Recent, frequent, or severe hypoglycemia episodes tend to exacerbate this fear, while useful strategies to reduce the frequency of hypoglycemia, such as insulin pump adjustments or CGM, may alleviate such fear. There is clearly concern about the adverse consequences of hypoglycemia. These concerns primarily include damage to the brain and increased cardiovascular risk. Fear of hypoglycemia sometimes leads to deliberate undertreatment with insulin therapy [38].

A large study with 764 participants concluded that the frequency of severe hypoglycemia is the most important factor in the development of fear of hypoglycemia.

A retrospective study of 335 participants with either T1D or T2D found that hypoglycemia and fear of future hypoglycemia had an impact upon T1D and T2D patients. Self-treatment was the predominant means of coping with mild or moderate and severe hypoglycemia. Following mild or moderate event, neither T1D nor T2D patients utilized healthcare resources and did little more than mention the episode to their physician. Severe hypoglycemia was shown to have a considerable impact upon patient lifestyle. A major alteration to daily activities was noted with respect to fear of driving [50].

Fear of hyperglycemia is a psychological construct characterized by excessive worry about high blood glucose in combination with acceptance (and non-avoidance) of hypoglycemia—as a necessary evil to evade the development of long-term complications. It may lead to inappropriate blood glucose-lowering behaviors, including deliberate overtreatment or overzealous use of insulin, reluctance to attend to the early symptoms of hypoglycemia, and inappropriate pursuit of low blood glucose despite recurrent hypoglycemia.

Critical Illness and Hospitalization

Persons with diabetes are three times more likely to be hospitalized than those without diabetes, and approximately 25% of hospitalized patients (including people without a history of diabetes) have hyperglycemia. Inpatient hyperglycemia has been associated with prolonged hospital length of stay and with numerous adverse outcomes including mortality. Several studies have shown that aggressive lowering of glycemia in the ICU is not beneficial, markedly increases the risk of severe hypoglycemia, and may be associated with increase mortality [1].

A cohort of 33,675 hospitalized patients with and without diabetes, followed for almost 3 years, found that hypoglycemia, insulin related or non-insulin related, was associated with increased short- and long-term mortality. In this study, patients with moderate hypoglycemia during hospitalization had a more than twofold increase in mortality

compared with patients without hypoglycemia. Severe hypoglycemia was associated with a threefold increase in mortality [14].

Treatment of Hypoglycemia

Treatment is aimed at restoring euglycemia, preventing recurrences, and, if possible, alleviating the underlying cause. Providers should continue to counsel patients to treat hypoglycemia with fast-acting carbohydrates at a hypoglycemia alert value of 70 mg/dL or less. This should be reviewed at each patient visit. Hypoglycemia requires ingestion of glucose or carbohydrate-containing foods. The acute glycemic response correlates better with the glucose content of food than with the carbohydrate content of food. Pure glucose is the preferred treatment, but any form of carbohydrate that contains glucose will raise blood glucose. Added fat may retard and then prolong the acute glycemic response. In T2D, ingested protein may increase insulin response without increasing plasma glucose. Therefore, carbohydrate sources high in protein should not be used to treat or prevent hypoglycemia. Ongoing insulin activity or insulin secretagogues may lead to recurrent hypoglycemia unless more food is ingested after recovery. Once glucose returns to normal, the individual should be counseled to eat a meal or snack to prevent recurrent hypoglycemia [2].

Mild Hypoglycemia

When the patient can self-treat, mild hypoglycemia is managed with the oral administration of 15–20 g of oral carbohydrate. This should be repeated every 15–20 min until glucose is >70 mg/dL (3.9 mmol/L). Treatment and follow-up testing should be repeated if hypoglycemia persists. Several sources of short-acting carbohydrate exist (Table 45.8). Employing premeasured glucose products instead of juice or food is recommended, because patients tend to consume more than 15 g of juice or food, and additional calories from fat or protein may cause weight gain. Commercially available glucose tablets have the added benefit of being premeasured to help prevent overtreatment [36].

The glycemic response to oral glucose is transient, typically <2 h. Therefore, ingestion of a snack or meal shortly after the plasma glucose or SMBG is raised is generally advisable [8].

Table 45.8 Sources of carbohydrates

	Portion	Carbohydrates
Glucose products (preferred)		
Glucose tablets	1 tablet	4 g
Glucose gel	1 gel	15 g
Insta-glucose gel	1 tube	24 g
Food/beverage (if the aforementioned are not available)		
Juice	½ cup (200 mL)	15–20 g
Soft drink (regular)	½ cup (200 m)	15–20 g
Syrup or honey	1 tbsp	6 g
Sugar	2 tbsp in water	8 g

Based on [34, 38]

Key Points

- Rule of thumb—15 g of carbohydrate will raise blood glucose at around 50 mg/dL.
- Rule of 15 (15 × 15): 15 g of carbohydrate every 15 min until the SMBG level is >70 mg/dL (3.9 mmol/L) [40].

Moderate Hypoglycemia

Individuals with moderate reactions will often respond to oral carbohydrates but may require more than one treatment and take longer to fully recover. These patients may be alert but will frequently be uncooperative or belligerent.

Severe Hypoglycemia

Severe hypoglycemia requiring assistance of a second or third party should be assessed in the hospital setting. Patients with impaired consciousness or an inability to swallow may aspirate and should not be treated with oral carbohydrate. These patients require either parenteral glucagon or intravenous glucose. If these are not available, glucose gels, applied between the patient's cheek and gum, may be of some help until professional care arrives.

Glucagon

The use of glucagon is indicated for the treatment of hypoglycemia in people unable or unwilling to consume carbohydrates. Those in close contact with, or having custodial care of, people with hypoglycemia-prone diabetes (family members, roommates, school personnel, childcare providers, correctional institutional staff, or coworkers) should be instructed on the use of glucagon, including where the glucagon product is kept and when and how to administer it. An individual does not need to be a healthcare professional to safely administer glucagon [2].

Currently available glucagon preparations are injectable glucagon emergency kits, recently approved nasal glucagon, and liquid glucagon rescue pen. When delivered correctly,

glucagon is efficacious as a rescue therapy for severe hypoglycemia [51].

Glucagon Emergency Kits

Recombinant crystalline glucagon is available as a lyophilized powder that is mixed with an aqueous diluent to a concentration of 1 mg/dL. Because aqueous glucagon is unstable, it must be used immediately; the currently available glucagon emergency kits contain powdered glucagon that must be reconstituted using a multiple-step process before the drug can be administered parenterally [5]. The dose of glucagon needed to treat moderate or severe hypoglycemia for children <5 years old is 0.25–0.50 mg; for older children (aged 5–10 years), 0.50–1 mg, and for those >10 years old, 1 mg. Glucagon should be given intramuscularly or subcutaneously in the deltoid or anterior thigh region. Glucagon can cause nausea or vomiting, and patients should be placed on their side to reduce the risk of aspiration. The effects of glucagon are delayed by approximately 10 min from the time of injection and are only inducible in those with available glycogen stores [14, 36].

Nasal Glucagon

It is a ready-to-use drug/device combination to treat severe hypoglycemia in people with diabetes aged >4 years. A 3 mg dose of nasal glucagon powder, which does not require reconstitution, is administered in the patient's nostril. Nasal glucagon is passively absorbed through the anterior nasal mucosa without the need for inhalation, making it suitable for a comatose person with profound neuroglycopenia.

The effectiveness and ease of use of nasal glucagon (3 mg) in moderate or severe hypoglycemia events were evaluated in two real-world studies involving adults, children, and adolescents with T1D. Nasal glucagon was effective in resolving 96% of hypoglycemia events in adults within 30 min. All severe events were resolved within 15 min. The time to nasal glucagon administration was <30 s for most hypoglycemic events. Most common symptoms related to nasal glucagon administration were nasal irritation and headache. Nausea and vomiting were reported in 13%.

Nasal glucagon can be delivered by a caregiver of a person experiencing a severe hypoglycemic event using a compact, portable, single-use device with no reconstitution required.

Administration of nasal glucagon is faster and has much higher success rate for the delivery of the full dose with fewer errors than injectable glucagon [5, 51].

Liquid Glucagon Rescue Pen

A novel, ready-to-use, body temperature-stable rescue pen containing liquid glucagon was recently approved for the treatment of severe hypoglycemia in people with diabetes aged 2 years and older. The glucagon rescue pen is available in two premeasured doses: 0.5 mg for pediatric use and 1.0 mg for use in adolescents and adults. Administration of glucagon with the rescue pen is a two-step process, with no need for reconstitution [51].

Emerging Rescue Therapies for Severe Hypoglycemia

BioChaperone Glucagon

A stable, ready-to-inject, aqueous formulation of human glucagon, BioChaperone glucagon (BCG) is currently being developed to treat severe hypoglycemia.

Dasiglucagon

Dasiglucagon is a novel stable peptide analogue of human glucagon in an aqueous solution at neutral pH, with improved physical and chemical stability compared with currently available glucagon formulations [51]. This formulation is being tested in the bi-hormonal closed loop system insulin pump.

Remember

- Family members or responders should avoid sublingual placement of carbohydrate in an unconscious or impaired individual because this can increase the risk of aspiration.
- Place the patient on their side to reduce the risk of aspiration.
- Those in close contact with people with hypoglycemia-prone diabetes should be instructed on the use of glucagon.

Intravenous Glucose

If medical staff and equipment are available, intravenous glucose should be given as a primary treatment in preference to glucagon. Comatose patients should receive intravenous glucose. The usual dose is 25 g of 50% dextrose in water (D50) over 1–3 min. D50 comes in 50 mL; therefore, administration of 25 mL is equivalent to 12.5 g of carbohydrate. Sustained intravenous infusion of dextrose 5% (D5) or dextrose 10% (D10) at 100 cm^3/h should follow, aimed at keeping the blood glucose level at approximately 80–100 mg/dL (4.4–5.6 mmol/L) to avoid hyperglycemia, causing further

stimulation of insulin release and setting in motion a vicious cycle. Blood glucose levels should be monitored initially every 15–30 min for at least 2 h or longer depending on the etiology [7, 36].

Additional Facts

- D50 is an irritant, and delivery through a large gauge port and vein, followed by a saline flush, is preferable.
- Alternatively, D10 and D5 are less irritating and can be administered via a peripheral vein in a proportionally higher volume [14].

Treatment of Hypoglycemia After Exercise

Several approaches are used to minimize hypoglycemia risk with exercise. In those injecting insulins, meal insulin doses taken a few hours before exercising often are reduced by one-half for moderate activity (such as 30-min walk) to one-quarter or less for vigorous activity, such as running or swimming. Both the intensity and the duration of activity influence the need for adjustments. The meal immediately after exercising also usually will require some reduction in dose [36].

With insulin pumps, an added benefit is the ability to reduce basal rates using temporary basal infusions. During and for a period of time after vigorous exercise, reductions in 40–90% are not uncommon [36].

Snacks taken before exercise may provide protection against hypoglycemia episodes during exercise or for a short time afterward. Some people prefer not to use fast-acting carbohydrate but instead use a mixed snack with protein, fat, and carbohydrate. It is important to make the distinction between eating to prevent hypoglycemia and eating to treat hypoglycemia. Mixed snacks are less rapidly effective in raising low blood glucose and should not be preferred to pure dextrose or other rapidly effective treatment when hypoglycemia is occurring [36].

Strategies to Reduce or Prevent Hypoglycemia

Prevention

The prevention of hypoglycemia is preferable to its treatment. Improving glycemic control while minimizing hypoglycemic episodes represents a challenge but can be accomplished safely. Physicians can use this three-step strategy to minimize hypoglycemia [8]:

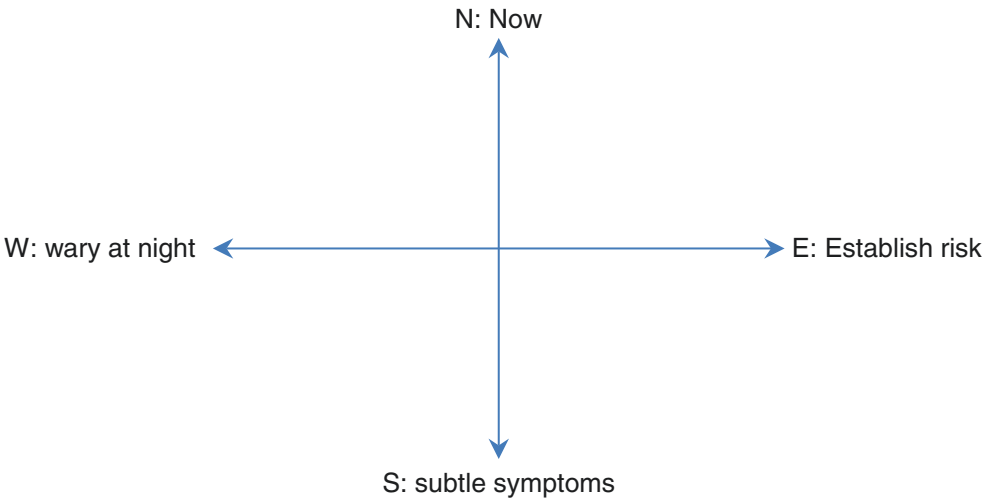
1. Addressing the issue of hypoglycemia in each patient encounter. This should be addressed in each patient visit.

   If patients report a history of hypoglycemia, details regarding the time of episodes need to be identified and the treatment regimen adjusted accordingly [40]. It is important to determine what the patient's symptoms were. When did they occur in relation to the patient's last meal, and what was the patient doing when the episode occurred? Was it an isolated event, or had it occurred before? How frequently do they occur? Is there any pattern to the occurrences? How long have these events been occurring? Did weight gain or weight loss occur during this period? Is the patient taking any other medication? Did the patient lose consciousness? If so, were premonitory sings present? Was the hypoglycemia documented? Did the patient recover spontaneously? What did the patient do to prevent recurrences or relieve symptoms?
2. Applying the principles of aggressive therapy. The principles of aggressive glycemic therapy include the following:
   (a) Patient education and empowerment
   (b) Frequent SMBG
   (c) Flexible insulin and other drug regimens
   (d) Individualized glycemic goals
   (e) Professional guidance and support

   Education regarding all aspects of diabetes care is important in the prevention and treatment of hypoglycemia. Carbohydrate counting, insulin and oral medication dosing, concomitant medications, alcohol intake, exercise, and even driving should be included in the discussion. Education will help alleviate fear of hypoglycemia that may impede ideal glycemic control.

   The Blood Glucose Awareness Training (BGAT) program is a behavioral intervention designed to improve avoidance, prediction, recognition, and treatment of hypoglycemia and hyperglycemia. Classically, BGAT consists of eight weekly group sessions during which participants are trained in behavioral techniques (self-monitoring and direct feedback) and symptoms awareness and educated about food, exercise, and insulin. Studies have reported a significantly improved detection of low blood glucose and reduced frequency of hypoglycemia and hyperglycemia, particularly in people with impaired awareness of hypoglycemia from baseline to 6 months. Benefits are maintained at 12-month follow-up with significantly fewer severe hypoglycemic events. In 2008, BGAT was adapted for Internet delivery, with data demonstrating that education can be made easily accessible to large numbers [20].

Fig. 45.4 HypoCOMPaSS



An education program has been developed in Germany, which focuses specifically on hypoglycemia. HyPOS consists of five weekly 90-min sessions, during which participants learn about hypoglycemia as a "vicious cycle" and are trained in symptom awareness (using diaries and SMBG). A randomized controlled trial comparing HyPOS to standard T1D education in 164 participants with impaired awareness or severe hypoglycemia found significant improvements in awareness as measured by the validated Clarke questionnaire and a modified version of the Gold score. No difference was detected in either severe hypoglycemic rate or overall glycemic control. At long-term (31 months) follow-up, incidence of severe hypoglycemia was lower in the HyPOS group with 12.5% compared with 26.5% in the controlled group [20].

The Dose Adjustment for Normal Eating (DAFNE) T1D education program that was derived from a training program developed in Düsseldorf provides a holistic approach to improving glycemic control. There is growing evidence suggesting that it reduces severe hypoglycemia and improves hypoglycemia awareness [20].

The four points of the HypoCOMPaSS (Fig. 45.4) are as follows: never delay hypoglycemia treatment, recognize personalized times of increased risk, detect subtle symptoms, and detect symptoms through regular self-monitoring, particularly for nocturnal hypoglycemia. In a multicenter randomized controlled clinical trial, the HypoCOMPaSS program was used in 110 adults with negative C-peptide T1D and impaired hypoglycemia awareness. They found that hypoglycemia awareness can be improved and recurrent severe hypoglycemia prevented in adults with long-standing T1D and impaired awareness through strategies delivered in clinical practice, targeted at rigorous avoidance of biochemical hypoglycemia without relaxation of overall control. Biochemical hypoglycemia was rapidly reduced in all groups within the first 4 weeks, driven by the insulin dose adjustment algorithm and sustained throughout the 24-week trial [52].

3. Considering both the conventional risk factors and those indicative of compromised glucose counterregulation [8].

Hypoglycemic episodes that are not readily explained by conventional factors, for example, skipped or irregular meals, unplanned exercise, alcohol ingestion, etc., may be due to excessive doses of medications used to treat diabetes. A thorough review of blood glucose patterns may suggest vulnerable periods of the day that mandate adjustments to current medications.

A history of severe iatrogenic hypoglycemia is a clinical red flag. Unless it was the result of an obviously remediable factor, such as a missed meal after insulin administration or vigorous exercise without appropriate regimen adjustment, a substantive change in the regimen must be made. If it is not, the risk of recurrent severe hypoglycemia is unacceptably high.

In patients injecting insulin, the following strategies can help minimize hypoglycemia. With basal-bolus insulin regimen, morning fasting hypoglycemia implicates the long- or intermediate-acting insulin. Daytime hypoglycemia may be caused by the rapid, fast, or longer-acting insulins. Nocturnal hypoglycemia may also be caused by rapid and longer-acting insulins. Substitution of preprandial regular insulin with fast-acting insulin (lispro, aspart, glulisine) reduces the frequency of daytime hypoglycemia. Similarly, substitution of a long-acting insulin analogue (glargine, detemir, degludec) for intermediate-acting insulins such as NPH or premix 70/30 also reduces the frequency of nocturnal or daytime hypoglycemia [8].

With a CSII regimen using a fast-acting insulin such as lispro, nocturnal and morning fasting hypoglycemia implicate the basal insulin infusion rate, whereas daytime

hypoglycemia may implicate the preprandial insulin bolus doses, the basal insulin infusion rate, or both.

Insulin secretagogues can also produce hypoglycemia related to absolute or relative insulin excess. However, sulfonylureas may pose the greatest risk of hypoglycemia in patients with altered renal or hepatic function and in older individuals. Substitution with other classes of oral agents or even GLP-1 receptor agonists (GLP-1 RA) should be considered in the event of hypoglycemia.

In patients with clinical hypoglycemia unawareness, a 2- to 3-week period of scrupulous avoidance of hypoglycemia is advisable and can be assessed by return of awareness of hypoglycemia.

Strategies to Reduce Hypoglycemia

Since the first injection of insulin in 1922, interest has increased in replacing insulin in the most physiologic manner for patients with diabetes. In the 1980s, the introduction of recombinant human insulin reduced the formation of antibodies and provided more predictable pharmacokinetic profiles. The next decade produced analogue insulins that initially were designed to provide a faster onset and shorter duration of action. These insulins (lispro, aspart, glulisine) were designed to reproduce more closely the typical physiologic prandial spikes of insulin observed following meals.

The second wave produced long-acting basal types of insulin (glargine U100, detemir) and more recently ultra-long-acting analogues (degludec, glargine U300) designed to mimic background constitutive insulin release. Studies in T1D have demonstrated that hypoglycemia (particularly nocturnal) can be reduced with fast-acting analogues rather than regular insulins. Similarly, long-acting analogues have been demonstrated to reduce hypoglycemia by 20–33% in patients with T2D when compared with NPH-based regimens. Thus, current recommendations are to use analogue-based insulin replacement whenever possible [7].

Technology in the Reduction and Prevention of Hypoglycemia

The rapid technological advances in the management of diabetes with CGM systems or integrated CGM and insulin pump use have empowered individuals with T1D to further address and reduce hypoglycemia.

Continuous Glucose Monitoring

Advances in technology have allowed the development of real-time continuous glucose monitoring (CGM) devices that can be programmed to alarm in response to failing glucose or when hypoglycemia or hyperglycemia occurs or is predicted. CGM devices provide a broad spectrum of information on real-time glucose trends. Currently available CGM devices measure interstitial glucose concentrations subcutaneously at 5- to 15-min intervals.

CGM can be divided into three categories: blinded/retrospective CGM, real-time CGM, and intermittently scanned/viewed CGM, also known as flash glucose monitoring [53].

Randomized controlled trials (RCTs) evaluating the benefit of CGM mainly focused on HbA1c as the primary outcome. Apart from the SWITCH study showing a significant effect of adding CGM to insulin pump therapy on time spent in hypoglycemia, most studies failed to demonstrate a significant or relevant reduction in mild hypoglycemia. Notably, RCTs primarily aimed at hypoglycemia prevention did demonstrate a significant reduction in mild hypoglycemia in terms of reducing the time spent in hypoglycemia by approximately 40% and reducing the number of mild hypoglycemic events per day [53].

In patients with T1D and impaired hypoglycemia awareness, data from a recent RCT and from an observational study suggested reduced severe hypoglycemia using CGM compared with SMBG.

Real-time CGM can reduce the frequency of severe hypoglycemia in people with impaired awareness of hypoglycemia and in those with long-standing T1D.

Continuous Subcutaneous Insulin Infusion (CSII)

Commonly known as insulin pump therapy, CSII has been recommended by several professional organizations as a therapeutic option for T1D complicated by problematic or severe hypoglycemia [20].

Insulin pump development began in the 1970s and over the last 20 years has become a major method of insulin replacement. Studies in children and pregnant women have demonstrated reduction in hypoglycemia when compared with MDI regimens [7].

A review and meta-analysis that only included studies of more than 6-month duration, comparing the frequency of severe hypoglycemia and the associated HbA1c during MDI and CSII, revealed a significant reduction in severe hypoglycemia in people with T1D who used CSII compared with the non-analogue-based MDI. However, most of the trials used NPH insulin as the basal insulin [54].

In multiple trials comparing CSII with multiple daily injections (MDI), there has been a modest improvement in HbA1c; however, the majority of the systematic reviews have failed to confirm a significant reduction in severe hypoglycemia. A Cochrane review found no relevant benefit of

CSII over multiple daily injections (MDI) for reducing non-severe hypoglycemic events, but data indicated a possible benefit of CSII over MDI in terms of reducing severe hypoglycemia [55]. As these meta-analyses are based on clinical trial data obtained prior to 2008, the pumps utilized are at least 10 years older than the current technology available; thus, they lack some more advanced features now available on newer pumps.

In the HypoCOMPaSS trial, the authors concluded that the restoration of hypoglycemia unawareness and the prevention of hypoglycemia could be achieved with either self-monitoring blood glucose (SMBG) and MDI or CSII and RT-CGM (real-time continuous glucose monitoring) when management is truly optimized using fast-acting and basal insulin analogues with appropriate therapeutic targets and regular SMBG including interval nighttime testing [52].

Sensor-Augmented Pumps (SAP)

SAP therapy, defined as a combination of insulin pump and CGM, represents the first step on the path toward an artificial pancreas. The first RCT to insulin pump therapy in those with T1D showed similar reductions in HbA1c after 6 months, but this was associated with significant increased hypoglycemia exposure in the insulin pump with the SMBG group.

The Sensor-Augmented Pump Therapy for A1c Reduction (STAR) 3 study randomized participants to either SAP or maintained them on MDI therapy with conventional SMBG checks for a 1-year study period and reported a greater reduction in HbA1c was associated with an increased frequency of sensor use. Those using SAP were more likely to attain the HbA1c targets and have decreased hypoglycemic exposure and decreased glycemic variability.

Sensor-Augmented Pumps with Low Glucose Suspension (Suspend on Low)

This insulin pump model is connected to a CGM that automatically suspends basal insulin delivery for a maximum of 2 h if the individual does not respond to a hypoglycemia alarm. This has been shown to reduce the duration of hypoglycemia in those with very frequent hypoglycemia at baseline, especially at night. This function also reduces moderate and severe episodes of hypoglycemia in patients with hypoglycemia unawareness. The reduction in hypoglycemia was not associated with deterioration of glucose control or ketosis [5].

The Automation to Simulate Pancreatic Insulin Response (ASPIRE) in-clinic study demonstrated that the mean duration of hypoglycemia was shorter on SAP-suspend on low and the nadir glucose was higher.

The ASPIRE in-home study reported a 37.5% reduction in the primary end point for nocturnal hypoglycemia in the SAP with low suspend vs. SAP alone. Despite this reduction in hypoglycemia, there was no deterioration in glycemic control [51].

An RCT of 247 participants showed that the use of a sensor-augmented insulin pump therapy with the threshold-suspend feature over a 3-month period reduced nocturnal hypoglycemia, without increasing HbA1c levels [56].

Sensor-Augmented Pump Therapy with Predictive Low Glucose Management (Suspend Before Low)

The Predictive Low Glucose Management system suspends basal insulin infusion with the prediction of hypoglycemia. Basal insulin infusion is suspended when sensor glucose is at or within 70 mg/dL (3.9 mmol/L) above the patient-set low limit and is predicted to be 20 mg/dL (1.1 mmol/L) above this low limit in 30 min. In the absence of patient interference, following pump suspension, the insulin infusion resumes after a maximum suspend period of 2 h or earlier if the auto-resumption parameters are met. The PLGM reduced hypoglycemia under in-clinic conditions and in short-term and long-term home studies. There was no deterioration of glycemic control with the use of the system in a 6-month randomized controlled home trial [5].

In 45 participants between the ages of 15 and 45 years, the system reduced hypoglycemia exposure by 81% and time spent <60 mg/dL (<3.3 mmol/) by 70%, while not leading into a difference in blood glucose levels in the morning [53].

Closed Loop Systems

Automated insulin delivery consists of three components: an insulin pump, a continuous glucose sensor, and an algorithm that determines insulin delivery. These systems not only suspend insulin delivery but also can increase insulin delivery based on sensor glucose values. Closed loop systems have been under development for several years with numerous algorithms and tested in clinical research centers, hotels, camps, supervised outpatient settings, and free-living conditions. Despite variable clinical and technical characteristics, artificial pancreas systems uniformly improve glucose control with a 50% relative risk reduction in hypoglycemia in outpatient settings compared to conventional pump therapy. Closed loop systems appear to hold great promise for the future as a tool to help prevent hypoglycemia in T1D [20, 53].

Fig. 45.5 Glycosylated hemoglobin compared with severe hypo rate in patient. (Adapted from [17, 36, 56])

One interesting development has been the evaluation of dual-hormone delivery systems with an additional pump delivery the counterregulatory hormone dasiglucagon, potentially increasing the effect in rescuing failing blood glucose.

The development of newer technologies and devices has made it possible to achieve glycemic control while minimizing the risk of hypoglycemia, first with the CGM and then with SAP (Fig. 45.5).

Beta Cell Replacement

The transplantation of isolated islets or a whole pancreas is a potential therapy for the treatment of T1D, particularly when complicated by recurrent episodes of hypoglycemia. Patients undergoing whole pancreas transplantation require a major surgery and will be on life-long immunosuppressive therapy with a mortality rate of 3–5%. This is why it is largely performed together with kidney transplantation (simultaneous pancreas-kidney or SPK), as they will need immunosuppressive therapy [20, 57].

Both approaches can restore insulin secretion, but the transplantation of islets isolated from more than one donor pancreas is usually necessary to achieve insulin independence. The durability of insulin independence is superior following whole pancreas transplantation, especially when it is SPK.

The magnitude of the beta-cell secretory capacity responses following whole pancreas transplantation appears normal and may be sustained for more than a decade despite ongoing immunosuppression drug exposure. In the absence of immunologic graft loss, the beta-cell secretory capacity can remain stable for years during longitudinal follow-up, while first-phase insulin response to glucose may decrease coincident with lessening of glucocorticoid doses and improvement in insulin sensitivity.

In T1D recipients of intrahepatic islet transplants, there is recovery of the physiologic islet cell hormonal responses to insulin-induced hypoglycemia whereby endogenous insulin secretion is appropriately suppressed and glucagon secretion is partially restored. Rickels and colleagues have demonstrated normalization of the glycemic thresholds for counterregulatory epinephrine, autonomic symptoms, and growth hormone responses in islet transplant recipients with T1D [57].

The CIT-07 Trial (Clinical Islet Transplantation Consortium Protocol 07) was a phase 3 clinical trial of transplantation of islet products in subjects with TID, impaired awareness of hypoglycemia, and intractable severe hypoglycemia. This trial showed that 87.5% of the subjects achieved freedom of severe hypoglycemia along with glycemic control (HbA1c <7%) at 1 year post-initial islet transplantation. The subjects reported consistent, statistically significant, and clinically meaningful improvements in condition-specific health-related quality of life as well as self-assessment of overall health [58].

Pancreas transplantation has been performed in patients with T1D for >25 years. In general, hypoglycemic rates improve dramatically in the first year after transplantation. Most studies also demonstrate that counterregulatory defenses are improved after pancreatic transplantation. Most notably, glucagon response to hypoglycemia increases, accompanied at an early stage by some improvement in epinephrine and symptomatic responses [7].

Concluding Remarks

- Patients with T1D and long-standing T2D have an altered counterregulatory response to hypoglycemia, making them more susceptible.
- Hypoglycemia is a major limiting factor in the management of diabetes; nonetheless, it is possible to improve glycemic control by acknowledging the problem, considering the risk factors, applying the principles of intensive therapy, and individualizing glycemic goals.
- It is possible to achieve optimal glycemic control while minimizing hypoglycemia by structured patient education concerning self-monitoring and appropriate lifestyle and physiologic and flexible insulin regimen.
- As time passes, safer and more physiologic insulin analogues are being manufactured, and novel technologies are being developed, which will facilitate achieving normoglycemia.

Multiple-Choice Questions

1. A 28-year-old T1D patient is experiencing palpitations, anxiety, shakiness, and hunger 2 h after running 10k. He checks his capillary blood glucose and it is 48 mg/dL (2.7 mmol/L). How would you classify this hypoglycemia?
   (a) **Symptomatic hypoglycemia**
   (b) Severe hypoglycemia
   (c) Moderate hypoglycemia
   (d) Hypoglycemia unawareness
   (e) Hypoglycemia-associated autonomic failure
2. An 18-year-old healthy college student is experiencing headaches, palpitations, anxiety, and hunger after a 2-h figure-skating practice; she forgot to eat breakfast before her practice. Her coach performs a capillary blood glucose with a value of 54 mg/dL (3 mmol/L). Which of the following is correct regarding the normal counterregulatory response?
   (a) Glucagon stores are depleted; therefore, cortisol and growth hormone are the principal hormonal response.
   (b) As blood glucose levels fall, there is an increased release of insulin, glucagon, and epinephrine within minutes to increase glycogenolysis and gluconeogenesis.
   (c) There is a decreased brain glucose uptake; therefore, epinephrine and cortisol will rise within minutes to increase glycogenolysis and gluconeogenesis.
   (d) **The first response is a decreased insulin level, followed by an increase in glucagon and epinephrine.**
3. A 35-year-old patient with long-standing T1D had a morning capillary blood glucose of 36 mg/dL (2 mmol/L). He denies any symptoms of hypoglycemia, although he has been having difficulty sleeping and nightmares. Which of the following statements is correct regarding his counterregulatory response to hypoglycemia?
   (a) As blood glucose levels decrease, his insulin levels will not decrease; therefore, glucagon and epinephrine become the critical response and will increase within minutes.
   (b) Cortisol and growth hormone become the principal response, since there is deficient release of glucagon and epinephrine.
   (c) **The patient is experiencing hypoglycemia unawareness, with blunted glucagon and epinephrine responses.**
   (d) Insulin levels do not decrease, and glucagon response becomes impaired; therefore, epinephrine becomes a critical response and will rise within minutes.
4. A 75-year-old patient with long-standing T2D is experiencing frequent episodes of hypoglycemia. He has background retinopathy, symmetrical neuropathy, and nephropathy with an estimated GFR of 50 mL/min. The patient states that he sometimes misses his meals. His last HbA1c was 7.5%. He is on glyburide, metformin, and bedtime insulin NPH. What changes in management will decrease his episodes of hypoglycemia?
   (a) Change insulin NPH to a more physiologic long-acting insulin analogue.
   (b) His HbA1c is at goal; ensure the patient does not skip meals and advise him to take snacks between meals.
   (c) Advise the patient to decrease the dose of his NPH by half.
   (d) **Discontinue glyburide, but continue the same dose of insulin NPH.**

5. A 35-year-old female patient with T1D had an episode of hypoglycemia on Sunday morning. Her basal insulin dose was recently increased since her fasting capillary blood glucose was not at goal. She has been experiencing abdominal cramps and fatigue as she started her menstrual period on Friday. On Saturday, she had a light dinner with two cups of wine and administered fast-acting insulin according to her carbohydrate counting. What is the most likely cause of her hypoglycemia?
   (a) The increase in her basal insulin dose.
   (b) Hormonal imbalance due to her menstrual period.
   (c) The fast-acting insulin dose was excessive.
   (d) **Alcohol intake.**
6. A 59-year-old patient with long-standing T1D with microvascular complications (diabetic proliferative retinopathy, diabetic nephropathy (estimated GFR of 45 mL/min), distal symmetric neuropathy, autoimmune hypothyroidism, dyslipidemia, and ischemic heart disease) is experiencing frequent episodes of hypoglycemia. The patient is on a flexible insulin regimen with a basal insulin analogue and a fast-acting insulin analogue, aspirin, beta-1 selective blocker, angiotensin-converting enzyme inhibitor (ACEI), and levothyroxine. His last HbA1c was 7.8%, TSH 3.2 mUI/L, and Cr 1.8 mg/dL. Which of the following confers the greatest risk for hypoglycemia?
   (a) Age
   (b) Background retinopathy
   (c) **Diabetic nephropathy**
   (d) Ischemic heart disease
   (e) HbA1c level
   (f) Current medications: insulin, salicylate, beta-selective blocker, ACEI
   (g) Hypothyroidism
7. A 65-year-old patient with long-standing T2D with a history of background retinopathy, autonomic neuropathy, diabetic nephropathy, and ischemic heart disease is experiencing frequent episodes of hypoglycemia. He had an acute myocardial infarction with subsequent coronary artery bypass grafting (CABG) a few months ago. He is on metformin, NPH insulin, statin, beta blocker, aspirin, and angiotensin receptor blocker. His HbA1c is 7%. Which of the following is the most appropriate statement?
   (a) He needs tight glycemic control to decrease the progression of microvascular complications.
   (b) His HbA1c is at goal; therefore, changing insulin NPH to insulin analogue will decrease the risk of subsequent hypoglycemia while ensuring optimal glycemic control.
   (c) **He has high cardiovascular risk; therefore, his HbA1c goal should be higher; consider decreasing his insulin NPH.**
   (d) He has high cardiovascular risk; therefore adding an SGLT2 inhibitor will decrease his cardiovascular risk.
8. What are the clinical implications of hypoglycemia on a patient with long-standing T2D and ischemic heart disease, diabetic nephropathy, diabetic retinopathy, and peripheral neuropathy?
   (a) Hypoglycemia may accelerate the progression of diabetic retinopathy to proliferative retinopathy.
   (b) Hypoglycemia is associated with worsening of glomerular filtration rate and proteinuria.
   (c) **Hypoglycemia can increase his cardiovascular risk by triggering arrhythmias or thromboembolic events.**
   (d) Repeated hypoglycemia may worsen his peripheral neuropathy.
9. A 68-year-old patient with T2D is brought to the emergency department with altered mental status. He is awake but very confused and combative. He has a history of alcohol abuse. He is currently on basal insulin analogue, sulfonylureas, and metformin. He has a blood glucose level of 35 mg/dL. Which of the following is the most appropriate treatment for this patient?
   (a) 15–20 g of carbohydrate every 15 min until his blood glucose is more than 70 mg/dL and then provide a meal.
   (b) 1 mg of intramuscular glucagon, placing the patient on his side to ensure that he does not aspirate.
   (c) Administer 25 g of 50% dextrose over 1–3 min, and discharge the patient when his blood glucose is more than 70 mg/dL.
   (d) **Administer a bolus of dextrose 50%, and then continue with IV glucose infusion 5–10% for 2–3 days, checking blood glucose every hour.**
10. A 15-year-old patient with T1D is experiencing frequent noon and nocturnal hypoglycemia. The patient frequently misses meals, has erratic schedules, and gets confused with her insulin regimen. Which of the following strategies will most likely decrease her risk of subsequent hypoglycemia.
    (a) Write down a prescription with a detailed insulin regimen and advise the patient to eat at a regular basis and avoid missing meals.
    (b) Organize a meeting with her parents addressing the importance of regular meals and explain in detail and writing her insulin regimen.
    (c) **Explain to the patient the importance of SMBG, explain in detail and in writing her insulin regimen, explain the importance of regular meals, and schedule an appointment with a diabetes educator.**
    (d) Change the insulin regimen to a fixed dose so the patient does not get confused.

Inpatient Management of Diabetes and Hyperglycemia

46

William B. Horton

Introduction

Individuals with diabetes mellitus (DM) are more likely to be hospitalized and have longer durations of hospital stay than those without DM [1]. Approximately one in four patients admitted to the hospital has a known diagnosis of DM [2, 3], and about 30% of patients with DM require two or more hospitalizations in any given year [3]. A 2007 study estimated that 22% of all hospital inpatient days were incurred by people with DM and costs associated with hospitalization for DM patients accounted for half of all healthcare expenditures for the disease [4]. Given the increasing incidence and prevalence of DM in the Unites States since that time [5], it is likely that these figures have only increased.

Recent studies show that one-third of all hospitalized patients will experience significant hyperglycemia [6], and patients without preexisting DM can even experience stress-related hyperglycemia while hospitalized [7]. Uncontrolled hyperglycemia in inpatients with or without a previous diagnosis of DM is associated with numerous adverse outcomes, including postoperative complications and mortality [2, 8–14]. This association is observed for both admission blood glucose (BG) and mean BG level throughout hospitalization [15]. Inpatient hyperglycemia has been specifically linked to increased duration of hospital stay, increased incidence of infection, increased mortality, and greater disability after hospital discharge in various studies [2, 16–20]. Observational and randomized controlled studies indicate that improved glycemic control results in lower rates of hospital complications in general medicine and surgery patients [15] and decreased length of hospital stay [7]. Moreover, inpatient glycemic control is cost-effective [1]. In the Portland Diabetic Project, initiation of continuous intravenous (IV) insulin therapy to achieve predetermined target BG values in patients with DM undergoing open-heart surgical procedures reduced the incidence of deep sternal wound infections by 66%, resulting in a total net savings of $4638 per patient [21]. In another study, intensive glycemic control in 1600 patients treated in a medical intensive care unit (ICU) was associated with a total cost savings of $1580 per patient [22]. With mounting evidence demonstrating the value of reducing both hyper- and hypoglycemia, optimizing inpatient glycemic control should be a priority for all healthcare providers.

Recognition and Diagnosis of Hyperglycemia and Diabetes on Admission

Inpatient hyperglycemia is defined as any BG value >140 mg/dL (7.8 mmol/L) [1, 15] and can occur not only in patients with known DM but also in those with previously undiagnosed DM and others who experience "stress hyperglycemia" during an acute illness or procedure [1, 15, 23, 24]. Various studies have identified hyperglycemia in 32–38% of patients in community hospitals [2, 25], 41% of critically ill patients with acute coronary syndromes [13], 44% of patients with heart failure [13], and 80% of post-cardiac surgery patients [26, 27]. In these studies, approximately one-third of non-critically ill patients and 80% of critically ill patients had no history of DM prior to admission [2, 13, 28–31].

Current guidelines recommend the initiation of BG monitoring for those with DM and those without a known history of DM who are receiving therapies associated with hyperglycemia [32]. Further sources suggest that an initial BG measurement on admission is appropriate for all hospitalized patients, regardless of the presence of preexisting DM or exposure to known inducers of hyperglycemia [15]. Guidelines also recommend that all inpatients with known DM or hyperglycemia be assessed with a laboratory measure of hemoglobin A1c (if this has not been performed in the preceding 3 months), both for diagnosis of DM and identification of patients at risk for DM [15, 32]. Hemoglobin A1c (HbA1c) values ≥6.5% suggest, in previously undiagnosed

patients, that DM preceded hospitalization [33]. Measurement of HbA1c during periods of hospitalization also provides the opportunity to identify patients with known DM who might benefit from intensification of their glycemic control regimen [15]. In patients with newly diagnosed hyperglycemia, HbA1c may help differentiate patients with previously undiagnosed DM from those with stress-induced hyperglycemia [34, 35].

Therapeutic Agents and Regimens for Inpatient Glycemic Control

For many reasons, inpatient hyperglycemia is best managed with insulin therapy. Patients with type 1 diabetes mellitus (T1DM) have an absolute insulin requirement and necessitate treatment with basal plus prandial insulin regimens to avoid severe hyperglycemia and ketoacidosis [15]. Patients with type 2 diabetes mellitus (T2DM) are often treated with a variety of therapies in the outpatient setting, including diet, lifestyle modifications, oral agents, non-insulin injectable medications, insulin, and/or any combination of these options [15]. However, the use of oral and other non-insulin therapies presents many challenges in the inpatient setting, as there are frequent contraindications to their use in hospitalized patients (e.g., sepsis, IV contrast dyes, pancreatic disorders, renal dysfunction, etc.) [1]. The majority of hospitalized patients will not be proper candidates for regimens other than insulin therapy, and each class of oral antidiabetic therapies possesses characteristics that may limit their desirability for inpatient use [6]. Despite these concerns, it should be noted that in certain circumstances, it may be appropriate to continue home regimens including oral glucose-lowering medications [32]. Clinical judgment should be used by the healthcare provider to evaluate patient criteria for the continued use of these agents in the hospital, including patients who are clinically stable and eating regular meals along with having no specific contraindications to the use of certain oral antidiabetic drugs [15]. Several recent randomized trials have demonstrated the potential effectiveness of glucagon-like peptide-1 (GLP-1) receptor agonists and dipeptidyl peptidase-4 (DPP-4) inhibitors in specific groups of hospitalized patients [32, 36–39]. Their inpatient use, however, remains limited by the fact that GLP-1 receptor agonists can cause nausea and should be withheld in acutely ill inpatients [6] and that a Food and Drug Administration (FDA) bulletin advised discontinuation of the DPP-4 inhibitors saxagliptin and alogliptin in patients who develop heart failure [40]. Safety and effectiveness data for sodium-glucose cotransporter-2 (SGLT2) inhibitors are currently lacking; thus, these agents are not recommended for routine inpatient use [32].

Insulin works reliably and can be quickly titrated based on changes in diet or glucose levels, making it ideal therapy in the inpatient setting [41]. For insulin-naive patients with BG levels >140 mg/dL (7.8 mmol/L) who are eating regular meals, insulin therapy can safely be initiated at a total daily dose of 0.2–0.5 units/kg body weight [42–45]. The lower starting dose is advised for leaner patients and those with renal dysfunction, while the higher starting dose is recommended for obese patients and those receiving glucocorticoids [6]. Fifty percent of the calculated total daily dose should be given as a basal component, and the remaining 50% should be split into thirds and given preprandially as the meal component [42, 43]. Patients who are NPO may receive basal insulin alone plus correctional doses with a rapid-acting analog every 4 h or regular insulin every 6 h [15, 17, 44]. Table 46.1 provides examples of basal plus prandial insulin regimens along with correctional dose protocols for inpatient glycemic control in non-critically ill inpatients.

Patients (either T1DM or T2DM) already receiving treatment with insulin prior to admission should continue treatment with a scheduled subcutaneous (SC) insulin regimen during admission [15]. These patients should have their insulin regimen modified according to clinical status both upon admission and throughout hospitalization as a way to reduce the risk for both hypo- and hyperglycemia [15]. The home total basal and prandial insulin dose should be reduced on admission for patients with poor nutritional intake, impaired kidney function, or admission BG levels <100 mg/dL (5.6 mmol/L) [15].

Finally, it should be noted that using sliding scale insulin (SSI) as the sole method for glycemic control of hospitalized patients is an ineffective therapy that should be avoided [15]. Scheduled basal plus prandial (BPP) insulin regimens mimic normal pancreas hormonal physiology and are designed to prevent hyperglycemia, whereas SSI alone only attempts to lower hyperglycemia after it has occurred [6]. SSI as sole management for inpatient hyperglycemia has routinely been shown to provide suboptimal glycemic control [46–49], and its regular use has been described as providing "action without benefit" [50]. Despite mounting evidence showing the inferiority of SSI alone, it remains ingrained in the practice of some healthcare facilities [51]. Clinician fear of hypoglycemia, clinical inertia, and resistance to institutional change have all been suggested as factors contributing to the continued use of SSI monotherapy in the inpatient setting [52]. A study comparing scheduled BPP insulin to SSI alone showed a significantly higher percentage of patients achieving goal BG levels in the BPP group than in the SSI group (66% vs. 38%) without an increase in hypoglycemia [45]. In another study [48], the risk for hyperglycemia (defined as BG >200 mg/dL or 11.1 mmol/L) was three times greater in patients managed with aggressive SSI regimens. For inpatients requiring insulin therapy to manage hyperglycemia,

Table 46.1 Basal plus prandial and correctional dose insulin regimens for glycemic control of the non-critically ill patient

A. Basal insulin orders			
• Calculate TDD as follows:			
– 0.2–0.3 units/kg body weight per day in patients: aged ≥70 years and/or GFR <60 mL/min			
– 0.4 units/kg body weight per day for patients not meeting the criteria above who have BG concentrations of 140–200 mg/dL (7.8–11.1 mmol/L)			
– 0.5 units/kg body weight per day for patients not meeting the criteria above when BG concentration is 201–400 mg/dL (11.2–22.2 mmol/L)			
• Distribute total calculated dose as approximately 50% basal insulin and 50% prandial insulin			
• Give basal insulin once (e.g., glargine) or twice (e.g., NPH) daily, at same time each day			
• Give rapid-acting (i.e., prandial) insulin in three equally divided doses before each meal. Hold prandial insulin if patient is unable to eat			
• Adjust insulin doses based on bedside POCT BG measurements			
B. Supplemental (correction) rapid-acting insulin analog or regular insulin			
Supplemental insulin orders			
• If a patient is able and expected to eat all or most of his/her meals, give rapid-acting insulin before each meal and at bedtime following the "usual" column (*Section C below*)			
• If a patient is unable to eat, give regular insulin every 6 h or rapid-acting insulin every 4–6 h following the "sensitive" column (*Section C below*)			
Supplemental insulin adjustment			
• If fasting and premeal BG are persistently >140 mg/dL (7.8 mmol/L) in the absence of hypoglycemia, increase scale of insulin from the insulin-sensitive to the usual or from the usual to the insulin-resistant column (*Section C below*)			
• If a patient develops hypoglycemia (BG <70 mg/dL or 3.8 mmol/L), decrease regular or rapid-acting insulin from the insulin-resistant to the usual column or from the usual to the insulin-sensitive column (*Section C below*)			
C. Supplemental insulin scale			
BG (mg/dL)	*Insulin sensitive*	*Usual*	*Insulin resistant*
>141–180	2	4	6
181–220	4	6	8
221–260	6	8	10
261–300	8	10	12
301–350	10	12	14
351–400	12	14	16
>400	14	16	18

TDD total daily dose, *GFR* glomerular filtration rate, *BG* blood glucose, *POCT* point-of-care testing
Adapted with permission from Reference [15]
[a] The numbers in each column of *Section C* indicate the number of units of regular or rapid-acting insulin analogs per dose. "Supplemental" dose is to be added to the scheduled insulin dose. Give half of supplemental insulin dose at bedtime. If a patient is able and expected to eat all or most of his/her meals, supplemental insulin will be administered before each meal following the "usual" column dose. Start at the insulin-sensitive column in patients who are not eating, elderly patients, and those with impaired renal function. Start at the insulin-resistant column in patients receiving corticosteroids and those treated with more than 80 units/day prior to admission. To convert mg/dL to mmol/L, divide by 18

BPP insulin regimens are superior to SSI alone and should be the preferred method utilized for glycemic control.

Glycemic Control of the Non-critically Ill Patient

Management strategies and glycemic target values vary by inpatient population and location; thus, an appropriate understanding of the protocols, procedures, and system environments needed to optimize inpatient glycemic control for various patient groups is of vital importance for all healthcare facilities and providers. Non-critically ill patients are hospitalized for management of a wide variety of issues and illnesses, though diabetes and/or hyperglycemia are often not the primary reason for admission. Nevertheless, the benefit of appropriate glycemic control should not be minimized in this scenario.

Glycemic Monitoring

Bedside capillary point-of-care testing (POCT) is the preferred method for guiding ongoing glycemic management of the non-critically ill patient [15]. Recommendations include POCT before meals and at bedtime in patients who are eating regular meals [1, 15]. Matching the timing of POCT with nutritional intake and medication administration is an important component of proper inpatient glycemic control. Premeal POCT should be obtained as close to the time of meal tray delivery as possible and no greater than 1 h before meals [53, 54]. POCT should be performed every 4–6 h in patients who are NPO or receiving continuous enteral (EN) or parenteral (PN) nutrition [1, 15]. More frequent POCT is indicated after a medication change that could affect glycemic control (e.g., glucocorticoid use or discontinuation of EN or PN) [32, 55, 56], or in patients who experience frequent episodes of hypoglycemia [17, 29].

Healthcare providers should be aware of the fact that the accuracy of most POCT meters is far from optimal [57]. Consistent BG sampling sites and methods of measurement should be used because results can vary greatly when alternating between fingerstick and alternative sites, or between samples run in the laboratory and a POCT device [15, 57]. There are also potential inaccuracies of POCT testing including intrinsic issues with technology and variability between different lots of test strips, varying tissue perfusion states and hemoglobin concentrations, and other interfering hematological factors in acutely ill patients [58–60].

Patients may be allowed to bring their personal glucometer device to the hospital, but personal meters should not be used for documentation or treatment of inpatient hyperglycemia [15]. Hospital glucometers should be used to obtain POCT results and subsequently log them into the electronic health record to allow evaluation of individual and hospital-wide trends and patterns of inpatient glycemic control [15, 61]. Real-time continuous glucose monitoring (CGM) provides frequent measurement of interstitial glucose levels as well as direction and magnitude of glucose trends [32]. Recent studies have shown that CGM provides accurate estimation of BG levels in the hospital [62, 63] and may be more effective in detecting hypoglycemic episodes [62–64]. Despite its demonstrated advantages over POCT for inpatient glycemic monitoring, CGM has not yet received full FDA approval for inpatient use. However, the FDA did grant breakthrough device designation to DexCom in March 2022 for the use of its CGM devices in the hospital setting [65]. This designation provides a more efficient and streamlined review pathway so CGM technology can hopefully get to the hospital market faster. Notably, some hospitals with established glucose management teams already allow CGM use in selected patients on an individual basis (provided both the patient and the glucose management team are well-educated in the use of this technology [32]).

Glycemic Target Values

For the majority of non-critically ill patients treated with SC insulin, a target glucose range of 140–180 mg/dL (7.8 mmol/L) is recommended [32]. Guidelines also recommend that these targets should be modified according to clinical status [1, 15]. Glucose concentrations between 180 and 250 mg/dL (10–13.9 mmol/L) may be acceptable in patients with severe comorbidities and in inpatient care settings where frequent glucose monitoring or close nursing supervision is not feasible [32]. Glycemic levels >250 mg/dL (13.9 mmol/L) may be acceptable in terminally ill patients with short life expectancy. In such patients, less aggressive insulin regimens to minimize glucosuria, dehydration, and electrolyte disturbances are often more appropriate [32].

Consideration should be given to reassessing the insulin regimen if BG levels are consistently <100 mg/dL (5.6 mmol/L) [1, 15]. For avoidance of hypoglycemia (BG <70 mg/dL), the total basal and prandial insulin doses should be reduced if BG levels are consistently between 70 and 100 mg/dL (3.9–5.6 mmol/L) [15]. Modification of the treatment regimen is necessary when BG values fall <70 mg/dL (3.9 mmol/L) [1].

Approach to Management

As previously discussed, inpatient hyperglycemia is best managed with insulin therapy. The preferred insulin regimen for inpatient glycemic control of non-critically ill patients includes two different insulin preparations administered SC as BPP therapy [15]. The basal component requires administration of an intermediate- or long-acting insulin once or twice daily [15]. The bolus component consists of a short- or rapid-acting insulin given in conjunction with meals or nutrient delivery [15]. The safety and efficacy of BPP insulin regimens in non-critically ill patients have been demonstrated in numerous studies [44, 45, 66–68]. Correctional insulin refers to the administration of supplemental doses of short- or rapid-acting insulin together with the usual dose of bolus insulin for BG values above the target range and is usually customized to match the insulin sensitivity of each patient [15]. Table 46.1 provides examples of BPP insulin regimens along with correctional dose protocols for glycemic control in non-critically ill inpatients.

Adjustment of scheduled BPP insulin dosing can be based on total doses of correctional insulin administered in the previous 24 h [15, 45, 66]. When correctional insulin is required before most meals, it is usually the basal insulin component that should be titrated upward [15]. If BG remains consistently elevated at one time point, the dose of prandial insulin preceding that measurement should be increased [15, 43, 69]. For example, if the premeal BG at lunch is persistently elevated, it should be the breakfast dose of prandial insulin that is titrated upward. Appropriate inpatient glycemic control for many patients will often require daily insulin adjustment to reach glycemic targets while simultaneously avoiding hypoglycemia.

In patients who are NPO or unable to eat, bolus insulin should be held until nutritional intake is resumed. Basal insulin should be continued once daily (glargine or detemir) or twice daily (detemir or neutral protamine Hagedorn

[NPH]) [15]. Correctional doses of a rapid-acting insulin analog (e.g., aspart, lispro, etc.) or regular insulin can be given every 4–6 h as needed to treat BG above the desired range [15].

Medical nutrition therapy (MNT) should also be included as an essential component of any inpatient glycemic control program [15]. MNT is defined as the process of nutritional assessment and individualized meal planning in consultation with a nutrition professional [15, 70]. The goals of inpatient MNT include optimizing glycemic control, providing adequate calories to balance metabolic demands, and creating a discharge plan for follow-up care [15, 17, 32, 70–73]. Lack of attention to MNT in the hospital has been shown to contribute to unfavorable changes in BG [15, 29, 54, 74].

Many variables during hospitalization (e.g., abrupt discontinuation of meals in preparation for procedures or diagnostic studies, variability in meal intake due to acute illness, limitations in food choices, and poor coordination between insulin administration and meal delivery) can complicate nutritional management and create difficulties in predicting the efficacy of glycemic control strategies [15, 54]. Consistent carbohydrate (CHO) meal plans, in combination with MNT, may help facilitate inpatient glycemic control and negate some of these variables [15, 17, 32, 54]. Consistent CHO meal plans are preferred by many hospitals as they facilitate matching the prandial insulin dose to the amount of CHO consumed [32, 54] and may contribute to reductions in hypoglycemia [17, 71]. Current standards of care also recommend that if CHO counting is provided by the hospital kitchen, this option should be used in patients counting CHO at home [32, 75].

Successful inpatient glycemic control of non-critically ill patients requires a multifactorial approach that includes recognition of appropriate glycemic monitoring practices and target values along with institution of BPP insulin and MNT. Table 46.2 summarizes the procedures and strategies that should be employed to help achieve appropriate glycemic control in this patient population.

Table 46.2 Appropriate strategies for successful inpatient glycemic control in various patient populations

Patient population	Glycemic monitoring	Glycemic targets	Insulin regimen
Non-critically ill	• POCT FSG before meals and at bedtime if eating regular meals	• BG levels should generally be maintained between 140 and 180 mg/dL	• Scheduled subcutaneous basal plus prandial insulin therapy (see Table 46.1 for further details):
	• POCT FSG every 4–6 h in patients who are NPO or receiving continuous EN or PN	• Higher glycemic targets are acceptable in those who are terminally ill or have severe comorbidities	– Intermediate- or long-acting insulin (e.g., glargine, detemir, or NPH) given once or twice daily as basal component
	• More frequent POCT FSG may be considered for patients who experience or have increased risk for hypoglycemia		– Rapid-acting insulin (e.g., aspart or lispro) given in conjunction with meals as bolus component
			– Correctional doses of rapid-acting insulin given supplementally with the usual dose of bolus insulin for premeal BG values above target
Critically ill	• Patients whose severity of illness justifies invasive vascular monitoring:	• BG levels should be maintained between 140 and 180 mg/dL	• IV insulin infusion should be administered by means of validated written or computerized protocols
	– All blood samples should be drawn from an arterial line	• BG levels <110 mg/dL are not recommended and should be avoided	• Once clinically improved and/or eating regular meals, IV insulin infusion should be transitioned to SC insulin therapy (see Table 46.3 for further details)
	– If an arterial line is unavailable, sample from a venous line		
	– POCT FSG can be inaccurate and should be avoided, if possible		
	• Patients whose severity of illness does not justify invasive vascular monitoring:		
	– POCT FSG is appropriate		

(continued)

Table 46.2 (continued)

Patient population	Glycemic monitoring	Glycemic targets	Insulin regimen
Perioperative	• Determine the level of glycemic control during preoperative evaluation by checking hemoglobin A1c in patients with diabetes	• Premeal BG targets <140 mg/dL in conjunction with random BG targets <180 mg/dL in preoperative and postoperative patients who are eating regular meals	• In ambulatory patients undergoing relatively short procedures, BPP insulin therapy should be used
	• In stable patients undergoing relatively short outpatient procedures, check BG on admission, before procedure, and at discharge	• Intraoperative BG levels should be maintained between 100 and 180 mg/dL	• The day of surgery, use 75–100% of daily long-acting insulin (glargine or detemir) dose
	• For longer outpatient procedures or patients receiving intraoperative subcutaneous insulin, BG should be monitored every 1–2 h	• If a patient must be monitored in a surgical ICU post-procedure, BG should be maintained between 140 and 180 mg/dL	• Prandial insulin should be withheld while a patient is fasting
	• For extensive surgical procedures or patients receiving intravenous insulin infusion, BG should be monitored every 30 min		• Once the patient resumes eating regular meals, full BPP regimen can be resumed
			• IV insulin therapy is appropriate for patients undergoing long, extensive surgical procedures or those who will need to be monitored in an ICU setting post-procedure

POCT point-of-care testing, *IV* intravenous, *SC* subcutaneous, *FSG* fingerstick glucose, *ICU* intensive care unit, *EN* enteral nutrition, *BPP* basal plus prandial, *PN* parenteral nutrition, *BG* blood glucose, *NPH* neutral protamine Hagedorn

Table 46.3 Transitioning from intravenous to subcutaneous insulin in the patient who is eating regular meals

	Time (h)								
Patient data	0000	0100	0200	0300	0400	0500	0600	0700	0800
IV insulin infusion rate (units/h)	2.2	2.2	2.1	2.0	2.0	2.0	1.9	1.8	1.8
Blood glucose (mg/dL)	148	143	145	141	137	139	135	133	131

The above data demonstrates both good glycemic control and relatively stable insulin infusion rates. To calculate subcutaneous basal plus bolus insulin doses, follow these steps

1. Calculate the 24-h intravenous insulin requirement
   (a) In the example above, the patient has an average insulin infusion rate of 2 units/h
   (b) Calculated 24-h intravenous insulin requirement: 2 units/h × 24 h = 48 units
2. Calculate the subcutaneous basal insulin dose
   (a) Most sources [1, 76] recommend using 80% of the 24-h intravenous insulin requirement as the subcutaneous basal insulin dose
   (b) 80% of 48 units = 38 units
   (c) As this was calculated from an overnight period of time while the patient was not eating, the dose can be administered as 38 units of basal insulin once daily
3. Calculate the subcutaneous bolus (prandial) insulin dose using a weight-based calculation
   (a) Given the possibility of decreased appetite, starting with a conservative estimate of 0.2 units/kg for total prandial dose is appropriate
   (b) 0.2 units/kg × 80 kg = 16 units and 16 units/3 meals = approximately 5 units per meal
4. Final orders
   (a) 38 units subcutaneous daily (insulin glargine/detemir)
   (b) 5 units subcutaneous three times daily with meals (insulin lispro/aspart/glulisine)

[a] The patient weighs 80 kg; data extracted from an overnight period of time when the patient is not eating

Glycemic Control of the Critically Ill Patient

Hyperglycemia is common in critically ill patients, including those without a known history of DM [78]. Patients receiving treatment for critical illness develop hyperglycemia due to the effects of endogenous stress responses and the by-products of medical interventions [78]. Inflammatory cytokines and stress hormones, such as epinephrine and cortisol, inhibit insulin release and promote insulin resistance, functionally increasing BG levels by stimulating gluconeogenesis and glycogenolysis while impeding glucose uptake in peripheral tissues [78–80]. Many medical therapies utilized in the treatment of critically ill patients also promote hyperglycemia, including administration of exogenous catecholamines and glucocorticoids, infusion of dextrose for parenteral nutrition, and even bedrest itself, which may impair glucose uptake in skeletal muscles [78, 81, 82]. In the past two decades, glycemic control among critically ill patients has been a topic of extensive study, leading to many changes in clinical practice [83].

Glycemic Monitoring

Measurement of BG concentration in critical care settings is often performed in intermittent fashion, with analysis using either POCT glucometers, laboratory blood draws, or blood gas analyzers [83]. The accuracy of glucometers has been the subject of numerous studies, with the majority concluding that they are insufficiently accurate for exclusive evaluation of BG values in the ICU [58, 83–86]. Many current glucometers are susceptible to interference from reducing substances such as ascorbic acid and acetaminophen (paracetamol), and accuracy is also affected by a patient's hematocrit levels [57, 83, 87]. The effect of hematocrit is particularly concerning in the ICU, where levels can fluctuate for many reasons. One study has demonstrated that a patient with a true BG of 80 mg/dL and a hematocrit of 0.25 may have a positive bias as great as 18 mg/dL [83, 87]. Another consideration is that BG concentration varies in different vascular beds and the site from which blood is sampled may introduce errors [83]. Sampling capillary blood in ICU patients, particularly those who are hemodynamically unstable and treated with vasopressors, can introduce large errors when compared to a reference method in which BG is measured from central venous or arterial draws [83, 84, 88]. Sampling from indwelling arterial or venous catheters in ICU patients is a reasonable option that is preferable to venipuncture, given the frequency with which BG is measured in the ICU [83].

Alternatives to the use of glucometers are measurements in the hospital's central laboratory or using a blood gas analyzer in the ICU [83]. Although central laboratory measurement is more accurate, the time delay in obtaining results makes this a less-than-ideal option in most ICU settings [83]. Using a blood gas analyzer to measure BG concentration is a practical solution but may have considerable cost implications [83]. Measurements from a properly maintained blood gas analyzer will have similar accuracy to central laboratory measurements [83, 84].

Current guidelines for BG measurement in the ICU recommend that all patients whose severity of illness justifies the presence of invasive vascular monitoring (i.e., indwelling arterial and/or central venous catheter) should have samples for measurement taken from the arterial catheter as the primary option [83]. If an arterial catheter is temporarily or permanently unavailable, blood may be sampled from a venous catheter as a secondary option (appropriate attention should be paid to maintaining sterility and avoiding contamination of the sample by flush solution in this scenario) [83]. When a patient's severity of illness does not require the presence of invasive vascular monitoring, POCT capillary BG samples obtained via glucometer are acceptable [83].

Although intermittent BG measurement is the current standard practice for critically ill patients, CGM holds great promise in this patient population. Potential advantages of CGM include the ability to observe trends in BG concentration and intervene before values enter an unacceptable range and removal of error both in timing of BG measurements and in sampling and analysis of blood [83]. Primary concerns with CGM use in the ICU relate to the effects of hemodynamic changes, pressor use, and potential interfering medications [89]. At this time, more data are needed before recommendations either for or against CGM use in critically ill patients can be made. A recent real-world preliminary analysis of the accuracy of CGM compared to POCT in 11 ICU patients with confirmed coronavirus disease 2019 (COVID-19) demonstrated early feasibility, considerable accuracy, and meaningful reduction in the frequency of point-of-care glucose testing [90]. Larger studies are needed to confirm these findings.

Glycemic Target Values

Current BG target values for critically ill patients are primarily based on results from the Normoglycemia in Intensive Care Evaluation—Survival Using Glucose Algorithm Regulation (NICE-SUGAR) study, a multicenter and multinational randomized controlled trial that tested the effect of tight glycemic control on outcomes among 6104 critically ill patients, the majority of whom (>95%) required mechanical ventilation [1, 91]. In this study, patients were randomized to intensive or conventional insulin therapy group. The glycemic target range was 81–108 mg/dL in the intensive insulin therapy group, while target BG was ≤180 mg/dL in the conventional insulin therapy group (with insulin administration reduced and then discontinued if BG levels fell below 144 mg/dL [84]). Both 90-day mortality (78 more deaths; 27.5% vs. 24.9%; $p = 0.02$) and rates of severe hypoglycemia (6.8% vs. 0.5%; $p = <0.001$) were significantly higher in the intensive versus conventional group [91]. Subsequently, several randomized controlled trials evaluating intensive insulin therapy among mechanically ventilated neurologic patients [92], patients with traumatic brain injuries [93], and critically ill pediatric patients [94] have all failed to demonstrate a clinical benefit to tight glycemic control in ICU patients [83]. Based on these findings, current guidelines for glycemic targets in critically ill patients on IV insulin therapy recommend that BG should be maintained between 140 and 180 mg/dL (7.8 and 10 mmol/L), with greater benefit potentially realized at the lower end of this range [1]. Somewhat lower glycemic targets may be appropriate in select patients, but strong evidence is currently lacking and prevents such a recommendation [1]. Targets <110 mg/dL (6.1 mmol/L) are not recommended and should be avoided [1].

Approach to Management

In the ICU setting, continuous IV insulin infusion is the most effective therapy for achieving recommended glycemic tar-

gets [17, 32]. Due to the short half-life of circulating insulin, IV delivery allows for rapid dosing adjustments to address alterations in clinical status [1]. Current guidelines recommend that IV insulin should be administered based on validated written or computerized protocols that allow for predefined adjustments in the infusion rate, accounting for glycemic fluctuations and insulin dose [32]. Several examples of published protocols are available for review [95–98]. Continued education of healthcare staff along with ongoing review of patient data and protocol results is critical for successful implementation of any insulin protocol [1, 95–98]. Table 46.2 summarizes appropriate strategies for successful inpatient glycemic control in critically ill patients.

Critically ill patients receiving IV insulin therapy will typically require transition to SC insulin once they begin eating regular meals or have clinically improved enough to be transferred to lower intensity care [1]. A safe transition requires appropriate planning and must be carried out systematically. SC basal insulin must be given at least 2–4 h prior to discontinuation of IV insulin therapy to prevent rebound hyperglycemia [76, 77]. There are currently no consensus guidelines for transitioning from IV to SC therapy, but typically 75–80% of the total daily IV infusion dose is proportionally divided into basal and prandial components [1]. The safest method is to find a several-hour period of time during which BG values are at goal and IV insulin rates are not particularly elevated or variable (i.e., the rate is reasonable and stable) [77]. The healthcare provider can then look at infusion rates during this stable period of time (ideally 6–8 h in length [99]) and extrapolate these data into a 24-h time period [77]. Utilizing this method allows for a reasonable calculation of the patient's 24-h IV insulin utilization [77]. Table 46.3 provides an example of calculating the insulin regimen necessary to transition a patient from IV to SC insulin therapy.

Glycemic Control of the Perioperative Patient

Patients with DM are more likely to undergo surgery than patients without DM [17, 44]. Surgery in DM patients is associated with longer length of hospitalization, greater perioperative morbidity and mortality, and increased rates of perioperative complications and healthcare resource utilization than in patients without DM [17, 44, 100, 101]. One retrospective observational study of 409 cardiac surgical patients demonstrated that intraoperative hyperglycemia was an independent risk factor for perioperative complications (including mortality) after adjusting for postoperative BG concentrations [102, 103]. The authors of this study also indicated that each 20 mg/dL (1.1 mmol/L) increase in BG concentration above 100 mg/dL (5.6 mmol/L) during surgery was associated with a 34% increased likelihood of postoperative complications [102]. Another retrospective cohort study of infra-inguinal vascular surgery patients showed that the rise in BG was proportional to an increased frequency of postoperative infections [104].

Surgical patient populations pose many unique challenges to clinicians. Despite the increased risk of perioperative complications, hyperglycemia is frequently overlooked and inadequately addressed [29, 44]. Given the growing evidence linking perioperative hyperglycemia to many poor outcomes, it is imperative that healthcare providers identify and proactively address this issue.

Glycemic Monitoring

Preoperative identification of patients with DM and those at risk for perioperative dysglycemia provides a potential opportunity to reduce morbidity and mortality [105]. However, it should be noted that the incidence of preoperative hyperglycemia might not be entirely due to DM. For example, a prospective study of 493 non-DM patients undergoing elective, non-cardiac surgery found that 25% had elevated fasting plasma glucose the morning of surgery [106].

Glycemic monitoring approaches for perioperative patients are similar to those used for non-critically ill and critically ill patients, depending upon the type and length of surgery performed [103] and whether the patient is monitored in the surgical ICU, general surgical floor, or discharged home after the procedure is completed. General recommendations include determining the level of glycemic control during the preoperative evaluation by checking HbA1c values [103]. Elevated HbA1c, as a marker of poor glycemic control, correlates with increased perioperative risk in DM patients [102]. Further recommendations include checking BG levels on the patient's arrival before surgery and prior to discharge home [103]. The recommended frequency of intraoperative BG monitoring depends on many factors. In metabolically stable DM patients undergoing relatively short (i.e., less than 2 h) outpatient procedures, it is only necessary to check BG on admission, before operation, and at discharge [105]. For longer outpatient procedures or for patients receiving intraoperative SC insulin, BG should be monitored every 1–2 h at minimum [103, 105]. For higher-acuity patients undergoing extensive surgical procedures or those on intraoperative insulin infusion therapy, the American Diabetes Association recommends BG monitoring as frequently as every 30 min [32]. If the patient is observed in the hospital after the procedure, POCT is an appropriate monitoring method unless the patient is in the ICU. Once the patient is eating regular meals, recommendations for glycemic monitoring mirror those for non-critically ill patients.

Glycemic Target Values

BG goals for preoperative and postoperative patients who are eating regular meals are similar to those of non-critically ill

patients and generally target values between 140 (7.8 mmol/L) and 180 mg/dL (10 mmol/L), as long as these targets can be safely achieved [1, 15]. Intraoperative BG levels should be maintained between 100 and 180 mg/dL (6–10 mmol/L), with appropriate steps taken to prevent intraoperative hypoglycemia [103, 106]. If a patient must be monitored in a surgical ICU post-procedure, glucose should be maintained between 140 and 180 mg/dL (7.8 and 10 mmol/L) [1].

Approach to Preoperative Management

Healthcare providers should have a detailed understanding of the patient's history of disease, including specific diagnosis (T1DM, T2DM, gestational DM, etc.), duration of disease, current treatment regimen, adequacy of control, and the presence and/or severity of any comorbidities [104]. Persons with DM admitted for surgical procedures should generally have their home oral antidiabetic medications discontinued [9], and it is reasonable to stop most of these medications on the morning of surgery [107, 108]. However, SGLT2 inhibitors require special attention given that the FDA now recommends that these agents should be stopped 3 days before scheduled surgeries (4 days in the case of ertugliflozin) [32] due to a higher risk of ketoacidosis. All patients with a known history of DM should be thoroughly evaluated before entering the operating room to aid in creating a successful perioperative treatment regimen. Postponing surgery in patients who present on the morning of procedure with significant dehydration, ketoacidosis, and/or hyperosmolar nonketotic states is recommended [103]. Table 46.2 summarizes recommendations for achieving appropriate inpatient glycemic control in perioperative patients.

Consensus guidelines recognize IV insulin therapy as the best method for controlling hyperglycemia in critically ill and non-critically ill surgical patients [1]; however, many logistical difficulties limit the use of this therapy in most hospital settings (particularly in non-ICU patient populations [103]). For ambulatory patients undergoing relatively short procedures, the preferable method for perioperative glycemic control is SC BPP insulin therapy. When SC insulin is continued in patients who are fasting, adjustment of their long-acting basal insulin dose is often not necessary, provided they have been receiving an adequate dose prior to admission [103, 109]. Specific recommendations include avoiding alterations of basal insulin the day before surgery unless there is report of hypoglycemia or the patient is on a diet restriction in the preoperative period [103]. On the day of surgery, use 75–100% of daily long-acting insulin dose [103]. If NPH is being used as the basal insulin, the evening dose should be reduced to 75% the day before surgery, and 50–75% of the usual morning dose should be given the day of surgery [103]. Prandial (bolus) insulin should be withheld while a patient is fasting [103]. The use of basal insulin in combination with correctional insulin can be effective at maintaining glycemic control in the desired range with low risk of hypoglycemia [44]. Once a patient is eating regular meals and monitored in a non-ICU setting, a BPP insulin regimen can be fully resumed. IV insulin therapy is appropriate for patients undergoing long, extensive surgical procedures or those who will need to be monitored in an ICU setting post-procedure [103]. IV insulin has the advantage of being quickly titratable with a rapid onset of action [105], allowing for precise glycemic control in the perioperative period. For patients treated with IV infusions, it is important to safely transition to SC insulin while maintaining glycemic control as patients transfer across different hospital units [103]. Table 46.3 details methods for converting IV therapy to an appropriate SC insulin regimen.

Special Considerations

Many special circumstances are encountered during routine inpatient care of DM patients. Not all patients are able to tolerate regular PO intake and may require EN or PN, and the approach to glycemic control of such patients is a little different than other management strategies previously described. Other special circumstances include patients who are admitted with insulin pumps and those who experience glucocorticoid-induced DM while hospitalized.

Enteral and Parenteral Nutrition

Malnutrition is reported in up to 40% of critically ill patients [75] and is associated with many poor outcomes, including increased risk of hospital complications, higher mortality rates, longer length of hospitalization, and increased healthcare costs [15, 110]. Improving the nutritional state is an important goal of inpatient care for malnourished patients; unfortunately, not all patients are able to tolerate PO intake and require EN or PN therapy. There are several retrospective and prospective studies demonstrating that the use of EN or PN therapy is an independent risk factor for the onset or aggravation of hyperglycemia independent of a prior history of DM [15, 78, 111, 112]. Early intervention to prevent and correct hyperglycemia in these patients may improve clinical outcomes [15]; however, achieving desired glycemic goals in this population poses many unique challenges [68, 78]. Current recommendations include initiating POCT in patients with or without a history of DM receiving PN or EN [15]. Several different management strategies utilizing SC insulin have been suggested, and recommendations vary by whether the patient is receiving PN or intermittent, continuous, or cycled EN [15]. For those receiving continuous EN, recommendations include administering basal insulin once (if glargine) or twice (if NPH or detemir) daily in combination with a short- or rapid-acting insulin analog in divided doses every 4 (if lispro, aspart, etc.) to 6 (if regular insulin)

hours [15]. For patients on cycled EN, guidelines recommend administering basal insulin in combination with a short- or rapid-acting insulin analog upon the initiation of EN [15]. Repeating the dose of rapid-acting insulin at 4-h intervals or short-acting insulin at 6-h intervals for the duration of EN therapy is also recommended [15]. It is also preferable to give the last dose of rapid-acting insulin approximately 4 h before and short-acting insulin approximately 6 h before discontinuation of EN [15]. For those receiving bolus EN, administer short-acting or rapid-acting insulin before each bolus is delivered [15]. Finally, for patients receiving PN, regular insulin administered as part of the PN formulation can be both safe and effective [15]. Subcutaneous correctional dose insulin can be utilized in addition to the insulin that is mixed with the PN to correct any hyperglycemic excursions that may occur [15].

Glucocorticoid Therapy

Hyperglycemia is a common complication of glucocorticoid therapy, with several studies demonstrating a prevalence between 20% and 50% among patients without a previous history of DM [56, 113]. Glucocorticoid therapy increases hepatic glucose production, impairs glucose uptake in peripheral tissues, and stimulates protein catabolism with resulting increased concentrations of circulating amino acids, thus providing precursors for gluconeogenesis [114–116]. It is generally accepted that these physiological changes ultimately exacerbate postprandial hyperglycemia [117]; thus, all patients treated with glucocorticoid therapy should be evaluated for hyperglycemia whether they have a known history of DM or not. Current recommendations include initiating bedside POCT in any patient receiving treatment with glucocorticoids [15]. POCT can be discontinued in persons without DM if all BG results are <140 mg/dL (7.8 mmol/L) without insulin therapy for a period of 24–48 h [15]. Insulin therapy should be initiated in patients demonstrating persistent hyperglycemia [15]. The majority of patients with steroid-induced hyperglycemia can be treated with SC BPP regimens to achieve glycemic control, with the insulin regimen based on a starting dose of 0.3–0.5 units/kg/day [15]. Adjustment of insulin doses is often required when the glucocorticoid dose is changed [15]. During glucocorticoid tapers, insulin dosing should be proactively adjusted to avoid hypoglycemia [1].

Insulin Pumps

Patients treated with continuous subcutaneous insulin infusion (i.e., insulin pump) therapy in the outpatient setting require unique attention when hospitalized. With increasing utilization of pump therapy, many institutions allow patients on insulin pumps to continue using these devices in the hospital. Patients who utilize pump therapy in the outpatient setting can be considered for diabetes self-management while hospitalized, provided they have the mental and physical capacity to do so [1, 17, 118, 119]. In this scenario, nursing personnel should document basal rates and bolus doses (at least daily) [1]. The availability of hospital personnel with expertise in pump therapy is also vital [118, 119]. Clear policies and procedures should be established at the institutional level to guide the continued use of insulin pump technology in hospitalized patients [15].

Hypoglycemia

Hypoglycemia (both spontaneous and iatrogenic) is associated with higher risk of complications among hospitalized patients, including longer and more expensive hospital stays and increased mortality rates [120–122]. The risk for hypoglycemia is higher in hospitalized patients due to variability in insulin sensitivity related to the underlying illness, changes in counter-regulatory hormonal responses to procedures or illness, and interruptions in usual nutritional intake [123, 124]. Hospitalized patients who are elderly or severely ill are especially vulnerable to its adverse effects [120]. Given the negative outcomes associated with inpatient hypoglycemia, it is imperative that appropriate steps be taken to prevent and reduce episodes as much as possible.

Inpatient hypoglycemia is classically defined as any BG <70 mg/dL [122], as this level correlates with the initial threshold for the release of counter-regulatory hormones [15, 125, 126]. Insulin therapy is the most common preventable cause of iatrogenic hypoglycemia, followed by improper prescribing of other glucose-lowering medications, inappropriate management of the first episode of hypoglycemia, and nutrition-insulin mismatch (often related to an unexpected interruption of nutrition) [32].

For avoidance of hypoglycemia, consideration should be given to reassessing the insulin regimen if BG values <100 mg/dL are consistently noted. Modification of the regimen is necessary when BG values are <70 mg/dL, unless the event is easily explained by other factors such as a missed meal [1, 32]. Guidelines also suggest that a standardized hospital-wide, nurse-initiated hypoglycemia treatment protocol should be in place to immediately address any blood glucose <70 mg/dL (3.9 mmol/L) [32]. Additionally, the Joint Commission recommends that all hypoglycemic episodes be evaluated for a root cause and that such episodes be aggregated and reviewed to address any systemic issues [32, 127].

Emerging technologies focused on the prediction of inpatient hypoglycemia have recently been tested. While this work is in its infancy stages, early results are promising. Several groups have developed machine-learning predictive algorithms for inpatient hypoglycemia in both non-critical [128–131] and ICU [132] populations. Models like these are

potentially important and, once validated for general use and prospectively tested (ideally in randomized controlled clinical trials), could provide a valuable tool to reduce rates of hypoglycemia in hospitalized patients [32]. One study has even shown that a real-time predictive informatics-generated alert, when supported by trained nurse responders, significantly reduced severe hypoglycemia among patients hospitalized on acute care medical floors [133].

Transitioning from Hospital to Home

Preparation for transition to the outpatient setting is an important goal of inpatient diabetes management and begins with hospital admission [1]. Hospital discharge itself represents a critical time for ensuring a safe transition to the outpatient setting and reducing the need for emergency department visits and rehospitalization [15], and poor coordination of patient care at the time of discharge is associated with medical errors and readmission [134]. Successful coordination of this transition requires a team approach that includes physicians, nurses, dietitians, case managers, and social workers [17]. An outpatient follow-up visit with the primary care provider, endocrinologist, or diabetes care and education specialist within 1 month of discharge is advised for all patients experiencing hyperglycemia while hospitalized [32]. If glycemic medications are changed or glycemic control is not optimal at discharge, an earlier appointment (e.g., 1–2 weeks) is preferred, and frequent contact may be needed to avoid hyperglycemia and hypoglycemia [32]. For patients discharged home on insulin therapy as a new medication, it is important that patient education and written information be provided for method and timing of insulin doses and recognition and treatment of hypoglycemia [15, 135]. Initiation of insulin administration should be instituted at least 1 day before discharge to allow assessment of safety and efficacy [15]. Measurement of HbA1c during hospitalization can assist in tailoring the glycemic management of DM patients at discharge. For patients with acceptable preadmission glycemic control (i.e., HbA1c <7%), guidelines suggest reinstitution of their preadmission insulin regimen or oral and non-insulin injectable antidiabetic medications at discharge (if there are no contraindications to continued therapy [15]). Patients with elevated HbA1c often require intensification of the outpatient regimen at discharge [15].

Conclusion

Optimal glycemic control throughout hospitalization is a goal all healthcare providers should strive to achieve. Appropriate glycemic control during the hospital stay requires effort on many levels, including provider education to aid in ordering appropriate insulin regimens, nursing coordination on the timing of insulin administration and treatment of hypoglycemia, laboratory personnel measuring BG and reporting results promptly, and nutrition services assisting in dietary choices. Hospitals should take appropriate steps to achieve euglycemia and make patient safety in glycemic control a reality for all inpatients.

Multiple-Choice Questions

1. In the hospital, what blood glucose level is defined as representing hypoglycemia (values in mg/dL)?
   (a) <80
   (b) **<70**
   (c) <60
   (d) <50
   (e) <40
2. In the hospital, what blood glucose level is defined as representing hyperglycemia (values in mg/dL)
   (a) >100
   (b) >120
   (c) **>140**
   (d) >200
   (e) >250
3. In the hospital, what glucose range should be targeted for most patients?
   (a) 200–240
   (b) 160–200
   (c) **140–180**
   (d) 120–160
   (e) 100–140
4. Modification of the treatment regimen is necessary once any blood glucose value below what threshold is observed?
   (a) <80
   (b) **<70**
   (c) <60
   (d) <50
   (e) <40
5. Inpatient hyperglycemia is *best managed* with what form of therapy?
   (a) Metformin
   (b) Sulfonylureas
   (c) **Insulin**
   (d) GLP-1 agonists
   (e) SGLT2 inhibitors
6. In the ICU setting, what form of therapy has proven to be the *most effective* for achieving recommended glycemic targets?
   (a) Sliding scale insulin
   (b) Metformin
   (c) Sulfonylureas
   (d) **IV insulin infusion**
   (e) Basal insulin alone

7. If a patient is to initiate insulin therapy prior to hospital discharge, when should this be started to allow for assessment of safety and efficacy?
   (a) One week before discharge
   (b) After discharge
   (c) **At least 1 day before discharge**
8. What is the preferred method for blood glucose (BG) monitoring in the non-critically ill inpatient?
   (a) Continuous glucose monitoring
   (b) Venous BG sample
   (c) **Bedside capillary point-of-care testing (POCT)**
9. True or False: Patients being treated with glucocorticoid therapy should be evaluated for hyperglycemia, whether they have a known history of DM or not.
   (a) **True**
   (b) False
10. True or False: The accuracy of many glucometers can be altered by certain medications (e.g., acetaminophen [paracetamol]) and/or by a patient's hematocrit levels.
   (a) **True**
   (b) False

Diabetes and Infection

47

Atulya Atreja, Sanjay Kalra, and Joel Rodriguez-Saldana

Whether it be the plague or influenza,
one thing that we learn at the knee of our "alma mater"
is that diabetics are more likely to get it. (Larkin and colleagues [1])

Introduction

Before the discovery of insulin and antibiotics, it was estimated that infections were the cause of death of one in five diabetic patients [2]. Following the discovery of insulin, a decrease in mortality from sepsis and tuberculosis was documented since 1935 [3]; in the late 1960s, the estimated mortality from infections in people with diabetes was 5% [2]. Nevertheless, it has been shown that diabetes continues to increase the predisposition to infections, especially bacterial, fungal, and viral. Albeit not traditionally recognized, acute infections are among the ten leading clinical characteristics in patients with newly diagnosed type 2 diabetes [4]. For example, Drivsholm and colleagues reported that the prevalence of genital itching, balanitis in men, recurrent urinary tract and skin infections among 1137 Danish patients newly diagnosed with type 2 diabetes was 27.2%, 12.0%, 5.7%, and 4.3% [4]. Largely unperceived, the use and costs of antimicrobials in patients with diabetes are significantly higher in comparison with people without diabetes [5]. Using national registries from Finland, Reunanen et al. reported that over 1 year, 43.6% of patients used systemic antibacterials and 4.5% had used systemic antimycotics, in comparison with 29.1% and 1.9% respectively in people without diabetes [5]. Until the 1980s, controversy prevailed about the increased frequency of infections in patients with diabetes; many clinicians believed that people with diabetes had an increased susceptibility to infection, but this belief was not supported by strong evidence [1, 6, 7]. Contributing factors increasing the risk of infections in patients with diabetes include comorbidities and chronic complications such as foot ulcers and neurogenic bladder [6]. Beyond a disturbance of glucose metabolism, diabetes is an inflammatory disease in which chronic complications, including neuropathy, chronic vascular and renal diseases alter the response to pathogens [8].

Magnitude of Risk

The relevance of infections in the morbidity and mortality of people with diabetes has been neglected, is not addressed or reported in clinical trials, and is not recognized in clinical guidelines for diabetes management [9]. Nevertheless, infections impair quality of life and impose short-time and long-time threats on the life of people with diabetes. Despite the general belief investigations about the epidemiology of infections in people with diabetes are scarce [9].

The landmark specific studies—three retrospective and three longitudinal—were carried out in Canada, Netherlands, England, South Korea, and the United States [7, 10–14]. In the first retrospective trial, risk ratios of infections and death attributable to infectious disease were compared in two groups of 513,749 non-diabetic and diabetic patients [7]. The risk ratio for infections was equal in both groups, but the risk ratio for infectious-related hospitalization was 2.1 and the risk ratio for death attributable to infection was 1.92 in patients with diabetes [7]. Risk ratios for infectious disease hospitalization or physician claims for infectious disease were higher in patients with diabetes; almost half of the patients with diabetes had at least one hospitalization or physician claim [7]. In 2018, Carey, Critchley et al. published two reports from the retrospective analysis of 102,493 pri-

mary care patients with type 1 and type 2 diabetes aged 40–89 years [10, 11]. After 5 years of follow-up, 55.0% of patients with type 1 diabetes and 56.9% of patients with type 2 diabetes had at least one infection compared with 41.3% and 46.2% of control subjects respectively [10]. They reported clear trends for increasing risk of infection at poorer levels of glycemic control and that the long-term risk of skin, cellulitis, candidiasis, bone and joint infections, endocarditis, and sepsis tended to rise at higher HbA1c levels, albeit some infections showed elevated rates among patients with diabetes with HbA1c <6.0%. In other words, even patients with good glycemic control were at higher risk of infections than people without diabetes [11]. Patients with diabetes were three times as likely to be hospitalized for infection, especially those with type 1 diabetes who were also at higher risk of death [11].

Prospective studies about the risk of infection among patients with diabetes include one of 12-month duration in which 7417 adult patients with type 1 (N = 705) or type 2 (N = 6712) diabetes were compared with 18,911 patients with hypertension [12]. Patients with diabetes had higher risks of lower respiratory tract infections, urinary tract infection, bacterial and skin and mucous membrane infection, and mycotic skin and mucous membrane infection [12]. Adjusted odds ratios were higher in every category for patients with type 1 diabetes, and the risk increased with recurrences of common infections [12]. The second study comprised a cohort of 66,426 diabetes and 132,852 age-sex-region matched non-diabetes control from the general population in South Korea [13]. Compared to non-diabetes controls, people with diabetes had a higher risk of almost all types of infections with higher adjusted incidence rate ratios for hepatic abscess, central nervous system, skin and soft tissue infections [13]. Patients with diabetes were at higher risk to intensive care unit admission and death than the general population [13]. Last but not least, Fang and colleagues conducted a 30–32-year prospective cohort analysis to investigate hospitalization for infection among 12,379 patients with diabetes, from which in 4229 infection was the cause of admission [14]. After adjusting for potential confounders, people with diabetes had a higher risk for infection (HR 1.67), especially pronounced for foot infection (HR 5.99). Overall infection mortality was low in this study (8.5%), but the adjusted risk was increased in people with diabetes (HR 1.72) [14].

Pathogenesis

The search for "an intrinsic problem" to explain the association of diabetes and infection goes back to Lassar, who postulated in 1904 that organisms thrive in a high sugar medium [1]. In 1938 Marble and colleagues stated that "patients with diabetes have less resistance to infection than normal individuals is a fact met with in the everyday experience of the clinician" and admitted that the lessened ability to cope with infection was undeniable prior to the introduction of insulin and (even) afterwards in patients with poor glycemic control [15]. In this pioneering report, Marble et al. suggested various factors as the cause of the lower resistance to infection in people with diabetes, some of which have been confirmed over the years: (1) increased sugar content of blood and tissues, (2) decreased activity of blood elements associated with resistance to infection, (3) inadequate functioning of fixed tissue cells, (4) lower capacity of tissue to react to antigenic stimuli, (5) undernutrition [15].

Diabetes and infection exemplify a vicious circle: insulin resistance and beta cell failure impair the immune response, and increased susceptibility to infections precipitates metabolic complications in patients with diabetes. Acute infections impair glycemic control, and infection is an important cause of hyperglycemic crisis, including ketoacidosis and non-hyperglycemic hyperosmolar state [16]. Large population-based observational studies have reported strong associations between higher HbA1c levels and infection risks for patients with Type 1 and Type 2 Diabetes [9]. A recent review identified 13 studies in which infections could be associated with glycemic control [8]. Except for the Diabetes Control and Complications Trial (DCCT), all the studies discussed in this review were observational either cohort or case control, identifying associations but not clearly causality [9]. Importantly, all were carried out in high income countries, but associations between diabetes and infection could be also important (and higher) in low and middle resource countries, where diabetes prevalence is rising most rapidly, and glucose control is lower [9]. Despite their limitations to measure the impact of diabetes on infection, it has been shown that hyperglycemia has negative effects on the outcomes in people with diabetes. Glycemic control is an essential goal to reduce the risk of infections and to protect maintenance of normal host defense mechanisms that determine resistance and response to infection [16]. In support of this statement, Burekovic et al. studied 450 patients with diabetes hospitalized in an intensive care unit from Bosnia and Herzegovina and they found a positive correlation between HbA1c, C-reactive protein, and HbA1c levels with acute infections [17].

The Immune Response

Specific defects in innate and adaptive immune function in people with type 1 and type 2 diabetes have been identified in multiple studies [2]. Reported abnormalities include an increase in inflammatory markers (tumor necrosis factor, interleukin-6, C-reactive protein, plasminogen activator inhibitor) and ineffective functioning of T lymphocytes, neu-

Table 47.1 Pathogenic mechanisms of infection in patients with diabetes [2, 6, 8, 9, 15–26]

Mechanism	Disorder
Leukocyte count	Increased, larger and granular; diminished levels of antioxidant genes, increased levels of proapoptotic and proinflammatory genes
Innate immunity	Macrophage dysfunction: reduced phagocytosis
	Defects in pathogen recognition; impairment in the number and activity of dendritic (antigen-presenting) cells: higher susceptibility to opportunistic infections
	Disorders in pathogen elimination, including: (1) polymorphonuclear adhesion to vascular endothelium, (2) transmigration through the vessel wall down a chemotactic gradient, (3) phagocytosis and microbial killing
	Neutrophil dysfunction including: (1) decreased phagocytosis, (2) diminished respiratory burst capacity and degranulation, (3) glucose-dependent reduction in superoxide production, (4) reduced monocyte proliferation, (4) reduced bactericidal capacity, (5) delayed bacterial clearance, (6) increased severity of infections, (7) higher susceptibility to infections, (8) apoptosis
	Downregulation of Toll-like receptors: phagocyte inhibition and killing of *Staphylococcus aureus*
	Vascular dysfunction, including (1) upregulation of intercellular cell adhesion molecule-1, vascular cell adhesion molecule-1 and selectin, resulting in limited chemotactic migration out of vessels at sites of inflammation, (2) reduced endothelial-dependent relaxation, (3) blunted nitric oxide response to bradykinin, (4) dysregulation of nitric oxide production and release of prostanoids with resulting vasoconstriction, (5) increased endothelial permeability, tissue edema
	Disorders in the complement cascade, including (1) impairment in the lectin pathway, (2) reduced attachment of C-type lectin proteins, (3) upregulation of C3 and C4 gene expression, chronic inflammatory state, (4) inhibition of complement receptor and Fc gamma receptor, (5) reduced opsonization and phagocytosis of microorganisms
	Disturbances in cell signaling pathways, activation of mitogen-activated protein kinases, including nuclear factor-kB and protein kinase C
	Non-enzymatic glycosylation of immunoglobulins
	Bacterial biofilm formation, increased survival of microorganisms
Adaptive immunity	Specific defects in T lymphocyte function
	Glycosylation and impaired functioning of antibodies in proportion to HbA1c levels
	Paradoxical hyper-reactive antigen-specific T cell inflammatory response
	Impairment in cytokine function and reduced synthesis: high levels of single and double cytokine CD4+ Th1 cells
	High levels of type 1 (tumor necrosis factor-α, IFN-γ, interleukin-2), type 2 (interleukin-5), type 17 (interleukin-17 cytokines) and other proinflammatory cytokines (interleukin-1β, interleukin-6, interleukin-18, C-reactive protein), and an anti-inflammatory cytokine (interleukin-10): oxidative stress and insulin resistance
	Low levels of IL-22
	Decreased frequency and function of natural Treg cells
	Enhanced frequencies of central memory CD4+ and CD8+ T cells resulting in disturbances on central memory, effector memory, and naïve T cells
	Diminished expression of cytotoxic markers Perforin, Granzyme B, and CD107a, decreased antigen-stimulated CD8+ T cell cytotoxic activity
	NK cell dysfunction: reduction in natural killer (NK) receptor NKG2D
	Higher levels of tissue damage in diabetic patients with tuberculosis

trophils, oxidant-antioxidant imbalance, and deficient opsonophagocytosis [18–25]. These infections are often difficult to evaluate and eradicate due to reduced humoral immune responses. Host factors like microvascular and macrovascular insufficiency, sensory and autonomic neuropathy, and mucosal colonization with *Staphylococcus aureus* and *Candida albicans* further complicate the scenario [19]. A summary of the immune responses negatively affected by diabetes and hyperglycemia is presented in Table 47.1.

Diabetes and Viral Infections

Viral infections are associated with metabolic derangements and predispose to the development of type 2 diabetes. The prevalence of type 2 diabetes in patients with hepatitis C is higher than in the general population. Hepatitis C promotes insulin resistance through multiple pathogenic mechanisms, including (1) defects in post-receptor insulin signaling, (2) high levels of proinflammatory cytokines, (3) high levels of reactive oxygen species, (4) low levels of GLP-1, (5) diminished glucose-stimulated insulin release, and (6) beta cell apoptosis [27]. Patients infected with the human immunodeficiency virus (HIV) are also at high risk of type 2 diabetes associated with the use of combination antiretroviral therapy. The HIV virus itself has been proposed as a mechanism of hyperglycemia, but the association between obesity and diabetes is strong, as in non-infected patients [28].

The Coronavirus Pandemic and Diabetes

> It appears now that a new group of viruses is emerging with members which infect the respiratory tract of birds and man.
> One member of the group, strain 229E, grows and produces cytopathic effect in tissue culture. (Kennett McIntosh et al. [29])

Coronaviruses are large, enveloped, single-stranded RNA viruses found in humans and other mammals such as dogs, cats, chicken, cattle, pigs, and birds [30]. Human coronaviruses have long been considered innocuous pathogens responsible for "the common cold" in healthy people [31]. In the twenty-first century however, two highly pathogenic coronaviruses emerged from animal reservoirs to cause global epidemics with high rates of morbidity and mortality: severe acute respiratory syndrome coronavirus (SARS-CoV) in 2002 in China and Middle East respiratory syndrome coronavirus (MERS-CoV) in 2012 in Saudi Arabia [31, 32]. Clinically, flu-like symptoms are usual at the time of presentation for all three diseases, but these vary from asymptomatic to severe multisystem involvement [33]. The immune response to each of these viruses is highly complex and includes both humoral and cellular components that can have a significant impact on prognosis [33]. Global health studies confirmed higher mortality rates in persons with diabetes from infections caused by these viruses and announced the potential consequences of another emerging pandemic [24].

In December 31, 2019, a cluster of patients with pneumonia of unknown cause was linked to a seafood market selling many species of live animals in Wuhan China [31, 34]. This was reported to the World Health Organization Country Office, and the Chinese Centre for Disease Control and Prevention (China CDC) organized an intensive outbreak investigation program; by January 10, 2020, researchers from the Shanghai Public Health Clinical Center & School of Public Health released a full genomic sequence of 2019-nCoV to public databases [31, 34]. The etiology of the illness was attributed to a novel virus belonging to the coronavirus family, COVID-19, which is the acronym of "coronavirus disease 2019 [35]." COVID-19 is highly contagious and has quickly spread globally and primarily via respiratory droplets during close face-to-face contact. The average time from exposure to symptom onset is 4.6 days outside mainland China, 6.5 days in mainland China, and 5.1 days elsewhere [36, 37]. Starting with the first reports and afterwards, most of the infected patients are men and higher risk of infection is associated with comorbidities, such as diabetes, hypertension, obesity, respiratory and cardiovascular disease [32, 37, 38]. Of 120 studies with 125,446 patients, the most common comorbidities were hypertension (32%), obesity (25%), diabetes (18%), and cardiovascular disease (16%) [39]. Severity and risk of death from COVID-19 was associated with chronic kidney disease (51%), stroke (44%), and cardiovascular disease (44%) [40]. Systematic reviews and meta-analyses show that fatal outcomes associated with COVID-19 include male gender, older age, smoking, diabetes, obesity, chronic obstructive pulmonary disease, cardiovascular disease, cancer, acute kidney injury, and increased D-dimer [41]. The prevalence of comorbidities in people without diabetes is 25% [29] in comparison with 67% in people with diabetes [42], and the association with COVID-19 is more severe and conveys higher risks of mortality [42].

The World Health Organization classifies patients with COVID-19 into mild, moderate, severe, and critical disease [42]. Common symptoms include dry fever (77–90%), olfactory and/or gustatory dysfunction (64–80%), cough (64–86%), dyspnea (53–80%), myalgia (15–90%), or fatigue (38%); less common symptoms include sputum production, headache (16%), anorexia (19.4%), and diarrhea (9.42–39%) [30, 38, 43]. Clinical presentation of COVID-19 has several overlapping features with other pulmonary infections including pneumonia, chronic bronchitis, and chronic obstructive pulmonary disease [44, 45]. Mild disease is defined by patients meeting clinical and epidemiological criteria without the evidence of viral pneumonia or hypoxia, moderate disease is characterized by the evidence of pneumonia, severe disease is defined by pneumonia with a respiratory rate above 30 breaths/min or respiratory distress, and critical disease is defined by severe pneumonia complicated with respiratory distress syndrome, sepsis, or septic shock [45, 46].

Laboratory findings include a general decrease of the leukocyte count (21.5%), lymphopenia (50–83%), increased C-reactive protein level (58.3%), and high D-dimer levels (27–60%) [29, 46]. Liver function tests show increased levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) up to 18.3% and lactate dehydrogenase (48%) [30, 43]. Additional findings in chemical chemistry include increased high-sensitivity troponin (19%), creatinine kinase (42%), ferritin (14%), and serum creatinine (22.3%) [43]. Several biomarkers have become useful tools to differentiate patients with mild to severe COVID-19 infection including procalcitonin, C-reactive protein, serum amyloid A, interleukin-6, lymphocyte count, platelet count, lactate dehydrogenase, cardiac troponin, and serum ferritin [44]. Radiologic findings include patchy shadows in the peripheral zones of both lungs with higher involvement of the lower lobe of the left lung, ground glass opacities, and consolidations [43]. Laboratory tests for diagnosing COVID-19 infection include rapid antigen tests, serological testing, nucleic acid amplification tests, and viral sequencing [47]. Rapid antigen tests have the advantages of fast detection and low cost, but their disadvantages include (1) low sensitivity and specificity and (2) inability to identify patients in the incubation period [47]. Next generation sequencing is an accurate diagnostic method, but its high cost is an obstacle for widespread use [47]. Leading diagnostic tests for COVID-19 are IgM and IgG antibodies and nucleic acid amplification tests by real-time reverse transcriptase polymerase chain reaction (PCR) [47, 48]. Antibodies measure the immune response to COVID-19 infection and are detected in all patients between the third and fourth week of clinical illness [48]. IgM antibodies are detected 3–5 days after onset and IgG antibodies are above four times higher during the recovery period [47]. IgM titers begin to decline and reach lower levels after 5 weeks whereas IgG titers persist beyond 7 weeks [48]. The PCR test is highly sensitive and specific and has become the most commonly used and reliable test for diagnosis of COVID-19 [47].

The pathology associated with symptomatic severe acute respiratory syndrome and COVID-19 involves diffuse alveolar damage [33]. Complications include acute respiratory distress syndrome (ARDS) and multisystem involvement of the heart, brain, lung, liver, kidney, and coagulopathy [38, 45]. In severe cases, a dysregulated innate host immune system can initiate a hyperinflammatory syndrome dominated by endothelial dysfunction that may lead to a hypercoagulable state with microthrombi, resulting in microvascular and macrovascular diseases in children and adults [33, 49, 50].

Since the SARS COVID outbreak in 2002, extensive structural analysis revealed key atomic interactions between human pathogenic coronaviruses and host target cells through angiotensin-converting enzyme 2 (ACE2) receptor which is highly expressed by nasal and bronchial mucosal epithelial cells and pneumocytes [30, 51]. The high transmissibility of SARS-CoV-2 is probably related to active viral replication in the upper airways in the pre-symptomatic and symptomatic phases [52]. After receptor engagement, specific proteases like the type 2 transmembrane serine protease (TMPRSS2) present in alveolar epithelial type II cells, cleave the S protein, and trigger its fusion to cells (fusogenic activity) [30, 52]. Binding of ACE2 to the viral structural spike S protein induces endocytosis of the virion, fusion of the viral envelope with the endosomal membrane to enable the release of the viral genome into the cytoplasm or alternatively at the plasma membrane after receptor engagement [52]. Severe lymphopenia occurs and the host response to the virus activates the innate and adaptive immune system, additionally impairing lymphopoiesis and increasing lymphocyte apoptosis [30]. Observational studies have demonstrated strong antibody and T cell responses in a large proportion of patients, but the humoral response appears to be proportional to COVID-19 severity [45]. In later stages of the infection, epithelial-endothelial barrier integrity is compromised; COVID-19 infects pulmonary capillary endothelial cells, increasing the inflammatory response and the influx of monocytes and neutrophils. The last stage in severe COVID-19 involves critical activation of coagulation and consumption of clotting factors, viral sepsis, organ dysfunction, and multiorgan failure [30]. Extrapulmonary manifestations of COVID-19 involve brain/nervous system, kidney, liver, gastrointestinal tract, heart/cardiovascular system, endocrine system and skin with corresponding myriad symptoms and signs [45].

According to early data reported by CDC China from more than 44,000 confirmed cases of COVID-19 infection, death rates among patients with diabetes were 7.0% compared with 0.9% in people without diabetes [34]. Impaired immune function is a clinical feature of COVID-19 infection. As already mentioned, diabetes is characterized by defects in innate and adaptive immune responses in addition to micro-angiopathic changes in the respiratory tract and other organ systems, contributing to the progression and poor prognosis of COVID-19 (Table 47.2) [24, 30, 53].

Table 47.2 Immune abnormalities against COVID-19 in diabetes

Immune response	Cell type	Abnormality
Innate	Macrophages	Lung accumulation, ↑ proinflammatory activity
	Dendritic cells	↓ Amount and function
	Neutrophils	Entrapment, ↑ ACE2 receptors
	NK cells	↓ Function
	NKT cells	↑ CD57 and CD
Adaptive immunity	B cells	Changes in number, phenotype, and function
	T cells	Targeting of CD4T cells against viral spike protein

Modified from references [24, 30, 51]

Pathophysiology of COVID-19 Infection in Hyperglycemia and Diabetes

Hyperglycemia and diabetes are long-established risk factors for viral infections and pneumonia [54]. Diabetes induces lung oxidative stress and inflammation, apoptosis of alveolar cells, persistent matrix deposition, and increases the susceptibility to viral pneumonia [55]. In addition, diabetes induces functional abnormalities in the lung, including decrease in volumes, elastic recoil and diffusion capacity, and oxidative stress injury to pancreatic beta cells [55, 56]. Compared with hospitalized patients with COVID-19 without diabetes, patients with diabetes have worse clinical profiles and outcomes including higher levels of glucose, HbA1c, leukocytes, high-sensitive C-reactive protein, procalcitonin, ferritin, D-dimer, lactic dehydrogenase, natriuretic peptide, severity of disease, higher frequency of admission to intensive care units, and mortality [55, 56]. Plasma glucose levels and diabetes are independent predictors of mortality and morbidity in patients with COVID-19 infection, and mechanisms that increase the vulnerability include increased binding affinity and efficient virus entry, reduced viral clearance, impaired T cell function, increased susceptibility to cytokine storm, cardiovascular and pulmonary preexisting disease [55]. Host-cellular protein components involved in the entry of COVID-19 [55] include angiotensin-converting enzyme-2 (ACE2), Furin, serine protease TMPRSS2, interferon-induced transmembrane proteins (IFITM), desintegrin, and metalloproteinase domain 17 proteins (ADAM17) [55]. Patients with type 2 diabetes present more severe inflammatory responses and less lymphocyte counts than patients without diabetes, are more likely to worsen from moderate to severe disease, and inflammation and lymphocyte recovery are slower [57]. Respiratory viral infections predispose to bacterial co-infections leading to increased disease severity and mortality, particularly in people with diabetes [58].

Management of Patients with COVID-19 and Diabetes

Patients with diabetes require more medical interventions and had significantly higher mortality and multiple organ injury than patients without diabetes [59]. Glucose control is associated with markedly lower mortality compared to patients with poor glycemic control (above 180 mg/dL) and is a leading goal of treatment [59]. Management of patients with diabetes and infection by COVID-19 involves general and metabolically oriented measures, summarized in Table 47.3 [46, 60–69].

Table 47.3 General management of COVID-19 infection in people with diabetes [60–72]

HbA1c: <7.0%		
Fasting plasma glucose: 72.0–144 mg/dL		
Avoid hypoglycemia: <55.0 mg/dL		
Blood pressure: <140/80 mm Hg		
Low-density lipoproteins: <100 mg/dL		
Assessment and control of comorbidities		
Stage	**Recommendation**	**Comments**
	Sensitization about the importance of optimal metabolic control	
Primary prevention	Reduce social contact	Key measure to contain the spread
	Strategies of virtual support, including telephone and telemedicine	
	Vaccination	**BNT162b2 mRNA, two dose regimen**
		Efficacy: 89.0% in preventing hospitalization from COVID-19; 90.0% in preventing admission to intensive care unit; 91.0% in preventing emergency department or urgent care visit; ranging from 81.0% to 95.0% across subgroups defined by age, sex, race, ethnicity, body mass index, and comorbidities
		Safety profile: short-term, mild to moderate pain at the injection site, fatigue, and headache
		Low incidence of serious adverse effects, similar rates in the vaccine and placebo groups
		Antibody titers decline sharply by 6 months after vaccination and decline further after 8 months
		mRNA-1273 SARS-CoV-2, two dose regimen
		Efficacy: 94.1% across key secondary analyses, including 14 days after the first dose, evidence of SARS-CoV-2 infection at baseline and in people ≥65 years old
		Safety: moderate, transient reactogenicity, serious adverse events are rare and similar in patients receiving the vaccine or placebo
		Binding and functional antibodies against variants persist in most vaccinated subjects albeit at low levels, 6 months after the first dose
		Neutralizing antibody titers significantly decreased after 8 months
		Ad26.COV2.S, one dose versus two-dose regimen
		Efficacy: 76–83% in adults 18–55 years old; 60–77% in patients ≥65 years and older; 68.0% in preventing hospitalization, 73.0% in preventing emergency department or urgent care clinic visit
		Safety: most frequent adverse events included fatigue, headache, myalgia, pain in the site of injection, and fever, especially in patients ≥65 years old
		Differential kinetics of immune responses: substantially lower median titers than mRNA vaccines at peak immunity, 4 weeks after first dose, albeit remained stable over 8 months
		Purified inactivated SARS-Cov-2, two-dose regimen
		Efficacy: 65.6% for prevention, 87.0% for preventing hospitalization, 90.3% for preventing admission to intensive care unit, 86.3% for preventing COVID-19 death
		AZD1222 (ChAdOx1 nCoV-19), two-dose regimen
		Efficacy: 74.5% overall, 83.5% in people ≥65 years old; efficacy for preventing COVID-19 infection: 64.3%
		No severe or critical symptomatic COVID-19 cases among people vaccinated
		Spike binding and neutralizing antibodies increased after the first dose and increased further when measured 28 days after the second dose
		Safety: low incidence of serious and medically attended adverse events and similar frequency with placebo; mild or moderate local and systemic reactions in both groups
		Overall waning vaccine immunity, correlates of protection not yet defined
	Wearing masks	Control the source of infection
	Hand hygiene	Protect susceptible groups
		Reduce the risk of health providers from being infected when attending to patients
		Significant inhibitory effect on the spread of respiratory viruses for healthcare providers (80%) and non-healthcare workers (47%)
	Antidiabetics	All therapeutic classes
Mild COVID-19	Isolation to contain viral transmission	On an individual basis
		Close monitoring
	Symptomatic treatment	Analgesics
		Antipyretics

Table 47.3 (continued)

	Adequate nutrition and hydration	
	Patient and family counseling	Advise about signs and symptoms of disease complications and progression including dyspnea, chest pain, and dehydration
	Antidiabetics	At usual doses:
		Metformin
		Anti-inflammatory, antithrombotic properties, reduce mortality in type 2 diabetes patients with COVID-19
		Prevention of cytokine storm
		DPP-4 inhibitors
		Prevention of coronavirus from entering host cells
		Anti-inflammatory effects
		SGLT-2 inhibitors
		Increase the expression of ACE2 in the kidney, increase susceptibility to infection
		GLP-1 receptor agonists
		Systemic anti-inflammatory properties
		Insulin
		Downregulation of ACE2 receptors
		Anti-inflammatory, antithrombotic effect
		Sulfonylureas
		A-glucosidase inhibitors
		Use with caution:
		Thiazolidinediones
		Weight gain, fluid retention, edema, increasing heart failure
Moderate COVID-19	Immediate isolation to contain viral transmission on an individual basis, depending on clinical presentation, requirements for supportive care, risk factors for severe disease and conditions at home	At health facility
		At community facility
		Self-isolation at home
	Regular monitoring	Pulse oximetry
		Temperature
		Blood pressure
	Testing and treatment for other infections causing fever	Routine use of antibiotics not advised
	Antidiabetics	At usual doses:
		DPP-4 inhibitors
		SGLT-2 inhibitors
		GLP-2 receptor agonists
		Insulin
		Use with caution
		Metformin
		A-glucosidase inhibitors
		SGLT-2 inhibitors
		Contraindicated
		Thiazolidinediones
		Sulfonylureas
Severe COVID-19	Supplemental oxygen in patients with oxygen saturation levels <90.0%	Emergency airway management, target oxygen level ≥94.0%
		Nasal cannula for flow rates up to 5 L/min
		Venturi mask for 6–10 L/min
		Face mask with reservoir bag for 10–15 L/min
	Continuous monitoring for signs of clinical deterioration	Hematological and biochemical laboratory testing
		Electrocardiogram
		Chest imaging
	Immediate supportive care	Intravenous fluids
	Antidiabetics	At usual doses:
		DPP-4 inhibitors
		Insulin
		Contraindicated:
		Metformin
		α-glucosidase inhibitors
		SGLT-2 inhibitors
		Thiazolidinediones

(continued)

Table 47.3 (continued)

Critical COVID-19	Supplemental oxygen in patients with oxygen saturation levels <90.0%	Emergency airway management, target oxygen level ≥94.0%
		Mild acute respiratory distress syndrome:
		Noninvasive ventilation through continuous positive airway pressure and bilevel positive airway pressure
		Invasive ventilation including endotracheal intubation and tracheostomy in patients with hypercapnia, hypoxemic respiratory failure, hemodynamic instability, multiorgan failure, or abnormal mental status
		Prone ventilation 12–16 h/day
	Continuous monitoring for signs of clinical deterioration	Hematological and biochemical laboratory testing
		Electrocardiogram
		Chest imaging
	Immediate supportive care	Intravenous fluids
	Antivirals	Remdesivir: 200 mg/IV on day 1, 100 mg/IV on days 2–10
	Antidiabetics	At usual doses:
		DPP-4 inhibitors
		Insulin
		Contraindicated:
		Metformin
		α-glucosidase inhibitors
		SGLT-2 inhibitors
		Thiazolidinediones
Post-COVID	Monitoring for metabolic, physical, psychosocial, and cognitive impairments	Glycemic control
		Blood pressure control
		Lipoprotein profile control
		Rehabilitation
		Vaccination prioritization

As already mentioned, diabetes is a relevant comorbidity in people with COVID-19 infection and increases the risk of severity and mortality. Glycemic and overall metabolic control are essential at every stage. Patient and family support to address the disease and its consequences in mental health is also important.

By the end of October 2021, the WHO estimated more than 243 million confirmed cases of COVID-19 globally, 4.9 million deaths, and a mortality rate of 2.03% [73]. Since the beginning of the pandemic, diabetes was identified as an important risk factor for mortality and progression to acute respiratory distress syndrome in patients with COVID-19 [74]. After 18 months, epidemiologic studies confirm that diabetes is a central contributor to severe COVID-19 morbidity and that COVID-19 has had devastating effects on people with diabetes [75]. The evidence is compelling. Patients with type 1 or type 2 diabetes (1) represent 30–40% of hospital admissions by COVID-19, (2) 21–43% of people requiring intensive care, and (3) have a mortality rate of 25% [75]. The risk of severe morbidity and mortality is 100–250% higher among people with diabetes and the impact on the general population with diabetes has been 50% higher than historical trends, more than twice that of the general population [75].

The emergence of the COVID-19 pandemic has become a landmark in the history of mankind, a mass casualty incident [76]. Its effects at the global, political, economic, and individual level have been devastating and at the end of 2021 continue to be evolving. Quantifying the overall impact and its morbidity and mortality is still not feasible until cascades of metrics including (1) population at risk, (2) population exposed, (3) people infected, (4) people diagnosed, (5) people hospitalized, (6) people with severe forms of disease, and (7) mortality can be constructed at the global, regional, and national level. Living with diabetes during the COVID-19 pandemic is challenging. The established complexities of diabetes management have been exacerbated by the scarcity of access to healthy foods, scarcity of medicines or access to medical services, and limited physical activity or exercise because of confinement [77].

Diabetes Parasitic Diseases and "The Hygiene Hypothesis"

In comparison with the high risk of bacterial, fungal, and viral infections, an inverse association between soil-transmitted helminthiasis and diabetes was initially reported by Nazligul and colleagues in 2001 [78]. The evidence is scarce and comprises six experimental studies and seven cross-sectional studies which were summarized by de Ruiter and colleagues [79]. Under the hypothesis that having diabetes would affect the susceptibility to infections, six of these studies showed that the prevalence of intestinal parasites was significantly lower among patients with diabetes; by comparison, only one small study in Brazil reported a positive association between *Strongyloides stercoralis* infection and type 2 diabetes [80]. In this study, the frequency of positive *S. stercoralis* serology in diabetics was 23% versus 7.1% in the control group ($p < 0.05$).

The odds ratio for diabetics was 3.9 (CI, 1.6–15.9, $p < 0.05$) [80]. By comparison, the remaining six studies showed a significantly lower prevalence of intestinal helminth infections in patients with type 2 diabetes, metabolic syndrome, or insulin resistance [79]. The inverse relation or "protective effect" of type 2 diabetes and helminth infections could be related to a state of cellular immune hypo-responsiveness induced by parasites mediated by a helminth-induced regulatory network involving regulatory T cells and their associated cytokines IL-10 and transforming growth factor-β [81]. These observations are related to the revised hygiene hypothesis proposed by Strachan in 1989, who proposed that improved hygiene increased the rise of allergic diseases [81]. This hypothesis states that exposure to pathogens is critical to establish immunomodulatory cells to prevent inappropriate responses [81]. Albeit strongly criticized as "a dangerous misnomer which is misleading people away from finding the true causes of the rise in allergic disease [82]" and should not diminish the importance of personal hygiene in every age group, the inverse association between helminth infections and type 2 diabetes is an interesting observation that invites further study.

Categories of Infections in Patients with Diabetes

Three categories of infections have been described: (1) common infections also occurring in persons with diabetes; (2) uncommon infections strongly associated or typical of diabetes; (3) infections related to therapeutic interventions in people with diabetes [2]. The spectrum of disease and the likely causative organisms identified in people with diabetes are presented in Table 47.4.

Table 47.4 Disease spectrum, causative microorganisms, and main clinical features

	Spectrum of infections and references	Causative microorganisms	Clinical features	Diagnostic procedure
Head and neck				
	Herpes zoster ophthalmicus [83–86]	Human herpes virus type 3	Risk ratio: 1.31 (95% CI, 1.22–1.41)	Complete medical history Ophthalmologic examination
			Represents 10–20% of herpes zoster cases, 3.2 cases per 1000 person-years	
			Peak incidence: 50–79 years, higher in patients over 80 years	
			Three clinical phases: (1) Pre-eruptive, (2) acute eruptive, (3) chronic.	
			(1) Pre-eruptive symptoms and signs: headache, fatigue, malaise, photophobia, and fever; neuralgia around the eye and forehead with pinprick anesthesia and hyperesthesia to light touch (allodynia)	
			(2) Acute eruptive phase: involves skin, eyelids, the medial canthal area, conjunctiva and cornea. Skin lesions manifest as a vesicular eruption along the ophthalmic dermatome of the trigeminal nerve, erythematous coalescing papules evolving into clear vesicles with rupture, secondary bacterial infection, and discharge, and crusting over several weeks. The Hutchinson sign refers to involvement of the tip of the nose. Eyelid involvement includes cutaneous macular rash, ptosis, and lagophthalmos. Signs of conjunctival involvement include injection and chemosis with papillary reaction, hyperemic mucopurulent conjunctivitis, and petechial hemorrhages.	
			(3) Chronic stage: cornea and anterior segment: punctuate epithelial keratitis and pseudodendrites, nummular stromal keratitis, disciform stromal keratitis, neurotrophic keratopathy corneal neovascularization, lipid extravasation, and opacification diminished corneal sensation, corneal ulceration, eye perforation, uveitis, secondary glaucoma	
			Posterior segment: acute optic neuritis, orbital phlegmon, superior orbital fissure syndrome necrotizing retinopathy, and blindness.	
			Cranial nerves: Additional compromise includes involvement of the iris, the retina, and the optic nerve, motor palsies of the third, fourth, and sixth, diplopia.	
			Late complications: postherpetic neuralgia in 20% of the patients, higher in the elderly or in patients with involvement beyond the skin	

(continued)

Table 47.4 (continued)

	Spectrum of infections and references	Causative microorganisms	Clinical features	Diagnostic procedure
	Malignant external otitis [2, 87–89]	*Pseudomonas aeruginosa*	Three clinical stages: (1) Infection of the external auditory canal and adjacent soft tissues	Clinical examination
		Methicillin resistant *Staphylococcus aureus*	(2) Extension of infection with osteitis of skull base and temporal bone	Ear swab culture Positive Technetium (^{99}TC) scan of failure of local treatment after more than 1 week
		Proteus mirabilis	(3) Dissemination to intracranial structures, neck spaces, and large blood vessels	Computed tomography, magnetic resonance imaging to assess progression and resolution
		Klebsiella oxytoca	Major obligatory signs: Unrelenting pain	Culture of drainage material
		Pseudomonas cepacia	Otorrhea Edema	Biopsy from the infection site
		Staphylococcus epidermidis Candida *Aspergillus fumigatus*	Granulations	Histological examination shows nonspecific inflammation and hyperplasia of squamous epithelium
		Polymicrobial infections	Microabscesses	
			Minor or occasional: Hearing loss	
			Pain at the temporomandibular joint	
			Cellulitis	
			Osteomyelitis of the skull base	
			Cranial nerve palsies: Common: facial, glossopharyngeal, vagal, spinal accessory	
			Less common: hypoglossal Rare: trigeminal, abducens, optic	
	Periodontal infections [90, 91]	Most associated pathogens are indigenous to the oral cavity, but possible superinfecting microorganism may also inhabit periodontal pockets	Pain, gingival swelling	Oral examination
		Lesions usually contain a constellation of pathogens, mostly gram-negative anaerobic, but also gram-negative facultative rods		
	Oral candidiasis [92]	*Candida albicans*, Pichia, Trichosporon, Geotrichum	May be asymptomatic	Dental examination
			Sore throat, dysphagia	
			White patches on the surface of the oral cavity	
			Untreated candidiasis may lead to chronic hyperplastic candidiasis: candidal leukoplakia	
	Rhino-orbital or rhino-cerebral sinusitis [92–95]	Rhizopus, mucor, and absidia species	Preseptal or orbital cellulitis: Facial or ocular pain, fever, headache, nasal discharge, sinus pain	Clinical examination, culturing, magnetic resonance, histopathological evidence of fungal invasion of tissue
			Facial erythema or cyanosis	
			Sub-periosteal or orbital abscess: perinasal swelling, edema, proptosis, chemosis and even blindness	
			Facial numbness from damage to sensory branches of the fifth cranial nerve	
			Black, necrotic eschar on the palate or nasal mucosa, turbinate destruction	
			Intracranial complications: epidural and subdural abscesses, necrosis of frontal lobes, cavernous and sagittal sinus thrombosis	
			Clinical meningitis is rare	

Table 47.4 (continued)

	Spectrum of infections and references	Causative microorganisms	Clinical features	Diagnostic procedure
Respiratory system	Influenza [96, 97]	Type A influenza viruses: H1N1 and H3N2	Six times more frequent in patients with diabetes	Normal or decreased leukocyte count
			Wide range of manifestations, including: (1) asymptomatic, (2) conjunctivitis, (3) influenza-like illness, (4) viral pneumonia, (5) acute respiratory distress syndrome, (6) respiratory failure, (7) multiorgan failure	Lymphopenia and thrombocytopenia, high levels of C-reactive protein
			Sudden onset: fever, cough, malaise, wheezing, pulmonary rales, respiratory failure	Chest radiography: ground glass opacities and consolidation
				Confirmatory tests for influenza H1N1 including real-time or reverse transcriptase polymerase chain reaction
	Community-acquired pneumonia [98–110]	Outpatient: *Streptococcus pneumoniae*	Cough, fever, dyspnea, focal chest signs, respiratory failure	Clinical examination
		Mycoplasma pneumoniae	Prediction rule for diagnosis: Rhinorrhea—2, Sore throat—1, Night sweats 1, Myalgia 1, Sputum 1, Respiratory rate >25 breaths/min	Chest radiography
		Chlamydia pneumoniae	2 Temperature ≥100 °F (37.8 °C)	Pathogens are not detected in half of pneumonia episodes
		Klebsiella pneumoniae	2 Positive likelihood ratio: 3 points 14.0, 1 point: 5.0, −1 point: 1.5, ≤10.2 points	Clinical indications for extensive diagnostic testing include: (1) intensive care unit admission, (2) failure of outpatient antibiotic therapy, (3) cavitary infiltrates, (4) leucopenia, (5) alcoholism, (6) chronic liver disease, (7) obstructive/structural lung disease, (8) recent travel, (9) positive Legionella urinary antigen result, (10) positive urinary antigen pneumococcal result, (11) pleural effusion
		Legionella pneumophila		
		Haemophilus influenzae		
		Respiratory viruses		
		Inpatient, non-intensive care unit		
		Streptococcus pneumoniae		
		Mycoplasma pneumoniae		
		Chlamydia pneumoniae		
		Haemophilus influenzae		
		Legionella sp. aspiration		
		Intensive care unit		
		Streptococcus pneumoniae		
		Staphylococcus aureus		
		Legionella pneumophila		
		Gram-negative bacilli		
		Haemophilus influenzae		
	Pulmonary tuberculosis [111–114]	*Mycobacterium tuberculosis*	Fever, night sweats, weight loss, cough, sputum, hemoptysis	Chest radiography usually shows more lung cavities and parenchymal lesions in patients with diabetes than patients without diabetes. Sputum microscopy and culture: bacilloscopy from two samples collected at the same visit
			Patients with tuberculosis and diabetes are reported to be older and heavier, and more likely to be male	Xpert MTB/RIF: *M. tuberculosis* PCR

(continued)

Table 47.4 (continued)

	Spectrum of infections and references	Causative microorganisms	Clinical features	Diagnostic procedure
	Pulmonary coccidioidomycosis [115]	*Coccidioides immitis*, *Coccidioides posadasii*	Asymptomatic or mild respiratory illness in most cases	Chest radiography showing segmental or lobar consolidations, hilar or mediastinal adenopathy, pleural effusions, residual nodules, cavities, and chronic infiltrates
			Patients with diabetes may present with diffuse pneumonia	Definitive diagnosis is serological, by means of immunodiffusion to detect immunoglobulin G and IgM-specific antibodies
			Symptoms of severe illness include fever, malaise, pneumonia, chronic structural lung disease or cardiopulmonary disease, respiratory distress syndrome	Complement fixation tests for IgG-specific antibodies are useful in immunocompetent patients
			Improvement is slow in these cases	
	Pulmonary mucormycosis [92–95]	Rhizopus, Mucor	Pneumonia refractory to antibacterials	Computed tomography
			Hemoptysis	Histopathology
			Multiple mycotic pulmonary artery aneurisms and pseudoaneurysms, bronchial obstruction, asymptomatic solitary nodules	
			Endobronchial lesions with resulting obstruction of major airways or erosion into pulmonary blood vessels	
			Less common complications include mycetomas in preexisting lung cavities or slowly necrotizing pneumonia, hypersensitivity syndromes, and allergic alveolitis	
Abdomen	Acute emphysematous cholecystitis [1, 116, 117]	*Clostridium perfringens*	Fever, right upper quadrant abdominal pain, vomiting, jaundice, peritonitis, septic shock, sepsis	Radiography
		Escherichia coli		Computed tomography
		Bacteroides fragilis		
	Pyogenic liver abscess [118–120]	Invasive *Klebsiella pneumonia* serotypes K1 and K2	Fever, chills, and abdominal pain; nausea and vomiting	Computed tomography
			Higher rates of cryptogenic etiology, gas-forming nature, thrombocytopenia, growth of *Klebsiella pneumoniae* in blood cultures, metastatic infection, and bacteremia in patients with diabetes	Isolation of *Klebsiella pneumoniae* from blood or liver abscess
			Lower rates of right upper quadrant pain, biliary origin	Multiplex PCR
	Psoas and spinal epidural abscess [121, 122]	Most frequent: *Staphylococcus aureus*, but also *Escherichia coli*, *Mycobacterium tuberculosis*, Enterobacter, and Klebsiella	May be primary, from hematogenous spread from an occult source, or secondary, by spreading from contiguous anatomical structures	Leukocytosis
			Back pain, in the flank in the buttock or in the leg, fever, malaise	Computed tomography
Genitourinary tract	Asymptomatic bacteriuria [123, 124]	*Escherichia coli*	Asymptomatic	Urine examination and culture
		Staphylococcus saprophyticus		
		Enterococcus sp.		
		Candida		
	Candiduria [125]	*Candida* sp.	Frequently asymptomatic	Clinical examination
			Rare complications include prostatitis and epididymo-orchitis	Urinary dipstick, microscopy, urinary culture
	Acute pyelonephritis [126–129]	Bacterial: *Escherichia coli* Fungal: *Candida* sp.	Presentation of symptoms is variable, ranging from fever, malaise, costovertebral angle pain and tenderness, urgency and dysuria, to intense pain, nausea, vomiting, sepsis and septic shock in severe cases	Clinical examination
				Urinary dipstick, microscopy
				A quantitative count of $\geq 10^3$ cfu/mL in the urinary culture
				Pyuria

Table 47.4 (continued)

	Spectrum of infections and references	Causative microorganisms	Clinical features	Diagnostic procedure
	Emphysematous pyelonephritis [129]	*Escherichia coli*	Fever, chills, abdominal and flank pain, nausea, vomiting, dysuria, pyuria	Renal ultrasound, computed tomography
		Klebsiella pneumonia	Associated with poor prognosis: thrombocytopenia, mental status changes, proteinuria	
		Proteus mirabilis		
		Pseudomonas aeruginosa		
		Citrobacter		
		Candida		
	Perinephric abscess [130]	Common: *Escherichia coli*, *Enterobacter* sp., *Pseudomonas aeruginosa*, *Serratia* sp., *Citrobacter* spp.	Chronic presentation: persisting urinary infection, urine culture positive for *Proteus* spp.	Renal ultrasound, computed tomography, magnetic resonance imaging
		Less frequent: *Clostridium* spp. Bacteroides, *Actinomyces* spp., *Corynebacterium urealyticum*	Flank tenderness, localized rigidity and fullness, scoliosis, and palpable mass in some cases	
		Tuberculosis should always be considered	Signs in advanced stages: anemia, malaise empyema, psoas abscess or pyonephrosis necessitans	
		Proteus mirabilis in infected calculi	Acute: chills interspersed with high fever, loin and flank tenderness, history of bacterial skin infection	
	Bacterial cystitis [123, 124, 127, 128]	*Escherichia coli*	May be asymptomatic	Medical history
			More frequent in patients treated with sodium-glucose cotransporter-2 inhibitors	Urinalysis, urine culture
			Urgency, dysuria, fever	
	Fungal cystitis [125]	*Candida albicans*	Severe urgency, frequency, and nicturia	Medical history
			Sterile pyuria, microhematuria	Urine examination and culture
	Emphysematous cystitis [129]	More frequent: *Escherichia coli*, *Klebsiella pneumoniae Enterobacter aerogenes*, *Proteus mirabilis*, *Streptococcus* sp.	From asymptomatic (7%) to severe sepsis	Clinical examination: history of neurogenic bladder, complicated urinary tract infections, bladder outlet obstruction
		Less common: *Pseudomonas aeruginosa*, *Candida albicans*, *Clostridium perfringens*, *Enterococcus faecalis*, *Staphylococcus aureus*, *Clostridium welchii*, *Candida tropicalis*, *Aspergillus fumigatus*	Common symptoms: abdominal pain (80%) and gross hematuria (60%)	Urine examination and culture
			Less common: fever (30–50%), pneumaturia, dysuria, urinary frequency and urgency (50%)	Blood culture
				Plain film of the abdomen showing curvilinear areas of increased radiolucency delineating the bladder wall and intraluminal gas
				Computed tomography
	Vulvovaginal candidiasis [92, 131–136]	*Candida albicans*, *Candida glabrata*, *Candida tropicalis*	May be asymptomatic	Medical history
			Risk in patients treated with sodium-glucose cotransporter-2 inhibitors: 3–5 higher	Clinical examination of vaginal secretions including culture and wet mount, KOH microscopy, gram stain, Whiff test, pH measurement
			Acute pruritus, vaginal discharge, vaginal soreness, irritation, vulvar burning, dyspareunia, dysuria, odor, erythema, swelling of the labia and vulva	

(continued)

Table 47.4 (continued)

	Spectrum of infections and references	Causative microorganisms	Clinical features	Diagnostic procedure
	Balanoposthitis [137]	*Candida glabrata*, *Candida albicans*, *Candida tropicalis*	More frequent in uncircumcised men and in patients treated with sodium-glucose cotransporter-2 inhibitors	Medical history Physical examination
		Streptococci, Staphylococci, anaerobic bacteria, *Trichomonas vaginalis*, *Mycoplasma genitalis*, and herpes simplex virus have also been associated	Balanitis involves inflammation of the glans penis; posthitis is defined as inflammation of the prepuce	
	Necrotizing fasciitis [1, 2, 13]	*S. pyogenes*, *Clostridium* sp.	Pain, erythema, crepitation, bullous skin lesions	Medical history
			Involvement of skin, subcutaneous tissue, and superficial fascia	Clinical examination
				Plain radiography, computed tomography, or magnetic resonance imaging of the affected area
				Biopsy, gram stain, and culture
	Fournier's gangrene [138]	Mixed aerobes and anaerobes including *Escherichia coli*, *Klebsiella pneumoniae*, *Bacteroides fragilis*, Streptococcus, Enterococcus, Clostridium, Pseudomonas and Proteus	Male/female ratio: 10 to 1	Clinical examination
		Uncommon: Candida, *Lactobacillus gasseri*	Sudden pain and swelling in the scrotum	Imaging rarely necessary to ascertain extension
			Purulence or wound discharge, crepitation, fluctuance, prostration, fever	
			Necrotizing fasciitis of the external genitalia	
			Localized tenderness and wounds in genitalia and perineum	
			Fetid drainage and sloughing in affected sites	
			Sepsis, multiorgan failure	
Upper and lower extremities, skin and appendages	Hand ulceration and infection, "tropical diabetic hand syndrome" [139, 140]	*Staphylococcus* sp.	Under-reported, very few physicians are aware of its existence, resulting in late diagnosis and proper treatment	Clinical examination
			Largely reported in African countries, but also in the United States	Wound swab and culture
			More frequent in patients living in tropical and coastal areas	
			History of trauma including mild abrasions, lacerations, and insect bites; poor glycemic control, delayed presentation	
			Clinical presentation variable, ranging from localized swelling, cellulitis, and exudate, with or without ulceration, progressive hand sepsis and gangrene	
	Cutaneous zygomycosis [93, 94]	*Rhizopus* sp.	Single, painful area of erythema, induration, and cellulitis	Clinical examination
			Portals of entry include contaminated wounds, traumatic wounds, dressings, burns, and surgical sites	Skin biopsy
			Lesions secondary to trauma rapidly develop necrosis and extension to subcutaneous tissues, similar to ecthyma	
	Cellulitis [2, 6, 20, 141, 142]	*Staphylococcus aureus*, *Streptococcus pyogenes*, gram negatives and anaerobes less common	Painful, erythematous infection of the dermis and subcutaneous tissues presenting with warmth, edema, and advancing borders	Biopsy and histology examination
			Fever and leukocytosis	
			Most common sites include legs and digits, the face, feet, hands, torso, neck, and buttocks	

Table 47.4 (continued)

	Spectrum of infections and references	Causative microorganisms	Clinical features	Diagnostic procedure
	Foot ulcer infections [142–145]	Usually polymicrobial, including *Staphylococcus aureus*, *Proteus* spp., *Escherichia coli*, *Peptostreptococcus* sp., *Veilonella* sp., *Bacteroides* sp., *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*	Contaminating ulcers in the plantar aspect of foot, tip of the toe, lateral to fifth metatarsal	Culture preferably from tissue specimens rather than swabs
			Presence of purulence or at least ≥2 classic symptoms or signs of inflammation: erythema, edema, warmth, tenderness, pain, or induration	Deep tissue sampling; curettage or tissue scraping from the base of the ulcer
			In case of neuropathy, secondary signs include discolored granulation tissue, foul odor, non-purulent discharges, delayed wound healing	Gram staining and microscopy examination
	Herpes zoster [146, 147]	Varicella zoster virus	Odds ratio in patients with diabetes: 1.20 (CI 1.17–1.22)	Clinical examination
			Localized pain and paresthesia followed by erythematous macules or papules coalescing into grouped vesicular lesions or bullae usually in one dermatomal distribution, and unilateral	PCR testing for viral DNA from fluid from skin lesions
			Pustules and crusting afterwards	Direct fluorescent antibody testing on scrapings from active lesions
			Complete healing up to 4 weeks	
			Most common sites are the thoracic nerves and the ophthalmic division of the trigeminal nerve	
			Systemic symptoms include fever, headache, malaise, and fatigue	
	Tinea pedis, intertrigo [92]	*Candida*	Itching and scaling of the affected skin	Clinical examination
			Plantar or intertriginal fissures	Fungal culturing of skin samples
			Paronychial inflammation of the edge surrounding skin	
	Onychomycosis [92, 148, 149]	Dermatophytes: *Trichophyton rubrum*, *Trichophyton mentagrophytes*	Dystrophic, thick, brittle, and discolored nails, distal onycholysis, subungual hyperkeratosis, thickening of the nail bed and nail plate	Fungal culturing of samples from nail plates or subungual debris, direct microscopy
		Non-dermatophytes: *Candida* sp.		Histopathological examination
Hospital-acquired infections [2, 6, 20, 92, 124]				
Local	Postoperative wound infections	*Staphylococcus aureus*	7.7 higher risk	Clinical examination
			Mortality related to time with diabetes, glycemic control at hospital admission, and A1c level	Swab or biopsy examination
			Postoperative infections have been described in multiple surgical settings, including cardiothoracic, general, orthopedic, and vascular	
Systemic	Fungemia	*Candida albicans, Aspergillus fumigates, Candida glabrata*	Associated with disruption of skin barriers including injections or intravascular access	Clinical suspicion, isolation, and identification of pathogens by culturing and histopathology
	Mycosis in hemodialysis patients	*Candida* spp.	High risk in patients with onychomycosis	Clinical suspicion, isolation, and identification of pathogens by culturing and histopathology
	Urinary tract infection in post-renal transplant patients	*Escherichia coli*	Prevalence: 25–47%, higher risk in the first year post-transplant	Clinical examination, urine examination, and culture
			Additional risk factors include indwelling devices, immunosuppressive therapy and urologic abnormalities	
			May be asymptomatic or present with graft tenderness	
	Mycosis in post-transplant patients, including kidney and pancreas	*Candida* spp. *Cryptococcus neoformans*	May be asymptomatic	Clinical examination
				Blood culture

(continued)

Principles of Management

Managing infections in persons with diabetes is always a challenge for physicians. Principles of management include the following.

Awareness of Diabetes-Associated Diseases

Awareness regarding the variety and severity of diseases, in persons with diabetes, is essential for prevention and prompt treatment. Diabetes education, along with optimal glycemic control, can minimize the risk of life-threatening infections. Simple preventive measures like proper foot care can reduce disease-associated morbidity.

Adequate Choice of Antibiotics

Empirical broad-spectrum antibiotics should be used till microbiologic results can guide treatment; some infections are frequently resolved empirically. Choice of antibiotics should be based on possible causative organisms and local flora. Early suspicion of antibiotic resistance, in people with diabetes with complicated infections, can help in limiting the disease-associated morbidity and mortality. *P. aeruginosa* infections are commonly seen in hospitalized patients with cystic fibrosis, cytotoxic chemotherapy, mechanical ventilation, and broad-spectrum antibiotic therapy. Patients present with fever, shock, hypothermia, acute pneumonia, and occasionally ecthyma gangrenosum. Table 47.5 shows empirical therapies for infections in patients with diabetes, and Table 47.6 presents first

Table 47.5 Empirical selection of antimicrobial therapy and dose in adults

Infection	First choice	Alternate choice(s)
Herpes zoster ophthalmicus	Acyclovir, 800 mg PO five times daily/7–10 days	Valacyclovir 1000 mg PO three times daily/7–10 days
		Famciclovir, 500 mg PO/three times a day/7–10 days
Malignant external otitis (MEO)	Ciprofloxacin, 1.5 g IV/day plus Ceftazidime 2 g IV/8 h/10 weeks	Itraconazole, 200 mg PO or Voriconazole 200 mg PO daily/6 weeks, for MEO caused by Aspergillosis
Periodontal infections	Tetracycline, 250 mg PO/6 h or 500 mg PO/bid Clarithromycin, 500 mg PO/day	Azithromycin, 500 mg PO/3 days
		Amoxicillin, 500 mg PO/bid/10 days
		Metronidazole, 250 mg PO/6–8 h/10 days or 500 mg PO/8 h/10 days
Oral candidiasis	Nystatin, 400,000–600,000 units PO/4 times a day after meals/7–14 days	Fluconazole, 100–200 mg PO once daily/7–14 days after clinical improvement
		Itraconazole, 200 mg PO day/7–14 days
Rhino-orbital or rhino-cerebral sinusitis	Amphotericin B, 0.25–0.3 mg/kg IV/24 h, increasing by 5–10 mg/day to a final dose of 0.5–0.7 mg/kg/day for 12 weeks	Posaconazole, oral solution, 800 mg in 4 divided doses/day for 12 weeks
		Posaconazole, oral solution, 800 mg in 4 divided doses/day
		Isavuconazole, 200 mg orally or IV, loading dose: 200 mg/8 h/2 days; 200 mg/day afterwards for 12 weeks
Influenza	Neuraminidase inhibitors	M2 Inhibitors
	Laninamivir one single inhalation of 20 mg for children <10 years, one single inhalation of 40 mg for individuals ≥10 years	Amantadine 100 mg/12 h/5 days
	Oseltamivir 75 mg/12 h/5 days	Rimantadine 100 mg/12 h/5 days
Community-acquired pneumonia	Outpatients: β-lactam (i.e., Amoxicillin 875–1000 mg/clavulanate, 62.5–125 mg PO/12 h) plus macrolide (i.e., Clarithromycin, 500 mg/day PO/5–10 days or Azithromycin, 500 mg/day PO/3 days) within 4–8 h after diagnosis	Respiratory fluoroquinolone: Moxifloxacin, 400 mg PO once daily/7–14 days
	Inpatients, non-ICU: Respiratory fluoroquinolone (i.e., moxifloxacin or levofloxacin PO or IV)	Levofloxacin, 500 mg PO once daily/10–14 days or 750 mg once daily/5–7 days or 750 mg IV/24 h/7 days
	Inpatients, ICU: A β-lactam (cefotaxime, ceftriaxone, ampicillin-sulbactam IV) plus azithromycin or respiratory fluoroquinolone (i.e., moxifloxacin, levofloxacin IV)	
	For penicillin allergic patients: a respiratory fluoroquinolone and aztreonam IM or IV	

Table 47.5 (continued)

Infection	First choice	Alternate choice(s)
Pulmonary tuberculosis	Short therapy for isoniazid sensitive TB: Isoniazid plus rifampicin PO for 6 months, plus ethambutol and pyrazinamide PO for the first 2 months	Long therapy for isoniazid mono-resistant TB: Rifampicin, ethambutol, and pyrazinamide for the first 6 months, or for 9 months with rifampicin, ethambutol, and pyrazinamide in the intensive phase and for two additional months with rifampicin and ethambutol in the continuation phase
Pulmonary coccidioidomycosis	Fluconazole, 800–1200 mg PO or IV/day	Amphotericin B, 5.0 up to 7.5–10.0 mg/kg/day IV for 12 weeks
	Inability of azoles to eradicate the fungus results in the need to continue treatment indefinitely as suppressive rather than curative therapy	Because of multiple adverse events, it should only be used in patients with refractory disease
Pulmonary mucormycosis	Amphotericin B, 5.0 up to 7.5–10.0 mg/kg/day IV for 12 weeks	Posaconazole, oral solution, 800 mg in 4 divided doses/day for 12 weeks
		Posaconazole, oral solution, 800 mg in 4 divided doses/day
		Isavuconazole, 200 mg orally or IV, loading dose: 200 mg/8 h/2 days; 200 mg/day afterwards for 12 weeks
Acute emphysematous cholecystitis	Ampicillin-sulbactam, 3 g/IV/6 h	Ampicillin 2 g/IV/6 h plus gentamicin 5 mg/kg/24 h plus clindamycin 900 mg/IV/8 h or Ceftriaxone 1–2 g IM or IV/24 h plus clindamycin or metronidazole, loading dose 15 mg/kg followed by 7.5 mg/kg IV/6 h
Pyogenic liver abscess	Multiple combination therapies have been used, including aminopenicillins, antipseudomonal penicillins, first-generation, second-generation, third-generation cephalosporins, carbapenems, fluoroquinolones, aminoglycosides, metronidazole	
Psoas and spinal epidural abscess	Nafcillin, 1000 mg IV/4 h or Oxacillin, 1000 mg/day IV every 4–6 h or Cefazolin, 100 mg/kg/day IM or IV/8 h	Ciprofloxacin 750 mg/12 h for 6 weeks
Asymptomatic bacteriuria	Screening and treatment unwarranted	
Asymptomatic candidiuria	Fluconazole, 400–800 mg PO, single dose	Caspofungin 70 mg IV loading dose → 50 mg/day
		Anidulafungin 200 mg/kg IV loading dose →100 mg/day
		Voriconazole 6 mg/kg IV/12 h; afterwards, 4 mg/kg/12 h
		Amphotericin B 0.6–0.7 mg/kg/day ± flucytosine 25 mg/kg/6 h/7–10 days
Bacterial pyelonephritis	Uncomplicated: Ciprofloxacin, 500 mg PO/bid/7 days or Tobramycin, 3–5 mg/kg IV/24 h/3 days	Uncomplicated: Levofloxacin, 250–500 mg PO/day/10 days or Ceftriaxone, 1 g/IV/24 h/3 days
	Complicated	Complicated
Emphysematous pyelonephritis	Prolonged antimicrobial therapy (i.e., Trimethoprim-sulfamethoxazole, 160/800 mg PO or IV/bid) for weeks or months plus additional surgical measures (see Table 47.5)	

(continued)

Table 47.5 (continued)

Infection	First choice	Alternate choice(s)
Bacterial cystitis	Uncomplicated: short course of antimicrobial therapy	Uncomplicated: Trimethoprim-sulfamethoxazole, 1600/800 mg/bid/3 days
	Amoxicillin, 500 mg PO/tid/7 days, or Amoxicillin/clavulanic acid, 500 mg PO/tid/7 days or Cephalexin, 250–500 mg PO/tid/7 days or Norfloxacin, 400 mg PO/bid/3 days	Nitrofurantoin, 50–100 mg/qid/7 days
	Complicated infections: prolonged antimicrobial therapy	Complicated
Fungal cystitis	Fluconazole, 400 mg IV/day/14 days	Flucytosine, 25 mg/kg/6 h/14 days or Amphotericin B 0.5–0.7 mg/kg/day/14 days
Perinephric abscess	Nafcillin, 1000 mg IV/4 h or Oxacillin, 1000 mg/day IV every 4–6 h or Cefazolin, 100 mg/kg/day IM or IV/8 h	Oxacillin, 1000 mg/day IV every 4–6 h or Cefazolin, 100 mg/kg/day IM or IV/8 h
Emphysematous cystitis	Fluoroquinolone (i.e., Levofloxacin 250 mg IV/24 h/10 days or 750 mg IV/5 days, or Moxifloxacin, 400 mg PO or IV once daily/5–14 days or Ceftriaxone, 1–2 g IM or IV/24 h/10–14 days)	Carbapenem (i.e., Cilastatin/Imipenem, 500 mg IV/6 h or 1000 mg IV/8 h) or Aminoglycoside (i.e., Gentamicin, 3 mg/kg IM or IV/8 h/day/10 days)
Vulvovaginal candidiasis	Uncomplicated: Clotrimazole, 200 mg intravaginally/3 days	Uncomplicated: Fluconazole, 150 mg, single dose
	Miconazole, 2 ovules at bedtime/3 days	Recurrent: Fluconazole, 150 mg/week/6 months
	Butoconazole, 500 mg vaginal tablet single dose	
	Recurrent: Fluconazole, 200 mg PO/8 h/1 week	
	If symptom free, fluconazole, 200 mg once a week from weeks 2 to 8, 200 mg every 2 weeks from months 3 to 6 and 200 mg every 4 weeks from months 7 to 12	
Balanoposthitis	Clotrimazole, 1–2% cream until symptoms subside	Patients with severe symptoms: Fluconazole, 200 mg single dose
Necrotizing fasciitis	Penicillin G, 24 million U IV/day plus clindamycin, 900 mg IV/8 h plus gentamicin, 5 mg/kg IV/day or Meropenem, 1 g IV/8 h plus clindamycin, 600 mg IV/8 h or lincomycin 600 mg IV/8 h	Ampicillin-sulbactam 1.5–3.0 g IV/6–8 h or Ceftriaxone, 2 g IV/24 h plus clindamycin, 900 mg IV/8 h
Fournier's gangrene	Triple antibiotic therapy including (1) a broad-spectrum penicillin or third-generation cephalosporin, (2) an aminoglycoside, (3) metronidazole or clindamycin	Alternatively, triple antibiotic therapy including (1) a broad-spectrum penicillin or third-generation cephalosporin, (2) an aminoglycoside, (3) chloramphenicol
		Vancomycin in patients infected with methicillin-resistant *S. aureus*
		Amphotericin B in patients with fungal infections
Diabetic hand syndrome	Triple antibiotic therapy to cover Staphylococcus, Gram-negative organisms and anaerobes, including (1) third-generation cephalosporin, (2) aminoglycoside, (3) metronidazole or clindamycin	Second choice therapy based on results of wound swab and culture
Cellulitis	Amoxicillin-clavulanate	Third-generation cephalosporin with or without aminoglycoside
	First-generation cephalosporin	
	Macrolides	
	Fluoroquinolone	
	Ceftriaxone	

Table 47.5 (continued)

Infection	First choice	Alternate choice(s)
Foot ulcer infections	Mild to moderate: Amoxicillin-clavulanate, 875/125 mg PO/12 h or Ampicillin/sulbactam, 3 g IV/6 h	Mild to moderate: Cephalexin, 500 mg PO/6 h plus metronidazole, 400 mg PO/8–12 h or Ciprofloxacin, 500 PO/12 h plus clindamycin, 300–450 mg PO/8 h or 600 mg IV/8 h
	Severe: Ticarcillin-clavulanate, 0.1–0.3 g IV/h or Meropenem-cilastatin 500 mg IV/8 h	Severe: Ciprofloxacin, 750 mg VO/12 h plus clindamycin, 600 mg IV/8 h or lincomycin, 600 mg IV/8 h
Herpes zoster	Acyclovir, 800 mg PO/5 times a day/7–10 days	Famciclovir, 500 mg PO/7 days
		Valacyclovir, 1000 mg/tid/7 days
Onychomycosis	Terbinafine, 250 mg/day PO/12 weeks	Itraconazole, 200 mg/bid/1 week on, 3 weeks of/12 weeks
	Use with caution in patients with liver or kidney disease	Contraindicated in patients with congestive heart failure
	Fluconazole, 150, 300, or 450 mg PO/week/6 months	
Cutaneous zygomycosis	Amphotericin B, 5.0 up to 7.5–10.0 mg/kg/day IV for 12 weeks	Posaconazole, oral solution, 800 mg in 4 divided doses/day for 12 weeks
		Posaconazole, oral solution, 800 mg in 4 divided doses/day
		Isavuconazole, 200 mg orally or IV, loading dose: 200 mg/8 h/2 days; 200 mg/day afterwards for 12 weeks

Table 47.6 Choice of antimicrobial therapy by microorganisms and dose in adults

	First line, dose, and duration		Second line, dose, and duration	
Microorganism	Oral	Intramuscular or intravenous	Oral	Intramuscular or intravenous
Bacteria				
Streptococcus pneumoniae	β-lactam	Benzylpenicillin 1.2 g IV/6 h	Respiratory fluoroquinolone: Moxifloxacin, 400 mg PO once daily/7–14 days	Vancomycin, 25–30 loading dose for seriously ill patients, then 15–20 mg/kg IV/8–12 h in combination FDA approved labeling: 2 g/day IV divided either as 500 mg IV/6 h or 1 g IV/12 h
	(Amoxicillin, 500–875 mg) plus macrolide	Cefuroxime, 750–1500 mg IV/8 h; for life-threatening infections, 1.5 g IV/6 h	Gemifloxacin, Levofloxacin, 500 mg PO once daily/10–14 days or 750 mg once daily/5–7 days or 750 mg IV/24 h/7 days	Linezolid, 600 mg IV/12 h/10–14 days. Duration of treatment is 7–21 days for methicillin-resistant *Staphylococcus aureus*
	(Clarithromycin, 500 mg/day) within 4–8 h after diagnosis	Cefotaxime, for uncomplicated infections: 1 g IM or IV/12 h, for complicated infections, 2 g IV/6–8 h/7–10 days		
		Ceftriaxone, 1–2 g IM or IV/day/7–10 days, depending on clinical response		
Haemophilus influenza	Amoxicillin-clavulanate, 500–875 mg/8–12 h	Respiratory fluoroquinolone: Moxifloxacin, 400 mg PO once daily/7–14 days	Doxycycline, 100 mg/12 h day	Respiratory fluoroquinolone: Levofloxacin, 750 mg IV/24 h/7 days
		Levofloxacin, 500 mg PO once daily/10–14 days or 750 mg once daily/5–7 days	Azithromycin, 200 mg/day	
			Clarithromycin, 500 mg/day	

(continued)

Table 47.6 (continued)

	First line, dose, and duration		Second line, dose, and duration	
Microorganism	Oral	Intramuscular or intravenous	Oral	Intramuscular or intravenous
Staphylococcus aureus	Dicloxacillin, 125–250 mg PO/6 h for moderate infections, 250–500 mg PO/6 h for severe infections	Nafcillin, 500 mg IV/4 h for moderate infections, 1000 mg IV/4 h for severe infections	Clindamycin, 150–450 mg PO/6 h	Clindamycin, 600 mg IM or IV/6–12 h up to 900 mg/8–12 h
		Oxacillin, 1 g/day IV every 4–6 h		Vancomycin, 25–30 loading dose for seriously ill patients, then 15–20 mg/kg IV/8–12 h in combination FDA approved labeling: 2 g/day IV divided either as 500 mg IV/6 h or 1 g IV/12 h
		Cefazolin, 250–500 mg/kg/IM or IV/8 h for mild to moderate infections; 100 mg/kg/day IM or IV divided every 8 h for severe infections		Linezolid, 600 mg IV/12 h/10–14 days
Mycoplasma pneumoniae	Clarithromycin, 500 mg/day	Respiratory fluoroquinolone: Moxifloxacin, 400 mg PO once daily/7–14 days		
		Levofloxacin, 500 mg PO once daily/10–14 days or 750 mg once daily/5–7 days		
Mycobacterium tuberculosis	Short therapy for isoniazid-sensitive TB: Isoniazid plus rifampicin for 6 months, plus ethambutol and pyrazinamide for the first 2 months		Long therapy for isoniazid mono-resistant TB: Rifampicin, ethambutol, and pyrazinamide for the first 6 months, or for 9 months with rifampicin, ethambutol, and pyrazinamide in the intensive phase and for two additional months with rifampicin and ethambutol in the continuation phase	
Legionella sp.	Respiratory fluoroquinolone, i.e., Moxifloxacin, 400 mg PO once daily/7–10 days or Levofloxacin, 750 mg PO once daily/5–10 days		Azithromycin, 1000 mg PO/day followed by 500 mg/day/10 days or Doxycycline, 100 mg PO/day	
Klebsiella pneumoniae		Ertapenem, 1 g IM or IV/24 h/10–14 days		Avibactam/Ceftazidime, 2.5 g (2 g Ceftazidime, 0.5 g Avibactam) IV/8 h/7–14 days
		Imipenem-Cilastatin, 1 g IV/6–8 h		
		Meropenem, 1 g IV/8 h		
Escherichia coli		Ertapenem, 1 g IM or IV/24 h/10–14 days		Aminoglycosides, i.e., Amikacin, 15 mg/kg/day IM or IV/8–12 h or Gentamicin, 3 mg/kg IM or IV/day/divided in three doses/10 days or Tobramycin, 3–6 mg/kg IM or IV/day divided in 2–3 doses
		Imipenem-Cilastatin, 1 g IV/6–8 h		
		Meropenem, 1 g IV/8 h		

Table 47.6 (continued)

First line, dose, and duration			Second line, dose, and duration	
Microorganism	Oral	Intramuscular or intravenous	Oral	Intramuscular or intravenous
Acinetobacter		Ertapenem, 1 g IM or IV/24 h/10–14 days		Aminoglycosides, i.e., Amikacin, 15 mg/kg/day IM or IV/8–12 h or Gentamicin, 3 mg/kg IM or IV/day/divided in three doses or Tobramycin, 3–6 mg/kg IM or IV/day divided in 2–3 doses
		Imipenem-Cilastatin, 1 g IV/6–8 h		Third-generation Cephalosporins, including Cefotaxime, 1–2 g IM or IV/12 h
		Meropenem, 1 g IV/8 h		Ceftriaxone 1–2 g IM or IV/24 h
				Avibactam/Ceftazidime, 2.5 g (2 g Ceftazidime, 0.5 g Avibactam) IV/8 h
				Ampicillin-sulbactam, 1.5 g (1 g ampicillin and 0.5 g sulbactam) IM or IV/6 h
Pseudomonas aeruginosa	Levofloxacin, 250–750 mg PO/day	Cefepime, 0.5–1.0 g IM or IV or Ciprofloxacin 400 mg IV/12 h or Aztreonam, 500–1000 mg IM or IV/8–12 h		Ticarcillin-clavulanate 3.0–0.1 g IV/6 h or third-generation cephalosporin, i.e., Ceftazidime 2 g IV/8 h plus Aminoglycoside, i.e., Gentamicin, 4–6 mg/kg IV day
		Carbapenem, i.e., Imipenem/cilastatin 500–1000 mg IV/6–8 h or Meropenem, 1 g IV/8 h		Ciprofloxacin 1.5 g/day or Levofloxacin, 500 mg IV/day or Ticarcillin, 3.1 g (3 g ticarcillin and 0.1 g clavulanic acid) IV/4–6 h or Piperacillin/tazobactam, 3.375 g (3 g piperacillin and 0.375 tazobactam) IV/6 h
Fungi				
Rhizopus and *Mucor*	Amphotericin B, 5 mg/kg/day IV for 12 weeks		Posaconazole, oral solution, 800 mg in 4 divided doses/day for 12 weeks for patients who cannot tolerate or non-responders to Amphotericin B	
Candida	Oral: Nystatin 100,000 units/mL after meals	Toenail: Itraconazole, 200 mg once daily/12 weeks	Fluconazole 200 mg day/3 days	Itraconazole 200 mg day
	Toenail: Terbinafine, 250 mg once daily/12 weeks	Topical: Ciclopirox, once daily application, avoiding washing for 8 h after application		
		Efinaconazole, once daily application for 48 weeks		
		Tavaborole, once daily application for 48 weeks		

(continued)

Table 47.6 (continued)

	First line, dose, and duration		Second line, dose, and duration	
Microorganism	Oral	Intramuscular or intravenous	Oral	Intramuscular or intravenous
Aspergillus		Amphotericin B 2 g day IV/3 weeks for invasive Aspergillosis	Voriconazole 200 mg day/6 weeks, for invasive Aspergillosis	
Histoplasma capsulatum	Itraconazole	Amphotericin B 2 g day IV/3 weeks		Amphotericin B 2 g day IV/3 weeks
Coccidioides	Fluconazole, 800–1200 mg/day	Amphotericin B 2 g day IV/3 weeks for invasive Coccidioidomycosis	Voriconazole 200 mg day/6 weeks, for invasive Coccidioidomycosis	
	Warning: inability of azoles to eradicate the fungus results in the need to continue treatment indefinitely as suppressive rather than curative therapy		Posaconazole, oral solution, 800 mg in 4 divided doses/day for 12 weeks for patients who cannot tolerate or non-responders to Amphotericin B	
Viruses				
Influenza	M2 Inhibitors			
	Amantadine 100 mg/12 h/5 days			
	Rimantadine 100 mg/12 h/5 days			
	Neuraminidase inhibitors			
	Laninamivir one single inhalation of 20 mg for children <10 years, one single inhalation of 40 mg for individuals ≥10 years			
	Oseltamivir 75 mg/12 h/5 days			
Herpes zoster	Acyclovir, 800 mg 5 times a day, 7–10 days		Famciclovir, 500 mg 3 times a day, 7–10 days	
	In patients with persistent varicella DNA in the cornea, antiviral therapy may extend up to 30 days		In patients with persistent varicella DNA in the cornea, antiviral therapy may extend up to 30 days	
			Valacyclovir, 1 g 3 times a day, 7–10 days	
			In patients with persistent varicella DNA in the cornea, antiviral therapy may extend up to 30 days	

and second option choices of antibacterials, antimycotics, and antivirals. Microorganisms showing increasing rates of antimicrobial resistance like Pseudomonas and Acinetobacter are effectively treated combining two antibiotics. Diabetic foot infections, skin and soft tissue infections, periodontitis along with emphysematous cholecystitis often require polymicrobial cover, especially to include anaerobes.

Glycemic Control

Poor glycemic control, especially in the presence of infection, can lead to metabolic and infection-related complications. Insulin requirements may increase during infections. Insulin is an anabolic agent, and it should be the preferred drug for glycemic control in the background of infection.

Source Control

Source control in the form of drainage or debridement of the infective focus can lead to reduction in the bacterial load, help achieve better glycemic control, and reduce the risk of complications. In addition to antimicrobials, complementary interventions for selected infections are presented in Table 47.7.

Table 47.7 Additional therapeutic measures and prognosis

Disease	Therapeutic measure	Prognosis
Herpes zoster ophthalmicus	• Oral or topical corticosteroids	Complications related to bad prognosis: Meningitis, brain abscess, dural sinus thrombophlebitis
	• Frequent artificial tears	
	• Monitoring for signs of secondary bacterial infection	
	• Prophylactic erythromycin ophthalmic ointment	
	• Analgesics in the acute phase and in patients with post-herpetic neuralgia	
Malignant external otitis	• Six weeks or longer of culture-directed antibiotic therapy, based on the 3–4-week period for bone revascularization	Reported mortality rates in recent series is 30%
	• Otolaryngology management	More aggressive strains and increasing antibiotic resistance are requiring multidrug and long-term antibiotic therapy with extended hospital stays
	• Repeated debridement of the ear, the infratemporal fossa, or skull base	Signs of disease progression and poor outcomes:
	• Radical mastoidectomy with facial nerve decompression	Lack of glycemic control
		Cranial nerve involvement
		Extension to the jugular foramen and petrous apex
		Erythrocyte sedimentation rate
		C-Reactive protein
		Causes of death:
		Meningitis, large vessel septic thrombophlebitis or rupture, septicemia, pneumonia, stroke
		Predictors of symptom resolution for fungal malignant external otitis:
		No surgical debridement
		Absence of facial paralysis
		Aspergillus as causative pathogen
		Absence of imaging findings
		Indicator of disease resolution: negative results by Ga-67 citrate scan
Periodontal infections	Systemic antibiotics are important, but only in addition to reducing the bacterial load with periodontal scaling and root planning	Because of increasing resistance, combinations of antibiotics are increasingly used
Oral candidiasis	Glycemic control	
	Oral hygiene	
	Avoiding tobacco use	
Rhino-orbital mucormycosis	Surgical debridement of infected tissue, including removal of the palate, nasal cartilages, and orbit as soon as possible, is crucial to prevent dissemination	Mortality rate: 25–62%
		Poor outcome predictors: dissemination, renal failure, inability to achieve source control, brain or cavernous sinus involvement, lack of response to antifungals
Influenza	In addition to diabetes, higher risks of complications occur in children, the elderly, and pregnant	Worldwide mortality rate for influenza from subgroups H5N1 and H7N9 of influenza A virus: 53% and 39%

(continued)

Table 47.7 (continued)

Disease	Therapeutic measure	Prognosis
Community-acquired pneumonia	Recommended actions to improve the outcomes include: (1) using a risk stratification tool like CURB-65 (confusion, urea >7 mmol/L, respiratory rate ≥30/min, low blood pressure, and older than 65), (2) procalcitonin to confirm diagnosis and assess treatment response, (3) outpatient treatment, (4) use of empirical antibiotic guidelines in accordance to local microbial etiology, (5) measure time to achieve clinical stability, step-down to oral antibiotics, early physical therapy, patient and caregiver education, appropriate venous thromboembolism prophylaxis	Odds ratio for pneumonia: 1.5
	Criteria to transition from intravenous to oral therapy: (1) absence of mental confusion, (2) ability to take oral medications, (3) hemodynamic stability (heart rate <100 beats/min, systolic blood pressure >90 mmHg), (4) respiratory rate <25 breaths/min, (5) oxygen saturation >90%	Hazard ratio for pneumonia: 2.9
	Administration of macrolides before beta-lactams is associated with a statistically significant decrease in mortality, even in hospitalized patients. Data from many countries show an increased prevalence of macrolide-resistant *Streptococcus pneumonia*. For example, in the United Sates the overall rate of macrolide-resistant *S. pneumoniae* is 50%. Nevertheless, resistance does not automatically mean treatment failure. Another important factor is the increasing awareness of respiratory viruses and atypical species as co-pathogens	Risk of invasive pneumococcal disease: 1.4–4.6, especially in individuals younger than 40 years
		Odds ratio for bacteremia: 1.67
		Hyperglycemia is independently associated with adverse outcomes in patients with community-acquired pneumonia
		Preexisting diabetes and newly discovered hyperglycemia are associated with a higher risk of death, for several years. A pre-pneumonia diagnosis of diabetes is associated with a threefold increase in the risk of death up to 6 years after mild to moderate community-acquired pneumonia.
		Rather than disruption of the immune response, death may be related to worsening of preexisting cardiovascular and kidney disease
Tuberculosis	Although treatment schedule can be as high 95–98% under clinical trial conditions (directly observed therapy or DOT), high rates of non-adherence after 4 weeks of therapy (between 7% and 53.6%) are common. Therapeutic drug monitoring has been proposed to optimize treatment outcome and reduce drug resistance	Patients with diabetes are at a higher risk of developing active tuberculosis, drug-resistant disease, treatment failure, and mortality
	Drug-induced liver injury may be caused by isoniazid, rifampicin, or pyrazinamide, in the range of 5–33%	Compared with patients without diabetes, the risk of active tuberculosis is 1.55–3.59 higher
	Treatment of multidrug-resistant tuberculosis includes: (1) at least four drugs with proven or likely susceptibility, (2) a later generation fluoroquinolone (moxifloxacin, levofloxacin), plus an aminoglycoside (amikacin, kanamycin, capreomycin), (3) long duration of treatment (21–24 months), (4) oxazolidinones (linezolid) with monitoring for neuropathy and bone marrow toxicity, in patients with fluoroquinolone-resistant TB, (5) bedaquiline or delamanid for patients with toxicity or resistance to multidrug regimens, (6) psychological and economic support	Tuberculosis prevalence and incidence are more likely to increase in countries where diabetes prevalence has increased
		Death rates: for untreated smear-positive TB: 70%, for smear negative TB: 20%
		Patients with diabetes and tuberculosis have: (1) significantly higher rates of treatment failure and death; (2) higher risk of death during treatment and relapse following treatment; (3) remain sputum positive 2–3 months after starting TB treatment.
		Infection and treatment for tuberculosis impair glycemic control and peripheral neuropathy in patients receiving isoniazid

Table 47.7 (continued)

Disease	Therapeutic measure	Prognosis
Coccidioidomycosis	Exogenous adjunctive interferon-γ has been used in patients with chronic coccidioidomycosis, in addition to antifungal therapy	The disease is relatively benign in most cases but for others is debilitating and may be mortal
	Nikkomycin has shown promise as a cure in murine models of infection	Recurrence is possible in patients with benign disease
		Extrapulmonary disease occurs through hematogenous or lymphatic spread and may involve meninges, skeleton, skin, joints, glandular tissue, peritoneum, liver, pancreas, pericardium, bone marrow, kidney, bladder, and male and female reproductive organs
		In these cases treatment is prolonged, even for years with close follow-up for relapses
Emphysematous pyelonephritis	Percutaneous drainage	Delayed nephrectomy if necessary, once the patient is stable
Psoas abscess	Surgical drainage	Mortality 17%, for primary psoas abscess: 2.5%, for secondary psoas abscess: 18.9%
		Death largely related to comorbidities, delayed diagnosis, or inadequate therapy
Perinephric abscess	Percutaneous drainage	Percutaneous nephrolithotomy in case of infective stone
		In patients with chronic abscess, nephrectomy
Fungal urinary tract infections	Correct predisposing factors, including: (1) removal of indwelling devices, (2) improving urinary tract drainage, (3) discontinue systemic antibiotics, (4) treating underlying medical problems	Glycemic control is essential
		Strategies to reduce funguria include: (1) adequate hydration, (2) hygiene, (3) vaginal estrogens
Emphysematous cystitis	90% of cases are treated with medical treatment alone, 10% require medical and surgical intervention, including: bladder drainage, surgical debridement, partial cystectomy, total cystectomy, or even nephrectomy	Death rate: 7–12% from septic shock or late presentation
Necrotizing fasciitis	Surgical debridement of necrotic tissue is essential for recovery	
Fournier's gangrene	Early and aggressive surgical debridement improves survival	Wide reported mortality rate: 4.0–88.0%
	Additional interventions include negative-pressure wound therapy, hyperbaric oxygen therapy, fecal and urinary diversion, and reconstructive surgery	
Diabetic hand syndrome	Comprehensive management include: (1) hospitalization and hand elevation, (2) multiple intravenous antibiotics, (3) optimal glycemic control, (4) adequate and early surgical drainage, (5) prompt amputation if necessary, (6) rehabilitation	Life expectancy of high upper limb amputees may be lower, but the number of reported cases is low to be conclusive
Cellulitis	Most cases improve within 1 day, but thickening of the debris requires parenteral antibiotics before improvement	Recurrent cellulitis can compromise venous or lymphatic circulation and result in dermal fibrosis, lymphedema, and epidermal thickening
	Adjunctive treatment includes cool compresses, analgesics, and immobilization of the affected extremity	Prophylaxis with erythromycin, penicillin, or clindamycin is indicated in these cases

(continued)

Table 47.7 (continued)

Disease	Therapeutic measure	Prognosis
Foot ulcer infections	For mild to moderate infections, antimicrobial therapy for 1–2 weeks is adequate	Factors predicting healing include: (1) absence of exposed bone, (2) palpable pedal pulses, (3) blood pressure in the toe >45 mmHg or >80 mmHg in the ankle, (4) peripheral white cell count <12,000/mm^3, (5) lower extremity transcutaneous oxygen tension >40 mmHg
	Most severe infections and some moderate require parenteral antimicrobial therapy for 1–2 weeks with a switch to oral therapy according to clinical response	Failure to treat diabetes foot infections is associated with progressive tissue destruction, poor wound healing, amputation, sepsis, and death
	Patients with osteomyelitis not undergoing resection require 6 weeks of antimicrobial therapy	Beyond intervention, healthcare practitioners should focus on prevention in patients at high risk for diabetic foot ulcers
	Patients with osteomyelitis undergoing resection require 1 week of antimicrobial therapy	
	Urgent surgical intervention by certified specialists is necessary in case of deep abscess, compartment syndrome, and necrotizing soft tissue infections	
	Surgical intervention is advisable in cases of osteomyelitis associated with spreading soft tissue infection, destroyed soft tissue envelope, progressive bone destruction, or bone protruding through an ulcer	
Herpes zoster	Complications include post-herpetic neuralgia and secondary bacterial infections; less common complications are neurologic, and include aseptic meningitis, peripheral motor neuropathy, transverse myelitis, acute or chronic encephalitis, Guillain-Barré syndrome, and stroke symptoms resulting from vasculitis of cerebral arteries	Post-herpetic neuralgia is the most common complication; risk factors include advanced age and severity of rash and pain
Onychomycosis	Nail lacquers are an attractive option and include 8% ciclopirox, once daily/48 weeks and 5% amorolfine, once or twice weekly/6 months	Risk factors for *Candida* onychomycosis include peripheral vascular disease and female gender. Consider this diagnosis in patients with onycholysis, paronychia, or total dystrophic onychomycosis
	Unattached infected nail should be removed once a month	Onychomycosis is a significant predictor for the development of foot ulcers
	Filing of excess horny material should be done by trained professionals	Rates of mycological cure are low: 31% with azoles, 57% with terbinafine
	Patients should file away loose nail material and trim nails as directed by podologists, or every 7 days after weekly removal of medication with alcohol	
Cutaneous zygomycosis		

When to Refer

Any case which appears complex to the treating physician may be referred to a specialist. However priority referrals should be considered in case of diabetes complicating pregnancy, renal impairment, diabetic foot, life-threatening invasive mucormycosis, and coronavirus-19.

Conclusion

Hyperglycemia is associated with disorders in the immune system including lower secretion of inflammatory cytokines, impairment in neutrophile, humoral and T cell function, increased susceptibility, and delayed recovery of tissues [24]. Awareness of microvascular and macrovascular complications can help minimize the risk of infections and infection-related complications. Healthcare personnel need to be aware of unusual and severe forms of infection associated with diabetes mellitus. The use of empirical antibiotics is the same as with non-diabetics, but disease-associated complications should be anticipated and promptly treated. Immunization with influenza and pneumococcal vaccine is often recommended. Optimal glycemic control is essential for successful treatment of infections.

Multiple-Choice Questions

1. This class of drugs is associated with a higher risk of pruritis vulvae/balanoposthitis:
   (a) **SGLT2i**
   (b) Pioglitazone
   (c) Biguanides
   (d) Sulfonylureas
2. This class of drugs has an anabolic effect and is the preferred agent for glycemic control in the background of infection:
   (a) **Insulin**
   (b) GLP1RA
   (c) DPP4i
   (d) Bromocriptine
3. This parasitic infection may protect against diabetes:
   (a) **Helminthiasis**
   (b) Malaria
   (c) Mucormycosis
   (d) Lichen planus
4. Hypoglycemia may occur in all of the following setting, except
   (a) **Dengue fever**
   (b) Malaria
   (c) Insulin use
   (d) Quinine use
5. Anaerobic bacterial coverage is indicated in all of the following settings except
   (a) **Pyogenic meningitis**
   (b) Lung abscess
   (c) Infected diabetic foot
   (d) Emphysematous pyelonephritis
6. The causative organism of otitis externa is
   (a) *Klebsiella* sp.
   (b) Proteus
   (c) *Staphylococcus aureus*
   (d) **All of the above**
7. This infection is not associated with a higher risk of diabetes:
   (a) **Hepatitis A**
   (b) Tuberculosis
   (c) HIV
   (d) Hepatitis C
8. This antimicrobial drug may precipitate hypoglycemia:
   (a) **Gatifloxacin**
   (b) Azithromycin
   (c) Metronidazole
   (d) Streptomycin
9. Hyperglycemia increases the risk of COVID-19 infection because of
   (a) Oxidative stress
   (b) Inflammation
   (c) Apoptosis of alveolar cells
   (d) None of the above
   (e) **All of the above**
10. Glycemic threshold for high risk of severity and mortality from COVID-19 infection:
   (a) 120 mg/dL
   (b) 140 mg/dL
   (c) **180 mg/dL**
   (d) 200 mg/dL
   (e) 250 mg/dL

COVID-19, Diabetes, and Cardiovascular Disease

48

Marco A. Peña Duque, Arturo Abundes Velasco, José Carlos Núñez Gómez, Enid Andrea Islas Navarro, and Eduardo Armando Aguilar Torres

Pathogenesis

People with chronic-degenerative diseases usually present severe COVID symptoms, as well as a higher risk of postinfection complications. These comorbidities modify metabolism by increasing the expression of the enzyme ACE-2 in infected people. ACE-2 encodes the protein through which the virus enters the cell, so the increased production of ACE-2 in patients with these diseases facilitates the entry of SARS-CoV-2 [1] and induces a great deal of impact on underlying conditions, complications of infections, and other diseases [2, 3]. It has also been observed that COVID-19 infection leads to the worsening of conditions in the presence of CVD [4, 5]. Epidemiological studies have indicated that patients with DM and COVID-19 infection require more medical interventions, have higher mortality rates [7.8% versus 2.7%, adjusted hazard ratio (HR) 1.49], and have a greater frequency of multiple-organ damage than those without DM [6].

Epidemiology

Across the United States, there were 95,235 reported deaths officially attributed to COVID-19 from March 1 to May 30, 2020. By comparison, there were an estimated 122,300 (95% prediction interval, 116,800–127,000) excess deaths during the same period. Even in situations of ample testing, deaths due to viral pathogens, including SARS-CoV-2, can occur indirectly via secondary bacterial infections or exacerbation of comorbidities, mainly CVD [7, 8]. A study published in Italy compared excess deaths from CVD and excess deaths due to the new coronavirus. The trajectory of the number of excess deaths from CVD was highly parallel to the trajectory of the number of excess deaths related to COVID-19. The number of excess deaths from DM, influenza, respiratory diseases, and malignant neoplasms remained relatively stable over time. The parallel trajectory of excess mortality from CVD and COVID-19 over time reflects the fact that essential health services for noncommunicable diseases were reduced or disrupted during the COVID-19 pandemic, and the more severe the pandemic, the heavier the impact. Many European countries have experienced sharp increases in all-cause deaths associated with the pandemic [9].

DM is associated with an increased risk of infections, especially infections of the skin and urinary and respiratory tracts. This is due to immunological dysfunction secondary to the hyperglycemic milieu of people with DM [10]. Bacterial and fungal infections have a higher incidence in patients with DM, albeit previous studies do not associate DM with an increased incidence in viral infections such as COVID-19 [11]. Nevertheless, a meta-analysis of six Chinese studies including 1527 patients hospitalized with COVID-19 demonstrated significant differences in the prevalence of hyperglycemia in severe versus non-severe cases, in addition to a prevalence of DM of 11.7% in ICU cases, in comparison with 4.0% in non-ICU cases [12]. In line with these findings, a report from the Chinese Center for Disease Control and Prevention on 44,672 COVID-19 cases, which also included nonhospitalized patients, showed a lower prevalence of DM (5.3%). But it is associated with poor prognosis [12]. A meta-analysis with 6452 patients from 30 studies showed that DM was associated with a compound poor outcome (RR 2.38 [1.88, 3.03], $p < 0.001$; I^2, 62%) [13]. A group of researchers from Mexico published an article proposing a mechanistic approach to evaluate the risk for complications and lethality attributable to COVID-19 in which they included early-onset diabetes, obesity, chronic obstructive pulmonary disease, advanced age, hypertension, immunosuppression, and chronic kidney disease [14]. Among these variables, the results of this study showed that early-onset diabetes conferred an increased risk of hospitalization and obesity conferred an increased risk for intensive care admission and intubation [14].

Management of Diabetes, COVID-19, and Cardiovascular Disease

The management of DM in patients with COVID-19 infection has a remarkable impact on the mortality from this disease, according to the fact that patients with better control have fewer complications in comparison with the ones who are not in control [15]. General recommendations for DM management include increasing physical activity as part of the treatment. A study suggested that physical inactivity is correlated with a higher relative risk of COVID-19 hospitalization, even after controlling for age, sex, obesity, smoking, and alcohol intake [RR, 1.32 (95% confidence interval [CI], 1.10–1.58)] [16]. It is expected that inactivity or a sedentary lifestyle will increase to produce 11 million new patients debuting with DM2 and up to almost 2 million deaths related to metabolic syndrome leading to decreased physical activity and increased prevalence of obesity [17]. Strategies to avoid physical inactivity and reduce stress levels can promote cardiovascular protection. The promotion of physical activity is prioritized by public health agencies and has been incorporated into routine medical care [18]. A home-based training protocol could be an important and effective strategy for individuals who need to remain safe and physically active.

International guidelines have already standardized the use of a glucocorticoid, anti-inflammatory drug therapy, and prophylactic anticoagulant in patients with COVID-19 [19]. For this reason, frequent glucose monitoring in DM patients and COVID-19 is imperative. A relevant study by Lu et al. supports that less variability in glucose excursions measured as time in range was associated with a lower risk of all-cause mortality and cardiovascular mortality among patients with type 2 DM [20] . Many patients previously on oral hypoglycemic agents will require conversion to insulin during hospitalization; in severe cases of COVID-19, insulin requirements are extremely high; these patients had a worse prognosis, compared with their counterparts who had not received insulin. This finding is probably secondary to the hyperinflammatory state on insulin resistance, reflecting that insulin treatment is a marker for advanced DM [21]. The results of this review indicate that there is no reason to cease the use of antidiabetic medications, that long-term glycemic control is essential in patients with COVID-19, and that it can improve the prognosis in these patients. Although potential direct therapeutic benefits have been proposed, the safety of some glucose-lowering therapies is still questioned [22]. An observational cohort study in England to investigate the association between prescription of different classes of glucose-lowering drugs and risk of COVID-19 mortality in a population of almost three million people with type 2 diabetes showed the following hazard ratios (HR): 0.77 for metformin, 1.42 for insulin, 0.75 for meglitinides, 0.82 for SGLT2 inhibitors, 0.94 for glitazones, sulfonylureas and GLP-1 receptor agonists, 1.07 for DPP inhibitors, and 1.26 for α-glucosidase inhibitors [23]. The study provides compelling evidence about the associations of some prescription drugs, although the differences are small and likely due to confounding [23].

Sodium-glucose cotransporter 2 (SGLT2) inhibitors have raised high expectancies because of their cardioprotective effects. The EMPA-REG OUTCOME, a randomized, double-blind, placebo-controlled trial that evaluated the effect of empagliflozin, found a significant reduction in major adverse cardiovascular outcomes including cardiovascular death, myocardial infarction, or stroke, as well as death from cardiovascular causes, death from any cause, progression of renal disease, and hospitalization for heart failure (HF) [24]. These findings were confirmed in the DAPA-HF trial in which 4744 patients with HF and a reduced ejection fraction were randomly assigned to receive either dapagliflozin or placebo in addition to standard HF therapy [25]. Of the enrolled patients, 41.8% had DM and the primary outcome of cardiovascular death or worsening HF was significantly lower in the dapagliflozin group than in the placebo group (16.3% vs. 21.2%; hazard ratio, 0.74; 95% confidence interval [CI], 0.65 to 0.85; *P* 0.001) [25]. This effect was not attributable to its low antihyperglycemic or natriuretic effects. Ferrannini et al. and Mudaliar et al. postulated that the action of SGLT2 inhibitors to promote ketogenesis might account for their favorable effects on the heart and kidney since enhanced ketone bodies' formation might provide an efficient fuel that could increase the energy status of organs under stress [26]. This effect would explain why this benefit is observed in patients with HF without DM. The DARE-19 trial, a randomized, double-blind, placebo-controlled trial, suggested that the SGLT2 inhibitor dapagliflozin was safe and well tolerated in patients hospitalized with COVID-19 with at least one cardiometabolic risk factor [27]. This study excluded critically ill patients, however, and did not result in a significant risk reduction in organ dysfunction or death nor an improvement in clinical status [27]. Currently there is a strong rationale to avoid treatment with metformin or SGLT2 inhibitors in patients with severe COVID-19 to reduce the risk of lactic acidosis, ketoacidosis, and volume depletion associated with the use of these drugs in the presence of severe infection [21].

Cardiovascular Complications of COVID-19 Infection

The symptoms and clinical course of COVID-19 are broad, ranging from asymptomatic to severe respiratory failure requiring mechanical ventilation. Metabolic and cardiovascular comorbidities have an important role in outcomes of patients with COVID-19 infection [15]. A meta-analysis of

six published studies from China including 1527 patients with COVID-19 reported a 9.7%, 16.4%, and 17.1% prevalence of DM, cardio-cerebrovascular disease, and hypertension, respectively [11], and the increasing knowledge of COVID-19 has provided a clearer picture of its clinical evolution: The first phase is asymptomatic or primarily characterized by symptoms in the upper respiratory tract; approximately 80% of the cases are resolved. The second phase, or moderate pneumonia, occurs approximately in 15%, requiring supplementary oxygen. About 5% evolve to the third phase, or severe pneumonia, with worsening of the respiratory condition, hypoxemia, fever, and acute respiratory distress syndrome [28]. In addition to respiratory symptoms, many patients have cardiovascular symptoms, such as heart palpitations and chest tightness/pain, as the initial clinical manifestation of COVID-19 [29]. When the cardiovascular system is affected, a wide range of complications can occur, from myocardial injury and acute myocardial infarction to heart failure, myocarditis, dysrhythmias, and venous thromboembolic events [28].

Regardless of the phases in which the patient has been through, moreover, several studies also showed that COVID-19 can exacerbate preexisting cardiovascular disease and/or cause new cardiovascular injuries [30]. Increased risk for myocardial infarction, fulminant myocarditis rapidly evolving with depressed systolic left ventricle function, arrhythmias, venous thromboembolism, and cardiomyopathies mimicking STEMI presentations are the most prevalent cardiovascular complications described in patients with COVID-19 [31].

The hypothesis of the cumulative effect of previous CV disease and troponin increase was postulated due to the greater presence of ACE2 receptors in postmortem cardiac pericytes extracted from patients with heart disease compared with those without the previous disease. That explains the affinity to this system [32]. Shi et al. reported that myocardial injury may be caused by myocarditis and myocardial ischemia, which is mainly manifested by elevated troponin levels, and higher mortality rates than those in people without myocardial injury (51.2% vs. 4.5%; $p < 0.001$), being an independent risk factor for mortality [33]. Myocardial injury has also been described in 5 of the first 41 patients diagnosed with COVID-19 in Wuhan, China, with elevated serum high-sensitivity cardiac troponin I (hs-ctni) levels (>28 ng/l) [34]. However, in a cohort study of 1597 US-competitive athletes with CMR screening after COVID-19 infection, 37 (2.3%) were diagnosed with clinical and subclinical myocarditis. If cardiac testing was based on cardiac symptoms alone, only 5 athletes would have been detected for a prevalence of 0.31% [35]. Regardless of the actual incidence, acute cardiac injury has been consistently shown to be a strong negative prognostic marker in patients with COVID-19 [35].

Heart failure is an important cause of death in patients with COVID-19 and occurs as a result of different myocardial aggression mechanisms such as direct myocardial injury by viral action, indirect and direct inflammatory damage, an imbalance in oxygen supply-demand, and an increase of atherothrombotic events due to inflammatory destabilization of atheromatous plaques, which result in acute myocardial dysfunction [36]. A clinical study of 99 cases with confirmed COVID-19 from Wuhan showed that 11 (11%) patients had died, of which 2 patients had no previous history of chronic heart disease but developed heart failure and eventually died of sudden cardiac arrest [37]. Even in the absence of direct myocardial injury, patients develop disturbances in the conduction system that produce arrhythmias regardless of the previous cardiovascular state. Cardiac arrhythmias are common cardiac manifestations described in COVID-19 patients [38]. A study describing clinical profile and outcomes in 138 Chinese patients with COVID-19 reported a 16.7% incidence of arrhythmia [38].

Conclusion

Until today, the origin of SARS-CoV-2 disease and its acute repercussions have been established, but the long-term sequelae in diabetic patients with cardiovascular disease are not yet well known (long COVID). Patients with COVID-19 are at increased risk of a broad range of cardiovascular disorders including cerebrovascular disease, dysrhythmias, ischemic and non-ischemic heart disease, pericarditis, myocarditis, heart failure, and thromboembolic disease [39]. The risk and 1-year burden of cardiovascular disease in survivors of acute COVID-19 are substantial [40]. Most of these are lifelong conditions that will affect people for a lifetime and may impact their quality of life and other health outcomes [40].

Multiple Choice Questions

1. As a result of sedentary lifestyle, what is the expected amount of new patients who will develop type 2 diabetes?
   (a) 10 million
   (b) 9 million
   (c) 20 million
   (d) **11 million**
   (e) 15 million
2. What is the mortality rate from COVID-19 infection in patients with diabetes?
   (a) **7.8%**
   (b) 3%
   (c) 5.2%
   (d) 10%
   (e) 5.4%

3. What is the estimated percentage of patients with COVID-19 infection with severe pneumonia?
   (a) 80%
   (b) 15%
   (c) 45%
   (d) 100%
   (e) **5%**
4. What is the cardioprotective action attributed to SGLT2 inhibitors in patients with diabetes and heart failure?
   (a) Natriuretic effect
   (b) Low glycemic action
   (c) **Promote ketogenesis**
   (d) Lactic acidosis
   (e) Insulin sensibility
5. In severe COVID-19 infection, which classes of glucose-lowering drugs are recommended to avoid?
   (a) SGLT2 inhibitors and metformin
   (b) Insulin and SGLT2
   (c) DPP-4 inhibitors
   (d) Sulfonylureas
   (e) All are secure
6. What is the SGLT2 inhibitor that demonstrated a significant reduction in major adverse cardiovascular events and death from cardiovascular causes?
   (a) **Dapagliflozin**
   (b) Empagliflozin
   (c) Canagliflozin
   (d) Ertugliflozin
   (e) Phlorizin
7. What comorbidity is not associated with a higher prevalence of diabetes?
   (a) Parasitic
   (b) Bacterial
   (c) Fungicidal
   (d) **Viral**
   (e) Oncologic
8. In patients with CVD, the increase of which receptor is associated with a higher risk of cardiovascular complications?
   (a) CXCR4
   (b) GM2
   (c) **ACE2**
   (d) VLDLR
   (e) HLA-1
9. What is the percentage of athletes diagnosed with clinical and subclinical myocarditis after COVID-19 infection?
   (a) 0.31%
   (b) **2.3%**
   (c) 10%
   (d) 80%
   (e) 9.7%
10. What is the most prevalent comorbidity in patients with COVID-19 infection?
    (a) Diabetes mellitus
    (b) **Hypertension**
    (c) Chronic kidney disease
    (d) Parkinson's disease
    (e) Obesity

Part IX

Chronic Complications

Biochemical Mechanisms of Vascular Complications in Diabetes

49

Margarita Díaz Flores, María del Carmen Cortés Ginez, and Luis Arturo Baiza Gutman

Objectives

- To analyze the biochemical and molecular mechanism of vascular diabetic complications
- To analyze the role of metabolic alterations induced by hyperglycemia in diabetic complications (altered glycolysis, diacylglycerol production, protein kinase C activation, activation of polyol and hexosamine pathways, and glycation)
- To analyze the role of oxidative stress in diabetic complications, considering reactive oxygen species production and the biochemical, metabolic, and morphological alteration induced by them
- To analyze the role of inflammation during diabetes and its participation in vascular diabetic complications
- To analyze the integrative hypothesis that explains the rise and progression of vascular diabetic complications

Diabetes and Vascular Complications

Diabetes mellitus (DM) is a heterogeneous pandemic metabolic disorder characterized by a chronically elevated blood glucose concentration (hyperglycemia) due to resistance to insulin action, defective insulin secretion, or both (insulin dysfunction). This disease affects approximately 9% of the worldwide adult population. Type 2 diabetes is diagnosed often late when already 40% of diabetics show complications. Vascular complications of diabetes are frequently responsible for morbidity and mortality in diabetic patients [1, 2].

Hyperglycemia or chronic elevation of blood glucose has been considered as the major inductor of vascular diabetic complications [1]. Persistent exposure of tissues to high concentrations of glucose can lead to damage (glucotoxicity) of endothelium and small blood vessels (microvasculature) followed by alterations of tissues and organs, including kidney (nephropathy), eyes (retinopathy), and nerves and central nervous system (peripheral and autonomic neuropathy), which are known as microvascular complications of diabetes [3, 4]. Additionally, hyperglycemia leads to damage of big blood vessels and heart or macrovascular complications, which are associated with cardiovascular diseases such as accelerated atherosclerosis, cardiomyopathy, myocardial infarction, stroke, and peripheral arterial disease [5]. There is a growing recognition that cognitive dysfunction, encephalopathy, osteopathy, liver disease, and cancer are emerging complications of diabetes.

Besides hyperglycemia, other factors are involved in the development and progression of vascular complications such as dyslipidemia and accumulation of lipid metabolites (lipotoxicity) [6], chronic inflammation, oxidative stress, hormone and cytokine levels, hypertension, and nitric oxide (NO) deficiency.

Several mechanisms involved in the pathogenesis of diabetic complications induced by hyperglycemia have been proposed; all of them consider how the high concentration of glucose is metabolized by different pathways and conduced to the accumulation of metabolites or activation of signaling molecules that induce damage of endothelium, vascular vessels, and other tissues, causing morphological and physiological impairment of several organs. The proposed mechanism includes (Fig. 49.1):

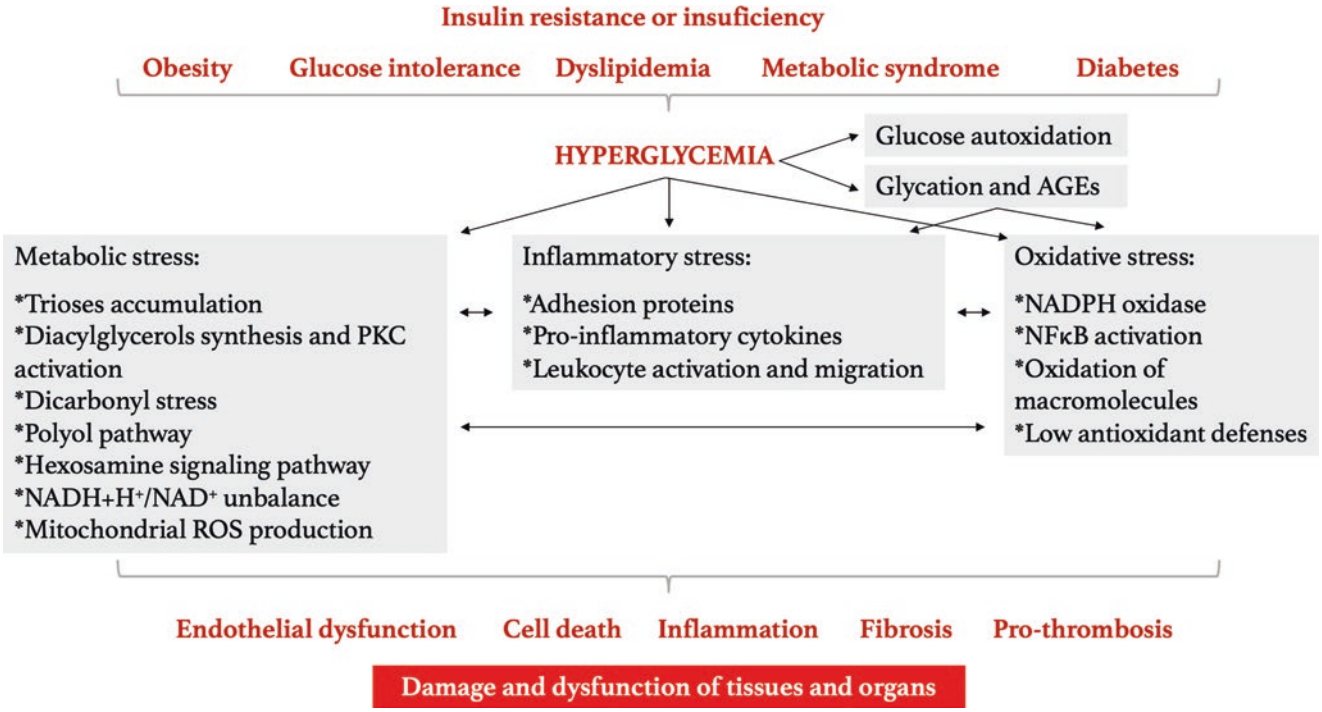

Fig. 49.1 Pathophysiological mechanisms of diabetic complications. Several chronic metabolic conditions lead to chronic or postprandial hyperglycemia, which induces metabolic, inflammatory, and oxidative stress, causing tissue and organ alterations characteristics of vascular diabetic complications. NFκB, transcription factor nuclear factor κB

1. Metabolic stress, caused by the increased flux of glucose in several metabolic pathways (Fig. 49.2), including [7]):
   (a) Glycolysis, accumulation of trioses, and generation of methylglyoxal. Trioses lead to increased formation of diacylglycerol and methylglyoxal, which are associated with the activation of protein kinase C (PKC) and intracellular glycation, respectively.
   (b) The polyol pathway and accumulation of sorbitol [7, 8].
   (c) The hexosamine signaling pathway [9].
   (d) Nonenzymatic glycation with increased formation of advanced glycation end products (AGEs) and the activation of its receptor (RAGE) [10].
2. Oxidative/reductive stress. The accumulation of reactive oxygen species (ROS) is dependent on different processes during hyperglycemia. ROS are extracellularly produced by glucose autoxidation and as a side product of glycation. Intracellularly, oxidative stress is promoted by the generation of ROS by a variety of sources such as mitochondrial electron transport chain, NADPH oxidase, xanthine oxidase, and uncoupled eNOS. An interesting point of view is that diabetic complications are majorly generated by oxidative stress driven by the NADH/NAD^+ redox imbalance (reductive stress) and mitochondrial dysfunction [4].
3. Inflammatory stress. Inflammation is a common pathophysiological mechanism in many diseases, including diabetes mellitus, where several pro-inflammatory mediators are upregulated and contribute to vascular complications.

Although multiple processes contribute to vascular complications, several researchers have treated to find one mechanism that drives the other mechanisms that conduce to the vascular complications. Three major unifying hypotheses have been proposed. The more accepted hypothesis proposes that the oxidative stress induced by hyperglycemia could be a unifying and common mechanism involved in the activation of the other mechanisms; initially, the production of ROS by the mitochondria was considered as the driver of vascular complications [9]; for example, the production of O^{2-} by the mitochondria mediates the high glucose-induced increased flux in the hexosamine pathway in bovine aorta endothelial cells [9, 11]. A second hypothesis considers the dicarbonyl stress as the key to diabetic complications [12, 13]. A third hypothesis suggests that the unifying mechanism is the polyol pathway [13, 14]. The real situation of the development of vascular complications in diabetic patients is complex. Antioxidants and pharmacological agents that inhibit these pathways have shown limited clinical success

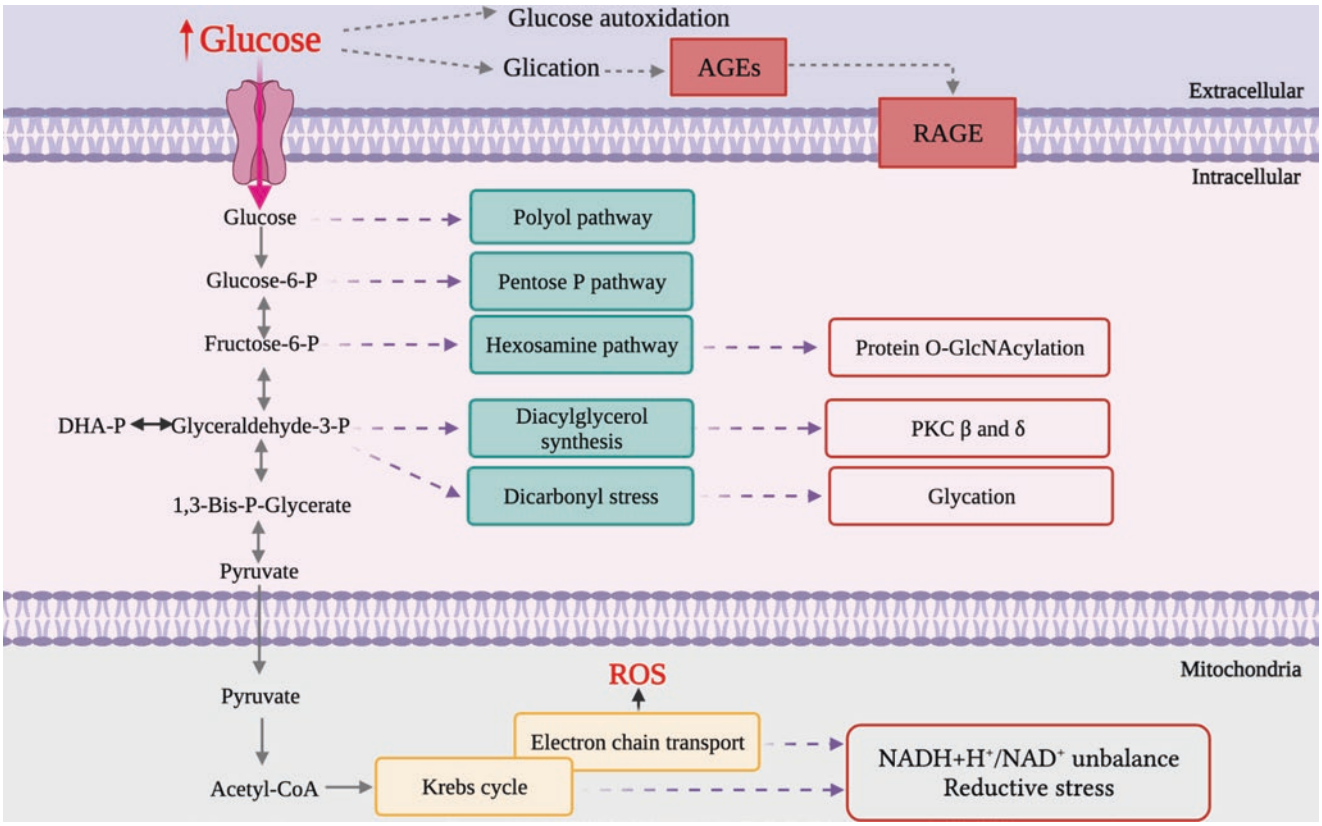

Fig. 49.2 Hyperglycemia and glucose metabolism by multiple pathways. In hyperglycemic conditions, there is an overflow of glucose uptake and metabolism in non-insulin-dependent cells, The overflow of glucose induces an NADH + H^+/NAD^+ imbalance and ROS production in the mitochondria, which lead to inhibition of glyceraldehyde-3-phosphate dehydrogenase and triose accumulation [dihydroxyacetone-phosphate (DHA-P) and glyceraldehyde-3-phosphate], leading to the activation of several pathways of glucose or glucose metabolites' disposal and associated with the induction of vascular complications. P, phosphate; RAGE, receptor for AGEs; *O*-GlcNAcylation, *O*-linked glycosylation with β, N-acetylglucosamine; PKC, protein kinase C

against nephropathy or retinopathy in diabetics. On the other hand, a proteomic analysis in long-duration type 1 diabetes mellitus patients (already of 50 years) found high levels of enzymes or the polyol pathway and electronic transfer chain in glomeruli of patients without nephropathy compared with glomeruli of patients with nephropathy [15, 16]; in this case also the enzymes of methylglyoxal depuration and the antioxidant enzyme superoxide dismutase were upregulated, and in some conditions, polyol pathway protects against inflammatory stress [15].

The central role of mitochondrial dysfunction as the initial driver of diabetic complications has been questioned [17, 18]. Some data indicate that reduced mitochondrial activity could be the basis of the progression of diabetic complications mediated by increased inflammation and pro-fibrotic factors [17]. However, the induction of inflammation by high glucose-induced oxidative stress in human vascular cells requires being primed with an inflammatory stimulus such as TNFα or IL-1β (inflammatory preconditioning), and it has been proposed that background of the inflammatory condition is necessary for the deleterious action of excessive glucose environment [19]. The inflammatory preconditioning stimulus promotes the ROS production inducing the overexpression of an important emergent source of O^{2-}, the NADPH oxidase, an enzyme that requires the coenzyme NADPH (reduced nicotinamide adenine dinucleotide phosphate), which also induces the expression of the major supply of this reduced coenzyme, glucose 6-phosphate dehydrogenase, increasing the flux of glucose in the pentose phosphate pathway [19]. Although mitochondria and NADPH oxidase have been considered the major sources of ROS during diabetes, several other ROS production pathways may be activated by hyperglycemia and glucose metabolites. These include glucose autoxidation, glycation, uncoupled endothelial nitric oxide synthase (NOS), xanthine oxidase, endoplasmic reticulum stress, cyclooxygenases, etc., and more studies are required to establish their role in diabetes pathogenesis [18].

Metabolic Stress

The mechanisms of glucose metabolism involved in diabetic complications include glucose autoxidation, the shunt of glucose to the polyol pathway, formation of AGEs, and elevated hexosamine pathway activity [7].

Polyol Pathway

The polyol pathway is linked with the progression of diabetic complications, especially retinopathy because of the formation of a vulnerable intermediate product during its course.

Polyol pathway is activated during hyperglycemia due to saturation of hexokinase (the enzyme that catalyzes the first step of glycolysis). This pathway is activated as blood glucose level rises and involves two enzymatic steps catalyzed by aldose reductase and sorbitol dehydrogenase, present in excess amounts in various body tissues. In the first step, glucose is converted into sorbitol, by the activity of aldose reductase 2 (ALR2), coupled to the oxidation of its cofactor NADPH. In the second step, sorbitol is further converted into fructose, by the action of sorbitol dehydrogenase, using NAD^+ as a cofactor and producing NADH.

This intracellular metabolic process results in the accumulation of sorbitol as an intermediate product because the cellular membranes are impermeable to sorbitol and prevent its efflux. Intracellular accumulation of sorbitol induces osmotic imbalance, water intake, and cellular death. Sorbitol is usually accumulated in the lens, retina, and kidney. The exact mechanism of sorbitol-induced cell death is unkwon but accounts for extensive cellular damage, leading to the progression of diabetic retinopathy, and contributes to nephropathy [7, 8]. The activation of ALR2 also leads to the overconsumption of NADPH, reducing its availability for glutathione reductase, the enzyme that restores reduced glutathione (GSH), the principal intracellular antioxidant, promoting oxidative stress [8].

Although the quantity of sorbitol remains high, sorbitol is converted into fructose in the second step of the reaction, and fructose also is overproduced due to 30% of blood glucose is consumed by the polyol pathway in diabetes. Fructose and some of its derivatives (3-deoxyglucose and fructose-3-phosphate) can glycate proteins altering their function, and in the liver, kidney, and intestine, fructose is phosphorylated to fructose-1-phosphate (F1P) by fructokinase. F1P is metabolized to dihydroxyacetone phosphate (DHAP) and glyceraldehyde 3-phosphate (G3P), which enter the glycolytic/gluconeogenic metabolite pools; these reactions depend on the fructose concentration because it lacks regulatory control, and acetyl-CoA is overproduced, leading to its overflow through the tricarboxylic acid cycle and increased reductive stress. The overproduction of acetyl-CoA contributes to the development of liver steatosis and non-alcoholic fatty liver disease (NAFLD) and protein functional impairment because of their increased acetylation. In addition, the NADH produced during the second reaction contributes to the reductive stress and conduces to the production of more O^{2-} in the mitochondria [7].

An increase in the activity of the polyol pathway in tissues like the retina, kidney, peripheral nerves, and blood vessels occurs in diabetes because in these tissues, insulin is not required for glucose uptake. The role of the polyol pathway in diabetic retinopathy is supported because increased polyol pathway activity is observed in the retina from animal models of diabetic retinopathy and diabetic human donors with retinopathy [20]. Also, the C allele of the polymorphism at position −106 in the promoter of the *ALR2* gene *has been* associated with diabetic retinopathy [21]. However, the clinical use of an inhibitor of aldose reductase (epalrestat, sorbinil, tolrestat, fidarestat, etc.) is limited because some inhibitors fail to produce significant protection against vascular complications or present cytotoxicity [8]. The cytotoxicity is because these inhibitors frequently also inhibit ALD1, another isoenzyme of aldose reductase, which is involved in the detoxification of aldehydes 3-deoxyglucosone, hydroxynonenal, and methylglyoxal. The accumulation of these aldehydes causes cytotoxicity. Of aldose reductase inhibitors, only epalrestat is used against diabetic neuropathy in Japan, China, and India. However for safety concerns, epalrestat has not been approved yet in some countries and was withdrawn from the market of a few countries [8]. Considering that in some conditions aldose reductase has a protective role against inflammatory and oxidative stress, the use of their inhibitors for the treatment of vascular complications must be carefully evaluated [16].

Hexosamine Biosynthesis Pathway and *O*-GlcNAcylation of Proteins (Fig. 49.3)

Increased flux of glucose into the hexosamine signaling pathway has been implicated in diabetic vascular complications and is induced by hyperglycemia. In this case, glucose 6-phosphate is isomerized to fructose 6-phosphate in glycolysis, and the overproduction of fructose 6-phosphate under hyperglycemic conditions is canalized to this pathway as an alternative to glycolysis [22]. Glucosamine 6-phosphate is produced by the transference of an amino group of glutamine to fructose 6-phosphate catalyzed by the rate-limiting enzyme glutamine-fructose-6-phosphate amidotransferase (GFAT). Finally, in the hexosamine pathway, uridine nucleoside diphosphate-N-acetylglucosamine (UDP-GlcNAc) is formed by sequential enzymatic steps. UDP-GlcNAc is a donor molecule that leads

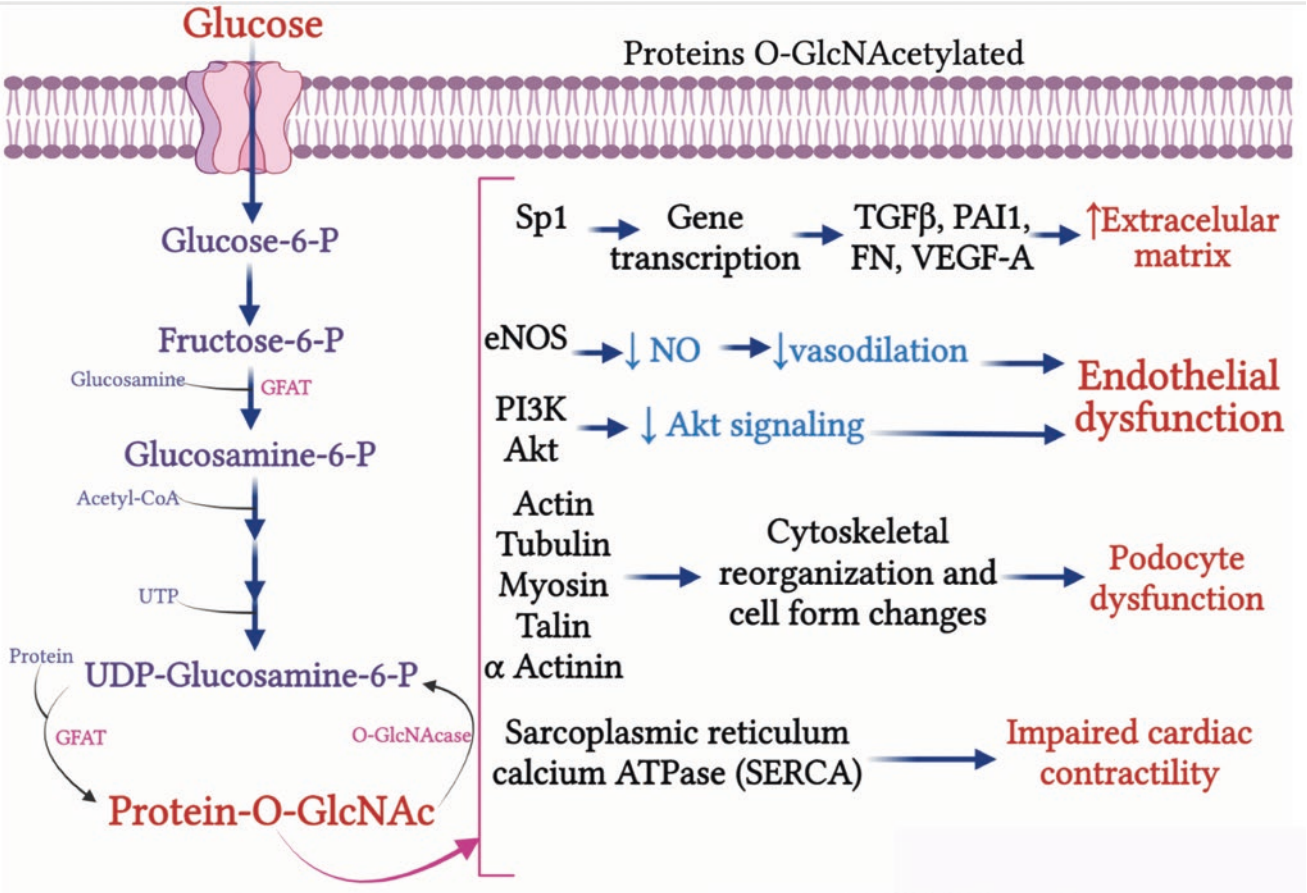

Fig. 49.3 O-GlcNAcetylated proteins and their contribution to vascular complications. The O-GlcNAcetylation of several proteins contributes to different alterations that conduce to vascular complications of diabetes. GFAT, glutamine-fructose-6-phosphate amidotransferase; Sp1, specificity protein 1; FN, fibronectin; NO, nitric oxide; P, phosphate

to *O*-linked glycosylation with the hexosamine-derived β, N-acetylglucosamine (*O*-GlcNAcylation) by the enzyme *O*-GlcNAc transferase (OGT) to serine and threonine residues on target proteins. Conversely, GlcNAc is removed from proteins by GlcNAcase (OGA) (Fig. 49.3).

O-linked N-acetyl glucosamine (O-GlcNAc) is highly increased in cells and tissues of diabetic animals and patients and serves as a nutrient/stress sensor since the synthesis of its donor UDP-GlcNAc depends on changes in the glucose, amino acid, fatty acid, and nucleotide concentrations. Activation of hexosamine signaling pathway mediates several deleterious effects of hyperglycemia through the *O*-GlcNAcylation of proteins modifying their activity. Acutely *O*-GlcNAc probably plays a protective function against stress-induced inflammation. However, persistent *O*-GlcNAcylation of proteins induced by hyperglycemia is involved in changes of gene transcription, cell signaling, vasodilatation, cytoskeletal organization, and apoptosis of endothelial cells and neurons associated with vascular complications [23]. For example, *O*-GlcNAcylation of endothelial nitric oxide synthase (eNOS), the protein kinase Akt, and the transcription factor specificity protein 1 (Sp1) lead to decreased NO production, attenuated endothelial migration, and altered gene expression, respectively.

The modification of gene expression by hyperglycemia is associated with increased *O*-GlcNAcylation and decreased serine/threonine phosphorylation of the transcription factor Sp1 (Fig. 49.3). Sp1 induces the expression of transforming growth factor-β (TGFβ), plasminogen activator inhibitor 1 (PAI-1), and vascular endothelial growth factor A (VEGF-A) [9, 24]. The proliferation of vascular cells is triggered by VEGF-A during diabetic retinopathy. These changes in gene expression could be prevented by the inhibition of the rate-limiting enzyme GFAT or inhibitors of OGT. On the other hand, inhibition or overexpression of the enzyme that degrades N-acetyl glucosamine, O-GlcNAcase (OGA), increases the expression of VEGF-A in cultured retinal cells [24] or reverses the coronary endothelial cell dysfunction in streptozotocin-induced diabetic mice [25].

Few studies link O-GlcNAc to vasculature dysfunction in human T2DM. Arterial or venous endothelial cells obtained from patients with T2DM are characterized by endothelial

insulin resistance and lower NO production. Endothelial O-GlcNAc levels are higher in T2DM patients than in non-diabetic controls and are directly correlated with serum fasting blood glucose and glycated hemoglobin A1c (HbA1c) levels. When endothelial cells from patients with T2DM are cultured in normal glucose conditions (24 h at 5 mmol/L), O-GlcNAc levels are lowered and insulin-mediated activation of endothelial nitric oxide synthase is restored. Moreover, the inhibition of the removal of O-GlcNAc from proteins using thiamet G, an O-GlcNAcase inhibitor, in endothelial cells increases O-GlcNAc levels and blunted the improvement of insulin-mediated endothelial nitric oxide synthase phosphorylation by glucose normalization. These data indicate that O-GlcNAc modification is implicated in the glucose-induced impairment of endothelial nitric oxide synthase activation in endothelial cells from patients with T2DM. O-GlcNAc protein modification may be used in the diagnosis and as a treatment target for vascular dysfunction in T2DM [26].

Synthesis of Diacylglycerols and Protein Kinase C Activation

In hyperglycemic conditions, triose phosphates and glycerol-phosphate are accumulated, resulting from the inhibition of the enzyme glyceraldehyde 3-phosphate dehydrogenase (GAPDH) by the NADH overproduction and oxidative stress. Both triose phosphate and fructose (end products of the polyol pathway) lead to the formation of methylglyoxal and diacylglycerol (DAG). DAG is located in the cell membrane and activates classical isoforms of PKC (PKCα, PKCβ, and PKCδ), which induce several cell responses and lead to the production of reactive oxygen species via upregulating the expression of NADPH oxidases. PKC is also activated by ROS.

Activated PKC functions through the phosphorylation of Ser and Thr residues in its target proteins and regulates various processes related to diabetic vascular complications such as NO production, vascular permeability, angiogenesis, apoptosis, endothelial dysfunction, and basement membrane thickening. PKCδ can accelerate apoptosis of pericytes, capillary cells, resulting in the degeneration of capillaries during retinopathy. This kinase also induces the apoptosis of podocytes in culture and endothelial dysfunction in renal glomeruli of diabetic rats and mice, in a mechanism mediated by the p38 MAPK and Src homology-2 domain-containing phosphatase-1 (SHP-1) [27, 28]. The relevance of PKCδ in diabetic complications is supported by the fact that the diabetic PKCδ-knockout (Prkcd(−/−) mice present decreased expressions of TGFβ, VEGF, and extracellular matrix and less albuminuria than diabetic PKCδ wild-type mice [28]. Poor wound healing in diabetic patients has been attributed to activation of PKCδ in fibroblasts, and pharmacologic inhibition and knockdown of PKCδ in diabetic fibroblasts improve wound healing when fibroblasts are implanted in nude mice [29].

Activation of the other isoform PKCβ in endothelial cells induces endothelin 1 expression and enhances VEGF action, increasing vascular endothelial permeability and endothelial dysfunction [27]. Clinical trials using a selective inhibitor of PKCβ ruboxistaurin that ameliorated retinal hemodynamic abnormalities in diabetic patients have not yielded very promising results; further additional clinical trials are needed using inhibitors of the PKCδ isoform.

Glycation and Advanced Glycation End Products

Glycation is defined as the no enzymatic reaction between glucose and reducing sugars with amino groups of proteins, lipids, or nucleic acids. This reaction is promoted under hyperglycemia, oxidative stress, or aging and alters the structure and function of macromolecules.

Glycation begins with the nonenzymatic reaction between aldehyde groups of glucose with amino groups in macromolecules forming first the reversible Schiff base adducts, which are rearranged to more stable, covalently bound Amadori products. Over days to weeks, early glycation products undergo further reactions such as rearrangements and dehydration to become irreversibly cross-linked, fluorescent derivatives called advanced glycation end products (AGEs), such as carboxymethyl lysine (CML), carboxyethyl lysine, pentosidine, or pyrraline derived from proteins, and N(2)-carboxyethyl-2′-deoxyguanosine (CEdG) derived from DNA [10]. AGEs are also generated in highly heated and processed foods and can be obtained from the diet.

AGEs are accumulated in several tissues of diabetic patients or experimental animals including microvasculature, aorta, retina, kidney, pancreas, colon, or skin [30, 31]. The plasma concentration of HbA1c, the Amadori adduct of the N-terminal valine of the hemoglobin β-chain, is used as a long-term biomarker of glycemic control in clinical practice; there is a linear relationship between HbA1c and mean blood glucose; however, HbA1c reflects the average glucose over ∼120 days, the mean lifetime of the erythrocyte. Plasma, serum, and urinary levels of AGEs are correlated with the severity of complications in diabetic patients [32–34].

AGEs directly affect the function of macromolecules; for example, nucleotide AGEs are associated with DNA single-strand breaks and increased mutation frequencies. Also AGEs bind with AGE-binding receptors (RAGE). RAGE is a multi-ligand cell surface protein, expressed by endothelial cells, monocytes/macrophages, smooth muscle cells, neu-

rons, podocytes, cardiomyocytes, adipocytes, podocytes, lung epithelial cells, and some cancer cells. The binding of AGEs with RAGE leads to the generation of oxidative stress, inducing proliferative, migratory, inflammatory, thrombotic, and fibrotic reactions in a variety of cells, which leads to alterations associated with diabetic vascular complications [5, 35]. Enhanced production of O^{2-} induced by hyperglycemia in vascular endothelial cells is linked with the production of AGEs and the expression of its receptor. Also, elevated levels of AGEs induce the expression of its receptor amplifying the AGE signaling [36]. The generation of ROS induced by AGEs-RAGE interaction is primarily mediated by the activation of NADPH oxidase, and further, the ROS production can be amplified in the mitochondria.

The fibrotic action of AGEs in renal and vascular cells is mediated by TGFβ-dependent and TGFβ-independent mechanisms, both are dependent on AGEs-RAGE interaction; in the first case, the expression of TGFβ is induced and TGFβ leads to the activation of the transcription factors Smads, which induce expression of pro-fibrotic proteins (ECM proteins, TGFβ receptor 1 or TGFβR1, connective tissue growth factor or CTGF, and PAI-1). In the second case, Smads are activated secondary to the activation of the ERK/p38 mitogen-activated protein kinases (MAPK) signaling pathway [37, 38].

The activation of RAGE also has been associated with sustained activation of the transcription factor NFκB (nuclear factor kappa B), resulting initially from the degradation of its inhibitor IkB and the translocation of NFκB to the nucleus and chronically by NFκB increased de novo synthesis [39].

The signaling mechanism induced by RAGE activation begins with the interaction of its highly charged cytoplasmic domain with the formin homology domain of diaphanous 1 (DAPH1). DAPH1 is required for RAGE signaling, which is blocked by the knockdown of the D*iaph1* gene. DAPH1 is a cytoplasmic actin-binding protein and after the activation of RAGE signaling leads to the activation of several effectors such as Rho GTPases (Rac 1 Cdc 42, and RHOA) and others. Rho GTPases are associated with actin cytoskeleton dynamics and the induction of cell migration in cancer and smooth muscle cells [5, 40]. Rac 1 also conducts the activation of NADPH oxidase and oxidative stress.

Recently, RAGE-DIAPH1 interaction has been considered therapeutic targets, and small molecule inhibitors of this interaction suppress the induction of migration and production of inflammatory cytokines by RAGE ligands in cultured smooth muscle cells and TH1 macrophage-like cells [41].

In addition, there are two forms of soluble RAGE: one derived from proteolytic processing of the membrane receptor or soluble RAGE (sRAGE) and another derived by alternative splicing or endogenous soluble RAGE (esRAGE).

Nuclear Factor Kappa B (NFκB)

The NFκB family of transcription factors regulates the expression of proteins involved in cell proliferation and survival, inflammation, and immune and oxidative stress responses. In physiological conditions, NFκB is induced in an adaptive response to maintain homeostasis; however, the sustained activation of NFκB is thought to have a central role in the pathogenesis of several chronic diseases including diabetes and their complications. NFκB induces the expression of several genes as a response to stressful stimuli like oxidative stress, hyperglycemia, and inflammation. The activation of NFκB is induced by a variety of stimuli including free reactive oxygen species, AGEs, pro-inflammatory cytokines, oxidized low-density lipoproteins, free fatty acids, and bacterial and viral antigens. When NFκB is not activated, it is located in the cytoplasm, forming a complex with its inhibitor IκB (inhibitor of NFκB); after the activation of the upstream signal, the inhibitor is phosphorylated by the IκB kinase (IKK) and degraded through the ubiquitin system. As a consequence, NFκB is released and translocated into the nucleus, where it activates the expression of target genes. The principal regulatory step in the activation of NFκB is the phosphorylation and activation of IKK. NFκB regulates the expression of pro-inflammatory proteins, including adhesion molecules in endothelial cells such as intracellular cell adhesion molecule (ICAM) and vascular cell adhesion molecule (VCAM), cytokines (TNFα, IL-1β), and chemokines. NFκB signaling is a potential target for therapeutic intervention, and several inhibitors of NFκB activation and signaling have been developed.

Dicarbonyl Stress, Methylglyoxal, and Endogenous Glycation

Levels of reactive aldehydes like methylglyoxal, glyoxal, and 3-deoxyglucosone are elevated in diabetes mellitus. Methylglyoxal has been related to diabetic complications for its ability to induce insulin and vascular dysfunction and to cause neuropathic pain because its generation is induced by chronic hyperglycemia. Also, its plasma concentration is elevated in diabetic patients [42]. Methylglyoxal is an α-dicarbonyl and might be the most important reactive aldehyde in diabetes and its complications. Methylglyoxal is formed as a by-product of glycolysis by fragmentation of triose phosphates accumulated in glycolysis and also is derived from the catabolism of threonine and ketone bodies, lipid peroxidation, and degradation of glycated macromolecules.

The accumulation of methylglyoxal and similar compounds also depends on their lower detoxification by the glyoxalase system. This system catalyzes the detoxification of

reactive dicarbonyls in the cytoplasm, providing the principal defense against dicarbonyl glycation. The efficiency of this system is reduced by chronic hyperglycemia, because the rate-limiting enzyme, glyoxalase 1 (Glo1), is down-regulated in a high-glucose environment [12]. Glyoxalase 1 down-regulation is induced by RAGE signaling and the pro-inflammatory activation of NFκB [12]; in this case, the action of NFκB is mediated by the non-transcriptional inhibition of the antioxidant response [43].

Methylglyoxal through the glycation reaction modifies proteins and nucleic acid, being the precursor of endogenous AGEs, including arginine-derived hydroimidazolones and deoxyguanosine-derived imidazopurinones, and also induces apoptosis in vascular cells fomenting endothelial dysfunction and the progression of vascular complications including atherosclerosis [44].

Recently, it was described that the plasma concentrations of methylglyoxal and other oxo-aldehydes (glyoxal and 3-deoxyglucosone) are enhanced after carbohydrate load in type 2 diabetes, which was associated with increased risk of diabetic complications induced by elevations of postprandial glycemia [45].

NADH Overproduction or Reductive Stress

During hyperglycemia, the uptake of glucose increases in non-insulin-dependent tissues, leading to a high level of glucose metabolism as glucose entry into the cells is not limited by insulin deficiency. The increased flux of metabolites in glycolysis and the citric acid cycle in the mitochondria leads to high production of NADH, a coenzyme that receives electrons derived from oxidative degradation of glucose and provides electrons to the electron transport chain, leading to the formation of ATP and oxygen reduction. The NADH/NAD^+ imbalance is accentuated also by the production of NADH in the activated polyol pathway and by the consumption of NAD^+ by the nuclear enzyme poly ADP-ribose polymerase 1 (PARP-1) that uses NAD^+ as substrate.

The redox imbalance of NADH/NAD^+ causes initially reductive stress or pseudohypoxic stress that leads to oxidative stress. The excess of NADH promotes oxidative stress because the overflow of electrons in the electron transfer chain leads to leaking of electrons and partial reduction of oxygen with increased production of O^{2-} and other reactive oxygen species [3, 4]. Accordingly, oxidative damage triggered by redox imbalance might be a major factor contributing to the development of diabetic complications, and the prevention of NADH/NAD^+ redox imbalance could provide further insights for the design of novel antidiabetic strategies.

Oxidative Stress

As we discussed before, the electron overflow in the electron transport chain in non-insulin-dependent tissue under a hyperglycemic microenvironment leads to electron leaking and O^{2-} production in the mitochondria [3, 4]. The excessive production of ROS during diabetes overwhelms endogenous antioxidant defense mechanisms causing an imbalance in the production of ROS and nonenzymatic and enzymatic antioxidant mechanisms in the body, which ultimately leads to oxidative stress.

Additionally, in the production of ROS in the mitochondria, other sources of ROS have been described in diabetic condition, including NADPH oxidase, xanthine oxidase, and uncoupled eNOS, with NADPH oxidases being of special importance. There are several isoforms of O^{2-}-producing NADPH oxidase in the endothelium, smooth muscle cells, and adventitia of the vascular wall [46]. The activation and upregulation of NADPH oxidases are induced by PKCβ and PKCδ, AGEs-RAGE interaction, and inflammatory cytokines (TNFα), all of them considered as promoters of diabetic complications. NADPH oxidase is a multiprotein complex associated with the membrane.

Enhanced ROS levels induce oxidative modification of macromolecules, including lipids in the membranes (lipid peroxidation), enzymes, and nucleic acids altering their functions and cell integrity. As products of lipid peroxidation, malondialdehyde and 4-hydroxy 2-nonenals (4-HNE) are formed; when ROS react with DNA, 8-dihydro-8-oxo-2′-deoxyguanosine (8-OxodG) is produced and is removed during oxidized DNA repair and excreted in the urine. These compounds have been used as markers of oxidative stress. The highly reactive 4-HNE form covalent adducts with nucleophilic functional groups in proteins, nucleic acids, and membrane altering their functions and causing cytotoxicity or modulating a variety of signaling processes. At physiological or low concentration, 4-HNE induces cell survival or antioxidant response, becoming cytostatic and cytotoxic at higher levels. The signaling action of 4-HNE is mediated by transcription factors sensible to stress, including NFκB, nuclear factor erythroid 2-related factor 2 (Nrf2), and activating protein-1 (AP-1) [47].

Oxidative modifications of proteins (carbonylation, intermolecular dityrosine cross-linking, thiol oxidation, etc.) lead to the formation of advanced oxidized protein products (AOPPs), which induce pro-inflammatory and pro-fibrotic processes and cell death associated with progression of nephropathy and atherosclerosis. AOPPs induce inflammation by the activation of neutrophils and monocytes through NFκB activation mediated by NADPH oxidase [48]. Some actions of AOPPs are induced by their binding to RAGE in endothelial cells and podocytes [49].

DNA damage caused by oxidative stress leads to the overactivation of PARP-1. PARP-1 transfers ADP-ribose from NAD^+, leading to the formation of poly ADP-ribose (PAR) and nicotinamide; the decrease in NAD^+ and ATP levels causes energy failure and cell necrosis [3, 4]. The mechanism of cell death induced by PARP has been recently elucidated; PARP induces the release of apoptosis-inducing factor (AIF) from the mitochondria, and AIF binds to macrophage inhibitory factor (MIF), a protein with a recently discovered activity of nuclease; this complex is translocated to the nucleus, resulting in DNA fragmentation and cell death, through a caspase-independent type of cell death, designated parthanatos [50].

The activation of PARP also conduces to an inflammatory condition, since PARP-1 promotes the expression of pro-inflammatory factors, including TNFα and IL-1β, and the inhibition of PARP is a promising strategy for the prevention and treatment of diabetic complications. The inhibition of PARP ameliorates cardiovascular complications and nephropathy in an animal model of type 2 diabetes, preventing oxidative stress, inflammation, and renal fibrosis [51, 52]. It also attenuates the development of retinopathy in streptozotocin-induced diabetic rats [53] and prevents the apoptosis of cultured cardiomyocytes under high glucose concentration [54].

Although supplementation with antioxidants has been considered in the treatment of diabetic complications, interventional trials with supplemented antioxidants have failed to show significant beneficial effects. Conversely, the use of natural foods shows promising results, and the employment of a balanced "Mediterranean diet" helps in the control of free radical production and increases intracellular antioxidant defenses [55]. Early intensive glucose control is still the best strategy to avoid oxidative stress and its associated diabetic complications.

Altered Lipid Metabolism, Dyslipidemia, and Accumulation of Cytotoxic Lipids

Diabetic dyslipidemia leads to changes in systemic and local lipid metabolism that drive the pro-inflammatory and pro-apoptotic cellular changes typical of diabetic complications. Abnormalities in metabolism, accumulation, and plasma profile of lipids have been associated with insulin resistance and vascular complications [6], and several studies support the potential benefits of lipid-lowering diets and drugs, such as Mediterranean diet, omega-3 fatty acids, fibrates, and statins, for the prevention and treatment of vascular complications. A positive association between high levels of total cholesterol, low-density lipoproteins (LDL), and LDL/high-density lipoproteins (HDL) ratio and vascular complications are well established. Recently the profile of plasma ceramides has been proposed as risk factors and prognosis indicators of predisposition and progression diabetes mellitus and its complications. Thus, the circulating levels of ceramide containing C16, C18, or C24 acyl chains display a superior predictive value for future adverse cardiovascular events (myocardial infarction and stroke) and plaque instability than LDL cholesterol.

Lipids and their transporting lipoproteins like LDL and HDL are glycated and/or oxidized during chronic hyperglycemia and oxidative stress. These modified lipoproteins promoted endothelial dysfunction and vascular injury due to the activation of RAGE receptors [56] and have cytotoxic, pro-inflammatory, and pro-atherogenic effects; for example, they activate the release of pro-inflammatory cytokines by retinal glial Muller cells and are cytotoxic to retinal capillary pericytes and retinal pigment epithelial cells promoting diabetic retinopathy.

Dyslipidemia and increased levels of plasmatic free fatty acids (FFA) lead to lipid peroxidation and the increased uptake of FFA in the cells. Intracellularly fatty acids are oxidized in the mitochondria producing acetyl-CoA or are used in the synthesis of di- and triacylglycerols, glycerophospholipids, and ceramide, the precursor of sphingolipids. Diacylglycerol can activate PKC, triacylglycerols can be accumulated in hepatocytes or cardiomyocytes causing steatosis and functional alterations, and ceramides have been associated with diabetic complications. The spectrum of sphingolipid actions in diabetes shifts from protective very-long chain (VLC) ceramides ($C \geq 26$) to pro-inflammatory and pro-apoptotic short-chain (SC) ceramides ($C \leq 24$). SC ceramides are mainly produced from sphingomyelins by acid sphingomyelinase (ASM), whose level increases in tissues and blood during diabetes.

SC ceramides promote intrinsic apoptosis by the increase of mitochondrial outer membrane permeability through the formation of protein-permeable ceramide channels that allow the release of cytochrome c in the cytoplasm. During diabetes, ceramides are accumulated and induce apoptosis in renal mesangial and tubular epithelial cells, contributing to diabetic nephropathy; also they induce apoptosis of retinal pericytes and contribute to the breakdown of the blood-retinal barriers and the development of retinopathy [6, 57].

Inflammatory Stress

Inflammation is induced by oxidative stress and diverse factors and is a common pathophysiological characteristic in many diseases, and diabetes is associated with a chronic pro-inflammatory condition, which is evidenced by increased serum levels of pro-inflammatory cytokines (TNFα) in diabetic patients and experimental animals [52]. Additionally,

the transcription factor NFκB is activated in circulating lymphocytes of type 2 diabetic patients [58] and in a variety of tissues of diabetic animals (kidney, heart) [51, 52]. NFκB is activated by oxidative stress, TNFα, or angiotensin II (Ang II) and regulates the expression of a variety of inflammatory-related genes, including pro-inflammatory cytokines like TNFα, interleukin (IL) 1β (IL-1β), IL-6, and monocyte chemoattractant protein 1 (MCP-1); additionally, it induces the expression of cyclooxygenase-2 (COX-2), the enzyme that controls the synthesis of pro-inflammatory eicosanoids.

Ang II is a key mediator of the renin-angiotensin system (RAS), whose activation is thought to be a major mechanism underlying inflammation in diabetic complications. Ang II induces the activation of NFκB and the synthesis and release of pro-inflammatory mediators, primarily cytokines TNFα, IL-1β, and IL-6. TNFα induces macrophage recruitment and synthesis and secretion of IL-6. IL-6 stimulates the production and secretion of C-reactive protein (CRP), a key risk factor for cardiovascular diseases.

TNFα induces the expression of MCP-1 and cellular adhesion molecules in the endothelium, such as intracellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1), which leads to recruitment of leukocytes to the surface of endothelium, contributing to the endothelial dysfunction. Further leukocytes migrate across the endothelium, causing endothelial damage and inflammation in the kidney and destruction of the blood-retinal barrier, characteristics of nephropathy and retinopathy. IL-1β induces the expression of inducible nitric oxide synthase (iNOS), causing overproduction of NO, which forms peroxynitrite when it reacts with O^{2-}, amplifying the inflammatory response and producing nitrosoactive stress.

TNFα and IL-1β can induce apoptosis directly or indirectly in cardiomyocytes and neurons, contributing to cardiac dysfunction, retinopathy, and neuropathy. Additionally, TNFα is associated with cardiomyocyte hypertrophy and cardiac fibrosis, leading to heart failure.

TGFβ and Epithelial Mesenchymal Transition in Diabetic Nephropathy (Fig. 49.4)

One of the tissue changes of diabetic nephropathy is the excessive deposition of extracellular matrix (ECM) in the

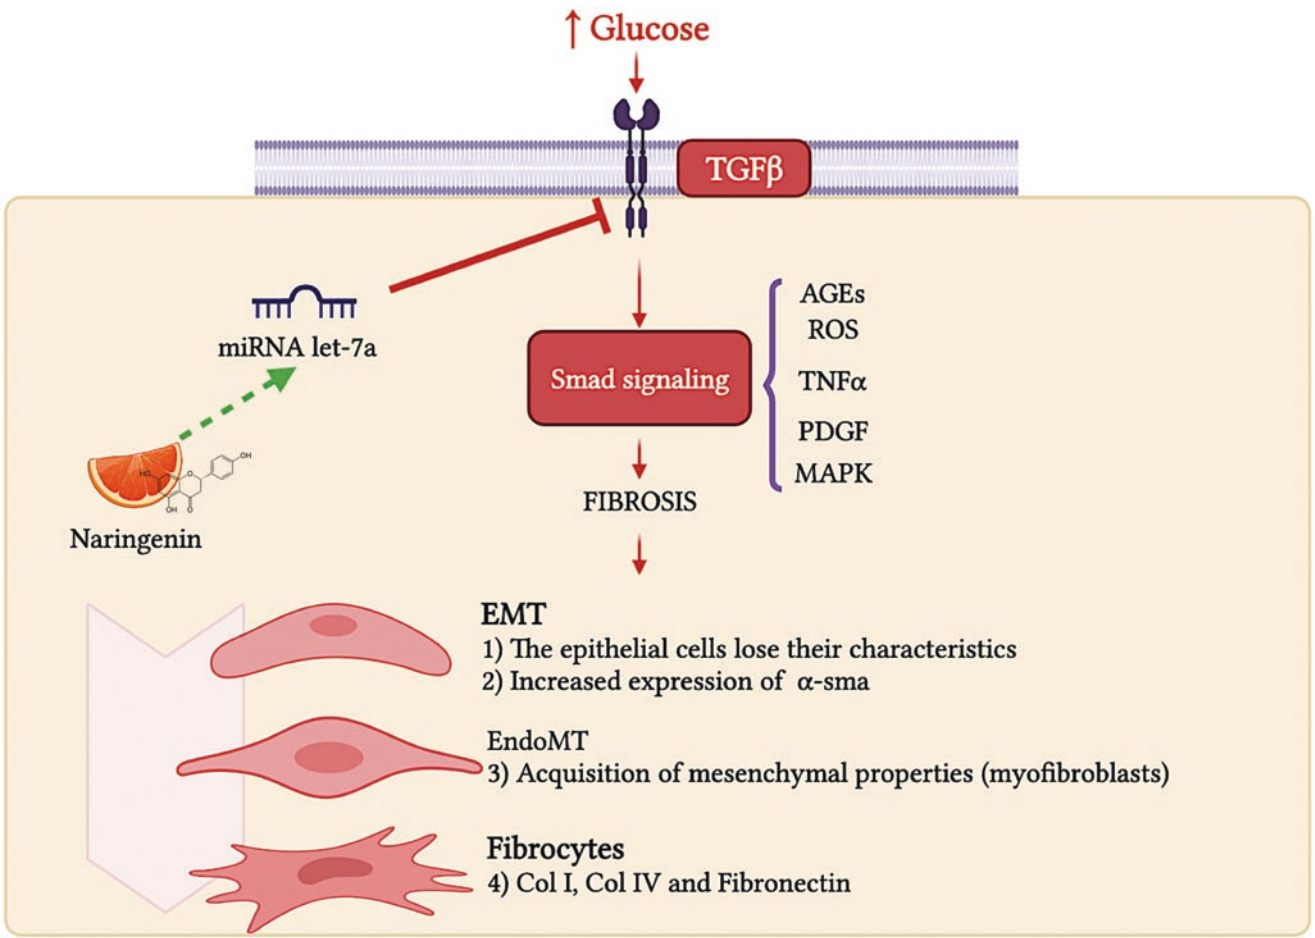

Fig. 49.4 TGFβ and epithelial mesenchymal transition in diabetic nephropathy

glomerulus and the tubular interstitium associated with the development of glomerulosclerosis and tubule interstitial fibrosis. The major source of renal ECM is myofibroblasts, whose number is increased in diabetic nephropathy. These cells are originated from different resources including activated renal fibroblasts, pericytes, epithelial-to-mesenchymal transition (EMT), endothelial-to-mesenchymal transition (EndoMT), bone marrow-derived cells, and fibrocytes [59].

EMT is one of the sources of matrix-generating fibroblast. During EMT, epithelial cells (proximal tubular cells and podocytes) lose their epithelial characteristics (down-regulation of epithelial adhesion protein, E-cadherin) and acquired mesenchymal properties originating from myofibroblasts [59, 60]. During the formation of myofibroblasts, the expression of α-smooth muscle actin (α-SMA) is induced. TGFβ is a major driver for renal fibrosis, and the inhibition of TGFβ signaling significantly reduces renal fibrosis, ameliorating kidney damage and dysfunction. TGFβ induces EMT, EndoMT, and synthesis of EMC proteins (collagen I, collagen IV, and fibronectin). The promotion of fibrosis by TGFβ is mediated by the activation of the transcription factors Smads; therefore, TGFβ/Smads signaling is considered a potential therapeutic target in the prevention and treatment of renal fibrosis [59, 61]. However, Smads signaling also can be activated for other factors, including AGEs, ROS, TNFα, platelet-derived growth factor (PDGF), MAPK, and chemokines [38, 59].

Recently, it was found that the microRNA, let-7a, negatively regulates the expression of TGFβR1, preventing the induction of fibrosis by hyperglycemia on kidney mesangial cell, and naringenin (4,5,7-trihydroxy flavanone), a flavanone compound extracted from citrus fruits, upregulates let-7a and prevents the ECM deposition in the kidney of diabetic rats [62].

Endothelial Dysfunction and Nitric Oxide Deficiency

The endothelium lines the inner surface of blood vessels and modulates vascular function and structure. It controls vascular morphology, tone, permeability, inflammation, and thrombosis by the production of a variety of mediators including vasodilators (NO and prostacyclin) and vasoconstrictors (endothelin and thromboxane). This tissue is a key in the development of diabetic complications. Endothelial dysfunction is induced in diabetes by the abnormal glucose concentration and the increase of AGEs linked with plasma lipoproteins. High glucose, the activation of RAGE by AGEs-lipoproteins, and inflammatory cytokines lead to an inflammatory reaction in the vascular wall, endothelial oxidative stress, and NO deficiency, which play a major role in inducing endothelial apoptosis. Endothelial dysfunction alters the control of vascular properties by endothelium toward reduced vasodilatation and a pro-inflammatory and pro-thrombotic state [56, 63].

Reduced vasodilatation is associated with NO deficiency or reduced availability of NO, which is induced by different factors, including reduced synthesis and the reaction of NO with O^{2-}-forming peroxynitrite ($ONOO^{-}$) in hyperglycemia and oxidative stress conditions. Although the enzyme that synthesizes NO in the endothelium, the eNOS, is upregulated by oxidative stress (hydrogen peroxide, product of the dismutation of superoxide) or PKC [64], its essential cofactor (6R-)5,6,7,8-tetrahydrobiopterin (BH4) is oxidized by peroxynitrite. When this cofactor is oxidized, the reaction of eNOS is uncoupled, and ROS are produced instead of NO, accentuating the vascular oxidative stress [63]. Inhibitors of PKC reduce eNOS expression levels in vascular endothelium. Additionally, there is a deficiency in the substrate of NOS L-arginine due to the increase of the enzyme arginase in plasma and tissues; arginase degrades L-arginine to urea and L-ornithine [65].

Since reduced bioactivity of nitric oxide (NO) is present in diabetes, some strategies are being considered to restore NO availability; one is the promotion of NO synthesis by the supplementation of L-arginine or L-citrulline; the former is the precursor of NO production by eNOS, and its plasma concentration is decreased by diabetes, whereas L-citrulline is a neutral alpha-amino acid, found in high concentrations in watermelon. L-citrulline is an inhibitor of arginase and prevents the degradation of L-arginine; also it can be recycled to L-arginine in the mitochondria by the urea cycle; therefore L-citrulline leads to increased L-arginine bioavailability. Another strategy is to supply inorganic nitrate abundant in green leaft vegetables and beetroots, which provide NO by an unconventional via.

Oral L-arginine supplementation has been inefficient to restore NO because it is removed from the intestinal tract and liver, which does not occur with L-citrulline, and its supplementation is effective at increasing blood L-arginine and endothelial NO synthesis. L-citrulline at a dose of 2000 mg/day for 1 month increased NO levels and decreased arginase levels in the plasma of T2DM patients [65]. L-citrulline can be beneficial for diabetic patients considering these data and that L-citrulline has shown an antihypertensive action in adult patients and, in preclinical assays, L-citrulline protects the endothelial function [65]. The supplements of nitrates ameliorate or prevent the risk of diabetes and its complications in animal models; nitrate is used as a precursor for NO synthesis through serial reductions of nitrate by the nitrate-nitrite-NO pathway. This pathway acts as a backup system when NOS system is compromised during diabetes and other pathological con-

ditions [66]. However, in human beings, nitrate-nitrite-NO pathway supplements have had poor results and probably required ascorbic acid complementation [67]. The protective action of NO has been attributed to the inhibition of NADPH oxidase activity mediated by the heme oxygenase-1 (HO-1)-dependent antioxidant mechanism, preventing the vascular oxidative stress and endothelial dysfunction [68].

When the endothelium is damaged, soluble forms of the adhesion proteins ICAM (sICAM-1), VCAM (sVCAM), and E-selectin are released from the endothelial surface, and its plasma concentration is evaluated as markers of endothelial cell dysfunction [56]. Plasma sICAM-1 concentration is increased in diabetic albuminuric patients before signals of nephropathy. Plasma ICAM-1 concentrations are negatively correlated with the vasodilatory function of the endothelium. Because oxidative stress contributes to endothelial dysfunction, a positive correlation was found between plasmatic concentrations of advanced oxidized protein products (AOPPs) and sICAM [69].

Anaerobic Metabolism and Neuropathic Pain

Nowadays, a link between anaerobic metabolism and neuropathic pain has been established. The pyruvate dehydrogenase kinase (PDK)-lactic acid axis is a critical link that connects metabolic reprogramming and neuropathic pain. Pyruvate dehydrogenase (PDH) catalyzes the irreversible oxidative decarboxylation of pyruvate to acetyl-CoA, and its activity is lost when is phosphorylated by PDK in anaerobic conditions. PDKs are upregulated in the tissues of patients and rodents with diabetes. A nociceptive role for lactate is recently recognized; lactate is the predominant end product of anaerobic glycolysis. Some tissues and organs like dorsal root ganglion are exposed to a low-oxygen condition (ischemia) during diabetes; in this condition, PDKs 2 and 4 are upregulated; these enzymes inactive PDH by phosphorylation; therefore pyruvate is transformed to lactate by lactate dehydrogenase, and the accumulation of lactate induces the expression of pain-related ion channels and neuroinflammation, leading to pain hypersensitivity and diabetic neuropathy. Suppression of *Pdk2 and Pdk4* expression attenuated the hyperglycemia-induced pain hypersensitivity and induced partial resistance to the diabetes-induced loss of peripheral nerve structure and function in streptozotocin-induced diabetic mice [70].

Concluding Remarks

- The pathophysiological mechanism leading to vascular diabetic complications includes the metabolic, oxidative, and inflammatory alterations induced by hyperglycemia.
- Increased metabolic flux of glucose leads to activation of polyol and hexosamine pathways and accumulation of trioses, dicarbonyl aldehydes, and diacylglycerols, together with NADH/NAD^+ redox imbalance, oxidative stress, and PKC activation.
- ROS, peroxynitrites, lipid peroxidation, and glycation cause chemical modification of macromolecules, leading to the loss of their function, nucleic acid alterations, and apoptosis.
- The interaction of AGEs with its receptor RAGE, oxidative stress, and Ang II activates different signaling pathways and transcription factors, including NFκB, which induce the expression of pro-inflammatory, pro-fibrotic, and pro-thrombotic proteins, such as TNFα, VEGF, TGFβ, and PAI-1.
- All these processes lead to endothelial dysfunction and tissue alterations (inflammation, hypertrophy, fibrosis, apoptosis, among others), as well as organ dysfunction characteristics of neuropathy, retinopathy, neuropathy, and diabetic cardiovascular disease.

Questions and Answers

1. Endothelial dysfunction is considered as the initial step in the development of vascular complications and is induced by
   (a) Low bioavailability of nitric oxide
   (b) Uncoupled of the endothelial nitric oxide synthase
   (c) **Oxidative stress and TNFα**
   (d) Glycolysis
   (e) ATP

   TNFα induces the expression of MCP-1 and cellular adhesion molecules in the endothelium, which leads to the recruitment of leukocytes to the surface of endothelium, initiating endothelial dysfunction. Oxidative stress induces the production of TNFα and ROS reacts with NO, reducing the availability of NO as a consequence of endothelial dysfunction and the reduced availability of reduced BH4, a coenzyme required for NO synthesis.

2. The activation of PKCδ caused by hyperglycemia is dependent on
   (a) Epithelial mesenchymal transition
   (b) **Increased synthesis of diacylglycerols induced by the accumulation of trioses**
   (c) Release of the apoptosis inducing factor (AIF) from the mitochondria
   (d) Increased expression of NADPH oxidase
   (e) Direct action of TGFβ

   Diacylglycerols accumulated in the membrane activate PKCβ and PKCδ; diacylglycerols are produced from trioses accumulated during glycolysis, due to the enzyme glyceraldehyde 3-phosphate dehydrogenase inactivated by oxidative stress and the low availability of its coenzyme NAD+ as a consequence of the NADH/NAD+ imbalance.
3. The fibrosis of renal glomerulus associated with diabetic nephropathy is due to
   (a) **Increased synthesis, release, and action of TGFβ**
   (b) Increased vascular permeability
   (c) Depuration of methylglyoxal
   (d) Increased activity of antioxidant enzymes
   (e) Reduced production of Ang II

   TGFβ is a major driver for renal fibrosis, and the inhibition of TGFβ signaling significantly reduces renal fibrosis. TGFβ induces the synthesis of extracellular matrix proteins. Renal fibrosis also can be induced by AGEs, TNFα, PDGF, and chemokines in a TGFβ-dependent and TGFβ-independent manner.
4. The role of the activation of the polyol pathway in the development of diabetic complications is directly due to
   (a) Formation of diacylglycerol and activation of PKC
   (b) Formation of AGEs and chemical alteration of macromolecules
   (c) Induction of the expression of TGFβ and fibrosis
   (d) **Osmotic stress by the accumulation of sorbitol and NADH/NAD$^+$ imbalance**
   (e) Induction of the production of ROS by NADPH oxidase

   In the polyol pathway, sorbitol is accumulated as an intermediate product, because the cell membrane is impermeable to sorbitol and prevents its efflux. Sorbitol accumulation induces osmotic imbalance, water intake, and cellular death. In the second step of this pathway catalyzed by sorbitol dehydrogenase, NAD$^+$ is reduced to NADH, contributing to NADH/NAD$^+$ imbalance.
5. The role of the activation of the hexosamine pathway in the development of diabetic complications is mediated by
   (a) Induction of signaling by activation of RAGE
   (b) Formation of diacylglycerol and activation of PKC
   (c) Induction of the expression of TGFβ and fibrosis
   (d) Osmotic stress by the accumulation of sorbitol and NADH/NAD$^+$ imbalance
   (e) **Formation of UDP-N-acetylglucosamine and *O*-GlcNAcylation of proteins**

   Overproduced fructose 6-phosphate during glycolysis is used by the hexosamine pathway to the production of UDP-GlcNAc; the N-acetylglucosamine of this compound is transferred during *O*-linked glycosylation of proteins (*O*-GlcNAcylation), altering their functions and inducing the expression of TGFβ, PAI-1, and VEGF-A.
6. The role of glycation in the development of diabetic complications is due to
   (a) **Production of AGEs and activation of RAGE**
   (b) Formation of diacylglycerol and activation of PKC
   (c) Induction of the expression of TGFβ and fibrosis
   (d) Osmotic stress by the accumulation of sorbitol and NADH/NAD$^+$ imbalance
   (e) Formation of UDP-N-acetylglucosamine and *O*-GlcNAcylation of proteins.

   The effects of AGEs are mediated by the chemical modification of macromolecules or by its interaction with their receptor RAGE. The binding of AGEs with RAGE leads to the generation of oxidative stress, inducing proliferative, migratory, inflammatory, thrombotic, and fibrotic reactions, which leads to alterations associated with diabetic vascular complications.
7. Dicarbonyl stress is associated with
   (a) Accumulation of sorbitol
   (b) Accumulation of diacylglycerols and activation of PKC
   (c) **Accumulation of glyoxal and methylglyoxal**
   (d) Production of pro-inflammatory cytokines
   (e) Production of AGEs

   Glyoxal and methylglyoxal are α-dicarbonyls and reactive aldehydes, produced as by-products of glycolysis by fragmentation of triose phosphates. These aldehydes react with proteins and nucleic acid (glycation), producing endogenous AGEs, and also induce apoptosis in vascular cells fomenting endothelial dysfunction and progression of vascular complications.
8. In a microenvironment with an excessive concentration of glucose, ROS are produced by
   (a) Aldose reductase and sorbitol dehydrogenase
   (b) **Electron transport chain and NADPH oxidase**
   (c) Glutamine-fructose-6-phosphate amidotransferase
   (d) Glyceraldehyde 3-phosphate dehydrogenase
   (e) Glucose 6-phosphate dehydrogenase

   In an excessive glucose environment, the principal sources of ROS are the electron transfer chain in the mitochondria and NADPH oxidase. ROS can be produced also by other sources such as uncoupled nitric oxide synthase and xanthine oxidase.

9. Oxidative stress contributes to vascular complications by
   (a) Activation of the transcription factor NFκB and production of TNFα
   (b) Inhibition of the glycolytic enzyme glyceraldehyde 3-phosphate dehydrogenase (GAPDH)
   (c) Oxidative modification of macromolecules
   (d) Induction of apoptosis by DNA damage
   (e) **a, b, c, and d**

   Enhanced ROS levels induce oxidative modification of macromolecules altering their functions and cell integrity. DNA damage leads to NADH/NAD imbalance and apoptosis or necrosis. Oxidation and NADH/NAD imbalance inhibit the activity of GAPDH. Also, ROS induce several signaling pathways, including the activation of NFκB and the production of TNFα.
10. TNFα contributes to diabetic complications by
   (a) NFκB activation
   (b) Induction of NADPH oxidase expression
   (c) Promoting leukocyte recruitment at the endothelial surface
   (d) Induces apoptosis in some cells
   (e) **a, b, c, and d**

   TNFα contributes to vascular complication through multiple actions, including the induction of NADPH oxidase and increased ROS production and activation of NFκB, a transcription factor that induces the expression of pro-inflammatory cytokines and MCP-1. Also, it induces the expression of adhesion molecules promoting leukocyte adhesion at the endothelial surface.

Receptor for advanced glycation end products (RAGE) and mechanisms and therapeutic opportunities in diabetes and cardiovascular disease: insights from human subjects and animal models. Front Cardiovasc Med. 2020;7:37. doi: 10.3389/fcvm.2020.00037.

   The central role of RAGE in diabetes, obesity, and cardiovascular diseases is discussed, considering its multiple ligands, its signaling mechanism, its role in macrovascular complications of diabetes, and finally the use of RAGE antagonists in preclinical and clinical studies.
3. Masaki N, Feng B, Bretón-Romero R, Inagaki E, Weisbrod RM, Fetterman JL, Hamburg NM. *O*--GlcNAcylation mediates glucose-induced alterations in endothelial cell phenotype in human diabetes mellitus. J Am Heart Assoc. 2020;9(12):e014046. doi: 10.1161/JAHA.119.014046.

   The linking of *O*-GlcNAcylation to the vasculature dysfunction in humans is analyzed in endothelial cells obtained by biopsy from a forearm vein of patients with T2DM. This study establishes that *O*-GlcNAc modification of proteins is implicated in the glucose-induced impairment of endothelial nitric oxide synthase activation in endothelial cells from patients with T2DM. It is suggested that *O*-GlcNAc protein modification may be used in the diagnosis and as a treatment target for vascular dysfunction in T2DM.

This review describes the mechanism of diabetic polyneuropathy, considering inflammation and oxidative stress as the major causes of this complication. Also, it analyzes the risk factors and methods of diagnosis and treatment of diabetic polyneuropathy.

8. Waris S, Winklhofer-Roob BM, Roob JM, Fuchs S, Sourij H, Rabbani N, Thornalley PJ. Increased DNA dicarbonyl glycation and oxidation markers in patients with type 2 diabetes and link to diabetic nephropathy. J Diabetes Res. 2015;2015:915486.

In this study, increased markers of DNA damage by glycation in plasma and urine in patients with type 2 diabetes were detected, which were further increased in patients with diabetic nephropathy.

Glossary

Advanced oxidized protein products (AOPPs) Products of oxidative modifications of proteins by ROS and hypochlorite, derived from the action of myeloperoxidase from activated leukocytes

Dicarbonyl stress Abnormal accumulation of reactive aldehydes like methylglyoxal and 3-deoxyglucosone that leads to endogenous glycation of proteins and DNA, associated with cell and tissue damage in chronic diseases and aging

Endothelial dysfunction Alteration of the regulatory function of the endothelium on the vascular tone and properties that conduce to reduced vasodilatation and a pro-inflammatory or pro-thrombotic state

Glycation The nonenzymatic reaction between glucose and reducing sugars with amino groups of proteins, lipids, or nucleic acids leads to the production of advanced glycation products or AGEs.

Hexosamine signaling pathway Pathway activated in hyperglycemic condition, where fructose-1-phosphate, an intermediate of glycolysis, is used in the formation of UDP-GlcNAc (hexosamine pathway), followed by the *O*-GlcNAcylation of proteins

Lipid peroxidation Oxidation of polyunsaturated fatty acids by ROS in cellular membranes through free radical chain reactions, with the formation of lipid hydroperoxides as primary products; which may decompose and lead to the formation of reactive lipid electrophiles like 4-hydroxy 2-nonenal

Reductive stress Redox imbalance between NADH and NAD^+ driven by the high metabolic flux in the citric acid cycle and the activation of the polyol pathway and poly ADP-ribose polymerase

Parthanatos Mechanism of caspase-independent type of apoptosis, where the translocation to the nucleus and activity of nucleases like the macrophage inhibitory lead to DNA fragmentation and cell death

Introduction

There are those who consider diabetes mellitus (DM) a cardiovascular disease since the most common and definitive final outcome with major sequelae is presented and depends on this system. In Mexico, the incidence of diabetic patients in the total number of patients treated by coronary intervention is higher than the world average, accounting for more than 40% of patients treated. Despite progress in contemporary pharmacological therapy in improving the management of diabetes and the more generalized use of statins and aspirin, the progression of atherosclerotic plaque and the regression percentage of the atherosclerotic plaque remains a prevalent issue among diabetic patients, as described by Raisuke [1]; see Fig. 50.1.

Since the 1980s, Colwell described the complexity of this problem in a classic paper [2] where he mentions that vascular disease in the diabetic patients is multifactorial with a wide myriad of derangements including endothelial, platelet, smooth muscle, lipoprotein, and coagulation abnormalities, all contributing to accelerated atherosclerosis, and has since proposed that a full understanding of the pathogenesis of this process could help design more effective preventive therapeutic approaches. The preventive approach with antiplatelet agents in the diabetic patient seems to be insufficient, since it is only focused on platelet function, forgetting the important contribution of the altered coagulation cascade in the diabetic, thrombo-fibrin, and resistance to fibrinolysis. That is why, currently there are multiple studies attempting to incorporate into the treatment of some component that improves fibrinolysis of the thrombus and thus increase the therapeutic spectrum that decreases the cardiovascular risk by this mechanism [3]. This is especially important in diabetic patients who undergo coronary intervention. Significant advances have been made in the knowledge of pathophysiology in relation to endothelial function, the role of inflammation, lipoproteins, and glucose metabolism, which begin to pro-

duce concrete results in the reduction of cardiovascular risk, for example, the use of inhibitors of sodium-glucose transport proteins has shown to decrease the occurrence of cardiovascular disease and mortality, compared to other types of hypoglycemic therapies [4]. It has been possible to modulate excessive vascular response and neointimal hyperplasia after the implantation of drug-eluting stents (DES) as demonstrated in multiple studies validated with ultrasound [5]; however, the main problem in the diabetic remains the progression of new plaques in sites not treated with stents. Advances in vascular intervention have been spectacular in the last few years; noninvasive and invasive imaging technology (IVUS, OCT) has greatly aided the understanding of vascular pathology in the diabetic patients and its evolution and behavior under diverse therapeutic approaches (pharmacological stents). There is no doubt that bioabsorbable stents are already a reality as current therapeutic tools [6]; however, there are certain technological improvements that will make the clinical results, especially in diabetic patients, be equated with nondiabetics. The bet on this adventure could be the search for a platform that could treat younger or incipient plaques and seek their "cure" preventing coronary lesions from reaching irreversible states in terms of anatomy and function.

We are glimpsing the future on the shoulders of giants.

Ischemic Heart Disease in Diabetic Patients

Epidemiology

Coronary artery disease is the leading cause of death in patients with diabetes mellitus [7]. Diabetes mellitus is associated with a two- to fourfold increased risk of coronary artery disease and stroke [8–10] and with 2–3 times the risk of an acute myocardial infarction [11]. The prevalence of coronary disease increases from 2% to 4% in the general population to as high as 55% in diabetic patients [12]. The excess risk of cardiovascular disease is present in patients with type 1 diabetes mellitus and type 2 prediabetic, obese, and patients with metabolic syndrome [13]. Survival is worse in the presence of coronary artery disease, and their mortality rate is higher after myocardial infarction [14, 15]. Diabetes is present in 18–44% of patients with coronary artery disease [16–18], while in the rest, it is usual to find certain degree of dysglycemia; and previously undiagnosed diabetes can be found in up to 14–22% of patients [16]. Diabetic subjects typically have more severe coronary disease, more extensive coronary calcification, a high prevalence of left main disease, and a reduction in the recruitment of collateral circulation [19–21]. In the United States, approximately one-third of all percutaneous coronary interventions are performed in patients with diabetes, and one-quarter of patients undergoing coronary bypass surgery have diabetes [22].

Pathophysiology of Atherosclerosis (Fig. 50.2) and Endothelial Dysfunction: Metabolic Syndrome

There are several potential mechanisms through which diabetes causes accelerated formation of atherosclerotic plaques [23]; factors such as hyperglycemia, dyslipidemia, and insulin resistance lead to endothelial dysfunction [24, 25] and alterations in platelet function and coagulation [26]. All these mechanisms converge to promote plaque formation and increase its burden and complexity.

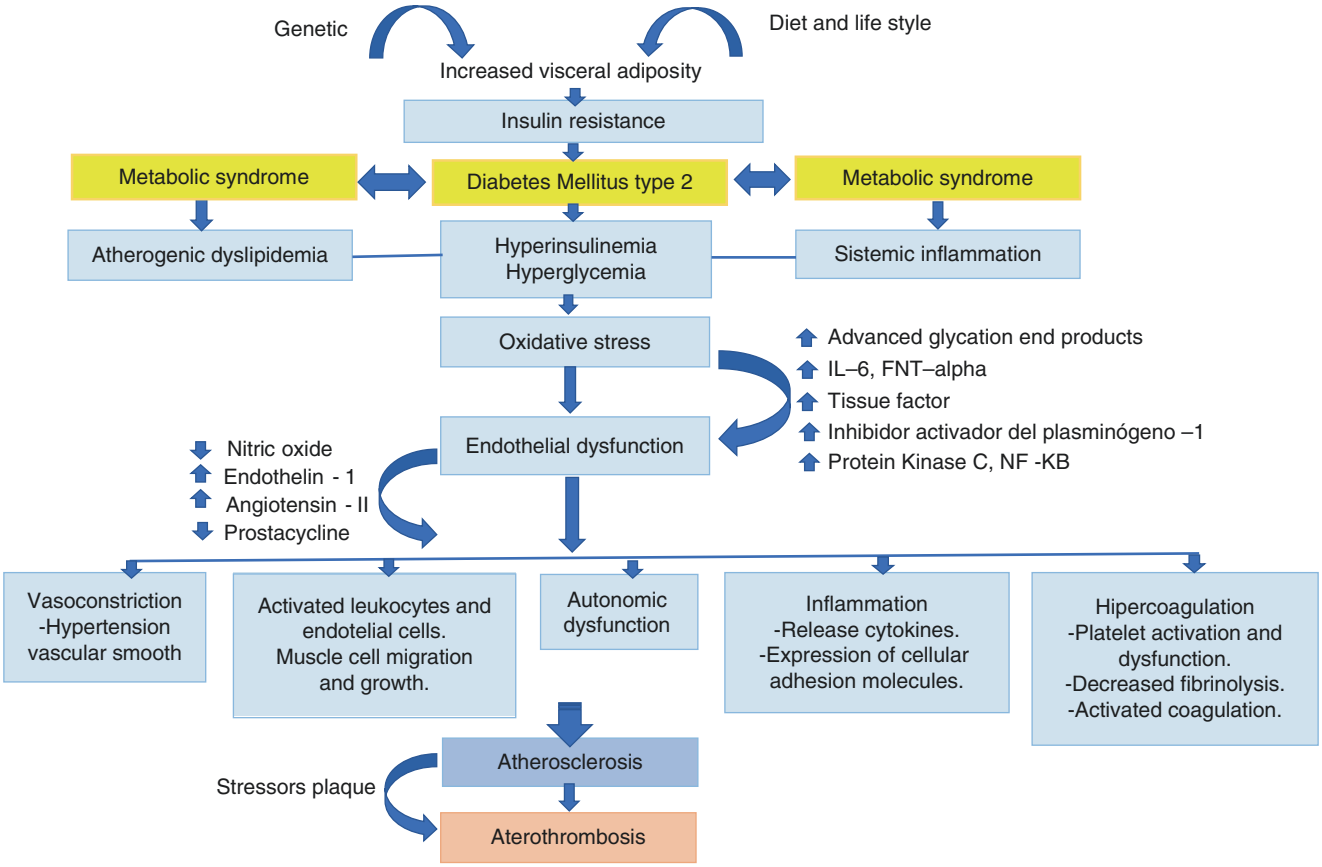

Fig. 50.2 Pathophysiology of atherosclerosis in diabetes mellitus

Treatment of Risk Factors and Its Impact on Primary Prevention

1. Hypertension Treatment: Scientific Evidence of Antihypertensive Treatment in Diabetic Patients and Lifestyle Changes and Arterial Pressure Goals in Diabetic Patients

   Hypertension is twice as common in diabetic patients as in nondiabetic patients [27]; it is postulated that hyperinsulinemia, arterial stiffness, and the expansion of extracellular volume play an important role in its presentation. This association significantly increases the risk of cardiovascular (CV) death [9, 28, 29], coronary disease [30], ventricular hypertrophy [31], heart failure [32], stroke [33], retinopathy, and nephropathy [34, 35]. Clinical trials have demonstrated the benefits of improving blood pressure (BP) [36]; thus, with each sustained reduction of 10 mm Hg in systolic blood pressure, there is a 15% reduction in the risk of cardiovascular disease, a lower risk of macrovascular and microvascular disease, and a reduction in mortality [37–39]. Diabetic patients have a higher prevalence of isolated systolic hypertension and are more resistant to treatment [40–43]. In the EUROASPIRE IV study, only 54% of patients achieved an adequate blood pressure [44]. Due to dysautonomic disorders, these patients suffer a lower reduction of nocturnal blood pressure, a higher heart rate, and a greater predisposition to orthostatic hypotension. Changes in lifestyle such as weight loss, low-sodium diet, and exercise produce beneficial effects [45]. The DASH (Dietary Approaches to Stop Hypertension) diet offers useful recommendations, such as reducing the sodium intake (<1500 mg/day), reducing the excess body weight, and increasing consumption of fruits and vegetables and low-fat foods while avoiding excessive alcohol consumption and increasing the physical activity [46]. Key management guidelines, including the Eighth Joint National Committee (JNC 8) [47] and the European Society of Hypertension and Cardiology [48], suggest that the goal of blood pressure in these patients should be less than 140/90 mmHg. Previous recommendations suggested a pressure goal of less than 130/80 mmHg. In the ACCORD-BP (Action to Control Cardiovascular Risk in Diabetes – Blood Pressure) study, they compared intensive blood pressure control (systolic blood pressure <120 mmHg) versus standard pressure control (systolic blood pressure <140 mmHg). They found a statistically

significant reduction in the annual incidence of stroke in the intensive control group, but there were no differences in all-cause mortality and in the primary point of nonfatal myocardial infarction/nonfatal stroke/cardiovascular death. Serious adverse events were reported in the intensive treatment arm, such as a significant increase in serum creatinine above 1.5 mg/dL, hyperkalemia, hypotension, and syncope [49].

Contrastingly, the results of the recent SPRINT (Systolic Blood Pressure Intervention Trial) study, performed in patients with systolic blood pressure greater than 130 mm Hg and high cardiovascular risk, but without diabetes, showed a clear benefit in intensive treatment mortality. These results have again fanned the debate about the optimal blood pressure goal [50]. A meta-analysis, including 31 randomized studies and more than 71,000 hypertensive diabetics, reported that intensive blood pressure control significantly reduces the risk of stroke but fails to reduce the incidence of myocardial infarction or total mortality [51]. Although it is widely acceptable to achieve a systolic blood pressure <130/80 mm Hg in most diabetic patients and <140–150/90 mm Hg in elderly diabetic patients (>70–80 years), there is a lack of solid evidence to support this [52]. JNC 8 suggests that in adult White patients, the initial antihypertensive regimen should include any of the following drugs: a thiazide diuretic, a calcium channel blocker, an angiotensin-converting enzyme inhibitor (ACEI), and an angiotensin receptor blocker (BRA); in Black adult patients, a thiazide diuretic or a calcium channel blocker should be included [47]. It is usually suggested to start with ACE inhibitors or BRA as a first-line treatment because of its cardioprotective and nephroprotective effects. ACE inhibitors or BRAs should be included in the treatment of patients with chronic kidney disease, and they are contraindicated in pregnancy [53]. Generally patients require treatment with two or more drugs to meet the goal [54]. If treatment goals cannot be achieved despite the use of three different antihypertensive drugs (including a diuretic), then secondary hypertension should be ruled out. Finally, it is recommended that blood pressure should be closely monitored and treatment should be adjusted to avoid excessive falls in blood pressure [52].

2. Antiplatelet Treatment

Platelets have an important role in hemostasis and atherothrombotic disease. They are the first to initiate hemostasis. Three stages are recognized in the formation of the thrombus: (1) platelet adhesion; (2) extension, activation, recruitment, and aggregation; and (3) perpetuation and stabilization of the clot. The damaged endothelium exposes the subendothelial extracellular matrix and initiates the platelet activation mediated by the GP (glycoprotein) receptor complex Ib-IX-V which binds to vWF (von Willebrand factor). The exposed collagen also activates the platelets via GP VI and GP Ia/GP IIa. During the extension phase, platelet factors including ADP (adenosine diphosphate), TxA2 (thromboxane A2), epinephrine, serotonin, collagen, and thrombin are activated [55].

Aspirin. Its mechanism of action is by irreversible inhibition of COX 1 and 2, which decreases the production of TxA2 and PGI2. Mature platelets express only COX 1, releasing it when the TP (thromboxane receptor) is stimulated. Current guidelines recommend a loading dose of 150–300 mg of aspirin followed by 100 mg per day for life [56].

Clopidogrel. Eighty-five percent of the absorbed drug is hydrolyzed by the carboxylesterase in the liver and subsequently inactivated; the remainder 15% is converted by the CYP (cytochrome 450) in two active metabolites: 2-oxo-clopidogrel and R-130964. Recommended dose is 300–600 mg (loading dose) followed by 75 mg daily [57]. The use of a 150 mg daily dose was considered beneficial; however, the GRAVITAS study did not show benefit in the short or medium term with this dosage [58]. A 12-month clopidogrel treatment in diabetic patients with low bleeding risk who have a first-generation DES has shown to reduce the incidence of myocardial infarction and death [59].

Prasugrel. More efficient biotransformation depends on CYP3A4/5 and CYP2B6. The loading dose is 60 mg followed by 10 mg daily. It does not have as much variability as clopidogrel. TRITON – TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel – Thrombolysis in Myocardial Infarction) concluded higher efficacy when compared to clopidogrel, but with a higher bleeding rate including fatal bleeding. It is contraindicated in patients over 75 years of age who weigh less than 60 kg and have history of CVA (cerebral vascular accident) [60]. In those weighing less than 60 kg, half the dose can be given safely [61].

Ticagrelor. It is an oral reversible inhibitor of P2Y12 that inhibits red cell recapture of adenosine (which produces bradyarrhythmias). Its elimination is hepatic and is metabolized by the CYP3A. The loading dose is 180 mg followed by 90 mg every 12 h. It has other adverse effects such as dyspnea, hyperuricemia, and ventricular pauses ≥3 s in the first week, limiting its use [62]. Dyspnea can be the sole manifestation of angina in diabetic patients, so we need to be careful not to interpret it as a side effect of the drug.

Cilostazol. It inhibits PDE (phosphodiesterases) III increasing cAMP (cyclic adenosine monophosphate) levels in platelets, endothelium, and smooth muscle, acting as a vasodilator and anti-aggregant. The loading dose is

50 mg twice daily; if tolerated, it is increased to 100 mg twice daily. The benefits are more marked in diabetics and patients with diffuse lesions with many stents. It produces headache, tachycardia, palpitations, soft stools, and diarrhea leading to drug withdrawal in up to 15% of patients. It should be avoided in patients with heart failure [63].

European guidelines for myocardial revascularization recommend the use of Prasugrel and Ticagrelor over Clopidogrel, especially in diabetic patients, due to their lower variability and resistance, with a more stable and sustained therapeutic effect [57].

3. Lipid Treatment: Scientific Evidence of Lipid-Lowering Agents in Diabetic Patients

Multiple studies correlate high glucose and LDL (low-density lipoprotein) with atherosclerotic coronary disease. Statins are grouped according to their intensity: low intensity (simvastatin 10 mg, pravastatin 10–20 mg, pitavastatin 1 mg), moderate intensity (atorvastatin 10–20 mg, rosuvastatin 5–10 mg, simvastatin 20–40 mg, pravastatin 20–40 mg, pitavastatin 2–4 mg), and high intensity (atorvastatin 40–80 mg, rosuvastatin 20–40 mg).

ATP (adult treatment panel) IV guidelines recommend initiating treatment as primary prevention in diabetic patients with LDL >70 mg/dL between 40 and 75 years of age with a moderate-high dose. The goal of lipid-lowering therapy for secondary prevention is a LDL <70 mg/dL [64]. Statins have shown to reduce LDL levels by 25–35% with a 4% reduction in absolute mortality and relative risk by 30% with a 42% reduction for coronary heart disease and 37% for revascularization. There is a linear relationship between LDL reduction and cardiovascular risk [65]. The Heart Protection Study demonstrated the magnitude of benefit of statins at any LDL level, reducing the rate of cardiovascular events by 24%, including diabetic patients [66].

Statins. Intensive therapy has been shown to further decrease the risk of cardiovascular death by 1.3% for all-cause mortality. The use of statins is recommended for all patients with atherosclerotic disease. Intensive therapy reduces mortality by 16%. The risk of clinical adverse events is greater in the first six months after an ACS (acute coronary syndrome). Intensive treatment reduces risk by 24% during the early stage (15–30 days), by reducing CRP (C-reactive protein) and LDL. Patients who tolerate the intensive dose should continue this dose indefinitely [67].

Niacin. HDL (high-density lipoprotein) goal as a secondary target should be >40 mg/dL. Niacin is useful for raising HDL cholesterol. There is a 1.7% risk reduction for every 1% that the HDL is increased with niacin, but its use is limited by its adverse effects. It can decrease and even reverse atherosclerosis according to the ARBITER study [68].

Fibrates. They have little benefit. The ACCORD (Action to Control Cardiovascular Risk in Diabetes) study demonstrated that they can be combined with statins without significantly increasing adverse effects in diabetic patients, showing only benefit in nonfatal infarction and reduction of revascularization [69].

Ezetimibe. Ezetimibe binds to the Niemann-Pick receptor reducing the absorption of sterols in the intestine. It reduces LDL cholesterol by 20% when combined with statins, but there is still no evidence of benefit. So far its indication is when LDL target levels are not achieved despite intensive treatment with statins [70].

Glitazones. They stimulate the PPARG (peroxisome proliferator-activated receptor gamma) receptor improving serum glucose levels and are part of the treatment of type 2 diabetes mellitus. Pioglitazone in the PROactive (PROspective pioglitAzone Clinical Trial In macroVascular Events) study decreased LDL/HDL by 9.5% with a nonsignificant end point reduction, but relative mortality was reduced by 16%. It increases the risk of heart failure by 41% and is contraindicated when it already exists [71].

4. Hyperglycemia Treatment: Scientific Evidence of the Impact of the Glucose-Lowering Drugs on the Cardiovascular Risk of Diabetic Patients

For the purpose of this section, we will focus on drugs that have been shown to decrease cardiovascular risk in diabetic patients. Metformin, the only drug available in the biguanide class, was studied in the UKPDS (UK Prospective Diabetes Study) trial [72], which randomized 4209 patients with newly diagnosed type 2 diabetes mellitus to receive dietary restriction or sulphonylurea or insulin treatment or metformin in overweight patients. After a ten-year follow-up, there was a significant decrease in the relative risk of death from all causes of 13% with sulfonylurea or insulin versus dietary treatment and 27% with metformin versus dietary restriction. Significant reductions in the incidence of myocardial infarction were also observed in long-term follow-up. Because metformin has been shown to be safe, is well tolerated, has low risk of hypoglycemia, is low cost, and decreases cardiovascular events, it has been proposed by international associations to be the first-line drug for type 2 diabetes in the absence of contraindications and that it can be continued after starting insulin treatment [73, 74].

Sulfonylureas are the oldest glucose-lowering drugs. They have the highest rate of hypoglycemia of all oral drugs available and favor weight gain. Tolbutamide is a first-generation sulfonylurea, which has fallen into disuse because of increased cardiovascular and all-cause mortality in a randomized study [75]; the second- and third-generation sulfonylureas have not shown to have cardiovascular adverse effects [76, 77], although some have been associated with deleterious effects in the isch-

emic preconditioning of the myocardium [78]. One of the more recent sulfonylureas, gliclazide, has been proposed as the best in this group and the only one associated with a lower risk of major adverse cardiovascular events (MACEs) and mortality, similar to metformin [79]. Cardiovascular safety of sulfonylureas was also confirmed in the UKPDS1 primary prevention study discussed above. It is important to emphasize that when these drugs are prescribed in patients with known coronary disease, dosages should be carefully adjusted to avoid hypoglycemia, which may exacerbate myocardial ischemia [80].

Regarding the thiazolidinedione group, pioglitazone showed a 16% reduction in all-cause death, myocardial infarction, and stroke at follow-up at three years in the PROactive study [81] that included 5238 diabetic patients with evidence of macrovascular disease. The efficacy of this drug in decreasing the MACE compound was corroborated in a meta-analysis of 19 clinical trials [82], with a significantly higher incidence of severe heart failure (2.3% vs. 1.8%). Similarly, two meta-analyses showed that rosiglitazone is associated with a higher incidence of myocardial infarction and heart failure, without increasing cardiovascular mortality, which led to severe restrictions in its use in the United States and its withdrawal from the market in other countries [83, 84].

Dipeptidyl peptidase 4 (DPP-4) inhibitors have discrete hypoglycemic potency and pose a low risk of hypoglycemia. In a meta-analysis of 70 phase II clinical trials of this pharmacological group, a significant reduction in the risk of MACE (OR 0.71, 95% 0.59–0.86), myocardial infarction (OR 0.64, 95% CI 0.44–0.94), and all-cause death (OR 0.60, 95% CI 0.41–0.88), but not stroke, during a mean follow-up of 44 weeks was shown [85]. In the SAVOR-TIMI (Saxagliptin Assessment of Vascular Outcomes Recorded in Patients with Diabetes Mellitus-Thrombolysis in Myocardial Infarction) study [86] that included 16,492 diabetic patients randomly assigned to saxagliptin or placebo, the drug had no effect on MACE at follow-up at 2.1 years but significantly increased the risk of heart failure from 2.8% to 3.5%. Alogliptin also failed to reduce MACE in the EXAMINE study [87] in patients with diabetes with acute myocardial infarction or unstable angina.

Recently, an inhibitor of sodium-glucose cotransporter 2 (SGLT2) called empagliflozin is demonstrated in the EMPA-REG OUTCOME trial [88], to be superior than placebo plus standard therapy in more than 7000 patients with type 2 diabetes and established cardiovascular disease. It also proved to significantly decrease the compound of cardiovascular death, myocardial infarction, and stroke by 14% and in 38% the risk of cardiovascular death, in a median follow-up of 3.1 years.

Liraglutide, a glucagon-like peptide 1 (GLP-1) agonist receptor, was compared in the LEADER (Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results) trial [89] versus placebo plus standard therapy in more than 9,000 patients with type 2 diabetes at high risk for cardiovascular disease or with cardiovascular disease and showed a 13% reduction in the primary MACE compound and 22% in cardiovascular death with a median follow-up of 3.8 years. Lixisenatide did not show a benefit when compared versus placebo in the ELIXA (Evaluation of Lixisenatide in Acute Coronary Syndrome) study [90], as it failed to decrease MACE at 25 months in patients with diabetes and acute myocardial infarction in the previous 6 months.

Inhibitors of α-glucosidase may reduce the incidence of myocardial infarction; however, the evidence is still insufficient [91]. There are other hypoglycemic drugs of new pharmacological groups, available recently or in the last phases of phase III trials [92], whose impact on cardiovascular risk is still unknown.

As for insulin, in the ORIGIN study [93], 12,537 patients with impaired fasting glucose or type 2 diabetes with known cardiovascular risk factors were randomized to receive insulin glargine or the "usual" treatment (which could be insulin, oral hypoglycemic agents, or no drugs according to local practices). The primary point of nonfatal myocardial infarction, nonfatal stroke, or death from cardiovascular causes, after a median follow-up of 6.2 years, was similar in both groups (2.94 vs. 2.85 episodes per 100 patients/year, $p = 0.63$), with higher rates of hypoglycemia and weight gain with insulin glargine and no effect on the incidence of cancer. The UKPDS [72] study also confirmed cardiovascular safety with insulin therapy. It is currently recommended to start insulin as soon as possible when blood glucose goals are not achieved with standard regimens.

The Steno-2 [94] study evaluated intensive versus conventional care strategy in the treatment of diabetic patients with microalbuminuria, with a mean follow-up of 5.5 years. The more aggressive treatment with a stepwise pharmacotherapeutic approach considering the achievement of the goals of blood glucose, blood pressure, microalbuminuria, total cholesterol and serum triglycerides, and platelet dysfunction decreased the all-cause mortality by 46% and the composite of cardiovascular events by 59%, both significantly.

In general, in diabetic patients with coronary artery disease, an HbA1c target of less than 7% is recommended according to the current ADA (American Diabetes Association) guidelines [73].

Cardiovascular Risk Evaluation in Diabetic Patients

In all patients with diabetes, the risk of atherosclerotic cardiovascular disease (ASCVD) defined as coronary death or nonfatal myocardial infarction or stroke (fatal or nonfatal) should be systematically evaluated at least every year. Among the risk factors that predispose to ASCVD are age, gender, race, diabetes, hypertension, dyslipidemia, smoking, family history of premature coronary disease (before 40 years), and the presence of albuminuria [73]. There are numerous cardiovascular risk scores, the most widely used are the American College of Cardiology/American Heart Association (ACC/AHA) ASCVD risk calculator, Framingham Risk Score, and UKPDS risk engine (which is specific for diabetic patients) named SCORE by its acronym in English Systematic Coronary Risk Evaluation. The ACC/AHA ASCVD risk tool [95] estimates the probability of having a cardiovascular event in the next ten years. It also offers treatment recommendations and is available online at http://static.heart.org/riskcalc/app/index.html.

The SCORE system [96, 97] is a simple tool that with five clinical variables estimates the risk of cardiovascular death at ten years but does not take into account diabetes since it is only considered as an independent cardiovascular risk factor after ten years of being diagnosed; this tool is available in an updated electronic version that offers treatment recommendations called HeartScore, which includes HDL cholesterol in its variables (http://www.heartscore.org).

In asymptomatic diabetic patients, routine screening studies are not recommended for coronary artery disease, as this does not improve outcomes whenever the risk factors for ASCVD are addressed [98].

Stable Ischemic Heart Disease

1. Clinical Manifestations and Risk Stratification

   Stable ischemic heart disease (SIHD) is defined as a disease that causes symptoms of angina related to stress or exercise secondary to coronary artery stenosis (≥50% in the case of the left main stem and ≥70% in one or more of the major coronary arteries) [99]. At present, "angina with normal coronary arteries" also known as microvascular angina and coronary vasospasm are also included in this definition. Usually diabetic patients with SIHD present with atypical symptoms such as non-anginal chest pain or unexplained dyspnea. Some diabetic patients may have "silent ischemic heart disease" with positive ischemia tests in the absence of symptoms. All diabetic patients with suspected SIHD should be evaluated with a probability pretest, which is based on simple clinical findings such as the pain characteristics, gender, and age [100]. In general, patients with low probability (<15%) require no additional diagnostic tests; with intermediate probability (15–85%), noninvasive ischemia-inducing studies are suggested (see next section); and in patients with high probability (>85%), invasive coronary angiography (ICA) is recommended as soon as possible, especially in the presence of severe angina at a low exercise level, with decreased LVEF (left ventricular ejection fraction) (<50%) or clinical signs of high-risk events.
2. Diagnosis

   Additional studies should be performed in search of SIHD in all diabetic patients with (1) typical or atypical cardiac symptoms; (2) in the presence of signs or symptoms of concomitant vascular disease such as carotid murmur, transient ischemic attack, stroke, claudication, or peripheral arterial disease; and (3) an abnormal resting electrocardiogram (ECG) with pathological Q waves, ST-segment, or T wave alterations suggestive of myocardial ischemia. The study most widely used is exercise ECG; however, its sensitivity is only 50%, so other noninvasive ischemia-inducing studies are currently preferred, such as exercise or vasodilator stress single photon emission computed tomography (SPECT), exercise or dobutamine or vasodilator stress echocardiography, dobutamine or vasodilator stress magnetic resonance imaging (MRI), and vasodilator stress positron emission tomography (PET), whose sensitivity, specificity, and positive and negative predictive values can be consulted in the stable coronary European clinical practice guide artery disease [99]. When patients are unable to exercise or have an ECG with complete left bundle branch block or pacemaker, then pharmacological stress with vasodilators such as dipyridamole or adenosine should be considered. Coronary artery calcium can be measured with computed tomography angiography (CTA) which is a noninvasive alternative to ischemia screening that offers a sensitivity of 95–99% and a very high negative predictive value. It also offers a very close correlation with invasive coronary angiography in terms of coronary anatomy [101]. Each of these diagnostic tests can stratify the patients in low, intermediate, or high risk which guides the decision as to whether start optimal best medical therapy (BMT) or request ICA with possible revascularization, either percutaneously or surgically.
3. Therapeutic Options
   (a) Optimal medical treatment patients with type 2 diabetes mellitus have a greater risk of developing coronary artery disease (CAD) than nondiabetic patients [102]. In addition, 75% of patients with T2DM die as a result of cardiovascular diseases, including CAD [12]. In patients with T2DM, CAD tends to be more complex characterized by multivessel disease, small

vessels, and calcified and diffuse lesions and are occasionally requiring additional coronary revascularization to control angina [103–105]. Current medical management emphasizes the importance of controlling risk factors, including successful blood glucose control and treatment with statins, angiotensin receptor blockers/angiotensin-converting enzyme inhibitors, and antiplatelet therapy [106]. Guidelines for the management of diabetes mellitus of the American Diabetes Association, the American College of Cardiology, and the American Heart Association recommend the following prevention strategy for coronary artery disease: blood pressure of 130/80 mm Hg or less, low-density lipoprotein cholesterol (LDL-C) below 70 mg/dL for patients with CAD, and immediate smoking cessation [107, 108]. In large-scale studies to assess clinical outcomes comparing revascularization and intensive medical management (COURAGE, BARI-2D, and FREEDOM), the one-year goal compliance rate to achieve LDL-C levels <100 mg/dL, systolic blood pressure <130 mmHg, glycosylated hemoglobin <7.0%, and smoking cessation was 18%, 23%, and 8%, respectively.

(b) Revascularization treatment. Recent advances in techniques and devices used in coronary interventional procedures have extended the indication of PCI toward more complex lesions. Drug-eluting stents (DES) have reduced restenosis and reintervention rates [108–110], although the mortality of CAD in patients with T2DM remains high.

Most clinical trials comparing the outcomes of patients with type 2 diabetes mellitus and multivessel coronary artery disease have shown that coronary artery bypass grafting (CABG) is superior to balloon angioplasty and angioplasty with bare metal stents (BMS) in terms of target vessel revascularization, myocardial infarction, and mortality.

More recently, the use of new scales to analyze angiographic and clinical variables (SYNTAX II, Euro SCORE II) has been proposed for a better decision-making process in revascularization strategies [111], particularly in patients with T2DM who will require a multidisciplinary discussion taking into account the patients' coronary anatomy, the characteristics of the lesions, age, and comorbidities.

Several clinical trials are currently being conducted in 85 centers in the USA and Europe that compare CABG with percutaneous coronary intervention (PCI) with drug-eluting stents. The "SYNergy between coronary intervention and cardiac surgery" (SYNTAX) study was a prospective randomized study comparing the efficacy of CABG and PCI with paclitaxel-releasing stents in patients with complex coronary artery disease [112]. In this study, 25.1% of the patients were diabetic. In the cohort of diabetic patients, the incidence of major coronary events and cerebrovascular disease at three years was 37.0% in the PCI group and 22.9% in the CABG group ($p = 0.002$). The incidence of target vessel revascularization was also higher in the PCI group when compared to CABG (28.0% vs. 12.9%, $p < 0.001$) [113].

In 2012, the FREEDOM study randomized a total of 1900 diabetic patients with multivessel coronary disease to CABG and PCI using mainly sirolimus-eluting stents (SES) and paclitaxel-eluting stents (PES) [114]. All-cause mortality and myocardial infarction were significantly lower in the CABG group when compared to the PCI group (18.7% vs. 26.6%). However, most patients in the PCI group were treated with first-generation DES. The use of new-generation DES, particularly everolimus-eluting stent, is changing the outcomes mainly because of a reduction in the incidence of stent thrombosis and myocardial infarction [115].

Recently, Banglore et al. published a meta-analysis of 68 randomized trials that compared the clinical outcomes of patients with CAD and diabetes revascularized with CABG versus PCI with DES, including sirolimus, paclitaxel, and everolimus-eluting stents [116]. All-cause mortality was higher in patients who were treated with sirolimus-eluting stents and paclitaxel-eluting stents compared to CABG. Meanwhile mortality rates between everolimus-eluting stents and CABG were similar. Bioabsorbable scaffolds are a new alternative that could have potential advantages over drug-eluting stents in terms of adverse coronary events. Muramatsu and colleagues compared bioabsorbable stents versus everolimus-eluting stents in diabetic patients in different clinical trials and reported that the incidence of cardiac mortality, myocardial infarction related to the treated vessel, and target vessel revascularization was similar with both types of stent (3.9% vs. 6.4%, $p = 0.38$) [117, 118].

Acute Coronary Syndromes

1. Clinical manifestations and diagnosis. Coronary disease is very common in the diabetic population; up to 32% of patients with acute coronary syndrome have diabetes mellitus [119]. Myocardial ischemia diagnosis can be challenging in diabetic patients [120, 121]. Physical

examination findings are variable and may be related to hemodynamic instability, electrical instability, or mechanical complications. Physical examination may rule out a different source of chest pain. A fundamental diagnostic aid is the 12-lead electrocardiogram, which must be acquired immediately in these patients [122]. This study may have discrete changes in more than 30% of patients and is less sensitive if there are alterations in intraventricular conduction [123, 124]. Cardiac biomarkers help in confirming the diagnosis and guiding the treatment, in addition to stratifying the risk. Troponins are more sensitive and specific, and their determination is fundamental for decision-making [125–127]. Measurement of CK-MB and copeptin is also useful [128–130]. Angiography is indicated if the suspicion of ACS is high; in other cases, coronary angiotomography may be performed. Other methods, such as echocardiography, magnetic resonance imaging, and cardiac nuclear test, complete the evaluation and diagnosis [131].

2. Risk stratification. The initial presentation characteristics are helpful markers for early prognosis; resting chest pain, heart failure, and mitral regurgitation are associated with a poorer prognosis [132]. There are many variables and scales that assess the risk of death; these scales are not always easy to apply. The TIMI risk score is a useful risk assessment tool in cases of myocardial infarction and ST-segment elevation amenable to reperfusion therapy [133]. High levels of high-sensitivity troponin are associated with an increased risk of death. A high serum creatinine and low glomerular filtration rate pose a grim prognosis to these patients; these variables are included in the Global Registry of Acute Coronary Events (GRACE) [134] and assess the risk of death or the combination of death and myocardial infarction at six months. This score showed that coronary revascularization is independently associated with better survival at one year in cases of acute coronary syndrome without high-risk ST-segment elevation; the same benefit was not observed in low- or intermediate-risk groups [135, 136]. The SYNTAX score uses angiographic criteria to make clinical decisions and thus estimate the likelihood of long-term cardiovascular and cerebral events in patients undergoing surgical or percutaneous revascularization; it predicts outcomes such as death, infarction and CVA and needs for revascularization, or the combination of all, in patients with surgical or percutaneous revascularization, based on the complexity and extent of coronary lesions. A low SYNTAX score is <22 points, intermediate from 23 to 32, and high when it is >33. Higher scores show better long-term outcomes with surgery [137, 138]. It is essential to evaluate the risk of bleeding in the treatment of myocardial infarction without ST-segment elevation. A controlled trial of patients with coronary artery disease of two or three vessels, randomized to revascularization surgery versus percutaneous treatment with drug-eluting stents, showed a significant decrease in all-cause mortality in the surgical revascularization group [139]. This finding was consistent with the SYNTAX trial. The CRUSADE scale quantifies the risk of major intrahospital bleeding [140].

3. Medical Treatment:
   (a) Glucose control in the context of an ACS and glucose goals and insulin therapy. Medical treatment in the acute phase of an acute coronary syndrome is similar in patients with and without diabetes mellitus. Patients with acute coronary syndrome and diabetes mellitus are the group with the highest death rate, myocardial infarction, recurrent ischemia, and CHF (congestive heart failure) during follow-up [141]. There is a close relationship between glucose levels and mortality in this group of patients. Both hyperglycemia and hypoglycemia have adverse effects on inhospital outcomes and mortality. The NICESUGAR study showed that intensive glucose control increased mortality in adults in intensive care: serum glucose of 180 mg/dL or less resulted in lower mortality than if it was 81–108 mg/dL [142]. There is no established role for the administration of glucose-insulin-potassium infusions in NSTE (non-ST-elevated myocardial infarction)-ACS.
   (b) Antiplatelet agents. Aspirin should be given to any patient with suspected or diagnosed acute coronary syndrome. When no contraindication exists, it should be started early. If there is any contraindication for its use, then clopidogrel should be started. Patients treated with early invasive reperfusion should receive the combination of aspirin with some P2Y12 inhibitor. Inhibitors of GP IIb/GP IIIa receptors in patients with acute coronary syndrome without ST-segment elevation are associated with a reduction in mortality at 30 days, particularly in patients with diabetes mellitus undergoing percutaneous revascularization. Several trials have shown the benefit of oral antiplatelet therapy in these patients with a reduction in ischemic events without an increase in bleeding complications with the use of prasugrel compared to clopidogrel [143]. In PLATO study, ticagrelor showed less ischemic events regardless of diabetic state and glycemic control, without increased bleeding than clopidogrel [144].
   (c) Renin-angiotensin-aldosterone antagonists. Optimal treatment in these patients includes the use of a renin-angiotensin-aldosterone antagonist, particularly in patients with heart failure and ejection fraction less than 40%. Patients intolerant to angiotensin-converting enzyme inhibitors should receive angiotensin receptor blockers as a class I indication.

(d) Beta-blockers. They should be used in the first hours after the diagnosis of an acute coronary syndrome, provided there are no contraindications to it. If there is contraindication in the acute phase of the infarction, it can be reevaluated in the following hours.

(e) Anticoagulation. The combination of anticoagulation with antiplatelet therapy is recommended regardless of the initial treatment. Enoxaparin, bivalirudin, fondaparinux, and unfractionated heparin are among the recommended anticoagulants. Enoxaparin significantly reduces the recurrence of ischemic events and the need for invasive procedures; this benefit was sustained for up to 1 year [145], although other studies did not demonstrate a significant difference in death or myocardial infarction at 30 days when comparing this drug with unfractionated heparin [146]. Anticoagulation with bivalirudin alone suppresses ischemic events similar to the use of heparin plus glycoprotein IIb/glycoprotein IIIa inhibitors while at the same time significantly reducing the risk of bleeding complications [147–149].

(f) Statins should be initiated or continued in all patients, with and without diabetes mellitus in the context of an acute coronary syndrome, provided there is no contraindication; they reduce the recurrence of infarction, coronary disease mortality, cerebral vascular event, and the need for revascularization.

(g) Nitrates. If chest pain persists, then sublingual nitroglycerin can be administered; if there is no improvement, it can be administered intravenously, as in the case of heart failure.

(h) Calcium channel blockers. They are an alternative to avoid the recurrence of ischemia or when there is contraindication to the use of beta-blockers, provided there is no left ventricular dysfunction or altered atrioventricular conduction. They are also indicated in patients with coronary spasm [150].

4. Revascularization therapy in acute coronary syndromes:

(a) Percutaneous coronary intervention (PCI) in ST-elevated myocardial infarction (STEMI).

The frequency of coronary events requiring primary intervention is well known. The impact of diabetes mellitus on the outcomes of patients with ST-segment elevation infarction since the onset of primary angioplasty has been well established. It was first described by the Mayo Clinic and Columbia University group [151], who concluded that despite similar TIMI 3 flow rates in patients with and without diabetes, patients with diabetes are more likely to have perfusion abnormalities assessed with the reduction of the ST-segment and myocardial blush; it is also contemplated that the reduction of myocardial perfusion after primary angioplasty may contribute to an increase in mortality in this population. Persistent ST elevation and abnormal myocardial blush in the presence of normal epicardial flow are indicative of decreased microvascular flow also known as a "non-reflux" phenomenon [152]. These alterations of the microvasculature are much more frequent in the diabetic population. Several mechanisms have been postulated for which diabetes contributes to microvascular damage. First, diabetes is associated with a prothrombotic and inflammatory state, accumulation of leukocytes, and thrombus formation in the capillaries of diabetics which leads to coronary microvascular obstruction [153].

Many studies have compared the impact of type 2 diabetes mellitus (T2DM) on prognosis in postcoronary intervention patients. In a recent meta-analysis published in 2016 [154] which included patients from the HORIZONS-AMI [155] trial and 12 other studies of which 7 were randomized controlled trials, 4163 patients were analyzed for major adverse cardiovascular events (MACE) and myocardial infarction (MI) and 17,015 patients analyzed for mortality. There was a significant increase in the rate of MACE and MI in the group of non-insulin-treated diabetes mellitus compared to the non-insulin group (OR: 1.63, 95% CI (1.17–2.27) $p = 0.04$) (OR: 1.82, 95 % CI (1.08–3.06) $p = 0.02$). These differences are also reflected in mortality. Recently published in 2017 is the largest cohort that includes patients with STEMI [156], from the UK and Wales health systems. This cohort of patients with STEMI included 281, 569 patients of which 120, 568 were patients with diabetes mellitus. STEMI with diabetes compared to patients with STEMI without diabetes were more prone to have a previous infarction (34.9 vs. 22.5%), heart failure (10.5 vs. 5.8%), and chronic renal failure (11.3 vs. 4.6%). After this cohort was adjusted for age, sex, and years of diagnosis, DM was associated with a 72% increase in the risk of mortality (1.72, 95% CI 1.66–1.79) for STEMI. The reperfusion rates managed for this cohort were 73.1% versus 79% in patients without DM.

In the final analysis, there were over 1,944,194 person years at risk, the median time to death was 2.3 (IQR 0.9–4.2) years, and 200, 360 (28.4%) died. At all-time points from hospitalization with AMI, unadjusted cumulative relative survival was significantly worse among patients with diabetes (log rank tests $p < 0.001$).

(b) Percutaneous coronary intervention (PCI) in non-ST-elevated myocardial infarction (NSTEMI).

Diabetics have a higher incidence of multivessel CAD. In the American registry CRUSADE (Can

Rapid risk stratification of Unstable angina patients Suppress ADverse outcomes with Early implementation of the ACC/AHA guidelines), the prevalence of diabetes was 33% among 46,410 patients with non-ST-elevation ACS. The PRESTO [157] trial showed that compared to NDM, patients with T2DM had an advanced age were mostly female patients and the majority had a history of heart failure and lower ejection fraction. These patients with T2DM were mainly overweight and obese and had a high rate of comorbidities. The FREEDOM [158] trial showed that in patients with diabetes and multivessel coronary artery disease, MACEs were higher in patients treated with insulin compared to patients without insulin therapy. Revascularization trends in patients with diabetes and patients with diabetes and multivessel CAD presenting with NSTEMI, ACTION Registry: 29,769 patients enrolled from July 2008 to December 2014. Overall, 36.4% were treated with CABG, 46.2% received PCI (77.2% with at least one DES), and 17.3% were treated with no revascularization. The proportion of patients receiving any kind of revascularization increased from 81.1% to 83.6% (PP < 0.0001 for trend), driven entirely by hospital-level use of CABG. Despite guidelines recommending CABG over PCI for diabetics with multivessel CAD, only about one-third of them actually receive CABG in the setting of NSTEMI. Accelerated atherosclerosis, atherosclerotic plaque rupture, and increased platelet activity, all of which increase the incidence of acute MI compared to nondiabetics. In the current propensity-matched analysis of contemporary real-life data, an early invasive strategy was associated with an increased inhospital survival in NSTE-ACS patients with concomitant DM. These results support the 2014 ACCF/AHA guideline recommendations for an early invasive strategy in diabetics, especially those with high-risk features (e.g., NSTEMI and cardiogenic shock). Meanwhile, the use of this strategy in lower-risk patients, such as those with UA (unstable angina), may not be associated with improved survival [159]. The incidence of inhospital mortality also was lower with an early invasive strategy in the secondary post-hoc analysis using a tighter match tolerance (2.5% vs. 3.7%; OR, 0.65; 95% CI, 0.56–0.75; $P < 0.0001$) and in the sensitivity analysis after excluding the patients with length of hospital stay less than 48 h in the propensity-matched cohort (2.1 vs. 3.3; OR, 0.63; 95% CI, 0.56–0.72; $P < 0.0001$). On subgroup analysis, the benefit of an early invasive strategy was demonstrated among a wide range of prespecified subgroups except in patients with UA, where there was no apparent evidence of survival benefit with an early invasive strategy (0.5% vs. 0.1%; OR, 7.86; 95% CI, 0.82–75.72; $P = 0.07$), with evidence of heterogeneity when compared to NSTEMI patients (P interaction=0.02). Diabetes was also associated with a significantly higher mortality at one year for both presentations (HR 1.7 and 1.2, respectively). At one year, patients with diabetes presenting with non-ST-elevation ACS had a risk of death that approached that of nondiabetic individuals presenting with STEMI (7.2% vs. 8.1%). In the TACTICS (Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy)-TIMI 18 trial, an early invasive strategy was associated with a significant 22% reduction in the relative risk of death, MI, or rehospitalization for ACS at six months compared with an early conservative strategy [160].

(c) Fibrinolytic therapy in STEMI.

Regarding to fibrinolytic therapy, a meta-analysis of the Fibrinolytic Therapy Trialists' Collaborative Group, which included all the large randomized trials of fibrinolytic therapy versus placebo in STEMI, demonstrated a greater survival benefit at 35 days among diabetic patients compared with nondiabetic individuals, corresponding to 3.7 lives and 1.5 lives saved per 100 patients treated, respectively. While CABG in the setting of STEMI is typically reserved for failed PCI and for MI-related mechanical complications, primary PCI may be preferred over thrombolytic therapy in diabetic patients. However, the data to support this notion are limited [161]. A pooled analysis of individual patient data from 19 randomized trials comparing primary PCI with fibrinolysis for the treatment of STEMI included 6315 patients, 877 (14%) of whom had diabetes. The 30-day mortality rate (9.4% vs. 5.9%; $P < 0.001$) was higher in patients with diabetes. Mortality was significantly lower after primary PCI compared with fibrinolysis in both patients with diabetes (unadjusted OR 0.49; $P = 0.004$) and those without diabetes (unadjusted OR 0.69; $P = 0.001$) [162].

Complete ST resolution at 90 minutes after fibrinolytic therapy has been shown to be less prevalent between diabetic patients when compared with nondiabetic patients [163].

(d) Coronary artery bypass grafting (CABG).

The impact of diabetes on morbidity and mortality in patients undergoing surgical coronary revascularization was remarked in a retrospective analysis of the Society of Thoracic Surgery database, including 41,663 diabetic patients among a total population of 146,786. At 30 days, the mortality was significantly higher in the diabetes group (3.7% vs. 2.7%). The

unadjusted and adjusted mortality OR (odds ratio) for diabetes were 1.4 and 1.2, respectively. With respect to diabetes treatments at presentation, the adjusted mortality OR for patients on oral hypoglycemic drugs and on insulin were 1.1 and 1.4, respectively. In addition, the overall morbidity and the infection rates were significantly higher among diabetic patients. Looking into long-term mortality following CABG, a prospective cohort study including 11,186 consecutive diabetic patients and 25,455 nondiabetic patients undergoing CABG from 1992 to 2001 detected a significantly higher annual mortality rate among diabetic patients (5.5%) compared with nondiabetic individuals (3.1%).The annual mortality increased to 8.4%, 16.3%, and 26.3% among diabetic patients with vascular disease, renal failure, or both, respectively. In addition to increased periprocedural morbidity and mortality as well as long-term mortality, diabetic patients must undergo repeat revascularization following CABG more frequently than their nondiabetic counterparts [164].

Heart Failure in Diabetic Patients

Introduction and Epidemiology

Cardiovascular death is the leading cause of death among patients with diabetes mellitus. The diabetic population is at higher risk of developing heart failure (HF) compared to the nondiabetic population, so diabetes mellitus (DM) is considered an independent risk factor for the development of HF, where a 1% increase in glycosylated hemoglobin increases the incidence of heart failure from 8% to 16% [165].

Bell et al. found that of 5757 patients with chronic HF treated with carvedilol, 25% had diabetes mellitus [166]. In an analysis of the European Heart Failure Pilot Survey which included 3226 patients with chronic HF, the prevalence of diabetes was 29%, and it was associated with older age, higher NYHA functional class, and predominance of ischemic HF etiology. The study concluded that DM is an independent predictor of death and hospitalization due to heart failure [167].

Pathophysiology

The development of heart failure in the diabetic patient is considered multifactorial, associated mainly with coronary disease, accelerated atherosclerosis, metabolic disorders, small vessel disease, and diabetic cardiomyopathy [168].

Diabetic cardiomyopathy was first described in 1972 when Rubler et al. [169, 170] found left ventricular dilation in the absence of ischemic heart disease in autopsies of diabetic patients. In this context, diabetic cardiomyopathy was clinically defined by the presence of structural alterations or abnormal myocardial function in the absence of hypertension, coronary disease, and valvular disease. The presence of diabetic cardiomyopathy is not essential for the development of HF in the diabetic patient.

The key for the development of HF is hyperglycemia, which leads to lipotoxicity, free fatty acid oxidation, oxidative stress, and apoptosis (apoptosis and myocardial cell necrosis is greater in the diabetic patient than in the nondiabetic patient). Other contributing factors are the constant activation of the renin angiotensin-aldosterone system, sympathetic nervous system (SNS), activation of proinflammatory cytokines, and formation of advanced glycosylation products. All of these in a greater or lesser degree lead to fibroblast proliferation and collagen deposits ultimately causing interstitial and perivascular fibrosis, the main features of diabetic cardiomyopathy [171–173]. Endomyocardial biopsy studies have found an increase in type III collagen deposits but not of type I and IV collagen in patients with type 2 DM. Others show collagen distribution patterns characterized by collagen types I and III at the perivascular level and IV at the endocardium. In both humans and animals, an increase in cardiac fibrosis has been found even before the onset of hyperglycemia [174, 175].

The end products of advanced glycosylation (EPAG) are derived from a nonenzymatic irreversible reaction between sugars and proteins, called the Maillard reaction. It is considered to play an important role in the pathophysiology of heart failure. It has been associated with endothelial dysfunction, development of atherosclerosis, diastolic dysfunction, and in advanced stages systolic dysfunction. EPAG can be covalently bonded to each other, resulting in the formation of additional bonds between matrix proteins such as collagen, laminin, and elastin. This type of binding increases the stiffness of the protein matrix and leads to diastolic dysfunction; the presence of EPAG has been associated with increased isovolumetric relaxation time and left ventricular diameter [176].

The alterations in sympathetic innervation, characteristic of diabetic neuropathy, have been associated with HF, due to alterations in the expression and activation of catecholamines and increased activation of beta 1 receptors, resulting in apoptosis, fibrosis, and ventricular dysfunction. Markers of diabetic neuropathy such as HRR (altered heart rate recovery) are associated with the development of heart failure in the diabetic patients [177].

1. Left ventricular hypertrophy (LVH) and diabetes mellitus.

   The association between left ventricular hypertrophy and DM has been controversial and has been explained by

other mechanisms, such as hypertension [178]. In the Northern Manhattan Study (NOMAS) [179], ventricular mass was determined with transthoracic echocardiography. DM was shown to be an independent risk predictor for the development of left ventricular hypertrophy (adjusted odds ratio 1.46, 95% CI, 1.13–1.88, $P = 0.004$), after adjusting for age, sex, race, mass index (BMI), systolic BP, education, history of coronary artery disease (CAD), physical activity, and alcohol consumption. There was also a direct interaction between abdominal circumference and LVH ($P = 0.01$) which translates the close relationship between insulin resistance, activation of RAAS (renin-angiotensin-aldosterone system), SNS activation, and left ventricular hypertrophy in the diabetic patient with and without arterial hypertension [180, 181]. Cardiac magnetic resonance has broadened our understanding of diabetic cardiomyopathy, demonstrating fat infiltration, fibrosis, altered ventricular geometry, and ventricular mass increase. Patients with HF have higher NT-BNP (N-terminal pro-B-type natriuretic peptide) levels than nondiabetic patients, with no difference in other biomarkers.

2. From diastolic dysfunction to symptomatic HF.

The spectrum of diabetic heart disease is broad and varies from normal heart, subclinical diastolic dysfunction, and systolic dysfunction (detectable only by imaging techniques) to symptomatic heart failure.

Diastolic dysfunction is present in up to 50% of the diabetic population and has a close relationship with the levels of glycosylated hemoglobin and diabetic microangiopathy [181]. Systolic dysfunction is a late appearing condition. Fang et al. found that up to 24% of asymptomatic diabetic patients had systolic dysfunction determined with echocardiographic Doppler and Strain imaging [182].

This subclinical dysfunction in the absence of silent coronary disease and left ventricular hypertrophy has been related to glycosylated hemoglobin levels. In a study that included 219 patients, Flag et al. found that 16% had systolic dysfunction and 21% had diastolic dysfunction. The independent predictors of systolic dysfunction were glycosylated hemoglobin levels ($p < 0.001$) and lack of pretreatment with angiotensin-converting enzyme inhibitors (ACEI) ($p = 0.003$) and for diastolic dysfunction the absence of treatment with insulin ($p = 0.008$), treatment with metformin ($p = 0.01$), age ($p = 0.013$), and arterial hypertension ($p = 0.001$) [183]. Thus, the mechanisms involved with the development of heart failure depend on the control of diabetes, type of treatment implemented for both diabetes control and blockade of the renin-angiotensin-aldosterone system, and other associated factors such as age and hypertension. From et al. showed that 23% of a 1760 patient cohort had diastolic dysfunction. The cumulative five-year HF development in these patients was 36.9%, compared to 16.8% in patients without diastolic dysfunction ($p = 0.001$). Diabetic patients with diastolic dysfunction had a significantly higher mortality rate than those without diastolic dysfunction. This association was independent of the presence of arterial hypertension, coronary disease, or other echocardiographic parameters [184].

The RELAX (Phosphodiesterase-5 Inhibition to Improve Clinical Status and Exercise Capacity in Heart Failure with Preserved Ejection Fraction) trial which included diabetic and nondiabetic patients with HF and preserved systolic function showed that diabetic patients ($n = 93$) were significantly younger, obese, and more frequently males and had a higher prevalence of hypertension, renal failure, lung disease, and vascular disease. Levels of uric acid, C-reactive protein, galectin-3, collagen I, and endothelin-1 were significantly higher in diabetic patients ($p < 0.05$). Diabetic patients had lower functional capacity and a significant increase in the risk of hospitalization for renal and cardiac causes (23.7% vs. 4.9%, $p < 0.001$) [185].

BNP is a good prognostic and diagnostic marker in diabetics with HF. Van Der Horst et al. demonstrated that the diabetic population with HF has higher levels of natriuretic peptides than the nondiabetic population ($p = 0.03$), being a predictor of mortality, along with norepinephrine, in diabetic patients with advanced HF [186].

Prevention and Treatment of HF and DM

HbA1c levels > 7% are associated with an increased risk of hospitalization for HF in patients with type 2 DM [187]. The STENO II trial [94] showed that intensive glucose treatment (glycosylated Hb <6.5%) and risk factor treatment (arterial pressure <130/80 mmHg, triglycerides <150 mg/dL, total cholesterol <175 mg/dL) were associated with a reduction in CV death and infarction and need for revascularization. However, other studies such as UKPDS [188], ACCORD, ADVANCE, and VADT (Veterans Affairs Diabetes Trial) showed no benefit between intensive glucose treatment and HF [189].

The blockade of the renin-angiotensin-aldosterone system is a cornerstone in the high cardiovascular risk patient; in the HOPE study, 38% of the population was diabetic; the use of ramipril was associated with a reduction in the relative risk of HF (9.2 vs. 11.7 OR 0.77, $P < 0.001$), as well as a lesser development of de novo diabetes with a 32% risk reduction ($p = 0.002$) [190]. In the EUROPA (European Trial on Reduction of Cardiac Events with Perindopril in Patients with Stable Coronary Artery Disease) study in diabetic patients treated with perindopril, there was a reduction in hospitalization for HF [191].

Empagliflozin is a potent and selective inhibitor of sodium-glucose cotransporter (SGLT2) used in the treatment

of type 2 DM. By inhibiting SGLT2, empagliflozin reduces renal glucose reabsorption and increases urinary glucose excretion. In addition to reducing hyperglycemia, empagliflozin is associated with osmotic diuresis, natriuresis, weight loss and visceral fat and blood pressure reduction, albuminuria with neutral effect on the sympathetic nervous system, and other favorable effects on the markers of arterial stiffness and vascular resistance [192]. The EMPA-REG OUTCOME study showed that empagliflozin reduced hospitalization and death from heart failure [2.8 vs. 4.5%; HR: 0.61 (0.47–0.79); $P < 0.001$] and was associated with a reduction in all-cause hospitalization [36.8% vs. 39.6%; HR: 0.89 (0.82–0.96); $P = 0.003$], arousing the discussion of HbA1c as the main therapeutic objective to reduce cardiovascular events, leaving the door open to other mechanisms involved in reducing cardiovascular death and hospitalizations for HF beyond of the strict HbA1c targets [193].

Patients with diabetes and HF in the PARADIGM-HF (Prospective Comparison of ARNI [Angiotensin Receptor Neprilysin Inhibitor] With ACEI [Angiotensin-Converting Enzyme Inhibitor] to Determine Impact on Global Mortality and Morbidity in Heart Failure) trial treated with a combination of sacubitril/valsartan had a greater long-term reduction of HbA1c than those receiving enalapril. The de novo use of insulin was 29% lower in patients receiving sacubitril/valsartan ($p = 0.0052$). These data suggest that sacubitril/valsartan may improve glycemic control in patients with diabetes and HF [194].

Pharmacological treatment of the patient with HF with and without diabetes mellitus should include ACE inhibitors, beta-blockers, and aldosterone blockers. Similar benefit has been seen in patients treated with carvedilol in both diabetic and nondiabetic patients (RRR 28% $p = 0.03$ and 37% $p < 0.001$, respectively). There was no significant difference between reducing the risk of death or NNT (number needed to treat) in patients treated with diabetes versus nondiabetics [166].

In the DIG (Digitalis Intervention Group) study, 28.4% of the patients had diabetes. In this study, the addition of digoxin to the treatment of HF reduced hospitalizations secondary to HF without a substantial increase in the risk of toxicity. However, in patients with HF treated with digoxin, it is necessary to identify predictors of toxicity, and strict control of serum levels is important to maintain their benefit [195].

Diseases of the Aorta in Diabetic Patients

Diabetes and Aortic Dissection/Aneurysm

Aortic dissection along with intramural hematoma and penetrating ulcer of the aorta comprise the acute aortic syndromes [196]. Acute aortic dissection is the result of spontaneous tear of the intima, followed by passage of blood between the intima and the aorta. This passage of blood generates a false lumen that progressively compresses the true lumen of the vessel. Clinically, it manifests as an acute and penetrating thoracic pain of sudden onset and of immediate maximum intensity with irradiation toward the back. Pathophysiologically, diabetes mellitus contributes to thickening and fibrosis of the intimal layer and degradation and apoptosis of smooth muscle cells in the media. These processes lead to necrosis and fibrosis of the elastic components of the arterial wall, which in turn produces wall stiffness and weakness, from which dissection and rupture may arise [197]. Although diabetes mellitus does not have a direct causal role in aortic dissection, its role in the development of atherosclerosis contributes to the risk of aortic dissection. Interestingly, a recent study published by Xe et al. demonstrated a paradoxical inverse relationship between DM and risk of aortic dissection in Chinese patients, suggesting that diabetes may play a protective role in the development of aortic dissection. Despite these findings, further information is necessary to elucidate the role of diabetes in aortic dissection [198, 199].

Aortic aneurysm refers to the pathologic enlargement of an aortic segment which tends to progress over time and generally cause no symptoms until they rupture. Atherosclerosis was believed to be the main factor for the development of aortic aneurysms, but recent evidence has shown that aneurysms represent a systemic disease of the vasculature associated with inflammation, smooth muscle cell apoptosis, and matrix degradation. Male gender, hypertension, smoking, and hypercholesterolemia are the main risk factors associated with aortic aneurysms [200]. Diabetic patients with aortic aneurysms are significantly less likely to present with rupture or to die from aneurysm rupture when compared to nondiabetic patients with aortic aneurysms. It is plausible that DM may have a protective effect on aortic aneurysm rupture. Again, further evidence is needed to prove this [201].

Treatment of both aortic dissection and aneurysms is complex and depends on many factors such as hemodynamic status, localization, and anatomical features, all of which are beyond the scope of this chapter.

Diabetes and Aortic Stenosis

Aortic stenosis is the most common primary valve disease in the developed world. It is characterized by a progressive narrowing of the aortic valve orifice due to degeneration, fibrosis, and calcification of the aortic leaflets [202]. This degenerative process has been associated with advanced age and atherosclerosis. Clinically, it manifests with angina, dyspnea, and syncope. A one-year survival among patients with severe aortic stenosis is approximately 50% [203].

Echocardiography is the key diagnostic tool. Aortic peak velocities >4 m/s with mean aortic gradients >40 mm Hg are consistent with severe aortic stenosis regardless of the aortic valve area (severe is >1 cm^2).

Diabetes mellitus has been associated with multiple aspects of aortic stenosis such as the following:

1. Increased inflammation: Patients with diabetes mellitus have accelerated inflammation which leads to calcification. This calcification appears earlier and is more severe than in nondiabetic patients.
2. Stenosis progression. Aortic valve area narrowing is faster in diabetic patients as a result of increased calcium and fibrotic deposits on the valve.
3. Heart failure: As mentioned previously in this chapter, diabetes contributes to left ventricular hypertrophy and with time to systolic dysfunction. The aortic valve stenosis potentiates this effect accelerating the decline in the contractile function of the heart [204].

Aortic valve replacement is the treatment of choice for patients with severe aortic stenosis. Diabetic patients with micro- and macrovascular complications (renal failure, coronary heart disease, neuropathy) have a higher surgical risk based on STS (Society of Thoracic Surgeons) score and EuroSCORE (European System for Cardiac Operative Risk Evaluation) II than nondiabetic patients. Percutaneous implant of an aortic valve (TAVI) has recently shown to be a safe and effective alternative to surgery in high-risk and intermediate-risk patients [205].

Arrhythmias in Diabetic Patients

Special Features of Arrhythmias and Atrioventricular Blocks in Diabetic Patients

In 1972, Rubler [169] introduced the term diabetic cardiomyopathy (DCM) to refer to structural and functional abnormalities of the myocardium in diabetic patients without coronary artery disease, systemic arterial hypertension, or any other morbid entity that affected the functioning of the heart. Interstitial and perivascular fibrosis is the histological landmark of the disease; hypertrophy of cardiomyocytes has also been described, although it does not appear to be a requirement [206]. The loss of normal microvasculature and remodeling of the extracellular matrix are involved and the systolic and diastolic contractile dysfunction of diabetic hearts. It is possible that in DM the increase in fibrosis is involved in the degeneration of the conduction system which may result in an increase in symptomatic bradycardias. Podlaha [207] found the presence of DM in 49.2% of patients with pacemakers and only 38.4% in nondiabetic patients of the same age, gender, and comorbidity. Perhaps more than the degeneration of the conduction system, DCM-related interstitial fibrosis has a greater impact on the progression of ventricular remodeling, which may result in delayed left ventricular depolarization with increased QRS associated with intra- and interventricular dyssynchrony. The response to cardiac resynchronization therapy does not appear to be different between diabetic and nondiabetic patients, but mortality is higher among the first [208]. At the atria, interstitial fibrosis in patients with DCM may also be secondary to oxidative stress, growth factors, and changes in cellular binding proteins [209]. Overall, fibrosis and atrial remodeling have been identified as primary elements in the generation and maintenance of atrial fibrillation (AF) in patients with DCM [210].

Atrial fibrillation is the most frequent sustained cardiac arrhythmia in clinical practice and is one of the most important determinants of increased cardiovascular morbidity and mortality in patients with heart disease and DM. Numerous studies have shown that poorly controlled DM is associated with new-onset AF [211, 212]. Huxley et al. showed that in patients without diabetes, there is a linear trend between the presence of AF and 1% increments in the level of HbA1c [213]. In diabetic patients, HbA1c levels above 6.5% are associated with a 40% increase in the risk of AF presentation especially in women [214].

Although DCM contributes to cardiovascular disease, the one factor that directly increases the risk of mortality is the development of autonomic diabetic neuropathy (ADN). In diabetic patients with severe ADN, the sympathetic-parasympathetic innervation imbalance may contribute to death by ventricular arrhythmias both in the absence and in the presence of ischemic heart disease [215]. Also, in diabetic patients, sympathetic denervation has been shown to be predictive of sudden death, due to a decrease in the ventricular arrhythmogenic threshold, which has greater expression during events of hypoglycemia or metabolic alterations related to hyperglycemia [216]. The prevalence of ADN is estimated to be as high as 50% in diabetic patients [217]. It is possible that at the initial stages of ADN, there is an increase in sympathetic tone which manifests as tachycardia, shortening of QRS and QT interval, increase in QT dispersion, and flattening of T wave. In advanced states, neurological denervation can lead to an increase in the parasympathetic tone that subsequently increases the risk of developing bradycardia, prolongation of QTc, and other alterations in repolarization [218]. During iatrogenic hypoglycemia, prolongation of the QT interval associated with calcium overload and potassium depletion may also lead to ventricular fibrillation risk. The poor sympathetic response to hypoglycemia is not enough to counteract the electrocardiac effects; on the contrary, it may represent a synergic proarrhythmic effect by increasing repolarization alterations [219].

Multiple Choice Questions

1. Pathological mechanisms associated with increased risk of coronary atherosclerosis in patients with diabetes include:
   (a) Vasoconstriction and hypertension of vascular smooth muscle
   (b) Activation of leukocytes/endothelial cells, release of cytokines, and expression of cellular adhesion molecules
   (c) Autonomic dysfunction
   (d) Hypercoagulation
   (e) *All of the above*
2. All of the following statements about diabetic patients are true, except:
   (a) Compared to nondiabetic, patients with diabetes have two- to threefold higher rate of coronary disease and are at increased risk of myocardial infarction, congestive heart failure, and death.
   (b) Compared to nondiabetic, patients with diabetes have twofold higher rate of systemic arterial hypertension.
   (c) The current guidelines suggest that therapeutic target of blood pressure control is less than 140/90 mmHg.
   (d) Antihypertensive treatment in patients with chronic renal disease should include an angiotensin-converting enzyme inhibitor or an angiotensin receptor blocker.
   (e) *The majority of patients require only one antihypertensive drug to achieve the goal blood pressure*.
3. If a patient tolerates the intensive dose of a statin, what is the best option to do next?
   (a) Increase the dose until the patient starts with secondary effects.
   (b) *Decrease the dose until LDL is over 70 mg/dL.*
   (c) Keep the dose.
   (d) Decrease the dose until HDL starts falling.
   (e) Add ezetimibe in all cases.
4. Dyspnea may be caused by which antiplatelet agent:
   (a) Aspirin
   (b) Clopidogrel
   (c) Prasugrel
   (d) *Ticagrelor*
   (e) Ticlopidine
5. In diabetic patients, what drug has been approved as first-line hypoglycemic drug to reduce cardiovascular events?
   (a) Gliclazide
   (b) Metformin
   (c) Alogliptin
   (d) *Empagliflozin*
   (e) Pioglitazone
6. In diabetic patients with known coronary artery disease, an HbA1c target of less than ___ is recommended:
   (a) 6%
   (b) 6.5%
   (c) 6.8%
   (d) *7%*
   (e) 7.5%
7. What is the most frequent sustained cardiac arrhythmia and one of the most important factors in the increase of cardiovascular morbidity and mortality in patients with diabetes?
   (a) Ventricular fibrillation
   (b) *Atrial fibrillation*
   (c) First-degree AV block
   (d) Third-degree AV block
   (e) Atrial flutter
8. What drug was associated with a reduction in the incidence of heart failure?
   (a) Ramipril
   (b) Sacubitril/valsartan
   (c) Carvedilol
   (d) *Spironolactone (aldosterone antagonist)*
   (e) All of the above
9. Which of the following risk factors is not associated with aortic aneurysms and may have a protective effect on aortic aneurysm rupture?
   (a) Male gender
   (b) Hypertension
   (c) Smoking
   (d) Hypercholesterolemia
   (e) *Diabetes*
10. In general, what is the preferred method of coronary perfusion in patients with an acute coronary ischemic syndrome, with or without diabetes?
   (a) Fibrinolytic therapy
   (b) Coronary artery bypass grafting
   (c) *Percutaneous coronary intervention*
   (d) Aspirin
   (e) Statins

Diabetes and Stroke: The Role of Glucose Regulation

51

Forrest Lowe, Wuwei Feng, and Carlos Cantú-Brito

Stroke as a Long-Term Complication of Uncontrolled Diabetes Mellitus

Introduction

The relationship between stroke and diabetes mellitus (DM) though complex is undeniable. Numerous studies have delineated a clear correlation between prediabetes, diabetes mellitus type 1, and diabetes mellitus type 2 as they relate to cerebrovascular disease with decades of research detailing the causality between hyperglycemia and stroke risk. The global prevalence of stroke continues to rise despite the advances in treatment options for cardiovascular risk factor modification such as diabetes. Diabetics represent a subset of the patients who are at 2–3 times higher risk of mortality from stroke than the general population [1]. The purpose of this chapter is to look over essential epidemiological concerns about DM and stroke and mainly to detail the microvascular and macrovascular mechanisms that promote cerebrovascular disease in diabetics which leads to stroke. Subsequently, the remarkable role of hyperglycemia in acute ischemic stroke will be revised. Additionally, the importance of glucose control for both primary and secondary stroke prevention will be discussed in terms of the role of therapeutical options for attaining normoglycemia. Finally, there will be in-depth discussion of the optimization of diabetic control as it relates to other stroke risk factors such as atherosclerosis, hypertension, and atrial fibrillation.

Epidemiological Overview of Diabetes and Stroke

In 2019, according to the global burden of disease collaborators, stroke remains as the second leading cause of death and the third leading cause of death and disability combined (as measured by disability-adjusted life-years [DALYs]) in the world [2]. DM is included within the five leading specific risk factors contributing to stroke DALYs, with a population attributable fraction (PAF) of 20.2% (95% uncertainty intervals [UIs] 13.8–29.1) of all stroke DALYs. It should be noted that among cerebrovascular diseases, DM is usually associated with the ischemic stroke type (PAF 19.5% [(10.6–34.6)]), ranking as the third most important risk factor for this type of stroke. However, in the last years, it is becoming evident that DM is also associated with hemorrhagic strokes: the PAF for intracerebral hemorrhage is 17.3% (11.2–24.8) and for subarachnoid hemorrhage of 16.8 (11.0–23.4), ranking as the fourth and five most important risk factors, respectively, for these stroke types.

The large increase in the global burden of stroke is probably not only due to population growth and aging but also because of the substantial increase in exposure to several important risk factors such as high BMI, high fasting plasma glucose, high systolic blood pressure, and low physical activity. DM is among the risk factors with an outstanding increase in the age-standardized stroke PAF from 1990 to 2019 (from 14.4% to 20.2%), corresponding to a 40.3% increase. In other words, if high fasting plasma glucose exposure were reduced to its theoretical minimum risk exposure level, there would be a 20.2% reduction in stroke in 2019 [2].

Microvascular Complications of Diabetes

Diabetes mellitus is a modifiable risk factor for ischemic stroke and is defined by one of the following: a fasting blood glucose (fbg) of ≥ 126, a hemoglobin A1C (HbA1C) of ≥ 6.5%, 2 h postprandial glucose of ≥ 200 mg/dL after

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-031-25519-9_51

administration of a 75 g glucose tolerance test, or a random serum glucose ≥ 200 mg/dL in a patient with classic signs of hyperglycemia/hypoglycemia [3]. The pathophysiology of DM is complex and its interrelation with the development of cerebrovascular disease is well studied. However, the microvascular and macrovascular changes that occur due to persistent hyperglycemia have not been fully elucidated. Microvascular changes within cerebrovasculature and systemic vasculature occur through multiple cellular pathways that are directly modulated by fluctuations of serum glucose.

Microvascular changes due to hyperglycemia, which are noted on both the cellular and genetic levels, occur due to a chronic, systemic, inflammatory state induced by the production of reactive oxygen species (ROS) with early changes noted on both the cellular and genetic levels. The sources of the ROS are diverse and include excess superoxide production via mitochondria, direct oxidation of serum glucose, endothelial cell nitrogen oxygen synthase (eNOS), NADPH (nicotinamide adenine dinucleotide phosphate) oxidase activation from abundance of advanced glycosylation end products (AGEs) [4], and the upregulation of mitochondrial matrix metalloproteinase (MMP-9) [5]. The dysfunction of microvascular endothelium begins to occur via these pathways in addition to many others that are far less well understood and mimic the changes found in the vasculature that is exposed to chronic inflammatory processes.

Chronic hyperglycemia causes abnormal production of ROS from normal glycolytic processes that metabolize glucose and results in excess side products including ROS which overwhelm the cellular antioxidants such as superoxide dismutase and glutathione peroxidase. To prevent continued production of ROS, many systemic cells will downregulate glucose transporters (GLUTs). However, endothelial cells normally express non-insulin-dependent GLUTs which allows for continued intracellular glycolytic generation of ROS. In addition to continued generation of ROS via glycolysis, mitochondrial dysfunction begins to occur with persistent hyperglycemia inducing a chain reaction during which multiple intracellular pathways are activated leading to further endothelial dysfunction [4].

Electron transport chain uncoupling within mitochondria propagates unmitigated binding of ROS to available intracellular oxygen further promoting oxidative stress. Indeed in numerous studies, it has been shown that inhibition of ROS production within endothelial mitochondria prevents the cumulative oxidative endothelial cell dysfunction in the setting of hyperglycemia. Apoptotic events, genetic expression of pro-inflammatory markers, and nitrogen oxide inhibition are all mitigated by inhibition of mitochondrial free radical production due to hyperglycemia [3]. In one study, Mishiro et al. demonstrated that the mitochondrial involvement in endothelial cell dysfunction is more complex than previously discerned in that hyperglycemia not only disrupts normal metabolic processes but also alters mitochondrial membrane permeability to the point of self-induced organelle apoptosis, MMP-9 production, and death of endothelial cells comprising the cerebral microvasculature [5].

Advanced glycation end products (AGEs) are byproducts of glycosylated proteins or lipids that normally occur in the presence of hyperglycemia. The exact mechanism by which AGEs are derived is via the Maillard reaction which in short produces ketoamine that form AGEs via a dual pathway. In the setting of sustained hyperglycemia such as that which exists in diabetes mellitus or even in prediabetic states, these AGEs accumulate rapidly and are deposited within various tissues. Receptors for advance glycosylation end products, RAGE, exist in normal endothelial cells and not only can prevent endothelial cell repair but also promote infiltration of the vascular endothelium by inflammatory cells. Activation of RAGE and its promoted binding to AGE in DM causes endothelial cell dysfunction which manifests in some DM patients as diabetic microangiopathy [6]. However, not all AGE-related endothelial cell dysfunction are RAGE dependent [4].

RAGE-independent endothelial dysfunction can occur due to glycation of LDL (low-density lipoprotein), extracellular cell matrix proteins, or activation of signaling proteins other than RAGE [4]. Kim et al. noted that AGE overproduction causes excessive LDL modification as well as increased expression of CD36 ligands [7]. This CD36 expression occurs predominantly in monocytes and blunts the inflammatory reaction that occurs in DM patients who experience endothelial cell injury thereby inhibiting proper endothelial repair [7]. Similarly, in the setting of hyperinsulinemia commonly present in DMII patients, macrophages derived from monocytes demonstrate insulin receptor dysfunction which is pro-atherogenic in the setting of an already compromised endothelial integrity [8].

It is also important to note that other inflammatory proteins such as monocyte chemoattractant protein-1 (MCP-1) and IL-6 are also upregulated in diabetics with the elevation of MCP-1 causing both increased macrophage recruitment and increased adipocyte insulin resistance. In fact, many inflammatory markers such as C-reactive protein (CRP), intracellular adhesion molecule 1 (ICAM-1), and vascular cell adhesion molecule 1 (VCAM-1) are overexpressed in hyperglycemia not only in the diabetic but also in normal subjects who experience impaired glucose tolerance (IGT) or postprandial hyperglycemia [9]. Persistent hyperglycemia in DMII leads to concomitant improper physiologic response yielding a state of chronic hyperinsulinemia due to insulin resistance which in and of itself is disruptive to the integrity of cerebrovascular endothelium [8].

In animal studies involving cardiac endothelium, per Bornfeldt et al., hyperinsulinemia led to downregulation of

insulin-mediated endothelial pathways that promote alteration of endothelial gene expression and production of transmembranous proteins [8]. Sustained elevation of serum insulin causes saturation of insulin receptors and increased activation of 3-phosphoinositide-dependent protein kinase 1 (PDK1) which through a series of reactions promotes increased transcription of metabolic genes [8]. The epigenetic and genetic changes induced by chronic hyperglycemia can persist even years after serum glucose is controlled [10]. Consequently, these metabolic genes allow for increased rates of glycolysis, lipid synthesis, and GLUT (glucose transporter) production. Additionally, when vascular smooth muscle cells are exposed to hyperinsulinemia, they demonstrate activation of pathways influenced by insulin-like growth factor-1 receptors (IGF1R) that are known to be proatherogenic [8]. All of these pathways, as noted in Fig. 51.1, lead to ROS overproduction, glycolysis upregulation, and genetic modifications.

Disruption of vasculature endothelium at the microvascular level in diabetics is most commonly seen in diabetics in the form of complications such as microangiopathy, arterial retinopathy, nephropathy, and peripheral neuropathy. Moreover, emerging evidence has demonstrated that cerebral microvascular dysfunction and damage in DM are common as depicted mainly by MRI (magnetic resonance imaging) showing typical features of cerebral small vessel disease [11]. Indeed, microvascular involvement of other known areas such as retinal microvascular abnormalities in patients with type 2 diabetes correlates with the presence of cerebral small vessel lesions [12]. Optimal brain function depends on a healthy microvasculature including the delivery of nutrients and removal of waste products in response to changes in neuronal activity maintaining the interstitial milieu for proper function of the so-called neurovascular unit (a complex interaction of several cell types including endothelial cells, astrocytes, pericytes, and neurons). In addition, cerebral microvasculature is a crucial site of the blood-brain barrier that protects the neurons from external factors and maintains the internal milieu within the CNS (central nervous system) highly regulated and also decreases and stabilizes the pulsatile hydrostatic pressure at the level of capillaries and participates in the cerebrovascular reactivity and cerebral autoregulation that regulates and maintains global brain perfusion. Cerebral microvascular dysfunction

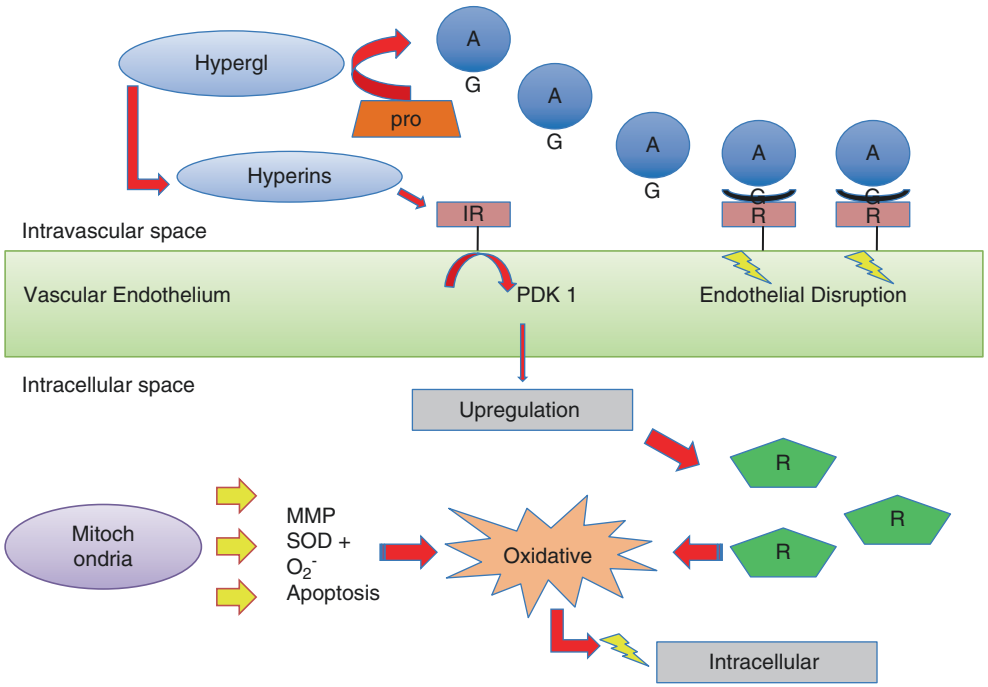

Fig. 51.1 Process of hyperglycemia-induced vascular endothelial dysfunction. Chronic hyperglycemia causes glycosylation of both fats and lipids resulting in the production of advanced glycosylated end products (AGEs). AGEs bind to receptors for advanced glycosylation end products resulting in endothelial disruption. Hyperglycemia results in concomitant hyperinsulinemia that can cause oversaturation of insulin receptors as well as overproduction of 3-phosphoinositide-dependent protein kinase (PDK1). PDK1 overproduction causes upregulation of glycolysis and subsequent overproduction of reactive oxygen species (ROS). Mitochondrial dysfunction under the influence of chronic hyperglycemia can result in overproduction of mitochondrial matrix metalloproteinase (MMP-9), superoxide dismutase, and organelle-induced apoptosis. All of these mitochondrial products as well as glycolytic-induced ROS lead to oxidative stress resulting in intracellular dysfunction, abnormal metabolic gene transcription/upregulation allowing for increased rates of glycolysis, lipid synthesis, and GLUT transporter production. *AGE* advanced glycosylated end products, *RAGE* receptor for AGEs, *PDK1* 3-phosphoinositide-dependent protein kinase, *IR* insulin receptor, *MMP* mitochondrial matrix metalloproteinase, *SOD* superoxide dismutase, and *ROS* reactive oxygen species

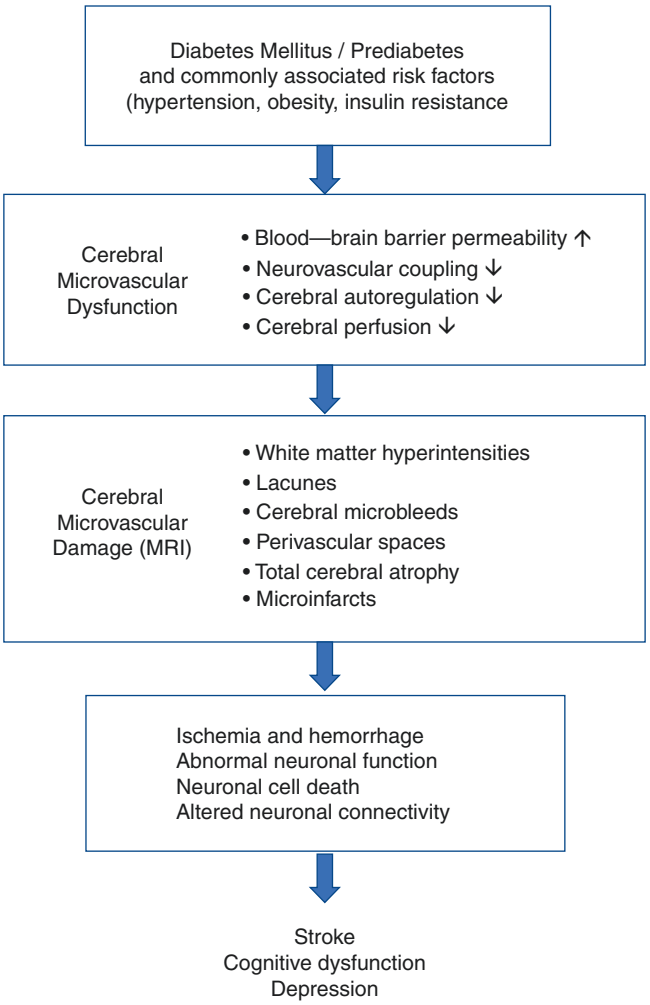

Fig. 51.2 Assumed pathway by which type DM-related cerebral microvascular dysfunction contributes to stroke and other mental disorders such as cognitive dysfunction and depression. Prediabetes and DM and commonly associated risk factors (hypertension, obesity, and insulin resistance) induce cerebral microvascular damage and dysfunction including an increase of permeability of the blood-brain barrier and decrease of neurovascular unit coupling and cerebral autoregulation as well as reduction of cerebral perfusion. These abnormalities give rise to the typical features of cerebral small vessel disease as depicted by MRI (see Fig. 51.3) and manifested clinically as stroke, cognitive disorders, and depression. (Modified from Fig. 2, [11])

may be defined as an impairment in any of these previous functions. Figure 51.2 summarized the assumed pathway by which type 2 diabetes-related cerebral microvascular dysfunction contributes to stroke and other mental disorders such as cognitive dysfunction and depression [11]. Figure 51.3 shows illustrative lesions of small vessel disease commonly observed by MRI in patients with diabetes.

Furthermore, microvascular complications were initially delineated in the landmark UK Prospective Diabetes Study (UKPDS). This was the first comprehensive study to demonstrate that strict regulation of serum glucose levels can prevent microvascular complications of hyperglycemia [13]. The data derived from this prospective study of DMII patients noted that over a period of ten years if aggressive glucose control was achieved via sulphonylurea or insulin administration, there was a significant reduction in microvascular complications regardless of intervention. Up to a 25% reduction in nephropathy and ophthalmic complications was noted in the patient arm randomized to receive intensive serum glucose control. Additionally, the final average HbA1C of patients under intensive glucose control was 11% lower with a median value of 7% which directly corresponded to an improved rate of microvascular complications in that study arm. No macrovascular benefit was observed in either study arm nor were significant deleterious macrovascular outcomes [13].

Further studies such as the Action to Control Cardiovascular Risk in Diabetes Mellitus (ACCORD) evaluated whether even more aggressive serum glucose control than that achieved by patients in UKPDS would further prevent microvascular disease. However, the ACCORD study with its target HbA1C of 6% was stopped prematurely due to a significantly increased mortality rate in the intensive therapy treatment arm [14]. Unsurprisingly, it was noted in the Heart Outcomes Prevention Evaluation (HOPE) trial that concomitant treatment of hypertension and hyperlipidemia (HLD) in diabetics leads to improved outcomes with significantly decreased frequency of microvascular complications [15]. These significant interactions between hyperglycemia and hyperlipidemia as they relate to increased risk of ischemic stroke on the microvascular level are complex and exist in both the prediabetic and diabetes mellitus patients.

As mentioned in the preceding paragraphs, persistent hyperglycemia activates the AGE/RAGE complex. Interestingly, the blockade of the excess activation of the ligand/receptor complex decreases atherosclerotic formation as well as diabetic nephropathy in hyperglycemia [9]. Increased production of vascular smooth muscle cells (VSMCs) is also encouraged during periods of hyperglycemia and has been demonstrated in DMI and DMII. Though the pathways responsible for atherosclerotic formation in diabetics are not fully understood, it is likely that vascular endothelial injury is caused by hyperglycemia which is directly responsible for creating a pro-inflammatory state promoting VSMC proliferation, microangiopathy, and microvascular changes [16]. It is this pro-inflammatory state created by hyperglycemia that forces endothelial cells such as those present in the retinal vasculature to overexpress factors such as vascular endothelial growth factor (VEGF) in order to survive in an ischemic environment [9]. According to Prasad et al., VEGF also was found in animal studies to increase vascular permeability resulting in microvascular changes as well as compromise of the blood barrier itself even in the setting of only transient hyperglycemic events [17].

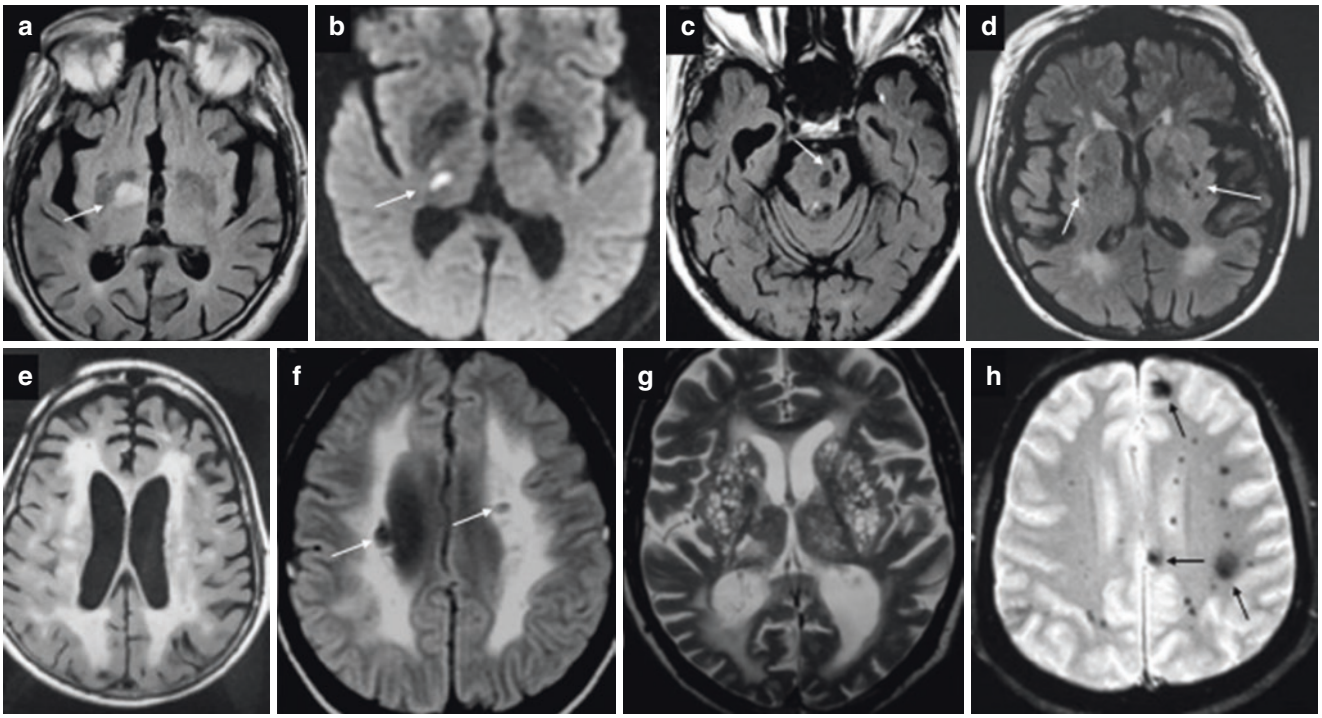

Fig. 51.3 MRI imaging characteristics of features of cerebral small vessel disease commonly seen in patients with diabetes. (**a**) FLAIR sequence depicts a thalamic lacunar infarct (arrow). (**b**) Diffusion-weighted shows a hyperintense lesion corresponding to an acute small deep (lacunar) infarct (arrow): less than 2 cm diameter. (**c**) T1-weighted imaging with a hypointense lesions in the pons corresponding to old lacunar infarcts (arrow). (**d**) FLAIR sequence showing multiple small deep lacunar infarcts (arrows). (**e**) FLAIR imaging of typical large confluent areas of white matter hyperintensities (WMH) extending from the periventricular to the center of the bilateral semioval tissues. (**f**) FLAIR imaging of WMH similar to (**e**) but including hypointense lesions (old lacunar infarcts) within the WMH (arrows). (**g**) Extensive areas of perivascular spaces on T2-weighted imaging are hyperintense because they contain CSF-like fluid, less than 3 mm diameter, seen bilaterally in the basal ganglia. (**h**) Multiple foci of microbleeds within cortex and subcortical structures on gradient-echo T2 imaging (larger lesions with arrows)

Macrovascular Complications of Diabetes

Macrovascular changes due to hyperglycemia have been shown to result in neointimal expansion after the initial endothelial injuries have begun to accumulate within the diabetic patients. Normal vascular neointimal healing and formation are adversely affected by hyperglycemia creating systemic vasculature that is abnormally thickened by abnormally proliferating VSMCs [18] leading to noncompliant vasculature, hypertension, and increased stroke risk. Involvement of multiple cerebrovascular territories including vasculature to the blood brain barrier is also compromised in the setting of hyperglycemia with dysfunction of arterial smooth muscle elasticity leading to stenosis, ischemia, and stroke [19]. Other animal studies demonstrate that cerebral arterioles likely undergo deleterious changes to endothelium more rapidly than larger cerebrovasculature such as the basilar or carotid arteries [20]. According to Zhou et al., animal studies in which arterial injury was created via balloon dilatation resulted in hyperplasia of the neointima likely due to a pro-inflammatory vascular environment from both hyperglycemia and hyperinsulinemia [21]. In summary, these animal studies demonstrating the microvascular and macrovascular effects of hyperglycemia and atherosclerosis were later partially confirmed in several human trials. The Action in Diabetes and Vascular Disease (ADVANCE) trial showed that microvascular events were significantly decreased in diabetics though the mitigation of macrovascular complication did not reach significance. The targeted HbA1C of the ADVANCE (Action in Diabetes and Vascular Disease-PreterAx and DiamicroN Controlled Evaluation) trial was 6.5% in the intensive treatment arm with the most significant benefit evident in the rate of nephropathy complications which were decreased by 21%. Later trials including the Veterans Affairs Diabetes Trial (VADT) as well as the Diabetes Control and Complications Trial (DCCT) also demonstrated similar results in short-term monitoring of the intensive treatment arms in both studies again showing significant improvement in microvascular outcomes with non-significant macrovascular event decrements. However, after longitudinal follow-up in the DCCT patients, it was determined that patients in the intensive glucose control arm did, in fact, demonstrate a significant reduction in ischemic car-

diac diseases, strokes, or CV deaths (n = 711 patients in intensive treatment arm vs. n = 730 in conventional treatment arm, p = 0.02) [20]. This was in agreement with prior data that noted diabetics were up to ten times more likely to suffer CAD (coronary artery disease), peripheral vascular disease (PVD), or stroke compared to nondiabetics [22].

DM and Hyperglycemia in Acute Ischemic Stroke

One of the conditions adversely affecting outcome in patients with acute ischemic stroke is hyperglycemia. Hyperglycemic diabetic patients admitted to the hospital for acute ischemic stroke are up to two times more likely to die within the first month compared to normoglycemic patients. Lau et al. [23], in a meta-analysis of 39 studies, report a significant relationship between DM and mortality, and poor neurological and functional outcomes. They also found an association with length of hospital stay, readmission rate, and stroke recurrence. Also, the Get With The Guidelines Stroke registry found a similarly significant association between acute ischemic stroke patients with DM and mortality as well as readmission three years post-discharge in an analysis of 409,060 American patients with cerebral ischemia including transient ischemic attack [24]. Several factors may potentiate the increased risk of stroke in DM patients, including endothelial dysfunction, arterial stiffness, and systemic and local inflammation. Also, diabetes and postischemic acute hyperglycemia are likely to be associated with poor reperfusion and recanalization outcomes due to several factors including vascular injury, clot composition, and impaired collaterals; and then, hyperglycemia appears to interfere with the efficacy of reperfusion therapies (Fig. 51.4) [25]. Several studies investigating the impact of thrombolysis and thrombectomy show significantly worse outcomes measure by the Modified Rankin Score between DM and non-DM groups. However, this association has not been found in several other reperfusion studies, and therefore, patients with DM and acute ischemic stroke should receive reperfusion therapy, in particular thrombolysis within a 3 h time window. Although current standards of care, indicated by the 2019 AHA (American Heart Association) guidelines, do not recommend intravenous thrombolysis treatment for patients within a 3–4.5 h time window with a history of concurrent DM and prior stroke, further large-scale studies on the relationship between DM and prior stroke properly determine its use in this population [26].

In spite that hyperglycemia is present in approximately 40% of patients with acute ischemic stroke and is associated with worse clinical outcomes, the efficacy of intensive treatment of hyperglycemia in this setting has been disappointed. Current acute stroke guidelines from the American Stroke Association suggest treating hyperglycemia to achieve a blood glucose level in the range of 140–180 mg/dL (7.8–10.0 mmol/L) and close monitoring to prevent hypoglycemia [26]. The Stroke Hyperglycemia Insulin Network Effort (SHINE) randomized clinical trial was conducted to assess the efficacy of intensive versus standard blood glucose control in 1151 patients with hyperglycemic acute ischemic stroke who received either intensive treatment of hyperglycemia (target blood glucose concentration of 80–130 mg/dL) or standard treatment of hyperglycemia (target glucose concentration of 80–179 mg/dL). Intensive compared with standard glucose control did not improve 90-day functional outcomes

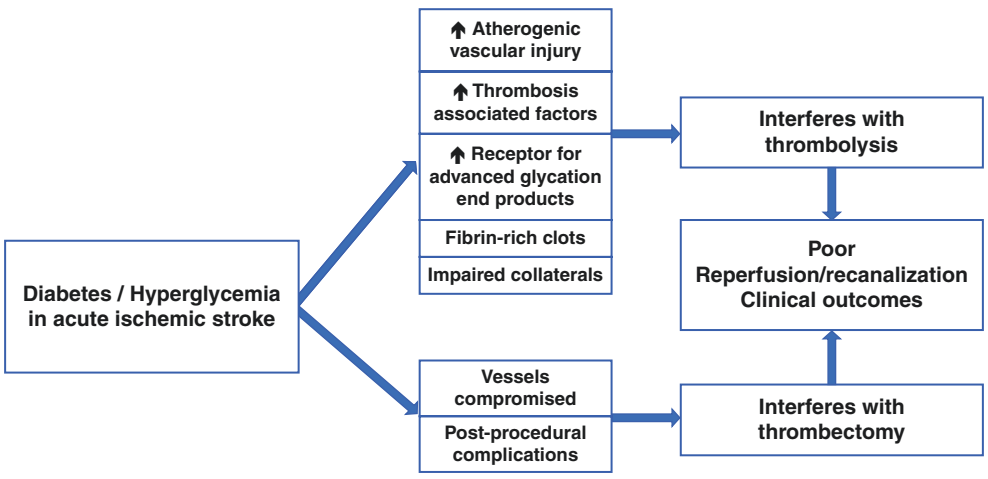

Fig. 51.4 Reperfusion outcomes in patients with diabetes and acute ischemic stroke presenting with acute hyperglycemia. Diabetes and acute hyperglycemia are likely to be associated with poor reperfusion and recanalization outcomes in patients with acute ischemic stroke, due to several factors including vascular injury, clot composition, and impaired collaterals; and then, hyperglycemia appears to interfere with the efficacy of reperfusion therapies (thrombolysis or thrombectomy). (Modified from Fig. 4, [25])

in patients with acute ischemic stroke and hyperglycemia. These findings do not support using intensive glucose control in this setting [27].

On the other hand, though the primary purpose of both parenteral insulin and oral diabetic medications is to prevent hyperglycemia, there is data that suggests that certain classes of these drugs may improve outcomes during the acute phase of an ischemic stroke, through the so-called neuroprotection process. Neuroprotection for stroke defines any strategy directly targeting brain parenchyma with the goal of antagonizing the harmful molecular and cellular events responsible for the ischemic damage thereby allowing brain cells to survive to reduced cerebral blood flow [28, 29]. White et al. noted that in a systematic review of animal studies, the administration of TZDs (thiazolidinediones) during the time of cerebral ischemic injury was associated with improved neurologic outcomes and a decrement in the overall stroke burden [30]. Though these studies have not yet been extrapolated for validity in human subjects, it is noteworthy that rosiglitazone reduced infarct volume regardless of administration before or after induction of ischemia in rat brains [28]. Interestingly, GLP-1 Ras and DPP-IVIs are endowed with a variety of pleiotropic (neuroprotective) properties demonstrated in experimental stroke models, suggesting a possible role in the treatment of acute cerebral ischemia [31]. Considering that they share several neuroprotective effects, an adequate basis exists for explorative clinical investigations on additive GLP-1 agonist plus DPP (dipeptidyl peptidase)-IVI treatment of hyperglycemia in patients with acute ischemic stroke. This strategy would assume that, while GLP-1R agonists directly interact with cerebral receptors, the action of DPP-IVIs is mediated by increasing the effects of GLP-1 including pleiotropic effects. This therapeutic option represents a basically novel strategy to confront hyperglycemia in acute ischemic stroke [31].

Diabetes and Primary Stroke Prevention

Ischemic stroke is a direct complication of diabetes with a complex interplay of multiple risk factors for cerebrovascular disease including hypertension, atherosclerosis, smoking, atrial fibrillation, and a myriad of less well-studied pathophysiological processes of contributors such as obstructive sleep apnea (Table 51.1). Macrovascular complications of hyperglycemia have been less well studied and are more difficult to directly correlate with a specific glucose control target for treatment as has been noted in UKPDS, ACCORD, and ADVANCE trials. Fortunately, microvascular complications as they relate to target HbA1C have been easier to correlate with longitudinal study data, and the cellular pathways by which hyperglycemia affects vascular endothelial cell dysfunction are beginning to be better understood. Primary prevention of ischemic stroke clearly requires hyperglycemic control, but the degree of glycemic control and its effect on other primary stroke risk factors is of equal importance for stroke prevention [32].

A review of the most current literatures reveals that primary stroke prevention is dependent on chronic control of hyperglycemia with a target HbA1C of < 7% as well as the monitoring of both fasting serum glucose and postprandial dysglycemia. What the ACCORD, ADVANCE, and VADT trials helped demonstrate was that all diabetics benefited from a target HbA1C of around 7% regardless of their baseline HbA1C, duration of disease, or baseline comorbidities. More intensive glucose control can lead to increased mortality in some subgroups while in young patients with DM disease duration of less than 15 years may in fact benefit from intensive glucose control with a lower target HbA1C [33].

The Nateglinide and Valsartan in Impaired Glucose Tolerance Outcomes Research (NAVIGATOR) trial demonstrated that patients with impaired fasting blood glucose, although not meeting diagnostic criteria for diabetes, were at increased risk of developing DM and subsequently at higher

Table 51.1 AHA/ADA guidelines for primary stroke prevention

Diabetes	Hyperlipidemia	Hypertension	Atrial fibrillation	Other risk factors
BP goal <140/90 mmHg	Statin use for patients with high CV risk	Lifestyle changes and BP screening[a]	Coumadin for CHA_2DS_2-VASc score ≥ 2[b]	Weight reduction if BMI ≥ 25
Statin use for CV risk reduction	Fibric acid derivatives only for elevated triglycerides[c]	Goal BP of <140/90, reduction more important than BP agent used	Nonvalvular AF and CHA_2DS_2-VASc of 0, no anticoagulants	Smoking cessation in all patients
No role for aspirin or fibrates	No role for statin lipid-lowering medications	Self-measurement of BP	Screening for AF in patients 65 or older with exam and EKG	40 min, three days/week moderate exercise

ADA guidelines per the following: Cefulu W et al. "American Diabetes Association: Standards of Medical Care in Diabetes—2015," *The Journal of Clinical and Applied Research and Education: Diabetes Care* 2015; 38 (1): S1–S93

[a]*BP* blood pressure, *CHA2DS2-VASc* congestive heart failure, hypertension, age, diabetes, stroke, and vascular disease, *CV* cardiovascular, *AF* atrial fibrillation, and *BMI* body mass index

[b]In patients with low hemorrhage risk and valvular AF (atrial fibrillation)

[c]No role for fibric acid derivatives in decreasing future stroke risk

risk for ischemic stroke [22]. According to Mi et al., elevated fasting blood glucose was an independent predictor for first-ever ischemic stroke or recurrent stroke [34]. Additionally, it has been surmised for years that prediabetic or diabetic patients who experience repeated episodes of dysglycemia are at higher risk of cerebrovascular disease and dysfunction of the neurovascular endothelium [35]. However, data from trials to date such as NAVIGATOR are conflicting, and it is not currently understood how to best reduce cardiovascular risks in patients with impaired fasting blood glucose or postprandial glucose [36]. What has been better studied is the impact that various antidiabetic drug classes have on benefiting patients in primary stroke prevention.

Influence of Antidiabetic Drug Classes for Primary Stroke Prevention

Though DMI patients typically use forms of synthetic insulin for glycemic control, it is well known that DMII diabetics have a wide range of oral medications available for the treatment of hyperglycemia. These diabetic drugs (Table 51.2) include multiple medications with varying mechanisms of action and benefit for treating hyperglycemia as it pertains to primary stroke prevention. In addition to reviewing these medications by drug class, it is also important to address the use of these medications around the time of an ischemic stroke as some antihyperglycemics such as thiazolidinediones can potentially improve patient outcomes [30].

The use of parenteral insulin is the most obvious and well-studied mechanism to control hyperglycemia in DMI patients. In DMI and DMII patients self-administering glargine or NPH compared to basal insulin peglispro, there has been no reported clinically significant difference in preventing future ischemic strokes or CV events. There has been associated cardiovascular benefit with insulin use and improvement of comorbid stroke risk factors outside of the documented physiologic benefits of achieving normoglycemia. Interestingly, prior studies in type 2 diabetes mellitus patients have noted that long-acting insulin formulations may be implicated in exacerbating CAD leading to increased risk of myocardial infarcts [37]. A cross-sectional, international cohort study performed by Al-Rubeaan et al. as well as studies derived by data from the Hong Kong Diabetes Registry noted clinically significant elevation in stroke risk for patients using insulin for control of hyperglycemia [38]. However, this associated stroke risk was possibly due to the fact that type 2 DM patients who are parenteral insulin users

Table 51.2 Diabetic drug classes and primary stroke prevention

Hyperglycemic medication	Mechanism of action	Stroke risk factors	Side effects	Supporting studies	Important findings
IV insulin (glargine, NPH)	Serum glucose absorption	Hyperglycemia, CAD	Hypoglycemia	UKPDS	Macrovascular outcomes similar to oral antihyperglycemics
Biguanides (metformin)	Decreased hepatic gluconeogenesis	HLD, CAD, HTN	Hypoglycemia Weight gain	UKPDS Gejl et al.	Improved outcomes in the obese
Sulfonylureas (glipizide, glyburide)	Pancreatic secretagogue	Hyperglycemia[a]	Cardiac deaths	UKPDS Azimova et al.	↓ mortality in DM patients
Meglitinides (nateglinide)	Pancreatic Secretagogue	Hyperglycemia	Hyperglycemia	NAVIGATOR Azimova et al.	No improvement in CV outcomes in IGT/DM patients
DDP-4 inhibitors (sitagliptin)	Inhibit incretin, GLP-1, GIP degradation[b]	Postprandial hyperglycemia	CKD (rare)	Azimova et al. Fisman et al. Enders et al.	↓ risk of CV outcomes Rate of MI or stroke in DM patients unchanged
Glucosidase inhibitors (acarbose)	Intestinal α-glucosidase inhibitor	Postprandial hyperglycemia HTN	GI side effects, hepatotoxicity (rare)	STOP-NIDDM	Acarbose can prevent conversion of IGT patients to DM status
Thiazolidinediones (pioglitazone)	PPAR activators	HTN	HLD CAD exacerbation	Azimova et al. White et al.	Pioglitazone ↓ risk for macrovascular events in high-risk patients
GLP-1 (exenatide, liraglutide)	Inhibits glucagon Insulin secretagogue	Weight loss, HTN, and HLD	GI side effects	Azimova et al. Mearns et al.	20% ↓ risk of CVD in DM II patients
SGL2 inhibitors (gliflozins)	Sodium glucose cotransporter inhibitor	HTN, HLD, and weight loss	AKI and CKD	Mearns et al.	Reduces SBP ↑ weight loss
Bile acid sequestrant (colesevelam)	Binds intestinal bile acids	HLD and CAD	None	Ganda et al. Porez et al.	↓ future CV events

[a]Did not reach significance for macrovascular outcomes

[b]*GLP-1* glucagon-like peptide 1 receptor, *GIP* glucose-dependent insulinotropic peptide, *DDP-4* dipeptidyl peptidase-4 inhibitors, *GLP-1* glucagon-like peptide 1, *SGL2* sodium glucose cotransporter, *GIP* gastric inhibitory polypeptide, *PPAR* peroxisome proliferator-activated receptors, *CAD* cardiac arterial disease, *HLD* hyperlipidemia, *HTN* hypertension, *CKD* chronic kidney disease, *AKI* acute kidney disease, *GI* gastrointestinal, *DM* diabetes mellitus, *CV* cerebrovascular, *IGT* impaired glucose tolerance, *MI* myocardial infarct, and *SBP* systolic blood pressure

have poorly controlled hyperglycemia [38]. Treating hyperglycemia with oral agents in DMII patients is more complex than just parenteral insulin formulations; however, many options exist for treating this patient population.

Biguanides such as metformin are a class of oral antihyperglycemics currently available for treating DMII. Metformin was used in the UKPDS trial and demonstrated a 32% relative risk reduction of cardiac ischemia and ischemic stroke in diabetics as well as 42% reduction in all macrovascular deaths related to diabetes. Interestingly, the combination of metformin and injected insulin in the same study demonstrated a significantly decreased risk for the development of macrovascular disease including ischemic stroke when patients were followed for over four years after completion of the study [39]. These data are significant in so far as that it has been documented that newly diagnosed DMII patients have a 10% increased absolute risk of stroke within five years of initial diagnosis [40]. Treatment of DMII with metformin not only decreases the increased absolute risk of ischemic stroke but also may help treat comorbid risk factors such as hypertension and hyperlipidemia, thereby further decreasing the risk of future ischemic stroke (Table 51.1) [39].

According to Gejl et al., the biguanide drug class may affect multiple stroke risk factors such as hyperglycemia and hyperlipidemia yielding a decrease in the occurrence of major cardiac or cerebral ischemic events [41]. Similarly, in large retrospective cohort studies comparing diabetics treated with metformin and diabetics treated with antihyperglycemics not including metformin, there was a significantly lower risk of stroke with an adjusted hazard ratio of 47 in the metformin group [39]. Metformin's mechanism of action in reducing cholesterol levels is not completely understood but may involve decreasing hepatic secretion of lipoproteins resulting in lower VLDL, plasma triglycerides, and LDL/HDL ratio. The cardioprotective effects of metformin in animal studies have also been well documented, and it is likely that diabetics who have an MI while on metformin have a reduction in both MI size and burden of reperfusion injury [42]. The mechanism by which metformin decreases hypertension in the diabetic is less well understood.

Sulfonylureas such as glipizide and glyburide have been long used to treat DMII, but a large body of evidence has provided conflicting data on this drug class's cardiac profile especially in patients with pre-existing CAD [39]. Per data in the UKPDS trials, intensive treatment of DMII patients with sulfonylurea monotherapy led to a significant decrease in microvascular complications though the decrease in macrovascular complications such as ischemic stroke did not reach significance [10]. Sulfonylureas likely carry an increased risk of cardiovascular complications and are still not considered a first-line monotherapy drug for any DMII patient that has concomitant underlying CAD [39].

Though meglitinides, such as repaglinide and nateglinide, are short-acting glucose-lowering drugs that do not affect lipid levels, they do lower HbA1C levels and manage hyperglycemia [39]. In prediabetics or patients with IGT, nateglinide was associated with a significant increase in episodes of hyperglycemia and unfortunately was unable to reduce the incidence of patients suffering cardiovascular or cerebrovascular ischemic events. Interestingly, it was noted that prediabetics who used nateglinide compared to placebo were not at lower risk of developing diabetes over the median five-year period of longitudinal analysis [43]. Conflicting data also exist on repaglinide's ability to decrease stroke risk in diabetics. While repaglinide did demonstrate similar efficacy in controlling hyperglycemia, metformin is more effective in decreasing the risk of CVD in DMII patients [39]. Whether meglitinides are associated with increased cardiovascular risk is not known; however, since their mode of action is similar to sulfonylureas, the same concern exists.

Dipeptidyl peptidase 4 (DDP-4) inhibitors are diabetic medications such as sitagliptin, linagliptin, alogliptin, and saxagliptin, which prolong the bioavailability of incretins, thereby better controlling postprandial hyperglycemia. Along with the regulation of postprandial glucose, these medications have been associated with decreasing vascular endothelial inflammation and improvement of endothelial dysfunction existing in diabetic vasculature as discussed earlier [39]. Gliptin-induced changes including a decrease in serum lipid levels and hypertension were also noted in animal studies [44]. However, according to Enders et al., diabetics taking DDP-4 inhibitors in combination with metformin when compared to patients taking metformin and sulfonylureas did not experience significantly reduced risk of future ischemic stroke [45]. Linagliptin was associated with a noninferior risk of a composite CV outcome in the CARMELINA (Cardiovascular and Renal Microvascular Outcome Study With Linagliptin in Patients With Type 2 Diabetes Mellitus) study [46]. Regarding CV safety of DPP-4 inhibitors (especially for heart failure), a recent meta-analysis by Mannucci et al. demonstrated a safe cardiovascular profile as its use was not associated with any major cardiovascular events [47].

Acarbose, an alpha-glucosidase inhibitor (AGI), serves a similar role in glycemic control as DDP-4 inhibitors in that they reduce postprandial hyperglycemia. Though its complete cardiovascular safety profile is not known, data from the Study to Prevent Non-Insulin-Dependent Diabetes Mellitus (STOP-NIDDM) trial reflects a positive effect of AGIs in the management of comorbid stroke risk factors with patients experiencing a hypertension relative risk reduction of 34%. STOP-NIDDM also demonstrated a nearly 50% relative risk reduction in cardiovascular events for patients taking acarbose though a head-to-head comparison study with metformin has yet to be performed [39].

Pioglitazone and rosiglitazone improve the utilization of available serum glucose and decrease the pro-inflammatory state of vascular endothelium in diabetics [39]. These two medications belong to a drug class known as thiazolidinediones. Their ability to help mitigate the oxidative injury from ROS in vascular endothelium may contribute to an overall decrease in future stroke risk in diabetics [24]. However, stroke risk in patients who take rosiglitazone remains uncertain as previous studies have implicated this medication with worsening hyperlipidemia, thereby potentially putting diabetics at increased risk of ischemic stroke. Data is conflicting concerning TZDs, especially rosiglitazone, and their role in risk development or worsening of baseline cardiac disease in diabetics. The thiazolidinediones are not recommended for use in patients with diabetes and concomitant severe congestive heart failure or prior CAD [39].

Glucagon-like peptide 1 agonists are oral antihyperglycemics with a mechanism of action similar to DDP-4 inhibitors in that they work on incretin deficiencies inherited to the pathophysiology of DMII. The GLP-1 agonists including exenatide, liraglutide, dulaglutide, albiglutide, lixisenatide, and semaglutide have been shown to significantly decrease overall HbA1C in diabetics. Additionally, the use of GLP-1 agonists in overweight diabetic patient populations has resulted in significant weight loss greater than five pounds resulting in subsequently improved control of stroke risk factors including hyperlipidemia and hypertension [48]. This class of antihyperglycemics has also been associated with cardiovascular protective effect, regulation of postprandial hyperlipidemia, and improvement of fasting LDL [39]. Recent trials (REWIND (Researching Cardiovascular Events With a Weekly Incretin in Diabetes) with dulaglutide, HARMONY with albiglutide, LEADER (Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Result) with liraglutide, SUSTAIN-6 (Trial to Evaluate Cardiovascular Other Long-term Outcomes with Semaglutide) with semaglutide, and EXSCEL (Exenatide Study of Cardiovascular Event Lowering Trial) with exenatide) have shown potential for GLP-1 receptor agonists in reducing cardiovascular events, including stroke [49–53]. In particular, a main reduction of stroke rate was observed for semaglutide, the oral and parenteral preparations associated with 26% and 39% reductions, and dulaglutide, associated with 24% reduction in stroke [54]; moreover, a recent systematic review with meta-analysis by Bellastella et al. regarding GLP-1RA trials involving 56,004 participants demonstrated a significant 16% reduction in stroke rates [55].

Other oral antihyperglycemics like sodium glucose cotransporter-2 (SGLT2) have similar efficacy to other oral diabetic medications in controlling HbA1C. SGLT2s are superior to sulfonylureas in improving hypertension and as a class are associated with significant weight loss in diabetics similar to GLP-1 agonists. Compared to placebo, SGLT2s have not been implicated in hypoglycemic events among diabetics though it should be noted that a majority of the data known about their efficacy and management of hyperglycemia comes from data in which patients used them concomitantly with metformin. Data suggest that SGLT2s, when compared to placebo, have clinically significant beneficial effects on controlling major stroke risk factors including hyperlipidemia and hypertension [48]. A recent 2021 meta-analysis by Tsai et al., of five trials, including CREDENCE and CANVAS trials with canagliflozin, VERTIS CV with ertugliflozin, DECLARE-TIMI 58 with dapagliflozin, and EMPA-REG OUTCOME with empagliflozin, involving 46,969 participants showed no significant or neutral effect of SGLT2 inhibitors on the risk of stroke in DM patients [56]. In subgroup analyses, no significant effects of SGLT2 inhibitors were observed against fatal stroke, nonfatal stroke, ischemic stroke, or TIA (transient ischemic attack). However, it was found a significant 50% reduction in hemorrhagic stroke, indicating a potential protective role of SGLT2 inhibitors against hemorrhagic stroke [56]. This could be of great importance because hemorrhagic stroke is the worst stroke type.

In terms of combination therapy for control of hyperglycemia in DMII patients, bile acid sequestrants such as colesevelam have also shown to be beneficial in improving glycemic control. Clinically significant reductions in LDL have been observed with colesevelam use especially when combined with statin [57]. Bile acid sequestrants regulate multiple pathways of lipid synthesis and also appear to have an anti-inflammatory effect on endothelial cells. Some retrospective studies have noted a stroke risk reduction of 43% in patients adherent to taking colesevelam with baseline hyperlipidemia and diabetes though this relatively large risk reduction may have been skewed by confounding variables [39]. Mitigating the deleterious effects of hyperlipidemia, bile acid sequestrants have the potential to reduce the incidence of future ischemic stroke as well as cardiovascular disease [58].

Optimization of Diabetic Control and Additional Stroke Risk Factors

American Heart Association (AHA) guidelines for the primary prevention in stroke in diabetics recommend that all patients with an elevated ten-year stroke risk, which includes all diabetics, benefit from treatment with a statin [32]. Even in diabetics without comorbid cardiovascular disease, the risk of stroke is significantly elevated in patients with uncontrolled LDL compared to diabetics with LDL ≧100 mg/dL [59] with a 24% reduction in ischemic stroke occurrence associated with statin use quoted in prior studies. It is impor-

tant to note that though increased LDL levels have a direct association with increased risk of ischemic stroke, there is no associated stroke risk for diabetics with elevated total cholesterol and increased HDL [32]. Trials such as the Justification for the Use of Statin in Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER) demonstrated that stroke risk is significantly decreased with statin administration even in healthy individuals devoid of increased risk for ischemic stroke [60]. The regulation of atherosclerosis and hyperglycemia is intricately related to an interrelated, complex pathophysiology as discussed earlier in this chapter.

According to current AHA guidelines and based on data derived from the UKPDS trial, it is recommended that aggressive blood pressure management should occur in all patients with DM. The UKPDS trial demonstrated that a goal blood pressure of 140/90 is associated with a 44% relative risk reduction of future ischemic stroke in patients with either DMI or DMII [32]. Which medication regimen to use for achievement of goal blood pressure in patients with DM and baseline increased CAD risk is a point of contention as conflicting data exist as to what constitutes best medical management. Nevertheless, DM patients without additional CAD risk factors at baseline have been consistently found to have an elevated risk of future stroke due to poorly controlled hypertension alone despite AHA recommendations [59]. Per Meschia et al., prior studies such as HOPE found that ramipril administration in diabetics with CAD risk factors resulted in a significant decrease in the relative risk of future ischemic stroke (25% RR, 95% CI: 12–36, $p = 0.0004$) as well as a significant reduction in cardiovascular-related death [32]. Other studies including the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) found that a blood pressure regimen consisting of both amlodipine and perindopril resulted in a 25% risk reduction in future strokes though more recent studies considered that successful reduction of BP is more important in reducing stroke risk than the choice of a specific agent, and treatment should be individualized on the basis of other patient characteristics and medication tolerance [32].

In the ADVANCE trial, ACE inhibitor use with concomitant indapamide administration did not result in a significant decrease in future stroke risk for DMII patients [32]. Similarly, in the diabetic subset of patients studied in the Avoiding Cardiovascular Events Through COMbination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial, it was found that an ACE inhibitor plus diuretic or calcium channel blocker did not result in decreased stroke risk over the three-year follow-up period [32]. Administration of ARBs (angiotensin receptor blockers) such as valsartan has also been investigated for their ability to decrease future stroke risk in diabetics. The NAVIGATOR (Nateglinide And Valsartan in Impaired Glucose Tolerance Outcomes Research) trial, which compared valsartan to placebo, demonstrated that patients with IGT and increased baseline risk for CAD did not have a significant decrease in future stroke risk [43]. Trials such as GEMINI (Genomic Medicine for III Neonates and Infants) suggest that β-blockers like carvedilol are effective and safe to use in diabetic patients to reduce blood pressures to goal. However, there have not been substantial investigations into the role of β-blockers and future stroke risk reduction in diabetics leaving this as a gap of knowledge within the literature [61].

Inflammatory changes induced by hyperglycemic states of DM patients have been shown to induce pathophysiologic changes conductive to the development of atrial fibrillation (afib). In fact, it is a commonly accepted knowledge that DM is a risk factor for the development of afib [62]. It is also known that patients with atrial fibrillation (afib) have a substantially elevated risk of ischemic stroke with diabetics at even higher risk based on the $CHADS_2$ score [32]. According to Dublin et al., treated diabetics have a 3% annual risk of developing afib that is additive based on the duration of diagnosed diabetic state [44]. A 14.9% incidence of afib exists within the diabetic population, and the incidence is nearly six times higher than that of the general population [63].

The recommendations for risk reduction of afib in diabetics are multifaceted. Depending on the $CHADS_2$ or CHADS-VASC score, patients with both DM and afib will carry at least a moderate risk of future cardioembolic, ischemic stroke [32]. As noted earlier during the discussion on diabetes and microvascular complications, the risk of peripheral arterial disease, hypertension, and aortic plaque development is elevated in all diabetics as well as those with IGT. Studies have shown that pathophysiologic changes similar to those that cause endothelial dysfunction in diabetics can also cause autonomic dysregulation which increases the risk for afib. Once these changes occur, it is important to decrease the risk of future ischemic stroke by either starting anticoagulation therapy in moderate- to high-risk patients, rate/rhythm control, or catheter ablation [64]. Unfortunately, DM patients often have neuropathy and may be unaware that they have afib, thereby making catheter ablation a less viable option due to higher rates of cardioversion failure [63]. Therefore, proper management of hyperglycemia is required to prevent changes on the cellular level that place DM patients at higher risk for the development of another ischemic stroke risk factor.

Some studies exist which have assessed whether specific oral antihyperglycemics such as metformin decrease future risk for DM to develop afib. A prospective cohort with 5.4-year median follow-up was performed by Chang et al. who noted that DM patients taking metformin had a significantly lower risk for developing afib than did DM patients not taking metformin [62]. The mechanism of benefit suggested is that metformin may reduce hyperglycemia-induced inflammatory

injury to atrial myocyte, thereby preventing tachyarrhythmias known to lead to afib [62]. Moreover, it has been established that there are both increased plasma viscosity and increased activation of thrombocytes in DM patients leading to further risk of clot formation in individuals already prone to developing afib [65]. In summary, DM in patients with AF is associated with increased cardiovascular and cerebrovascular mortality. DM is a known risk factor for thromboembolic events in patients with AF and is associated with a 70% relative increase in risk of stroke [66]. The pathophysiology of diabetes-related AF is not fully understood but is related to structural, electromechanical, and autonomic remodeling. For patients with diabetes and CHA2DS2-VASc scores ≥2, direct oral anticoagulants may be recommended over warfarin, in spite that the relative safety and efficacy of direct oral anticoagulants versus warfarin were similar regardless of diabetes status [67]. Moreover, patients with longer duration of diabetes or insulin-requiring diabetes may benefit more from oral anticoagulation, even in the absence of other major risk factors included in the CHA2DS2-VASc score [66].

Directly smoking tobacco products and second-hand smoke exposure put patients at increased risk for ischemic stroke and increase progression of diseases such as hypertension and atherosclerosis [32]. Nondiabetic smokers have twice the risk of suffering a future ischemic stroke [61] while DM patients who are active smokers carry a 50% higher risk for all-cause mortality and stroke based on data derived from a large meta-analysis [68]. It is likely that smoking acutely causes hypercoagulable states within the atherosclerotic vasculature and over time causes increased rates of atherosclerotic changes within intracranial and extracranial arteries [32]. AHA recommendations for smoking cessation treatment are similar to those made by O'Keefe et al. and include counseling in combination with medications such as varenicline, clonidine, bupropion, and nicotine supplementations [61]. The differences in future stroke risk for smokers who are diabetics versus nondiabetics have not been well delineated.

A risk factor for stroke that is now becoming more recognized is abdominal adiposity more so than patient BMI. However, it should be noted that no current studies have definitively associated increased future stroke risk with increased abdominal adiposity independent of associated comorbidities such as hypertension, DM, and smoking. Olofindayo et al. conducted a prospective cohort study which found that in patients who were both obese and diabetic, the risk for future ischemic stroke was 73% higher than in age-matched individuals with only DM or central obesity alone [69]. It has also been found that regardless of diabetic status, a patient's future stroke risk nearly triples in the setting of obesity with current 2014 AHA guidelines recommending weight loss in patients with BMI ≥25 to prevent future ischemic stroke [32].

According to O'Keefe et al., waist size has proven to be an independent risk factor for the development of DM [61]. Obesity, regardless of adipocyte corporal distribution, has also been linked to the development of tachyarrhythmias with some studies noting a 4.7% increased risk of afib per increase of each unit of 1 kg/m^2 in BMI [65]. It is also well known that a large percentage of patients with DMII or IGT are overweight or obese placing a large percentage of DM patients overall at increased risk of future ischemic events based on BMI and waist circumference alone. Class 1 level B evidence suggests that modification of lifestyle is necessary for DM patients in order to decrease the risk of ischemic stroke with higher-level evidence denoting a clear correlation with weight loss and achieving normotension [32].

DM patients who demonstrate central adiposity and insulin resistance often have metabolic syndrome [21] though other characteristics of the syndrome including IGT (fasting serum glucose ≥ 110 mg/dL), hyperlipidemia, and hypertension can also be present [32]. Metabolic syndrome is associated with increased risk of ischemic stroke due to the presence of the risk factors which define it rather than by the existence of the syndrome itself [34]. 2014 AHA guidelines currently recognize that up to 38.5% of the general US population meets criteria for metabolic syndrome. Data from large retrospective studies have demonstrated an increased prevalence of metabolic syndrome (43.5%) in patients with a history of ischemic stroke though no direct correlation between metabolic syndrome and increased risk of stroke has been found. Additionally, prospective trials such as Stroke Prevention by Aggressive Reduction of Cholesterol Levels (SPARCL) did not find an increased risk for future stroke in the subset of 642 patients with both metabolic syndrome and prior stroke. Currently, the guidelines for primary prevention of stroke as they pertain to metabolic syndrome are that patients should focus on the management of the individual risk factors that define the disease via weight loss and proper medication regimens [32].

Other less studied risk factors such as DM and ischemic stroke include obstructive sleep apnea (OSA). OSA is not only a risk factor for future ischemic stroke but also has been suggested to have a significant association with the development of DMII. Not surprisingly, obese diabetic patients are at higher risk for developing OSA though obesity itself is an independent risk factor for OSA with some studies quoting prevalence as high as 27% in patients with BMI ≥ 30 [70]. Per Kent et al., a recent prospective cohort comprised of nearly a thousand patients found that patients with moderate to severe OSA were about three times more likely to develop DMII within an average of 2.7 years compared to non-OSA participants [71]. Other larger cohort studies with an average follow-up of nearly five years demonstrated similar results establishing a clear clinical correlation between OSA and DMII [71].

The Wisconsin Sleep Cohort Study and the Sleep Heart Health Study both demonstrated increased stroke risk in patients with OSA. The Wisconsin study was comprised of a prospective cohort which demonstrated that severe OSA conferred a triple risk for future ischemic stroke (OR, 3.09, 95% of CI: 0.74–12.81) [72]. The Sleep Heart Health Study found that when adjusting for all confounding risk factors, there was still a linear positive correlation between rising apnea-hypopnea index (AHI) and risk of stroke [73]. There have been few randomized trials to test the efficacy of OSA treatment as it relates to primary prevention of ischemic stroke though a recent study by McEvoy et al. did note that CPAP treatment versus sham treatment in patients with moderate to severe OSA and concomitant CAD/cerebrovascular disease did not result in a significant difference in cardiovascular-related deaths including stroke ($p = 0.34$; HR, 1.1; CI, 0.91–1.32) [74]. Currently, screening based on symptoms such as daytime sleepiness, snoring, and clinical suspicion is recommended [32]. However, the link between OSA and primary stroke prevention is becoming more and more clinically relevant with up to 4% of the US population now having a form of sleep apnea [32]. The final risk factor for primary stroke prevention that will be discussed is physical inactivity.

Moderate- to high-intensity physical activity has been shown to decrease risk for future cardiovascular events in patients with diabetes independent of any concomitant stroke risk factors including HLD (hyperlipidemia), HTN (hypertension), obesity, and smoking [33]. However, in the general population, some studies report that baseline low physical activity level is not associated with increased rates of future stroke when adjusting for confounding stroke risk factors [75]. Conversely, based on more recent meta-analysis derived data, the current AHA guidelines indicate that active men and women have a 30% lower annual risk of stroke than their inactive counterparts. The degree of intensity, duration, and frequency needed to achieve maximal protective effect from the development of future stroke is a point of debate. Overall, the current recommendation is for 40 min of moderate to intense, aerobic exercise at least three days per week. The data for current recommendations are derived from observational studies as clinical trials delineating clear risk reduction have not been performed [32].

Diabetes and Secondary Stroke Prevention

DM and prediabetes are present in around 30% of patients with acute ischemic stroke and are associated with increased risk for stroke recurrence [76]. Up to 95% of patient with diabetes mellitus are type II with hyperglycemia preceding DM diagnostic criteria in the form of impaired fasting glucose, impaired glucose tolerance (IGT), and episodic hyperglycemia. Wu et al. conducted a prospective cohort study which found that after initial stroke, prediabetic patients with HbA1c $\geq$ 6.1% had a 61.3% recurrent stroke risk at three months that was still elevated at 51.1% after a year [77]. This was a significant finding due to the traditional threshold for HbA1c of 6.5% being diagnostic for DM, but in lieu of the previously discussed initial stroke risk conferred to patients that only have IGT, this is less surprising. Duration of DM diagnosis at the time of initial stroke may play a role in determining the level of glucose control needed to help prevent future strokes. According to Wu et al., patients with a long-standing history of DM did not benefit from intensive glycemic control as it relates to secondary stroke prevention [77]. However, this contrasted with the benefit found in newly diagnosed DM patients with a history of stroke who were noted to have decreased recurrent stroke risk with a goal of near normoglycemia [77].

It remains a fact that DM is highly prevalent in the global population and places patients within all age demographics at risk for poor outcomes after an initial stroke. In fact, DM is an independent predictor for both primary lacunar strokes as well as for poor prognosis for recurrent ischemic cerebrovascular events [78]. Even young adults <50 years of age with a history of DMI had a high incidence of recurrent ischemic stroke independent of concomitant risk factors [79]. Recently, in a large, cross-sectional multicenter study of DMII patients, it was noted that in the setting of poststroke recovery, only about 60% of patients achieved an HbA1c of $\leq$7.5%. Persistently, elevated HbA1c values are concerning in terms of hyperglycemia's influence on microvascular outcomes though the relativity to recurrent stroke in DM patients was again indeterminate [80].

Rigorous measures of secondary prevention are of paramount importance to avoid stroke recurrence in patients with diabetes. The main messages of the recently published AHA guidelines for secondary stroke prevention in patients with an ischemic stroke or TIA who also have diabetes include the following [76]:

- The goal for glycemic control should be individually based, and for most patients, achieving a goal of HbA1c $\leq$7% is recommended.
- Treatment of diabetes should include glucose-lowering agents with proven cardiovascular benefit to reduce the risk for future major adverse cardiovascular events (i.e., stroke, MI, cardiovascular death). As has been previously discussed, recent clinical trials [54–56] demonstrated that at least one drug in each of the three classes of glucose-lowering medications can reduce the risk for major adverse cardiovascular events in patients with DM and established atherosclerotic vascular disease, including ischemic stroke or high risk: thiazolidinediones, glucagon-like protein 1 (GLP-1) receptor agonist, and sodium glucose cotransporter 2 inhibitor.

- Considering the limited number of therapies available for prevention and treatment of stroke and the substantial attendant disability and impact on patients and their families, recent data meaningfully supports the consideration of GLP-1 receptor agonists for stroke prevention in people with type 2 diabetes at increased cardiovascular risk [54]. In patients with established atherosclerotic cardiovascular disease, including ischemic stroke, when prevention of further vascular events is the priority, GLP-1 receptor agonist therapy should be added to metformin independently of baseline HbA1c [76, 81].
- Multidimensional care (i.e., lifestyle counseling, medical nutritional therapy, diabetes self-management education and support) is indicated to achieve glycemic goals and to improve other stroke risk factors.

Around 50% of patients without diabetes with ischemic stroke have insulin resistance. Both conditions have been associated with increased risk for first ischemic stroke. The Insulin Resistance Intervention after Stroke (IRIS) trial found that insulin-resistant patients with prior stroke receiving had a 2.8% risk reduction for future stroke compared to insulin-resistant patients randomized to placebo.

Pioglitazone reduced the risk of recurrent stroke or MI by 24% (RR, 0.76 [95% CI, 0.62–0.93]), from 11.8% among placebo versus 9.0% among pioglitazone [82]. However, active treatment was associated with adverse events like weight gain and increased bone fracture risk that have restrained clinical use of pioglitazone. To date, the IRIS trial is one of the few studies to evaluate insulin-resistant patients by treatment with hypoglycemic medications with a primary endpoint of recurrent stroke or MI.

The metformin and sitagliptin in patients with impaired glucose tolerance and a recent TIA and minor ischemic stroke (MAAS) trial was aimed to assess the feasibility, safety, and effects on glucose metabolism of metformin or sitagliptin in these patients. Results revealed that metformin and sitagliptin were both effective in reducing fasting glucose and HbA1c levels in patients with recent TIA or minor ischemic stroke and IGT. However, the reduction of glucose levels and sample size was relatively small precluding any clinical relevance. A phase III trial is needed to investigate whether medical treatment, compared with lifestyle intervention, not only improves glucose metabolism in IGT but also leads to reduction of recurrent TIA or ischemic stroke in these patients [83].

Management of Additional Risk Factors and Secondary Stroke Prevention in DM

The final part of this chapter will focus on the additional secondary stroke risk factors as they relate to recurrent stroke prevention. Clearly delineated recommendations have been made for the management of recurrent stroke risk factors including hypertension, hyperlipidemia, and atrial fibrillation, among others (Table 51.3).

Hypertension is one of the most important modifiable risk factors to regulate in order to prevent the recurrence of ischemic stroke. Studies including the Post-stroke Antihypertensive Treatment Study (PATS) and Perindopril Protection Against Recurrent Stroke (PROGRESS) both noted lower rates of recurrent strokes when patients randomized to antihypertensive treatment achieved systolic blood pressures of 140 mmHg. The PROGRESS trial found that further recurrent stroke risk reduction was achieved with systolic blood pressure < 140 mmHg. Confirmation of the importance of antihypertensive administration with goal titration to blood pressures of 140/90 mmHg was found via meta-analysis of poststroke individuals though at this time there is no recommendation of specific medication regimen to achieve [76]. Of note β-blockers and diuretics have both been associated with worsening of glucose control in DM patients. A meta-analysis revealed that β-blockers not only increase fasting blood glucose (0.64 mmol) but also raise HbA1C by 0.75% in patients with DM [84]. The same study

Table 51.3 AHA/ADA guidelines for secondary stroke prevention

Diabetes	Hyperlipidemia	Hypertension	Atrial fibrillation	Other risk factors
DM testing after initial stroke	Statin for patients with stroke and LDL ≥ 100[a]	Treat HTN if patient BP ≥ 140/90 mmHg	Antithrombotic for nonvalvular afib	ASA for all ischemic stroke patients
Goal HbA1c ≤6.5% per AHA Goal HbA1c ≤7% per ADA[b]	Goal LDL < 100 mg/dL	Goal BP of ≤140/90 mmHg	Aspirin for stroke patients unable to take anticoagulants	Smoking cessation recommended for all patients
Moderate-intensity treatment for stroke prevention	Dietary and lifestyle recommended	Diet, exercise, and decreased salt intake recommended	Can delay anticoagulants for two weeks if high bleeding risk present	40 min, three days/week moderate exercise

Stroke reduction with statin use in patients with TIA or ischemic stroke of atherosclerotic etiology, high-intensity statin unless patient's age ≥ 75

[a]Treat hypertension (HTN) if BP over 140/90 mmHg for the first few days after stroke

[b]ADA guidelines differ from AHA secondary stroke prevention HbA1c goals with less stringent glycemic control recommended based on data from the ACCORD study

by Hirst et al. also demonstrated that diuretics also raised fasting blood glucose by 0.77 mmol but did not have a significant effect on HbA1C [84]. These drugs and their role as antihypertensives in patients with IGT should be taken on a case-by-case basis.

Up to 87% of both primary and recurrent strokes are ischemic. When there is regulation of both hypertension and atherosclerosis, a significant mitigation in recurrent stroke risk has been observed [67]. In accordance with findings from the SPARCL (Stroke Prevention by Aggressive Reduction in Cholesterol Levels) study, it is advised that all individuals be placed on high-dose statin. Results of the SPARCL study showed that there was an absolute risk reduction of 3.5% (p = 0.002) for major cardiovascular events in patients receiving high-dose statin over a five-year follow-up period. In terms of preventing recurrent stroke, patients receiving atorvastatin 80 mg daily were noted having an absolute risk reduction of 2.2% (p = 0.03) without significant side effects. Guidelines for secondary stroke prevention set the benchmark for lipid control with a goal LDL of ≤100 [76, 85]. Of note in a post hoc exploratory analysis of SPARCL, there was found to be a 28% relative risk reduction of recurrent stroke with an LDL of <70 mg/dL without increased risk for intracerebral hemorrhage. There was also a 35% risk reduction for ischemic stroke if at least a 50% reduction in LDL is achieved [86]. Considering the results of the Treat Stroke to Target study, in patients with ischemic stroke or TIA and atherosclerotic disease (intracranial, carotid, aortic, or coronary), lipid-lowering therapy with a statin and also ezetimibe, if needed, to a goal LDL-C of <70 mg/dL is recommended to reduce the risk of major cardiovascular events [76, 87].

In patients with DM, the management of hyperlipidemia is similar as regards to goal LDL, but data from randomized control trials have shown statin benefit for all DM patients at increased risk for cerebrovascular disease [76, 86]. However, the use of statins in DM patients is not without elevated risk for hyperglycemia. Macedo et al. conducted a meta-analysis of the available literature to ascertain the statins may pose a risk of DM development [88]. It was shown that there is a slightly increased risk of developing DM in patients who use statins for at least three years though the odds ratio was low (OR, 1.31; 95% CI, 0.99–1.73) and the number need to harm was 44 patients for a new diagnosis of DM. Other studies produced contrasting results with no association found between statin and DM risk though many of them were of low quality [88].

The annual risk for recurrent stroke in all patients with untreated afib who have had a recent TIA or ischemic stroke is between 7 and 10%. Anticoagulation is the optimal choice for recurrent stroke prevention regardless of diabetic status. In patients with stroke or TIA in the setting of nonvalvular AF who have anticoagulation contraindications, it may be reasonable to consider percutaneous closure of the left atrial appendage with the Watchman device to reduce recurrent stroke and bleeding [76]. The AHA/ADA recommendations for choice of anticoagulant is case dependent, and the timing to prevent recurrent stroke in the patient with afib is no different in DM patients compared to the nondiabetic patient population; however, direct oral anticoagulants may be recommended over warfarin in patients who are unable to maintain a therapeutic INR level with vitamin K antagonist anticoagulants [76]. Other risk factors for recurrent stroke prevention in diabetics include metabolic syndrome and smoking.

Patients with metabolic syndrome may not be at increased risk of recurrent stroke from the syndrome itself, but elevated fasting blood glucose does put DM patients at risk for recurrent stroke [34]. Known risk factors for both recurrent stroke and metabolic syndrome such as HLD, HTN, and DM should be modified to prevent future strokes, but screening for metabolic syndrome is not recommended. Limited data exists concerning recurrent stroke risk and smoking though the increased risk of stroke associated with smoking is generally acknowledged. However, it is less well recognized that considerable scientific evidence implicates a strong dose-response relationship between smoking and stroke risk. Shah RS and Cole JW summarize the information regarding smoking-related stroke risk, their dose-response relationship, and the costs for the individual and society [89]. The data concerning hyperglycemic control in DM patients, smoking, and recurrent stroke risk association is currently lacking.

This chapter has summarized the microvascular and macrovascular complications of DM as well as the complex pathophysiologic changes that occur at the cellular level which make diabetic patients at high risk for ischemic stroke. An overview of the epidemiological concerns about DM and stroke was discussed. Also, the remarkable role of hyperglycemia in acute ischemic stroke was revised. Primary prevention of stroke in diabetic centers around the key concept of normoglycemia maintenance which in turn leads to the indirect regulation of concomitant risk factors for ischemic stroke such as hyperlipidemia and hypertension. Optimization of glucose control via oral antihyperglycemic medications is an important facet for hyperglycemia control. Considering the limited number of therapies available for prevention and treatment of stroke and the substantial attendant disability and impact on patients and their families, recent data meaningfully supports the consideration of GLP-1 receptor agonists for stroke prevention in people with type 2 diabetes at increased cardiovascular risk [54]. In patients with established atherosclerotic cardiovascular disease, including ischemic stroke, when prevention of further vascular events is the priority, GLP-1 receptor agonist therapy should be added to metformin independently of

baseline HbA1c. Secondary stroke prevention in diabetes again centers around achieving euglycemia to reduce recurrent stroke risk though there is even less evidence about optimization of risk factors than in primary stroke prevention.

Multiple Choice Questions

1. By comparison to the general population, the risk of mortality from stroke in patients with diabetes is:
   (a) Equal
   (b) Lower
   (c) **Two times higher**
   (d) **Three times higher**
   (e) Four times higher
2. Microvascular changes due to hyperglycemia occur:
   (a) Due to atherosclerosis
   (b) Due to intracapillary thrombosis
   (c) Due to production of reactive oxygen species at the cellular and genetic level
   (d) Due to persistent hyperglycemia
   (e) Due to intracapillary hypertension
3. By comparison of many systemic cells, endothelial cells:
   (a) **Express non-insulin GLUTs which allow for continued generation of ROS**
   (b) Downregulate glucose transporters to prevent continued prevention of ROS
   (c) Are highly resistant to the entrance of glucose
   (d) Express insulin-dependent GLUTs
   (e) Express unique GLUTs
4. Endothelial cell dysfunction results from:
   (a) Deposition of AGEs
   (b) Glycation of LDL
   (c) Increased expression of CD36 in monocytes
   (d) Upregulation of inflammatory proteins
   (e) **All of the above**
5. One of the first studies demonstrating that strict regulation of blood glucose prevented vascular complications was:
   (a) The DCCT trial
   (b) **UKPDS**
   (c) ACCORD
   (d) ADVANCE
   (e) VADT
6. Deleterious endothelial changes develop earlier:
   (a) In carotid arteries
   (b) In basilar arteries
   (c) **In cerebral arterioles**
   (d) In anterior cerebral arteries
   (e) In posterior cerebral arteries
7. Risk factors for ischemic stroke include the following except for:
   (a) **Microalbuminuria**
   (b) Sleep apnea
   (c) Atrial fibrillation
   (d) Hypertension
   (e) Smoking
8. Primary stroke prevention is dependent on:
   (a) An HbA1C target <7.0%
   (b) Monitoring fasting serum glucose
   (c) Monitoring postprandial glucose
   (d) **All of the above**
   (e) None of the above
9. In the UKPDS trial, patients treated with metformin showed:
   (a) A 24% relative risk reduction in ischemic stroke
   (b) **A 32% relative risk reduction in ischemic stroke**
   (c) A 40% reduction in ischemic stroke
   (d) **A 42% reduction in macrovascular deaths related to diabetes**
   (e) A 50% reduction in macrovascular deaths related to diabetes
10. Primary stroke prevention involves:
    (a) *Aggressive blood pressure management should occur in all patients with DM*
    (b) *The use of statins*
    (c) *Smoking cessation*
    (d) Screening and management of atrial fibrillation
    (e) **All of the above**

Acknowledgments We would like to thank Dr. Tarun Girotra for his generous inputs and comments to this book chapter. Dr. Feng would like to acknowledge grant supports from the National Institute of Health (P20GM109040 and HD086844), from the American Heart Association (14SDG1829003) and South Carolina Clinical and Translational Research Institute (UL1 TR001450).

Peripheral Arterial Disease and Diabetes Mellitus

52

Georges M. Haidar and Boulos Toursarkissian

Epidemiology

While the prevalence of PAD is not as high as that of diabetes, estimated at 5.9% among Americans age 40 and above, its prevalence is elevated to 20–30% among the diabetic population, according to National Health and Nutrition Examination Survey data. In a prospective cohort study of 48,607 men comparing diabetics and nondiabetics and the incidence of developing PAD, the relative risk was found to be 3.39. Even when adjusted for all other risk factors, the RR remained 2.61. Furthermore, the duration of diabetes was directly linked with the risk of developing PAD [1]. Diabetes has also been linked with the development of critical limb-threatening ischemia. The severity of diabetes has also been shown to correlate with PAD risk, with one study in the United Kingdom demonstrating a 28% increased risk of developing PAD with every 1% increase in glycosylated hemoglobin (HgA1c) [2]. Perhaps more importantly, diabetics with diagnosed vascular disease were found to have better management of their cardiovascular risk factors compared to diabetics with occult PAD, highlighting the importance of early recognition [3]. Other risk factors for the development of PAD include smoking, older age, male sex, hypertension, and hyperhomocysteinemia [4].

Diagnostic Challenge

Clinical detection of symptomatic PAD can be made through any number of history and physical exam findings, including claudication, diminished or absent pulses, femoral bruit, cool extremities, distal hair loss, nail thickening, or dependent rubor. Pulse exam in diabetics can be difficult to interpret, and a diminished pulse exam may simply be due to calcification of a vessel without a flow-limiting stenosis. Conversely, a palpable distal pulse does not preclude a more proximal flow-limiting stenosis. Vascular claudication is muscular pain, cramping, fatigue, or heaviness that is induced by walking, is relieved by rest, and is reproducible [5]. Clinical detection of symptomatic PAD in diabetics may be made more difficult by the presence of diabetic sensory neuropathy which may mask claudication symptoms and delay discovery of ischemic tissue loss, and motor neuropathy which may limit mobility enough that claudication is never provoked. Therefore, a careful exam and conscientious use of diagnostic studies are particularly important in the diabetic subset of PAD patients.

PAD is diagnosed and characterized through a variety of modalities inclusive of ankle-brachial index (ABI), duplex ultrasonography, continuous wave Doppler, com-

Table 52.1 Ankle-brachial index interpretation

ABI	Interpretation
≥1.4	Non-compressible
1.0–1.39	Normal range
0.9–0.99	Borderline
0.7–0.89	Mild disease
0.5–0.69	Moderate disease
<0.5	Severe disease

puted tomography and magnetic resonance angiography, and conventional arteriography. The ABI in particular is well used for its simplicity, noninvasiveness, and reproducibility. ABI is calculated by dividing the larger of bilateral ankle systolic pressures by the larger of bilateral upper arm systolic pressures. Although ranges do not always strictly correlate with the typical interpretations, values help characterize the degree of disease present (Table 52.1).

A report of the National Health and Nutrition Examination Survey found that a value greater than 1.4 is associated with PAD as well [6]. The ABI carries a U-shaped cardiovascular and mortality risk curve, associating higher mortality with values on either side of the normal range.

The diagnostic utility of ABI in diabetics can be more difficult to interpret given that diabetic arteries are not reliably compressible compared to their nondiabetic counterparts due to medial arterial calcification (MAC) particularly in the ankles, resulting in ABI elevation and often normal ABIs in the presence of PAD [7]. In a 2010 study evaluating the validity of ABI in PAD against a multitude of patient characteristics, when compared to lower-extremity angiography, diabetic patients had a 4.36 odds ratio for a normal ABI in the presence of proven PAD [8]. Given the distal and microvascular nature of diabetic angiopathy, there is also a component of microvascular ischemia that is missed when using ABI as the sole diagnostic modality. In a study performed in the United Kingdom, microvascular cutaneous responses were measured in diabetics and nondiabetics with and without PAD, and there was a significant subset of diabetic PAD patients in whom ABIs did not capture the presence of distal microvascular functional abnormalities [9]. This highlights the importance of adjunctive diagnostic modalities in diabetics with suspected PAD despite potentially normal ABI values.

The normal triphasic waveform obtained during noninvasive Doppler testing is characterized by a swift upward wave representing antegrade flow during early systole, a downward wave representing brief retrograde flow during late systole and early diastole, and a small slow upward wave in late diastole. The three phases of the triphasic waveform represent normal antegrade flow and pressure against a compliant vessel wall. The full noninvasive vascular study provides segmental pressures, ABI, and Doppler-derived waveforms (Fig. 52.1).

Alternative modalities have been proposed as adjuncts to the ABI for more accurate and prompt diagnosis of PAD in diabetics. The toe-brachial index (TBI) and toe systolic blood pressure (TSBP) have been investigated on the premise that toe arteries are typically spared of MAC relative to ankle arteries [10]. Brooks et al. found that ABI and TBI were essentially comparable in diagnostic accuracy in diabetics except in the case of overtly calcified crural vessels, proposing that ABI be supplemented with TBI or other adjunct diagnostic modalities when ABI is greater than 1.4 [11]. A major limitation of TBI lies in its less well-defined diagnostic criteria. A review of TBIs in the diagnosis of PAD found that 0.7 is commonly recommended as the lower limit of normal and that the sensitivity of detecting PAD ranged from 90 to 100% and specificity from 65 to 100%. These values however require further large-scale studies to firmly validate these limits [12]. The TBI and TSBP have also been studied as indicators of wound healing potential and amputation risk. A TSBP below 30 mmHg is generally considered insufficient for wound healing, conferring a 3.25-fold risk of nonhealing or amputation [13].

Other noninvasive adjuncts to diagnosis and lesion localization include pulse volume recordings, continuous wave Doppler, duplex ultrasonography, and MR and CT angiography. Continuous wave Doppler, when studied against ABI and TBI, is significantly more sensitive and specific in PAD diagnosis in both diabetics and nondiabetics [14]. This is true especially in infrapopliteal disease [15].

The gold standard of PAD diagnosis had been invasive angiography, although CT angiography is growing more popular due to its less invasive nature as well as its ability to visualize beyond intraluminal defects and provide cross-sectional imaging. Interpretation of CT angiography below the knee can be very challenging in diabetic patients due to the heavy-associated calcification. Conventional angiography provides the benefit of being able to demonstrate lesions and flow dynamics in real time as well as offering the potential for intervention on the spot. However, PAD patients frequently have comorbid cardiovascular disease which puts them at higher risk of adverse outcomes with procedural sedation, not to mention associated diabetic nephropathy which limits the use of intravenous contrast. The risk of the latter can be mitigated through the use of renal protective methods or carbon dioxide angiography; however not all centers have the capability for the latter. Furthermore, CO_2 angiography's ability to demonstrate infrapopliteal lesions, more common to the diabetic population, is inferior to that of iodinated contrast in conventional angiography [16].

Pathophysiology, Natural History, and Outcomes

Diabetes is characterized by hyperglycemia secondary to either an autoimmune impairment of insulin production (type I) or a gradually acquired insulin resistance (type II) and results in a number of acute and chronic metabolic derangements that ultimately manifest as microvascular and macrovascular disease that closely intertwines with PAD. As noted, PAD is most commonly due to atherosclerosis, which in turn results from a combination of endothelial dysfunction, vascular inflammation, and medial smooth muscle overgrowth which contributes to the development of flow-limiting lesions [17]. Vascular homeostasis relies

on a functional endothelium which is largely maintained by a steady production of nitric oxide (NO) which functions widely in vasodilatory, anti-inflammatory, antiplatelet, antioxidant, and antiatherogenic capacities. When dysfunctional, the vessel becomes vulnerable to atherosclerosis and thrombosis. Hyperglycemia promotes increased production of reactive oxygen species, which in turn blunts NO bioavailability as well as encourages smooth muscle cell hyperplasia and strongly predicts adverse cardiovascular events [17].

Not only on a cellular level do diabetes and PAD overlap, but they also demonstrate closely related clinical sequelae. Both diabetes and PAD are coronary artery disease risk equivalents and have well-established relationships with cardiovascular disease. Each disease independently as well as in conjunction increases the risk for major cardiovascular and cerebrovascular events as well as major adverse limb events. The Fremantle Diabetes Study of 1294 diabetics found that an ABI less than 0.9 was an independent predictor (HR 2.91) of first-time diabetes-related lower-extremity amputation over the mean 9.1 years of follow-up [18].

The progression of PAD follows a predictable yet not inevitable course. Two of the most commonly used tools for classifying symptomatic PAD are the Rutherford and the Fontaine classifications which aid in determining the selection of best medical therapy alone versus invasive interventions (Table 52.2).

PAD patients with diabetes are much more likely to present with more severe lower-extremity ulcers (Fig. 52.2), and given the common presence of diabetic sensory neuropathy, these ulcers are more difficult to detect and treat at an early stage. In diabetic patients presenting with critical limb-threatening ischemia (CLTI), 50% will develop CLTI in the contralateral limb within the next 5 years [19]. In a prospective cohort study of 1244 male claudicants followed for a period of up to 15 years, diabetes and ABI were the two strongest clinical factors found to be associated with the development of CLI [20]. Both lower-extremity amputation rates and survival have been demonstrated to be significantly higher in diabetic PAD patients compared to nondiabetic PAD patients [21]. Worsened disease severity relates not only to concomitant risk factors and diabetic vasculopathy but also to the more distal nature of PAD in diabetics. Diabetics more frequently demonstrate densely calcified infrapopliteal disease, making both open and endovascular interventions more challenging. In a study published in 2016 comparing a 10-year all-cause mortality in diabetics versus nondiabetics with and without PAD, the relative risk was 2.51 after age and sex matching [22].

A population-based cohort study of 444 German subjects who underwent a first-time lower-extremity major amputation stratified by diabetes diagnosis demonstrated a time-dependent influence of diabetes on mortality. Early in follow-up, nondiabetics actually demonstrated slightly worse survival compared to diabetics; however, after 2–3 years, the survival curves crossed and diabetic mortality surpassed nondiabetic mortality. The investigators proposed that diag-

Table 52.2 Rutherford classifications of peripheral arterial disease

Grade	Classification	Description
Grade 0	Asymptomatic	Asymptomatic disease may be detected incidentally or as part of a routine screening ABI. This stage is slow and insidious in the majority of patients, and many may not progress out of this. As major limb vessels gradually narrow, a variable amount of collateral disease may develop. It is believed that for every patient with symptomatic PAD, there are six with asymptomatic disease [19]. This unearths two management gaps in that asymptomatic PAD patients with diabetes are grossly underdiagnosed and that asymptomatic PAD patients are significantly undertreated for their cardiovascular risk factors [3]
Grade 1	Mild claudication	As the degree of major limb artery narrowing increases, demand may exceed perfusion to the affected extremity and result in various degrees of intermittent claudication. Patients may begin to complain of exercise-induced cramping, fatigue, or heaviness in the buttock, thigh, or calf. Claudication is highly reproducible and is typically relieved with a couple minutes of rest. With the commonly concomitant presence of diabetes, motor neuropathy, obesity, arthritis, and other comorbidities such as heart failure and coronary artery disease, a patient with diabetes and PAD may not achieve activity levels that are adequate to provoke claudication. Claudication may also be masked by sensory neuropathy. For these reasons, patient history must be actively and thoughtfully evoked, physical exam must be critically obtained, and the comorbidities of the patient carefully must be weighed into the diagnostic algorithm
Grade 2	Moderate claudication	
Grade 3	Severe claudication	
Grade 4	Rest pain	With continued narrowing, ischemic symptoms may occur at rest which marks the beginning of critical limb ischemia. Rest pain is classically described at night when the lower extremities are elevated and perfusion is no longer assisted by gravity. Patient will describe pain with leg elevation that is relieved by dangling the extremity over the edge of the bed or by sleeping in a chair. Again, rest pain may be masked by diabetic sensory neuropathy. The end stage of PAD, beginning with mild ischemic tissue loss to ulceration and gangrene, may result with further progression of PAD or after a minor trauma or infection. Again with diabetic peripheral neuropathy, a mild injury may go unnoticed and enter a vicious cycle of poor wound healing due to poor tissue perfusion
Grade 5	Minor tissue loss	
Grade 6	Gangrene	

Fig. 52.2 Classic end-stage peripheral arterial disease. Note thickened nails, dependent rubor, and gangrene

nosed diabetics had better general follow-up and were being closely monitored for their diabetes and incidentally any other comorbidities; therefore any issues with wound healing that arose may have been detected and addressed at earlier stages, suggesting that the more malignant natural history of diabetes could be held at bay with aggressive care. They also noted that the diabetic subset had more transtibial amputations, given their infrapopliteal disease, which are associated with better survival outcomes compared to transfemoral amputations [23].

Management

Better characterization of the association between diabetes and PAD strives toward earlier and more accurate diagnosis and subsequent management to achieve two major goals: improvement of lower-extremity symptoms and quality of life (inclusive of avoidance of lower-extremity amputations) as well as minimization of risk for adverse cardiovascular and cerebrovascular events. Management of PAD begins with lifestyle and risk factor modification followed by revascularization treatment algorithms when disease persists despite the former.

Risk Factor Modification

Diabetes

Interestingly, despite diabetes being one of the strongest predictors of PAD development and severity, there is no data to suggest that stringent glycemic control leads to improved outcomes or survival. In a recent meta-analysis, every 1% increase in HbA1c was associated with a 25% increase in CV disease mortality and 15% increase in all-cause mortality. Of the RCTs (randomized controlled trials) reviewed, however, intensive glycemic control never demonstrated improved CV or all-cause mortality [24]. For example, the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial was a randomized controlled trial that randomized 10,251 subjects to tight (<6.0% HbA1C) and standard (7.0–7.9% HbA1C) glycemic control arms to assess differences in cardiovascular events (nonfatal MI and CVA) and cardiovascular mortality. The tight arm was terminated after only 3.5 years due to an increased mortality rate noted in this arm [25].

Therefore to date, there is no recommendation for tight glucose control in diabetic patients, both with and without cardiovascular disease, and by extension in those with and

without PAD. Current American Diabetes Association guidelines, supported by the American Heart Association, offer a tiered approach to glycemic control, noting 7.0% or lower to be appropriate for most diabetic patients. A goal of 6.5% or lower may be appropriate in younger, healthier patients with less risk factors for hypoglycemia, and conversely a less stringent goal of less than 8.0% is considered appropriate for elder, altered, more frail patients with higher risk for hypoglycemia [26]. No specific recommendations for HbA1c targets in PAD patients exist to this date.

Smoking

The association between smoking and PAD and subsequent progression to CLI, amputation, CV events, and death has been well established, and it has time and again been implicated as the strongest and most preventable risk factor for the development of PAD. The Society for Vascular Surgery practice guidelines for the management of asymptomatic PAD and claudication identify smoking cessation as a GRADE 1A recommendation [27]. Not only is there a 2.2-fold increased risk of symptomatic PAD in active smokers versus nonsmokers, but there is also a significantly increased prevalence of PAD in former smokes compared to never-smokers, thus further emphasizing the importance of prevention in addition to cessation [28].

There is also a clear survival benefit with cessation. An observational cohort study of 739 patients with symptomatic PAD followed quitters versus nonquitters after lower-extremity angiography. Thirty percent were able to quit and maintain cessation 1 year out from angiography, and at a 5-year follow-up, quitters demonstrated significantly lower all-cause mortality (14% versus 31%) and higher amputation-free survival (81% versus 60%) compared to nonquitters [29]. Furthermore, patients who smoke and do require lower-extremity revascularization of any kind are at higher risk of failed intervention and postprocedural complications. A retrospective study of 15,534 patients who underwent infrainguinal bypass found significantly increased 30-day graft failure rates in smokers versus nonsmokers [8].

Despite the mountains of evidence in support of smoking cessation, tobacco use remains widely prevalent in the PAD population. From 2010 to 2015, 101,055 open and endovascular revascularization procedures were cataloged for smoking prevalence and cessation rates after intervention. At the time of intervention, 44% of patients were active smokers. Smoking was more prevalent among males, younger patients, and private insurance carriers. Smokers were also more likely to have lower overall medication compliance. At a 1-year follow-up, 36% of the smokers had quit—of these quitters, they were more likely to be older than 70, have an ABI > 0.9, and have undergone a bypass procedure rather than a percutaneous intervention [30]. Given the demographic findings of PAD patients who are most likely to be active smokers, this gives insight into targeted opportunities for prevention of disease progression through smoking cessation efforts.

Unfortunately, cessation is difficult to achieve and maintain, as demonstrated by multiple studies observing cessation efforts. A key issue identified is the clinician's preconceived belief that long-time smokers are unlikely to quit and that therefore efforts to promote cessation are futile [31]. A cluster-randomized trial of 156 tobacco-using patients at eight vascular surgery practices compared standard counseling to protocolized cessation counseling that included surgeon-driven cessation advice, prescriptions for cessation aids, and referral to a cessation hotline. At a 3-month follow-up, the intervention group demonstrated higher interest in quitting and better knowledge of the negative health effects of smoking [32]. This demonstrated that even with minimal intervention from the surgeon, there was a significant improvement in patient mindset with regard to smoking cessation.

Positive results have been found with intensive cessation regimens targeted at PAD patients. A study in 2 Minnesota vascular centers randomized 124 active smokers with PAD who expressed a desire to quit to intensive and minimal intervention groups. The intensive intervention group included counseling from the vascular provider to quit smoking, multiple sessions with a smoking cessation counselor providing education about smoking and PAD development and progression, offers of cessation pharmacotherapy, and identification of an outside social support person to facilitate cessation efforts. The minimal intervention group received a single admonishment to quit smoking and a list of referrals for outside cessation resources. At a 6-month follow-up, the intensive intervention group had biochemically verified quit rates of 21.3% compared to 6.8% in the minimal intervention group [33].

Hypertension

Numerous large-scale studies have demonstrated an overall decrease in adverse CV events including stroke and MI, chronic kidney disease, and mortality with improved blood pressure control [34]. Hypertension is also an independent risk factor for PAD; however, the association is not as strong as that of smoking and diabetes. The treatment of hypertension is mainly aimed at reducing the risk of adverse cardiovascular and cerebrovascular events and death. That said, the Treatment of Mild Hypertension Study demonstrated that pharmacologic antihypertensive

therapy in addition to dietary changes was associated with a decreased prevalence of intermittent claudication compared to dietary changes alone [35]. This is in contradiction to the theoretical concern that decreased systemic pressure may exacerbate symptomatic PAD due to decreased peripheral perfusion. The benefit of antihypertensive medications is clear; the choice of drug class is slightly murkier in the context of PAD. There existed debate about beta-blockers and their potential for worsening claudication—to date there is no clear evidence to support this, and in fact, a meta-analysis of 11 randomized trials found no association between beta-blockers and adverse effects on walking distance or claudication symptoms [36]. In the appropriate cardiac context, beta-blockers may be the preferred agent for antihypertensive control in PAD patients. That said, angiotensin-converting enzyme inhibitors (ACEIs) also demonstrate clear cardiac and renal protective effects and are potential for the improvement of claudication symptoms. The Heart Outcomes Prevention Evaluation study showed a 25% reduction of cardiac events with ramipril. A double-blind placebo-controlled trial in Australia demonstrated improvements in pain-free walk distance as well as maximum walk distance with ramipril versus placebo; however, this finding has not been reproduced in larger, long-term studies [37].

Dyslipidemia

Dyslipidemia is associated with a higher risk of adverse cardiovascular events, and reduction of cholesterol similarly reduces this risk. The Scandinavian Simvastatin Survival Study (4S) demonstrated that in patients with coronary artery disease, treatment with simvastatin was associated with a relative risk reduction of 42% for CAD-related death and 30% for all-cause mortality [38]. Many studies in the statin era have corroborated this finding and have even found cardiovascular benefits even in those patients with normal cholesterol levels. The pleiotropic effects of statins have been demonstrated in many large-scale, long-term studies.

Treatment of elevated low-density lipoprotein (LDL) has also been strongly implicated in slowing the progression of peripheral atherosclerotic disease burden as well as symptoms of PAD. In the Heart Protection Study, 6748 adults with PAD were randomized double-blindly to 40 mg of simvastatin daily versus placebo and followed for a mean of 5 years. The simvastatin arm demonstrated a 22% relative reduction in the rate of first major vascular event, defined as coronary artery events, strokes, or peripheral vascular events; and it showed a 16% relative reduction specifically for peripheral vascular events. The subgroup with normal LDL levels was conferred protection from adverse vascular events, suggesting as before that statin therapy's benefits extend beyond lowering serum lipid levels [39]. Some of these cholesterol-independent effects involve restoring endothelial function, stabilizing atherosclerotic plaques, and decreasing oxidative stress and vessel inflammation; however, the pleiotropic effects of statin therapy are incompletely understood [40].
