**Abstract.** We study the *time-bounded reachability problem* for *monotonic hybrid automata* (MHA), i.e., rectangular hybrid automata for which the rate of each variable is either always non-negative or always non-positive. In this paper, we revisit the decidability results presented in [5] and show that the problem is NEXPTIME-complete. We also show that we can effectively compute fixed points that characterise the sets of states that are reachable (resp. co-reachable) within **T** time units from a given state.

# **1 Introduction**

*Hybrid systems* form a general class of systems that mix *continuous* and *discrete* behaviors. Examples of hybrid systems abound in our everyday life, particularly in applications where an [\(in](#page-15-0)[he](#page-15-1)rently discrete) computer system interacts with a continuous environment. The need for modeling and analysing hybrid systems is thus obvious.

*Hybrid automata* are arguably among the most prominent families of models for hybrid systems [7]. Hybrid automata are finite automata (to model the discrete part of the system) augmented with a finite set of real-valued variables (to model the continuous part of the sy[stem](#page-15-2)). The variables evolve with time elapsing, at a rate which is given by a flow that depends on the current location of the automaton. The theory of hybrid automata has been well developed for about two decades, and tools to analyse them are readily available, for instance HYTECH [8,9].

Hybrid automata are thus a class of powerful models, yet their high expressiveness comes at a price, in the sense that the undecidability barrier is rapidly hit. Simple *reachability properties* are undecidable even for the restricted subclass of *stopwatch automata*, where the rate of growth of each variable stays constant in all locations and is restricted to either 0 or 1 (see [10] for a survey).

On the other hand, a recent and [suc](#page-15-3)cessful line of research in the setting of *timed automata* has outlined the benefits of investigating *timed-bounded variants* of classical properties [12,14]. For instance, while *language inclusion* is, in general undecidable for timed automata, it is decidable when considering only executions of *bounded duration*

<sup>-</sup>c Springer International Publishing Switzerland 2013

[14]. Following this line of research, we have recently investigated the decidability of *time-bounded reachability* for rectangular hybrid automata, i.e., whether a given state is reachable by an execution of duration at most **T**, for a given **T** [5]. We have shown that *time-bounded* reachability is *decidable* for *rectangular hybrid automata with nonnegative rates* ( $RHA^{\geq0}$ ), while it is well-known that (plain, time unbounded) reachability is undecidable for this class [10]. [W](#page-14-0)e have also shown that the decidability frontier is quite sharp: time-bounded reachability becomes *undecidable* once we allow either diagonal constraints in the guards or a single variable to have both positive and negative rates. The decidability result relies on [a so](#page-14-0)-called *contraction operator* that allows to construct, from any run of duration at most **T** of an RHA<sup> $\geq 0$ </sup> H, an *equivalent* run that reaches the same state, but whose length (in terms of number of discrete transitions) is *uniformly bounded* by a function  $F$  of the size of the automaton  $H$  and the bound **T**. Hence, deciding reachability within **T** time units reduces to exploring runs of bounded lengths only, which is algorithmically feasible [5]. Yet, this yields only a *nondeterministic algorithm with doubly exponential time complexity* for a strict subclass of RHA<sup> $\geq 0$ </sup>, and no lower bound is given.

In the present work, we revisit and extend the results from [5], both from the theoretical and the practical points of view. *First*, we consider the class of *monotonic hybrid automata* (MHA for short) which are rectangular hybrid automata where the rate of each variable is either always non-negative or always non-positive (thus, MHA generalise RHA≥<sup>0</sup>). *Second*, we provide a *new contraction operator* that allows to derive a *singly exponential upper bound* on the lengths of the runs that need to be considered, thereby providing an NEXPTIME algorithm for the whole class of MHA. *Third*, we show that this new algorithm is optimal, by establishin[g a](#page-14-1) matching lower bound. Hence, *time-bounded reachability for RHA*≥<sup>0</sup> *is* NEXPTIME*-complete*. *Fourth*, we extend those results towards practical applications, by showing that we *can effectively compute* the set of states that are reachable (resp. co-reachable) within **T** time units, from a given state. Finally, we apply those ideas to two examples of  $RHA^{\geq 0}$  for which the classical (time-unbounded) forward and backward fixpoints do not terminate. We manage to compute, using HYTECH, the set of states reachable within **T** time units for values of **T** that are sufficient to prove non-trivial properties of those examples

Note that the missing proofs can be found in the companion technical report [6].

# **2 Definitions**

Let *I* be the set of intervals of real numbers with endpoints in  $\mathbb{Z} \cup \{-\infty, +\infty\}$ . Let X be a set of continuous variables, and let  $\dot{X} = \{\dot{x} \mid x \in X\}$  be the set of dotted variables, corresponding to the variables' time derivatives. A *rectangular constraint* over X is an expression of the form  $x \in I$  where x belongs to X and I to I. A *diagonal constraint* over X is a constraint of the form  $x - y \sim c$  where x, y belong to X, c to Z, and ∼ is in  $\{\langle \xi, \xi, =, \rangle\}$ . Finite conjunctions of diagonal and rectangular constraints over X are called *guards*, and over X˙ are called *rate constraints*. A guard or rate constraint is *rectangular* if all its constraints are rectangular. We denote by  $\mathcal{G}(X)$  and  $\mathcal{R}(X)$ respectively the sets of guards and rate constraints over X.

*Linear, Rectangular and Singular Hybrid Automata.* A *linear hybrid automaton* (LHA) is a tuple  $\mathcal{H} = (X, \text{Loc}, \text{Edges}, \text{ Rates}, \text{Inv}, \text{Init})$  where  $X = \{x_1, \ldots, x_{|X|}\}$  is a finite set of continuous *variables*; Loc is a finite set of *locations*; Edges  $\subseteq$  Loc  $\times$   $\mathcal{G}(X)$   $\times$  $2^X \times$  Loc is a finite set of *edges*; Rates : Loc  $\mapsto \mathcal{R}(X)$  assigns to each location a constraint on the *possible variable rates*; Inv : Loc  $\mapsto$   $\mathcal{G}(X)$  assigns an *invariant* to each location; and Init  $\subseteq$  Loc is a *set of initial locations*. For an edge  $e = (\ell, g, Y, \ell')$ , we denote by src  $(e)$  and trg  $(e)$  the locations  $\ell$  and  $\ell'$  respectively g is called the *quard* we denote by src (e) and trg (e) the locations  $\ell$  and  $\ell'$  respectively, g is called the *guard*<br>of e and Y is the *reset* set of e. In the sequel, we denote by rmay and cmay the maximal of e and Y is the *reset* set of e. In the sequel, we denote by rmax and cmax the maximal constants occurring respectively in the constraints of  $\{Rate(\ell) | \ell \in Loc\}$  and of  $\{Rate(\ell) | \ell \in Loc\} | \{q \in Loc\}|$ {Rates( $\ell$ ) |  $\ell \in \text{Loc}$ }  $\cup$  {g |  $\exists (\ell, g, Y, \ell') \in \text{Edges}$ }.<br>An I HA has non-negative rates if for all variables

An LHA has *non-negative rates* if for all variables x, for all locations  $\ell$ , the constraint tes<sup>( $\ell$ )</sup> implies that  $\dot{x}$  must be non-negative. A *rectangular hybrid automaton* (RHA) Rates(*ℓ*) implies that *i*: must be non-negative. A *rectangular hybrid automaton* (RHA)<br>is a linear hybrid automaton in which all guards, rates, and invariants are rectangular. In is a linear hybrid automaton in which all guards, rates, and invariants are rectangular. In the case of RHA, we view rate constraints as functions Rates : Loc  $\times X \rightarrow \mathcal{I}$  that associate with each location  $\ell$  and each variable x an interval of possible rates  $Rates(\ell)(x)$ .<br>A monotonic hybrid qutamaton (MHA) is an RHA such that, for all variable x; either <sup>A</sup> *monotonic hybrid automaton* (MHA) is an RHA such that, for all variable x: either Rates( $\ell, x$ )  $\subseteq$   $[0, +\infty)$  in all locations  $\ell$ ; or Rates( $\ell, x$ )  $\subseteq$   $(-\infty, 0]$  in all locations  $\ell$  and for A singular hyptid automaton (SHA) is an RHA such that for all locations  $\ell$  and for all variables x: Rates( $\ell$ )(x) is a singleton. We note SMHA and RHA<sup>20</sup> for *singular*<br>MHA *non-negative rates* RHA resp. Note that MHA generalises RHA<sup>20</sup> . A *singular hybrid automaton* (SHA) is an RHA such that for all locations  $\ell$  and for the subset of  $\ell$  and  $\ell$  and MHA, *non-negative rates* RHA resp. Note that MHA generalises  $RHA^{\geq 0}$ .

*LHA Semantics.* A *valuation* of a set of variables X is a function  $\nu : X \mapsto \mathbb{R}$ . We denote by  $\bf{0}$  the valuation that assigns 0 to each variable. For a valuation x of X and a guard  $g \in \mathcal{G}(X)$ , we write  $v \models g$  iff v *satisfies* g. Given an LHA  $\mathcal{H} =$  $(X, \text{Loc}, \text{Edges}, \text{Rate}, \text{Inv}, \text{Init}, X)$ , a *state* of H is a pair  $(\ell, \nu)$ , where  $\ell \in \text{Loc}$  and  $\nu$  is a valuation of X. The semantics of H is defined as follows. For a state  $s - (\ell, \nu)$ v is a valuation of X. The semantics of H is defined as follows. For a state  $s = (\ell, \nu)$ <br>of H an adge stan  $(\ell, \nu)$ ,  $e_{\lambda}$ ,  $(\ell', \nu')$  can occur and change the state to  $(\ell', \nu')$  if of H, an *edge step*  $(\ell, \nu) \xrightarrow{e} (\ell', \nu')$  can occur and change the state to  $(\ell', \nu')$  if  $e = (\ell, \alpha, Y \ell') \in \text{Edges } \nu \models \alpha, \nu'(x) = \nu(x)$  for all  $x \notin Y$  and  $\nu'(x) = 0$  for all  $e = (\ell, g, Y, \ell') \in \text{Edges}, \nu \models g, \nu'(x) = \nu(x) \text{ for all } x \notin Y, \text{ and } \nu'(x) = 0 \text{ for all } x \notin Y, \text{ and } \nu'(x) = 0 \text{ for all } x \notin Y.$  $x \in Y$ ; for a time delay  $t \in \mathbb{R}^+$ , a *continuous time step*  $(\ell, \nu) \stackrel{t}{\to} (\ell, \nu')$  can occur and<br>change the state to  $(\ell, \nu')$  if there is a vector  $r - (r_1 - r_1 \nu)$  such that  $r \vdash$  Bates( $\ell$ ) change the state to  $(\ell, \nu')$  if there is a vector  $r = (r_1, \dots r_{|X|})$  such that  $r \models \text{Rates}(\ell),$ <br>  $\nu' = \nu + (r \cdot t)$  and  $\nu + (r \cdot t') \models \text{Inv}(\ell)$  for all  $0 \le t' \le t$  $\nu' = \nu + (r \cdot t)$ , and  $\nu + (r \cdot t') = \text{Inv}(\ell)$  for all  $0 \le t' \le t$ .<br>A nath in H is a finite sequence  $e_1$ ,  $e_2$ ,  $e_3$ ,  $e_4$ , of edges such

A *path* in H is a finite sequence  $e_1, e_2, \ldots, e_n$  of edges such that trg  $(e_i)$  = src  $(e_{i+1})$ for all  $1 \leq i \leq n - 1$ . A *timed path* of H is a finite sequence of the form  $\pi =$  $(t_1, e_1), (t_2, e_2), \ldots, (t_n, e_n)$ , such that  $e_1, \ldots, e_n$  is a path in H and  $t_i \in \mathbb{R}^+$  for all  $0 \le i \le n$ . For all k,  $\ell$ , we denote by  $\pi[k:\ell]$  the maximal portion  $(t_i, e_i), (t_{i+1}, e_{i+1}),$ <br>  $(t \cdot e_i)$  of  $\pi$  such that  $\{i, i+1 \}$   $i \in [k:\ell]$  (note that the interval  $[k:\ell]$  could ...,  $(t_j, e_j)$  of  $\pi$  such that  $\{i, i + 1, ..., j\} \subseteq [k, \ell]$  (note that the interval  $[k, \ell]$  could<br>be empty in which case  $\pi[k] \in \ell$  would be empty too). Given a timed path  $\pi$ be empty, in which case  $\pi[k : \ell]$  would be empty too). Given a timed path  $\pi = (t, e_1)$  ( $t, e_2$ ) ( $t, e_3$ ) ( $t, e_4$ ) of an SHA we let  $\text{Effect}(\pi) = \sum^n R \text{ates}(\ell, \pi) \cdot t$ .  $(t_1, e_1), (t_2, e_2), \ldots, (t_n, e_n)$  of an SHA, we let Effect  $(\pi) = \sum_{i=1}^n \text{ Rates}(\ell_{i-1}) \cdot t_i$ <br>be the *effect* of  $\pi$  (where  $\ell$  - src  $(e_1)$  for all  $1 \le i \le n$ ) be the *effect of*  $\pi$  (where  $\ell_i = \text{src}(e_i)$  for all  $1 \le i \le n$ ).<br>A run in  $\mathcal{H}$  is a sequence  $s_0$  (*t*<sub>1</sub>, *e*<sub>1</sub>)  $s_1$  (*t*<sub>0</sub>, *e*<sub>0</sub>).

A *run* in H is a sequence  $s_0, (t_1, e_1), s_1, (t_2, e_2), \ldots, (t_n, e_n), s_n$  s.t. (i)  $(t_1, e_1)$ ,  $(t_2, e_2), \ldots, (t_n, e_n)$  is a timed path in H, and  $(ii)$  for all  $0 \le i \le n$ , there exists a state  $s'_i$  of H with  $s_i \xrightarrow{t_{i+1}} s'_i$ <br>let first (a) = s<sub>o</sub> last (a) = s  $e_{i+1}$ ,  $s_{i+1}$ . Given a run  $\rho = s_0, (t_1, e_1), \ldots, s_n$ ,<br>duration  $(e)$  =  $\sum_{i=1}^{n} t_i$  and  $|e|$  =  $n + 1$ . We let first  $(\rho) = s_0$ , last  $(\rho) = s_n$ , duration  $(\rho) = \sum_{i=1}^n t_i$ , and  $|\rho| = n + 1$ . We say that a is T-time-bounded (for T  $\in \mathbb{N}$ ) if duration  $(a) \leq T$  Given two runs say that  $\rho$  is **T***-time-bounded* (for **T**  $\in$  N) if duration  $(\rho) \leq$  **T**. Given two runs

<span id="page-3-0"></span> $\rho = s_0, (t_1, e_1), \ldots, (t_n, e_n), s_n$  and  $\rho' = s'_0, (t'_1, e'_1), \ldots, (t'_k, e'_k), s'_k$  with  $s_n = s'_0$ ,<br>we let  $\rho \cdot \rho'$  denote the run  $s_0$  (t, e) (t, e) s (t, e) (t, e) (t, e) s' we let  $\rho \cdot \rho'$  denote the run  $s_0$ ,  $(t_1, e_1)$ ,  $\ldots$ ,  $(t_n, e_n)$ ,  $s_n$ ,  $(t'_1, e'_1)$ ,  $\ldots$ ,  $(t'_k, e'_k)$ ,  $s'_k$ .<br>Note that a unique timed nath TPath  $(a) - (t_1, e_1)$ ,  $(t_2, e_2)$ ,  $(t_3, e_2)$ , is

Note that a unique timed path TPath  $(\rho)=(t_1, e_1), (t_2, e_2), \ldots, (t_n, e_n)$ , is associated with each run  $\rho = s_0, (t_1, e_1), s_1, \ldots, (t_n, e_n), s_n$ . Hence, we sometimes abuse notation and denote a run  $\rho$  with first  $(\rho) = s_0$ , last  $(\rho) = s$  and TPath  $(\rho) = \pi$  by  $\frac{s_0}{\text{it}}$  $\frac{\pi}{\gamma}$  s. The converse however is not true: given a timed path  $\pi$  and an initial state  $s_0$ , could be impossible to build a run starting from  $s_0$  and following  $\pi$  because some it could be impossible to build a run starting from  $s_0$  and following  $\pi$  because some<br>guards or invariants along  $\pi$  might be violated. However, when the qutomaton is singuguards or invariants along π might be violated. However, *when the automaton is singular*, such a run is necessarily unique if it exists, and we denote by Run  $(s_0, \pi)$  the function that returns the unique run  $\rho$  such that first ( $\rho$ ) = s<sub>0</sub> and TPath ( $\rho$ ) =  $\pi$  if it exists, and  $\perp$  otherwise. Note that, when considering an SHA: if  $\rho = (\ell_0, \nu_0) \xrightarrow{\pi} (\ell_n, \nu_n)$  is a<br>run then for all x that is *not reset* along  $\alpha: \nu_\ell(x) = \nu_0(x) + \text{Effect } (\pi)(x)$ run, then for all x that is *not reset* along  $\rho$ :  $\nu_n(x) = \nu_0(x) + \text{Effect}(\pi)(x)$ .

*Time-B[ou](#page-14-0)nded Reachability Problem.* While the reachability problem asks whether there i[s a](#page-10-0) run reaching a given goal location, we consider only runs with *bounded duration*.

*Problem 1 (Time-bounded reacha[bil](#page-14-0)ity problem[\).](#page-12-0)* Given an LHA  $\mathcal{H} = (X, \text{Loc}, \text{Edges},$ Rates, Inv, Init), a location Goal  $\in$  Loc and a time bound  $\mathbf{T} \in \mathbb{N}$ , the *time-bounded reachability problem* is to decide whether there exists a finite run  $\rho = (\ell_0, \mathbf{0}) \stackrel{\pi}{\rightarrow}$ <br>(Goal .) of  $\mathcal{H}$  with  $\ell_0 \in$  Init and duration (*o*)  $\leq$  **T**  $(\text{Goal}, \cdot)$  of  $\mathcal H$  with  $\ell_0 \in \text{Init}$  and duration  $(\rho) \leq \mathbf{T}$ .

This problem is decidable [5] for  $RHA^{\geq 0}$ , but its exact complexi[ty](#page-4-0) was left open until now. We prove in Section 4 that it is **NEXPTIME-complete for MHA** . This problem is known to become undecidable either when diagonal constraints are allowed in the guards, or when non-monotonic RHA are considered [5]. In Section 5, we extend these results [by](#page-14-2) showing how to compute a finite and algorithmically manipulable representation of the set of states that are reachable within **T** time units.

L[et u](#page-12-0)s illustrate, by means of the MHA (actually an RHA<sup> $\geq 0$ </sup>) H in Fig. 1 (left), the difficulties encountered when computing the reachable states. In this example, one can show that the set of reachable states is not a finite union of polyhedra, see Fig. 1 (right). Moreover, one can observe that the number of bits necessary to encode the states reachable from  $(\ell_0, 0, 0)$  grows *linearly* with the length of the run. This example shows<br>that finding an adequate, compact and effective representation (such as regions in the that finding an adequate, compact and effective representation (such as regions in the case of Timed Automata [2]) for the set of reachable states of an MHA is not trivial (and, in full generality, impossible because reachability is undecidable for this class). Nevertheless, in Section 5, we show that, for MHA, an effective representation of the set of states that are reachable *within* **T** *time units* can be computed.

## **3 Bounding the Length of Time-Bounded Runs**

In this section, we prove the main technical result of the paper. For the sake of clarity, we consider a *singular* MHA  $\mathcal{H} = (X, \text{Loc}, \text{Edges}, \text{ Rates}, \text{Inv}, \text{Init})$  and explain later why the results extend to general MHA. The result we prove is that 'H *can reach a state* s *within* **<sup>T</sup>** *time unit iff it can reach* s *within* **<sup>T</sup>** *time unit by a run of bounded length*, where the bound is *uniform*: it depends only on **T** and on the number  $|\mathcal{H}|$  of bits

<span id="page-4-1"></span>**Fig. 1.** An MHA with its set of reachable states

necessary to encode  $H$  (with standard encoding for the constant[s\).](#page-4-1) More precisely, let  $F(\mathcal{H}, \mathbf{T}) = 24 \times (\mathbf{T} \times \text{rmax} + 1) \times |X|^2 \times |\text{Loc}|^2 \times (2 \times \text{cmax} + 3)^{2 \times |X|}$ . Then:

**Theorem 2.** Let  $H$  *be an SMHA,* **T** *be a time bound and let*  $s_1$  *and*  $s_2$  *be two states of* H. Then H admits a **T**-time-bounded run  $\rho$  with first ( $\rho$ ) = s<sub>1</sub> and last ( $\rho$ ) = s<sub>2</sub> iff it *admits a* **T***-time-bounded run*  $\rho'$  *s.t.*  $|\rho'| \leq F(\mathcal{H}, \mathbf{T})$ *,* first  $(\rho') = s_1$  *and* last  $(\rho') = s_2$ *.* 

This theorem will be used in the next sections to obtain optimal algorithms for deciding time-bounded reachability. Observe that  $F(\mathcal{H}, \mathbf{T}) = \mathcal{O}(\mathbf{T} \times 2^{|\mathcal{H}|})$ . Thus, Theorem 2 says that, to decide **T**-time-bounded reachability, we only need to consider runs whose l[e](#page-4-1)ngth is exponential in the size of the instance  $(\mathcal{H}, \mathbf{T})$ .

We establish this result in two steps. First, we show that **each time-bounded run can be split into a** *bounded* **number of so-called type-2 (sub-)runs** (see hereunder for the definitions of type-0, type-1 and type-2 runs). Because of the density of time, we cannot bound the length [of](#page-4-2) those type-2 runs, yet we show that they enjoy properties that allow us to **replace each type-2 run by an equivalent run of bounded length**. By *equivalent* we mean a run that starts and ends in the same states, and has the same duration. Combining the bounds on the number of type-2 runs and on the length of the [ru](#page-5-0)ns we substitute to the original type-2 runs, we obtain Theorem 2.

<span id="page-4-2"></span>*Contraction Operator.* To obtain the bounded [len](#page-5-0)gth runs that we substitute to the original type-2 runs, we rely on a *contraction operat[or](#page-8-0)*. As this operator is central to our proof we start by describing it intuitively<sup>1</sup>. Let  $\rho = (\ell_0, \nu_0), (t_1, e_1), (\ell_1, \nu_1), \ldots, (t_{n-1}, \ell_{n-1}), (t_{n-1}, \ell_{n-1})$  be a run and let  $\pi - \text{TPath}(\rho)$ . We contract  $\pi$  by looking for a pair  $(t_n, e_n)$ ,  $(\ell_n, \nu_n)$  be a run, and let  $\pi = \text{TPath}(\rho)$ . We *contract*  $\pi$  by looking for a pair of positions  $i < i$  s t  $\ell_i = \ell_i$  (i.e.  $\pi[i+1-i]$  forms a loop) and s t all locations of positions  $i < j$  s.t.  $\ell_i = \ell_j$  (i.e.,  $\pi[i + 1 : j]$  forms a loop) *and* s.t. all locations  $\ell_{i+1}$ ,  $\ell_{i+2}$ ,  $\ell_{i+3}$ ,  $\ell_{i+4}$  occur in the prefix  $\pi[1 : j]$ . An example is the timed path of the run  $\rho$  in the top of Fig. 2. Then, the contraction consists, roughly speaking, in *deleting* the  $i_{i+1}, \ell_{i+2}, \ldots, \ell_j$  occur in the prefix  $\pi[1 : i]$ . An example is the timed path of the run<br>in the top of Fig. 2. Then, the contraction consists, roughly speaking in deleting the portion  $\pi[i + 1 : j]$  $\pi[i + 1 : j]$  $\pi[i + 1 : j]$  from  $\pi$ , and in *reporting* the delays  $t_{i+1}, \ldots, t_{j-1}$  to the other occurrences of  $\ell_i, \ldots, \ell_{j-1}$  in  $\pi$  (that exist by hypothesis), see Fig. 2. Obviously, this contraction returns a timed path with shorter length. We show (Lemma 7 hereunder) occurrences of  $\ell_i, \ldots, \ell_{j-1}$  $\ell_i, \ldots, \ell_{j-1}$  $\ell_i, \ldots, \ell_{j-1}$  in  $\pi$  (that exist by hypothesis), see Fig. 2. Obviously, this contraction returns a timed path *with shorter length*. We show (Lemma 7 hereunder) that, by repeatedly applying this contraction, we obtain a timed path  $\text{Cnt}^*(\pi)$  whose length is bounded by  $|Loc|^2 + 1$ , i.e. a value that does not depend on the length of  $\pi$ .<br>Now we can lift the definition of the contraction operator to runs; for a run

Now, we can lift the definition of the contraction operator to runs: for a run  $\rho$ , Cnt ( $\rho$ ) = Run (first ( $\rho$ ), Cnt<sup>\*</sup> (TPath ( $\rho$ ))). Clearly, there is, in general, no guarantee

<sup>&</sup>lt;sup>1</sup> The definition of this operator is crucial to obtain the NEXPTIME algorithm in Section 4. It differs from the one introduced in [5], which does not allow to obtain an NEXPTIME algorithm.

<span id="page-5-0"></span>
$$
\rho = (\ell_0, \nu_0) \xrightarrow{t_1, e_1} (\ell_1, \nu_1) \xrightarrow{t_2, e_2} (\ell_0, \nu_2) \xrightarrow{t_3, e_3} (\ell_1, \nu_3) \xrightarrow{t_4, e_4} (\ell_2, \nu_4)
$$
  
Cut (TPath  $(\rho)$ ) =  $\ell_0 \xrightarrow{t_1 + t_3, e_1} \ell_1 \xrightarrow{t_2 + t_4, e_4} \ell_2$ 

**Fig. 2.** [Ill](#page-5-0)ustrating the contraction operator

that this contracted run exists, i.e. that Cnt ( $\rho$ )  $\neq \perp$  (see examples hereunder). However, we will show that, when correctly applied to so-called type-2 runs (see hereunder for the precise definition), Cnt( $\rho$ ) produces a genuine run of bounded length that starts and ends in the same states as the original run.

Let us now discuss several concrete examples of this contraction procedure. In all these examples, we assume an MHA with a single variable  $x$  whose rate is 1 in all locations, and we consider the run  $\rho$  depicted in Fig. 2. We also let  $\pi' = \text{Cnt}(\text{TPath}(\rho))$ and  $\rho' = \text{Run}((\ell_0, \nu_0), \pi')$  – thus,  $\rho'$  could be equal to  $\bot$ . *First* assume that  $\nu_0(x) = 0$ , that  $t_1 - t_2 - t_3 - t_4 - 1$  and that all edges  $e_1$  and not reset x. In this case that  $t_1 = t_2 = t_3 = t_4 = .1$  and that all edges  $e_1, \ldots, e_4$  dot not reset x. In this case,  $\rho'$  is a genuine run that reaches ( $\ell_2$ , 4). However, as remarked above, there are many<br>cases where either  $\rho' = \pm$  or  $\rho' \neq \pm$  but does not reach the same state as  $\rho$ . Let us cases where either  $\rho' = \perp$  or  $\rho' \neq \perp$  but does not reach the same state as  $\rho$ . Let us observe four of these cases, as they will be used later to justify our constructions.

**Case 1.** Assume x is never reset along  $\rho$ ,  $\nu_0(x) = 0$ ,  $t_1 = t_3 = 1$  and the guard of  $e_1$ is  $x = 1$ . Then,  $\rho' = \perp$  as  $\nu_0(x) + t_1 + t_3 = 2$  and does not satisfy the guard of  $e_1$ . Intuitively, the problem occurs because x crosses value 1 along  $\rho$ , and the compression reports the delay  $t_3$ , occurring *after* x crosses 1 in the original run, to a part where  $x \le 1$ in the original run. To avoid this, we split the run once a variable changes its *region*, where the regions are [0, 1) and all [a, a],  $(a, a + 1)$  for  $a \ge 1$ . Since we consider timebounded runs, we obtain a *bounded number of sub-runs*. Note that we *do not* split when a variable moves from  $[0, 0]$  to  $(0, 1)$  or vice-versa, because the density of time allows a variable to be reset and to increase strictly an *unbounded* number of times in any time interval. Hence, this splitting strategy is not sufficient to guarantee that Cnt( $\rho$ )  $\neq \bot$ and is equivalent to  $\rho$ , as shown by the next three cases, where x is in [0, 1) along  $\rho$ .

**Case 2.** Assume  $\rho' \neq \bot$ ,  $e_1$  resets x,  $e_2$ ,  $e_3$  and  $e_4$  do not reset x and  $t_1 = t_2 = t_3 =$  $t_4 = .1$ . Then,  $\nu_4(x) = t_2 + t_3 + t_4 = .3$ . Observe that  $\nu_4(x)$  depends only on the run portion that occurs *after*  $e_1$  because  $e_1$  is the last edge to reset x. On the other hand, ρ' reaches a state  $(\ell_2, \nu)$  with  $\nu(x) = t_2 + t_4 = .2 \neq \nu_4(x)$ , because the contraction<br>reports before the last reset (e,), the delay to that accurs after the last reset in a *reports, before the last reset* (*e*<sub>1</sub>), *the delay*  $t_3$  *that occurs after the last reset in ρ*.

**Case 3.** Assume  $\nu_0(x) = .8$ ,  $t_1 = t_3 = .1$ , the guard of  $e_1$  is  $x < 1$  and  $e_1$  resets x. Then,  $\rho' = \perp$ , as  $\nu_0(x) + t_1 + t_3 = 1$ , which does not satisfy the guard of  $e_1$ . Intuitively, the problem occurs because the time delay  $t_3$  that takes place *after the first reset of*  $x$  in ρ has been reported *before the first reset of* x.

**Case 4.** Assume  $\nu_0(x) = 0, t_1 = 0, t_2 = t_3 = t_4 = .1, e_2, e_3$  and  $e_4$  reset x, and the guard of  $e_1$  is  $x = 0$ . Further assume that that x has just been reset when entering Intuitively, the problem occurs because, x is null when entering *and* leaving the first<br>occurrence of  $\ell_0$ , while it is null when entering and non-null when leaving the second  $\ell_0$ . Then,  $\rho' = \bot$ , as  $\nu_0(x) + t_1 + t_3 = .1$ , which does not satisfy the guard of  $e_1$ . occurrence of  $\ell_0$ , while it is null when entering and non-null when leaving the second

occurrence of  $\ell_0$ . Thus, the time delay  $t_3$  should not be reported to the first occurrence<br>of  $\ell_2$ . To avoid this, we label locations with special regions telling us whether x is null of  $\ell_0$ . To avoid this, we *label locations* with special *regions* telling us whether x is null<br>when leaving the location (region  $0^{\pm}$ ) or not  $(0^+)$  and we will forbid the contraction when leaving the location (region  $0^=$ ) or not  $(0^+)$ , and we will forbid the contraction operator to report delay from one location to another with different regions.

The actual splitting into type-2 runs proceeds stepwise: we split a run into type-1 runs, then each type-1 in type-2 runs, so that we avoid the pitfalls described above. As explained in the discussion of case 1 above, we firs[t](#page-14-2) [n](#page-14-2)eed to track the *regions* of the variables, thanks to the following construction.

*Region Labelling.* Let Reg (cmax) =  $(\{[a, a], (a - 1, a) | a \in \{1, ..., \text{cmax}\}\}\cup$  $\{0^{\pm}, 0^{\pm}, (\text{cmax}, +\infty)\}\)$  be the set of *regions*, and further let Reg (cmax, X) denote the set of all functions  $r : X \mapsto \text{Res}$  (cmax) that assign a region to each variable. By the set of all functions  $r : X \mapsto \text{Reg (cmax)}$  that assign a region to each variable. By abuse of language, we sometimes call *regions* elements of Reg (cmax, X) too. Remark that the definition of Reg (cmax, X) differs from the classical regions [2] by the absence of  $[0, 0]$  which is replaced by two symbols:  $0^=$  and  $0^+$ , and by the fact that no information is retained about the relative values of the fractional parts of the variables. The reason of the introduction of the two regions  $0^{\text{=}}$  and  $0^{\text{+}}$  is to avoid the problem occurring in Case 4 above. When testing for membership to a region,  $0^+$  and  $0^-$  should be interpreted as [0, 0], i.e.,  $v \in \mathbf{0}^+$  and  $v \in \mathbf{0}^-$  hold iff  $v = 0$ . Given a valuation  $\nu$  of the set of variable X, and  $r \in \text{Reg (cmax, X)}$ , we let  $\nu \in r$  iff  $\nu(x) \in r(x)$  for all x, and, provided that  $\nu > 0$ , we denote by  $[\nu]$  the (unique) element from Reg (cmax, X) s.t.  $\nu \in [\nu]$ . Remark that for all sets of variable X and all maximal constants cmax:  $|\text{Reg (cmax, } X)| \leq (2 \times \text{cmax} + 3)^{|X|}$ . Let  $r_1$  and  $r_2$  be two regions in Reg (cmax, X), and let  $v : X \mapsto \mathbb{R}$  be a function assigning a rate  $v(x)$  to each variable x. Then, we say that  $r_2$  *is a time successor of*  $r_1$  *under* v (written  $r_1 \leq v$ ;  $r_2$ ) iff there are  $\nu_1 \in r_1$ ,<br> $\nu_2 \in r_2$  and a time delay t s t  $\nu_2 = \nu_1 + t_1$ , *n* Remark that by this definition we  $\nu_2 \in r_2$  and a time delay t s.t.  $\nu_2 = \nu_1 + t \cdot v$ . Remark that, by this definition, we can have  $r_1 \leq v_s r_2$ ,  $r_1(x) = \mathbf{0}$  and  $r_2(x) = \mathbf{0}^+$  for some variable x (for instance, if  $v(x) = 0$ )  $v(x)=0$ .

Let us now explain how we label the locations of H by regions. We let R  $(H)$  =  $(X, \text{Loc}', \text{Edges}', \text{Rates}', \text{Inv}', \text{Init}')$  be the SMHA where:

- $\mathbf{L} = \mathbf{L} \mathbf{o} \mathbf{c}' = \mathbf{L} \mathbf{o} \mathbf{c} \times \mathbf{Reg} (\text{cmax}, X)$  and  $\text{Init}' = \text{Init} \times \{ \mathbf{0}^= \mathbf{0}^+ \}^X$ <br>  $\mathbf{L} = \text{for all } (\ell, r) \in \text{Loc}' : \text{Rate}'(\ell, r) = \text{Rate}(\ell) : \text{Inv}(\ell, r) = \text{Inv}(\ell)$
- $\begin{split} \text{\textend{split}} \text{\textendash} \text{ for all } (\ell, r) \in \text{Loc}' : \text{Rates}'(\ell, r) = \text{Rates}(\ell); \text{Inv}(\ell, r) = \text{Inv}(\ell) \land \bigwedge_{x: r(x)} \text{Inv}$  $\bigwedge_{x:r(x)=\mathbf{0}^=} x=0$
- **–** There is an edge  $e' = ((\ell, r), g \wedge x \in r'' \wedge g_0, Y, (\ell', r'))$  in Edges' iff there are an edge  $e = (\ell, g, Y, \ell')$  in Edges and a region  $r''$  s.t.:  $r \leq_{ts}^{R \text{ates}(t)} r''$ , for all  $x \notin Y$ :<br>  $r'(x) = r''(x)$  for all  $x \in Y$ :  $r'(x) \in \{0, 0\}$  and  $g_0 = \Lambda$   $g_0(x)$  where ) in Edges and a region r'' s.t.:  $r \leq_{ts}^{\text{Rates}(\ell)}$ <br>sall  $x \in V$ ;  $r'(x) \in \Omega = 0^+1$  and  $g_0$  $r'(x) = r''(x)$ , for all  $x \in Y$ :  $r'(x) \in \{0^=, 0^+\}$  and  $g_0 = \bigwedge_{x \in X} g_0(x)$  where<br>for all  $x \in Y$ ;  $g_0(x) = (x - 0)$  if  $r(x) = 0^=$ ;  $g_0(x) = (x > 0)$  if  $r(x) = 0^+$ ; for all  $x \in X$ :  $g_0(x) = (x = 0)$  if  $r(x) = \mathbf{0}^=$ ;  $g_0(x) = (x > 0)$  if  $r(x) = \mathbf{0}^+$ ; and  $g_0(x)$  = **true** otherwise. In this case, we say that e is the (unique) edge of H *corresponding* to  $e'$ . Symmetrically,  $e'$  is the only edge corresponding to  $e$  between locations  $(\ell, r)$  and  $(\ell', r')$ locations  $(\ell, r)$  and  $(\ell', r')$ .

It is easy to see that this construction incurs an exponential blow up in the number of locations, but preserves reachability of states. More precisely,  $|Loc| \leq |Loc| \times$  $|\text{Reg (cmax, } X)| = |\text{Loc}| \times (2 \times \text{cmax} + 3)^{|X|}$  and:

**Lemma 3.** H *admits a run*  $\rho$  *with* first  $(\rho) = (\ell, \nu)$  *and* last  $(\rho) = (\ell', \nu')$  *iff there are*<br>*r and r' s t R (H) admits a run* o' with first  $(\rho') = ((\ell, \nu), \nu)$  last  $(\rho') = ((\ell', \nu'), \nu')$ *r and* r' *s.t.* R(H) *admits a run*  $\rho'$  *with* first( $\rho'$ ) = (( $\ell$ , r),  $\nu$ ), last( $\rho'$ ) = (( $\ell'$ , r'),  $\nu'$ ), duration ( $\rho$ ) and  $|\rho| = |\rho'|$ duration  $(\rho)$  = duration  $(\rho')$  *and*  $|\rho| = |\rho'|$ .

Intuitively, the regions that label locations in  $R(H)$  track the region to which each variable belongs when entering the location. However, in the case where a variable  $x$ enters a location with value 0, we also need to remember whether  $x$  is still null when crossing the next edge, to avoid the issue with the contraction operator described in case 4 above. This explains the two regions,  $0^{\text{=}}$  and  $0^{\text{+}}$ , corresponding to 0. They encode the fact that the variable is null (resp. strictly positive) when leaving the location.

<span id="page-7-0"></span>*Type-0 and Type-1 Runs.* Without loss of generality, we assume that, if a state is reachable, then it is reachable by a run of the same duration which can be split into at most  $\mathbf{T} \times \text{rmax} + 1$  portions of duration  $\langle \frac{1}{\text{rmax}} \rangle$ . In practice, this can be achieved by adding<br>one self-loop on all locations of  $\mathbf{R}(\mathcal{H})$  which does not impact time-bounded reachabilone self-loop on all locations of  $R(H)$ , which does not impact time-bounded reachability. Such runs of  $\rho$  of R (H) are called *type-0 runs* and are of the form  $\rho = \rho_0 \cdot \rho_1 \cdots \rho_k$ s.t. for all  $0 \le i \le k$ : duration  $(\rho_i) < \frac{1}{\text{max}}$ . Each  $\rho_i$  is called a *type-1 run. Intuitively*, each variable will cross at most one integer value different from 0 in each type-1 run. each variable will *cross at most one integer value different from 0* in each type 1 run, because the automaton is *monotonic*. For instance, if  $x \in (2,3)$  at the beginning of a type-1 run, then x can reach  $(3, 4)$  along the run, but will never cross 4. However, x could be reset and cross 0 an unbounded number of times because of time density.

*Type-2 Runs.* Let  $\rho = (\ell_0, \nu_0), (t_1, e_1), (\ell_1, \nu_1), \ldots, (t_n, e_n), (\ell_n, \nu_n)$  be a type-1 run s t duration  $(a) \leq T$ . Let S, be the set of all  $0 \leq i \leq n$  s t; s.t. duration ( $\rho$ )  $\leq$  **T**. Let  $S_\rho$  be the set of all  $0 < i \leq n$  s.t:

$$
\exists x \in X : (\lfloor \nu_{i-1}(x) \rfloor \neq \lfloor \nu_i(x) \rfloor) \text{ or } (\lfloor \nu_{i-1}(x) \rfloor > 0 \text{ and } 0 = \langle \nu_{i-1}(x) \rangle < \langle \nu_i(x) \rangle)
$$

where  $x \mid x$  and  $\langle x \rangle$  denote re[spe](#page-7-0)ctively the integral and fractional parts of x. Roughly speaking, each transition  $(t_i, e_i)$  with  $i \in S_\rho$  corresponds to the fact that a variable changes its region, except in the case where the variable moves from 0 to  $(0, 1)$  or from  $(0, 1)$  to 0: such transitions are not recorded in  $S_\rho$ . Since each variable crosses a strictly positive integer value at most once along the *type-1 run*  $\rho$ ,  $|S_{\rho}|$  can be bounded:

**Lemma 4.** *For all type-1 run ρ:*  $|S_{\rho}| \leq 3 \times |X|$ *.* 

Had we recorded in  $S_\rho$  the indices of the transitions from  $(\ell, \nu)$  to  $(\ell', \nu')$  s.t.  $\nu(x) = 0$ <br>and  $\nu(x) \in (0, 1)$  for some variable x. Lemma A would not hold, and we could not and  $\nu(x) \in (0,1)$  for some variable x, Lemma 4 would not hold, and we could not bound the size of  $S_\rho$  by a value independent from  $|\rho|$ . Indeed, in any time interval, the density of time allows a variable to be reset and increase an arbitrary number of times.

Let us now explain how we split type-1 runs into type-2 runs. We first consider an example. Consider an RHA with two variables x, y (with rate 1) and one of its runs  $\rho = (\ell_0, 2.1, .7) \xrightarrow{.4, e_1} (\ell_1, 2.5, 1.1) \xrightarrow{.1, e_2} (\ell_2, 2.6, 1.2) \xrightarrow{.1, e_3} (\ell_3, 0, 1.3) \xrightarrow{.1, e_4}$  $(\ell_4, 1, 1.4) \xrightarrow{1, e_5} (\ell_3, 0, 1.5)$ , and where  $e_3$  and  $e_5$  reset x. Then  $S_\rho = \{1, 3\}$  because y changes its integral part from  $(\ell_0, 2.1, .7)$  to  $(\ell_1, 2.5, 1.1)$  and x is reset by  $e_3$  and changes<br>its integral part. Also,  $\{A, 5\} \cap S = \emptyset$  as x and y stay resp. in [0, 1) and (1, 2). Then its integral part. Also,  $\{4, 5\} \cap S_\rho = \emptyset$  as x and y stay resp. in [0, 1) and (1, 2). Then,  $\rho$  is split in 5 parts: first  $\rho_0 = (\ell_0, 2.1, .7)$ ; then  $\rho'_1 = (\ell_0, 2.1, .7) \xrightarrow{.4, e_1} (\ell_1, 2.5, 1.1)$ ; <span id="page-8-1"></span>then  $\rho_1 = (\ell_1, 2.5, 1.1) \xrightarrow{1, e_2} (\ell_2, 2.6, 1.2)$ ; then  $\rho_2' = (\ell_2, 2.6, 1.2) \xrightarrow{1, e_3} (\ell_3, 0, 1.3)$ and  $\rho_2 = (\ell_3, 0, 1.3) \xrightarrow{.1, e_4} (\ell_4, .1, 1.4) \xrightarrow{.1, e_5} (\ell_3, 0, 1.5).$ <br>Formally assume  $\rho_2 = \frac{e_2}{\ell_1} (\ell_2, e_1) \cdot \frac{(1 - e_2)}{\ell_2}$ 

Formally, assume  $\rho = s_0, (t_1, e_1), s_1, \ldots, (t_n, e_n), s_n$ , and  $S_\rho = \{p_1, \ldots, p_k\}$ , with  $p_1 \leq p_2 \leq \cdots \leq p_k$ . Then, we let  $\rho_0, \rho_1, \ldots, \rho_k$  be the sub-runs s.t.:  $\rho =$  $\rho_0 \cdot s_{p_1-1}, (t_{p_1}, e_{p_1}), s_{p_1} \cdot \rho_1 \cdot s_{p_2-1}, (t_{p_2}, e_{p_2}), s_{p_2}, \ldots, s_{p_k-1}, (t_{p_k}, e_{p_k}), s_{p_k} \cdot \rho_k$ . Each  $\rho_i$  is called a *type-2 run*, and can be empty. In the example above,  $\rho_1$  and  $\rho_2$  are type-2 runs. The next lemma summarises the properties of this construction:

**Lemma 5.** Let  $\rho$  be a type-1 run of  $R(H)$  with duration  $(\rho) \leq T$ *. Then,*  $\rho$  *is split into:*  $\rho_0 \cdot \rho'_1 \cdot \rho_1 \cdot \rho'_2 \cdot \rho_2 \cdots \rho'_k \cdot \rho_k$  where each  $\rho_i$  is a type-2 run;  $k \leq 3 \times |X|$ ;  $|\rho'_i| = 1$  for all  $1 \leq i \leq k$ ; and for all  $1 \leq i \leq k$ ;  $\alpha = (\ell_0, \nu_0)$   $(t, \ell_1)$   $(t, \ell_2)$   $(t, \ell_1)$  implies  $1 \leq i \leq k$ ; and for all  $1 \leq i \leq k$ :  $\rho_i = (\ell_0, \nu_0), (t_1, e_1), \ldots, (t_n, e_n), (\ell_n, \nu_n)$  implies<br>that for all  $r \in X \cdot (i)$  either there is  $a \in \mathbb{N}^{>0}$  st for all  $0 \leq i \leq n$ ;  $\nu_i(x) = a$  and x *that, for all*  $x \in X$ *:* (*i*) either *there is*  $a \in \mathbb{N}^{>0}$  *s.t. for all*  $0 \le j \le n$ *:*  $\nu_j(x) = a$  *and* x *is not reset along*  $\rho_i$ *;* (*ii*) or *for all*  $0 \leq j \leq n$ *:*  $\nu_i(x) \in (a, a + 1)$  *with*  $a \in \mathbb{N}^{>0}$  *and* x *is not reset along*  $\rho_i$ ; (*iii*) or *for all*  $0 \leq j \leq n$ :  $\nu_i(x) \in [0, 1)$ *.* 

Observe that in the last case (i.e.,  $x \in [0, 1)$ ), the number of resets cannot be bounded *a priori*. For the sake of clarity, let us summarise the construction so far:

**Lemma 6.** *Each type-0 run of*  $R(H)$  *can be decomposed into* k *type-2 runs with*  $k \leq$  $3 \times (T \times \text{rmax} + 1) \times |X|$ .

<span id="page-8-0"></span>*Contraction of Type-2 Runs.* We finish the construction by defining formally the contraction operator and establishing its properties. The formal definition follows the intuition sketched at the beginning of the section (see Fig. 2). Let  $\pi = (t_1, e_1), (t_2, e_2), \ldots$ ,  $(t_n, e_n)$  be a timed path, let  $\ell_0 = \text{src}(e_1)$ , and, for all  $1 \le i \le n$ :  $\ell_i = \text{trg}(e_i)$ . Assume there are  $0 \leq i < j < n$  and a function  $h : \{i+1,\ldots,j-1\} \mapsto \{0,\ldots,i-1\}$ s.t. (i)  $\ell_i = \ell_j$  and (ii) for all  $i < p < j$ :  $\ell_p = \ell_{h(p)}$ . Then, we let  $\text{Cnt}(\pi) =$ <br> $\ell'_{h}(t', e') = \ell'_{h}(t', e')$  where (i)  $m = n - (i - i)$ ; (ii) for all  $0 < n < i$ ;  $\ell' = \ell$ ; (iii) for all  $1 \le p \le i$ :  $e'_p = e_p$  and  $t'_p = t_p + \sum_{k \in h^{-1}(p-1)} t_{k+1}$ ; (iv)  $e'_{i+1} = e_{j+1}$ ;<br>(a)  $e'_{i+1} = e_{j+1}$ ; and (a) for all  $i+1 \le p \le m$ ;  $e'_{i+1} = e_{j+1}$ ;  $\begin{array}{l} \n\frac{1}{2} & \frac{1}{2} & \frac{$  $(v)$   $t'_{i+1} = t_{i+1} + t_{j+1}$ ; and  $(vi)$  for all  $i + 1 < p \le m$ :  $\ell'_{p} = \ell_{p+j-i}$  and  $(t'_{p}, e'_{p}) =$  $(t_{p+j-i}, e_{p+j-i}).$ 

Then, given a timed path  $\pi$ , we let Cnt<sup>0</sup> ( $\pi$ ) =  $\pi$ , Cnt<sup>i</sup> ( $\pi$ ) = Cnt (Cnt<sup>i-1</sup> ( $\pi$ )) for  $\pi$ ,  $\leq$  1 and Cn<sup>tk</sup> ( $\pi$ ) continuously in the locatively quantity for  $\pi$ <sup>k</sup> ( $\pi$ ) any  $i \geq 1$ , and Cnt<sup>\*</sup> ( $\pi$ ) = Cnt<sup>k</sup> ( $\pi$ ) where k is the least value such that Cnt<sup>k</sup> ( $\pi$ ) = Cnt<sup>k+1</sup> (π). Note that Cnt<sup>\*</sup> (π) always exists since  $\pi$  is finite, and since, for all  $\pi$ : either  $|\text{Cnt}(\pi)| < |\pi|$  or  $\text{Cnt}(\pi) = \pi$ . Moreover, the length of  $\text{Cnt}^*(\pi)$  is always bounded by a value *that does not depend on*  $|\pi|$ .

**Lemma 7.** *For all timed path*  $\pi$ *:*  $|\text{Cont}^*(\pi)| \leq |\text{Loc}|^2 + 1$ *.* 

Let us now lift the definition of the contraction operator to *runs* of type-2. To this end, we first need to further split type-2 runs into type-3 runs by splitting type-2 runs according to the first and last resets (if they exist) of each variable. Formally, let  $s_0, (t_1, e_1), s_1, \ldots, (t_n, e_n), s_n$  be a type-2 run. Assume  $Y_i$  is the reset set of  $e_i$ , for all  $1 \leq i \leq n$ . We let  $FR_{\rho} = \{i \mid \exists x \in Y_i \text{ and } \forall 0 \leq j \leq i : x \notin Y_j \}$  and  $LR_{\rho} = \{\overline{i} \mid \exists x \in Y_i \text{ and } \forall i < j \leq n : x \notin Y_j\} \text{ be respectively the set of edge }$ indices where a variable is reset for the first (last) in  $\rho$ . Let  $R_{\rho} = FR_{\rho} \cup LR_{\rho}$  and assume  $R_{\rho} = \{p(1), p(2), \ldots, p(k)\}\$  with  $p(1) \leq p(2) \leq \cdots \leq p(k)$ . Then, we let

<span id="page-8-2"></span>

<span id="page-9-0"></span> $\rho_0, \rho_1, \ldots, \rho_k$  be the *type-3 runs* making up  $\rho$  s.t.  $\rho = \rho_0 \cdot s_{p(1)-1}, (t_{p(1)}, e_{p(1)}), s_{p(1)}$ .  $\rho_1 \cdots s_{p(k)-1}$ ,  $(t_{p(k)}, e_{p(k)})$ ,  $s_{p(k)} \cdot \rho_k$ . Note that each type-2 is split into at most  $2 \times |X| + 1$  type-3 runs (i.e.  $k \le 2 \times |X|$ ). We can now define the contraction of at  $2 \times |X| + 1$  type-3 runs (i.e.,  $k \le 2 \times |X|$ ). We can now define the contraction of  $\rho$ :<br>Cnt (a) = Run (first (a)  $\pi_{\mathcal{L}(\lambda)}$  where:  $\pi_{\mathcal{L}(\lambda)} =$  Cn<sup>\*</sup> (TPath (as)) (t (a)  $e(\alpha)$ ) Cnt  $(\rho)$  = Run (first  $(\rho)$ ,  $\pi_{\text{Cnt}(\rho)}$ ), where:  $\pi_{\text{Cnt}(\rho)}$  = Cnt<sup>\*</sup> (TPath  $(\rho_0)$ ),  $(t_{p(1)}, e_{p(1)})$ ,<br>Cn<sup>\*</sup> (TPath  $(\alpha_1)$ ),  $(t_{p(1)}, e_{p(2)})$  (to  $(\alpha_2)$ ), Cn<sup>\*</sup> (TPath  $(\alpha_1)$ ), Faultinged with Cnt<sup>\*</sup> (TPath  $(\rho_1)$ ),  $(t_{p(2)}, e_{p(2)})$ ,...,  $(t_{p(k)}, e_{p(k)})$ , Cnt<sup>\*</sup> (TPath  $(\rho_k)$ ). Equipped with this definition, we can show that Cnt (a) is not only of *hounded length* but is also this definition, we can show that  $\text{Cnt}(\rho)$  is not only of *bounded length*, but is also *equivalent* to the original type-2 run  $\rho$ , in the following sense:

**Proposition 8.** For all type-2 runs  $\rho$ , Cnt( $\rho$ )  $\neq \perp$ , first(Cnt( $\rho$ )) = first( $\rho$ )*,*  $\textsf{last}(\textsf{Cnt}(\rho)) = \textsf{last}(\rho) \textit{ and } |\textsf{Cnt}(\rho)| \leq 8 \times |\textsf{Loc}|^2 \times |X|.$ 

*Proof (sketch)*. We sketch the proof assuming  $H$  has only one variable x with non-negative rate (the arguments generalise easily). Let  $\rho = (\ell_0, \nu_0)$  $\left( \begin{matrix} 0, \nu_0 \end{matrix} \right) \xrightarrow{t_1, e_1}$  $\xrightarrow{t_1,e_1}$  $(\ell_1, \nu_1) \cdots \xrightarrow{t_n, e_n} (\ell_n, \nu_n)$  be a type-2 run,  $\pi = \text{TPath}(\rho)$ ,  $\pi' = \text{Cnt}^*(\pi)$  and  $\rho' = \text{Cnt}(\rho)$ . Observe that duration  $(\pi') = \text{duration}(\rho)$  and that Effect  $(\pi') =$  $\rho' = \text{Cnt}(\rho)$ . Observe that duration  $(\pi') =$  duration  $(\rho)$ , and that Effect  $(\pi') =$ <br>Effect  $(\pi)$ , Assume first that x is never reset along a and that  $\nu_0(x) \notin [0, 1)$ . Then Effect ( $\pi$ ). Assume *first* that x is never reset along  $\rho$ , and that  $\nu_0(x) \notin [0, 1)$ . Then, all valuations of x along  $\rho$  are in the same interval [a, a] or  $(a, a + 1)$  for  $a \ge 1$ , by Lemma 5 (thus the issue of case 1 above is ruled out). In this case, all the guards are still satisfied in  $\pi'$ , and  $\rho' \neq \bot$ . Finally, assuming last  $(\rho') = (\ell_n, \nu'_n)$ , we have  $\nu'_n(x) = \nu_0(x) + \text{Effect}(\pi')(x) = \nu_0(x) + \text{Effect}(\pi)(x) = \nu_n(x)$  $\nu'_n(x) = \nu_0(x) + \text{Effect}(\pi')(x) = \nu_0(x) + \text{Effect}(\pi)(x) = \nu_n(x)$  $\nu'_n(x) = \nu_0(x) + \text{Effect}(\pi')(x) = \nu_0(x) + \text{Effect}(\pi)(x) = \nu_n(x)$  because x is not reset along  $\rho$ . *Second*, assume x is never reset along  $\rho$  and that  $\nu_0(x) \in [0,1)$ . In this case, we have to rule out an additional difficulty. Let k, j be s.t.  $k < j$ .  $\nu_j(x) = 0$ ,  $t_{j+1} = 0$ ,  $e_{j+1}$  has guard ' $x = 0$ ' and  $t_k > 0$ : we must show that would not be satisfied, this is the problem identified in case 4).  $\ell_k \neq \ell_j$  holds be-<br>cause by construction of Reg (H)  $\ell_1 = (\ell \ 0^{\pm})$  and  $\ell_2 = (\ell' \ 0^{\pm})$  for some  $\ell \ \ell'$  $k \neq \ell_j$  (otherwise the delay  $t_k > 0$  could be 'reported' on  $\ell_j$ , and the guard of  $e_j$ <br>would not be satisfied, this is the problem identified in case A)  $\ell_j \neq \ell_j$  bolds be cause, by construction of Reg  $(H)$ ,  $\ell_k = (\ell, \mathbf{0}^{\pm})$  and  $\ell_j = (\ell', \mathbf{0}^{\pm})$  for some  $\ell, \ell'$ , hecause x is null when leaving  $\ell$ , but not when leaving  $\ell$ . Third assume x is rebecause x is null when leaving  $\ell_k$ , but not when leaving  $\ell_j$ . *Third*, assume x is re-<br>set along a hence x takes values in [0, 1] only along a by Lemma 5. Let *i*, k be s t set along  $\rho$ , hence x takes values in [0, 1) only along  $\rho$ , by Lemma 5. Let j, k be s.t.  $j < k$  and  $e_j$  (resp.  $e_k$ ) is the first (last) edge to reset x along  $\rho$ . Then, by definition,  $\pi' =$  Cnt\*  $(\pi[0 : j - 1])$ ,  $(t_j, e_j)$ , Cnt\*  $(\pi[j + 1, k - 1])$  $(t_k, e_k)$ Cnt\*  $(\pi[k + 1, n])$ . In Cnt<sup>\*</sup> ( $\pi$ [0 : j − 1]) and Cnt<sup>\*</sup> ( $\pi$ [k + 1, n]), x is not reset and takes values in [0, 1), thus Cnt<sup>\*</sup> ( $\pi$ [0 : j − 1]) and Cnt<sup>\*</sup> ( $\pi$ [k + 1, n]) yield genuine runs, by the same arguments as above. If x is reset in  $\pi[j + 1, k - 1]$ , this is not the first reset along  $\pi$ , so we avoid the issue of case 2. Thanks to the  $0^+$  and  $0^-$  regions, we are sure that the 'x = 0' guards are still satisfied in  $\text{Cnt}^*(\pi[j+1,k-1])$ , so it [yie](#page-3-0)lds a genuine run. [Thu](#page-9-0)s,  $\rho' \neq \bot$ . Note however that the value of x after firing  $\text{Cut}^*(\pi[0 : j-1]), (t_i, e_j), \text{Cut}^*(\pi[j+1, k-1])$  might not be the same as when firing  $\pi[0 : k-1]$ . Yet, this does not prevent from firing  $e_k$ . Moreover, the value of x at the end of the run is preserved (i.e., we avoid the issue of case 3 above): if last  $(\rho') =$ <br> $(\ell, \nu')$  then  $\nu'(x) = \text{Effect}(Gnt^*(\pi[k+1, n]))(x)$  (again because x is not reset  $(\ell_n, \nu'_n)$ , then  $\nu'_n(x) =$  Effect  $(\text{Cnt}^*(\pi[k+1, n]))(x)$  (again because x is not reset<br>along  $\pi[k+1, n]$ ) with Effect  $(\text{Cnt}^*(\pi[k+1, n]))(x) =$  Effect  $(\pi[k+1, n])(x) =$ along  $\pi[k+1,n]$ ) with Effect  $(\text{Cnt}^*(\pi[k+1,n])) (x) = \text{Effect}(\pi[k+1,n]) (x) = \nu_n(x)$ .  $\nu_n(x).$ 

We obtain Theorem 1 thanks to Proposition 8, Lemma 6 and the definition of Reg  $(H)$ .

*Rectangular Rates.* Let us now briefly explain how we can adapt the previous construction to cope with non-singular rates. Let us first notice that for all MHA  $H$ , R  $(H)$  is <span id="page-10-0"></span>still well-defined. Then, we adapt the definition of timed path as follows. A timed path is a sequence  $(t_1, R_1, e_1) \cdots (t_n, R_n, e_n)$ , where each  $R_i : X \mapsto \mathbb{R}$  gives the actual rate that was chosen for each variable at the  $i$ -th continuous step. It is then straightforward to extend the definitions of Cnt and Effect to take those rates into account and retain the properties needed to prove Theorem 2. More precisely, the contraction of a set of transitions  $(t_1, R_1, e_1), \ldots, (t_n, R_n, e_n)$  yields a transition  $(t, R, e)$  with  $t = \sum_{i=1}^n t_i$ and,  $R = \frac{\sum_{i=1}^{n} t_i \times R_i}{t}$ . Note that we rely on the convexity of the invariants and rates in an RHA to ensure that this construction is correct.

## **4 Time-Bounded Reachability Is NEXPTIME-Complete**

In this section, we establish our main result:

## **Theorem 9.** *Time-bounded reachability for MHA is* NEXPTIM[E](#page-15-4) *complete.*

*An* NEXPTIME *Algorithm.* Recall that an instance of the time-bounded reachability problem is of the form  $(H, \ell, T)$ , where H is an MHA,  $\ell$  is a location, and **T** is a<br>time bound (expressed in binary). We establish membership in NEXPTIME by giving a time bound (expressed in binary). We establish membership in NEXPTIME by giving a non-deterministic algorithm that runs in time exponential in the size of  $(H, \ell, T)$  in the worst case. The algorithm *quesses* a sequence of edges  $S = e_0e_1$ ,  $e_0$  of H such that worst case. The algorithm *guesses* a sequence of edges  $\mathcal{E} = e_0e_1 \dots e_n$  of H such that  $n+1 \leq F(\mathcal{H}, \mathbf{T})$  and trg  $(e_n) = \ell$  and builds a linear constraint  $\Phi(\mathcal{E})$ , that expresses all the properties that must be satisfied by a run following the sequence of edges  $\mathcal{E}$  (see [13] the properties that must be satisfied by a run following the sequence of edges  $\mathcal{E}$  (see [13] for a detailed explanation on how to build such a constraint). This constraint uses  $n + 1$ copies of the variables in X and  $n + 1$  variables  $t_i$  to model the time elapsing between two consecutive edges, and imposes that the valuations of the variables along the run are consistent with the rates, guards and resets of  $H$ . Finally, the algorithm checks whether  $\Phi(\mathcal{E})$  is satisfiable and returns 'yes' iff it is the case.

The number of computation steps necessary to build  $\Phi(\mathcal{E})$  is, in the worst case, exponential in the size of the instance  $(\mathcal{H}, \mathbf{T})$ . Moreover, checking satisfiability of  $\Phi(\mathcal{E})$ can be done in [po](#page-10-1)lynomial time (in the size of the constraint) using classical algorithms to solve linear programs. Clearly this procedure is an NEXPTIME algorithm for solving the time-bounded reachability problem for MHA.

<span id="page-10-1"></span>NEXPTIME*-Hardness.* To establish the NEXPTIME-hardness, we encode the membership problem of non-deterministic exponential time Turing machines (NExpTM for short) to time-bounded reachability for SMHA. An NExpTM is a tuple  $M =$  $(Q, \Sigma, \Gamma, q_0, \delta, F, \xi)$  where Q is the (nonempty and finite) set of control states,  $\Sigma =$  $\{0, 1\}$  is the (finite) input alphabet<sup>2</sup>,  $\Gamma = \{\sharp, 0, 1\}$  is the (finite) alphabet of the tape, where  $\sharp$  is the blank symbol,  $q_0 \in Q$  is the initial control state,  $\delta \subseteq Q \times \Gamma \times \Gamma \times \{L, R\} \times$ Q is the transition relation,  $F \subseteq Q$  is the set of accepting states, and  $\xi = \mathcal{O}(2^{p(n)})$  (for some polynomial  $p$ ) is an exponential function to bound the execution length some polynomial  $p$ ), is an exponential function to bound the execution length.

A state of M is a triple  $(q, w_1, w_2)$ , where  $q \in Q$ , and  $w_1, w_2 \in \Gamma^*$  are resp. the content to the left (to the right and below) of the reading head, excluding the trailing sequence of  $\sharp$ . We rely on the standard semantics for NExpTM: for example,

<sup>&</sup>lt;sup>2</sup> Having  $\Sigma = \{0, 1\}$  and  $\Gamma = \Sigma \cup \{\sharp\}$  is without loss of generality.

 $(q_1, a, b, L, q_2)$  means 'when in  $q_1$  and a is below the head, replace a by b, move the head to the left (L) and go to  $q_2$ '. We write  $(q, w_1, w_2) \triangleright (q', w'_1, w'_2)$  when there is a transition from  $(a, w_1, w_2)$  to  $(a', w', w'_1)$ . An execution of M on input w is a finite setransition from  $(q, w_1, w_2)$  to  $(q', w'_1, w'_2)$ . An execution of M on input w is a finite se-<br>quence of states  $\cos \alpha$ ,  $c$  such that:  $(i)$   $n \leq \xi(|w|)$ ;  $(ii)$   $c_2 = (a_2 \leq w_1 + \xi(|w|) - |w|)$ . quence of states  $c_0c_1 \ldots c_n$  such that:  $(i)$   $n \le \xi(|w|)$ ;  $(ii)$   $c_0 = (q_0, \varepsilon, w \cdot \sharp^{\xi(|w|)-|w|})$ ;<br>and  $(iii)$  for all  $0 \le i \le n$ ;  $c \in \mathbb{C}$  is accepting iff  $c_n = (q, w, w_0)$  with  $q \in F$ ; and (iii) for all  $0 \leq i < n$ :  $c_i \triangleright c_{i+1}$ . It is *accepting* iff  $c_n = (q, w_1, w_2)$  with  $q \in F$ .

Let us show how to encode all executions of  $M$  into the executions of an SMHA  $\mathcal{H}_M$ . We encode the words  $w_1$  and  $w_2$  as pairs of rational values  $(l_1, c_1)$  and  $(l_2, c_2)$ where  $l_i = \frac{1}{2^{|w_i|}}$  encodes the length of the word  $w_i$  by a rational number in [0, 1], and  $c_i$  encodes  $w_i$  as follows. Assume  $w_i = \sigma_0 \sigma_i$  as  $\sigma_i$ . Then we let  $c_i = \sqrt{2^{|w_i|} (w_i)}$  $c_i$  encodes  $w_i$  as follows. Assume  $w_1 = \sigma_0 \sigma_1 \dots \sigma_n$ . Then, we let  $c_1 = \text{Val}^{\leftarrow}(w_1) =$ <br> $\sigma_i : \frac{1}{n} + \sigma_{i+1} : \frac{1}{n} + \cdots + \sigma_0 : \frac{1}{n}$  Intuitively  $c_i$  is the value which is represented  $\sigma_n \cdot \frac{1}{2} + \sigma_{n-1} \cdot \frac{1}{4} + \cdots + \sigma_0 \cdot \frac{1}{2^{n+1}}$ . Intuitively,  $c_1$  is the value which is represented<br>in binary by 0. $\sigma$ ,  $\sigma_1$ ,  $\cdots$ ,  $\sigma_0$  i.e.,  $w_i$  is the binary encoding of the fractional part of in binary by  $0.\sigma_n\sigma_{n-1}\cdots\sigma_0$ , i.e.,  $w_1$  is the binary encoding of the fractional part of  $c_1$  with the most significant bit in the rightmost position. For instance, if  $w_1 = 001010$ <br>then  $\sqrt{a^2 + (w_1) - 0}$ ,  $\frac{1}{2} + 1$ ,  $\frac{1}{2} + 0$ ,  $\frac{1}{2} + 1$ ,  $\frac{1}{2} + 0$ ,  $\frac{1}{2} + 0$ ,  $\frac{1}{2} + 0$ ,  $\frac{1}{2} - 0$  3125 then  $Val^{\leftarrow}(w_1) = 0 \cdot \frac{1}{2} + 1 \cdot \frac{1}{4} + 0 \cdot \frac{1}{8} + 1 \cdot \frac{1}{16} + 0 \cdot \frac{1}{32} + 0 \cdot \frac{1}{64} = 0.3125$ , and so  $w_1$  is encoded as the pair  $(\frac{1}{64}, 0.3125)$ . Note that we need to remember the actual length of the word  $w_$ of the word  $w_1$  because the function  $Val^{\leftarrow}(\cdot)$  ignores the leading 0's (for instance, Val<sup>←</sup>(001010) = Val<sup>←</sup>(1010)). Symmetrically, if  $w_2 = \sigma_0 \sigma_1 \dots \sigma_n$ , we let  $c_2$  $\sqrt{2}$   $\sqrt{u_2} = \sigma_0 \cdot \frac{1}{2} + \sigma_1 \cdot \frac{1}{4} + \cdots + \sigma_n \cdot \frac{1}{2^{n+1}}$  (i.e.,  $\sigma_0$  is now the most significant bit). Then a state  $(q, w_1, w_2)$  of the NExpTM is encoded as follows: the control state q is remembered in the locations of the automaton, and the words  $w_1, w_2$  are stored, using the encoding described above using four variables for the values  $(l_1, c_1)$  and  $(l_2, c_2)$ .

With this encoding in mind, let us list the operations that we must be able to perform to simulate the transitions of the NExpTM. Assume  $w_1 = w_0^1 w_2^1 \cdots w_n^1$  and  $w_2 = w_1^2 w_1^2 \cdots w_n^2$ . To read the letter under the head we need to test the value of the bit  $w_1^2$ .  $w_0^2 w_2^2 \cdots w_k^2$ . To *read the letter under the head* we need to test the value of the bit  $w_0^2$ .<br>Clearly  $w_1^2 - 1$  iff  $l_2 < 1/2$  and  $c_2 > \frac{1}{2}$ ;  $w_1^2 - 0$  iff  $l_2 < 1/2$  and  $c_2 < \frac{1}{2}$  and  $w_1^2 - 1$ Clearly,  $w_0^2 = 1$  iff  $l_2 \le 1/2$ , and  $c_2 \ge \frac{1}{2}$ ;  $w_0^2 = 0$  iff  $l_2 \le 1/2$ , and  $c_2 < \frac{1}{2}$  and  $w_0^2 = \sharp$ <br>iff  $l_2 = 1$  (which corresponds to  $w_0 = \varsigma$ ). To test whether the head is in the leftmost iff  $l_2 = 1$  (which corresponds to  $w_2 = \varepsilon$ ). To *test whether the head is in the leftmost*<br>cell of the tape we must check whether  $w_1 = \varepsilon$  i.e.  $l_1 = 1$ . To read the letter at the *cell of the tape* we must check whether  $w_1 = \varepsilon$ , i.e.  $l_1 = 1$ . To *read the letter at the left of the head* (assuming that  $w_1 \neq \varepsilon$ ) we must test the value of the bit  $w_n^1$ . Clearly,  $w_1^1 - 1$  iff  $c_2 > \frac{1}{n}$  and  $w_1^1 - 0$  iff  $c_2 < \frac{1}{n}$  $w_n^1 = 1$  iff  $c_1 \ge \frac{1}{2}$  and  $w_n^1 = 0$  iff  $c_1 < \frac{1}{2}$ .<br>Then let us describe the operations the

Then, let us describe the operations that are necessary to update the values on the tape. Clearly, they can be carried out by appending and removing 0's or 1's to the right of  $w_1$  or to the left of  $w_2$ . Let us describe how we update  $c_1$  and  $l_1$  to simulate these operations on  $w_1$  (the operations on  $w_2$  can be deduced from this description). We denote by  $c'_1$  (resp.  $l'_1$ ) the value of  $c_1$  ( $l_1$ ) after the simulation of the NExpTM<br>transition To append a 1 to the right of  $v_1$ , we let  $l' = \frac{1}{2} \times l_1$ . We let  $c' = \frac{1}{2}$  if  $l_1 = 1$ transition. *To append a* [1](#page-12-1) *to the right* of  $w_1$ , we let  $l'_1 = \frac{1}{2} \times l_1$ . We let  $c'_1 = \frac{1}{2}$  if  $l_1 = 1$ <br>(i.e.  $w_1$  was empty) and  $c'_1 = \frac{1}{2} \times c_2 + \frac{1}{2}$  otherwise. To append a 0 to the right of  $w_1$ . (i.e.  $w_1$  was empty) and  $c'_1 = \frac{1}{2} \times c_1 + \frac{1}{2}$  otherwise. *To append a* 0 *to the right of*  $w_1$ , we let  $l' = \frac{1}{2} \times l_1$  and  $c' = \frac{1}{2} \times c_2$ . To delete a 0 from the rightmost position of  $w_1$ . we let  $l'_1 = \frac{1}{2} \times l_1$  and  $c'_1 = \frac{1}{2} \times c_1$ . To delete a 0 from the rightmost position of  $w_1$ ,<br>we let  $l' = 2 \times l_1$ ,  $c' = 2 \times c_2$ . To delete a 1 from the rightmost position of  $w_1$ , we we let  $l'_1 = 2 \times l_1$ ,  $c'_1 = 2 \times c_1$ . To delete a 1 from the rightmost position of  $w_1$ , we let  $l' = 2 \times l_1$  and  $c' = (c_1 - \frac{1}{2}) \times 2$ . In addition, note that we can flip the leftmost let  $l'_1 = 2 \times l_1$ , and  $c'_1 = (c_1 - \frac{1}{2}) \times 2$ . In addition, note that we can flip the leftmost<br>bit of  $w_0$  by adding or subtracting 1/2 from  $c_0$  (this is necessary when undating the bit of  $w_2$  by adding or subtracting  $1/2$  from  $c_2$  (this is necessary when updating the value under the head). Thus, the operations that we need to be able to perform on  $c_1$ ,  $l_1$ ,  $c_2$  and  $l_2$  are: to multiply by 2, divide by 2, increase by  $\frac{1}{2}$  and decrease by  $\frac{1}{2}$ , while keeping untouched the value of all the other variables. Fig. 3 exhibits four gadgets to perform these operations. Note that these gadgets can be constructed in polynomial time, execute in 1 time unit time and bear only singular rates.

**Fig. 3.** Gadgets (*i*) for multiplication by 2, (*ii*) adding  $\frac{1}{2}$  and (*iii*) subtracting  $\frac{1}{2}$ . The rates of the  $y \notin \{x, z\}$  is 0. Gadget (i) can be modified to divide by 2, by swapping the rates of x and z in the second location.  $x_0$  is the value of x when entering the gadget.

<span id="page-12-0"></span>We claim that all transitions of  $M$  can be simulated by combining the gadgets in Fig. 3 and the tests described above. For instance, consider the transition:  $(q_1, 1, 0, L, q_2)$ . It is simulated as follows. First, we check that the reading head is not at the leftmost position of the tape by checking that  $l_1 < 1$ . Second, we check that the value below the reading head is equal to 1 by testing that  $l_2 < 1$  and  $c_2 \geq \frac{1}{2}$ . Third, we change the value below the reading head from 1 to 0 by subtracting  $\frac{1}{2}$  from  $c_2$  using we change the value below the reading head from 1 to 0 by subtracting  $\frac{1}{2}$  from  $c_2$  using<br>an instance of gadget *(iii)* in Fig. 3. And finally we move the head one cell to the left an instance of gadget  $(iii)$  in Fig. 3. And finally, we move the head one cell to the left. This is performed by testing the bit on the left of the head, deleting it from  $w_1$  and appending it to the left of  $w_2$ , by the operations described above. All other transitions can be simulated similarly. Note that, to simulate one NExpTM transition, we need to perform several tests (that carry out in 0 time units) and to:  $(i)$  update the bit under the reading head, which takes 1 time unit with our gadgets;  $(ii)$  remove one bit from the right of  $w_1$  (resp. left of  $w_2$ ), which takes at most 3 time units and (*iii*) append this bit to the left of  $w_2$  (right of  $w_1$ ), which takes at most 3 time units. We conclude that each NExpTM tra[ns](#page-4-1)ition can be simulate in at most  $7$  time units. Thus  $M$  has an accepting execution on word w (of length at most  $\xi(|w|)$  iff  $\mathcal{H}_M$  has an execution of duration at most  $\mathbf{T} = 7 \cdot \xi(|w|)$  that reaches a location encoding an accepting control state of M. This sets the reduction.

# **5 Computing All the States Reachable within T Time Units**

Let us now show that Theorem 2 (lifted to MHA) implies that, in an MHA, we can compute a *symbolic representation* of the set of states reachable within **T** time units. We show, by means of two examples, that this information can be used to verify meaningful properties of MHA, in particular when time-*unbounded* fixed points do not terminate.

Post *and* Pre. Let s be a state of an MHA with set of edges Edges. We let Post(s) =  $\{s' \mid \exists e \in \text{Edges}, t \in \mathbb{R}^+ : s \stackrel{t,e}{\longrightarrow} s' \}$  and  $\text{Pre}(s) = \{s' \mid \exists e \in \text{Edges}, t \in \mathbb{R}^+ : s \stackrel{t,e}{\longrightarrow} s' \}$  $s' \stackrel{t,e}{\longrightarrow} s$ . We further let Reach<sup>≤**T**</sup>(s) = {s' |  $\exists \pi : s \stackrel{\pi}{\longrightarrow} s' \land$  duration ( $\pi$ )  $\leq$  **T**}, and coReach<sup>≤T</sup>(s) = {s' |  $\exists \pi : s' \stackrel{\pi}{\rightarrow} s \wedge$  duration ( $\pi$ )  $\leq$  T} be respectively the set of states that are reachable from s (that can reach s) within T time units. We extend all states that are reachable from s (that can reach s) within **<sup>T</sup>** time units. We extend all

those operators to sets of s[tat](#page-14-3)es in the obvious way. Our aim in this section is to compute effective representations of Reach<sup>≤T</sup>(s) and coReach<sup>≤T</sup>(s), using fixed points.

*Symbolic States.* To manipulate potentially infinite sets of MHA states, we need a symbolic representation that is manipulable algorithmically. We rely on the notion of *symbolic states* introduced as an *algebra of regions* in [11]. To manipulate sets of valuations, we use formulas of  $(\mathbb{R}, 0, 1, +, \leq)$ , i.e. the first-order logic of the reals<sup>3</sup>, with the constants 0 and 1, the usual order  $\leq$  and addition + [11]. Recall that the satisfiability problem for that logic is decidable [4] and that it admits effective quantifier elimination. Furthermore, all guards of an MHA can be represented by a formula from  $(\mathbb{R}, 0, 1, +, \leq)$  ranging over X. Let  $\Psi$  be a formula of  $(\mathbb{R}, 0, 1, +, \leq)$ , and let  $\nu$  be a valuation of the free variables of  $\Psi$ . Then we write  $\nu \models \Psi$  iff  $\nu$  satisfies  $\Psi$ , and we let  $\llbracket \Psi \rrbracket$  be the set off all valuations  $\nu$  such that  $\nu \models \Psi$ . To emphasise the fact that a formula  $\Psi$  ranges over the set of variables X, we sometimes denote it by  $\Psi(X)$ .

Then a *symbolic state* of an MHA  $H$  with set of variables  $X$  is a function  $R$  mapping each location  $\ell$  of  $\mathcal H$  to a quantifier free formula of  $(\mathbb R, 0, 1, +, \leq)$  with free variables in  $\ell$ . X, representing sets of valuations for the variables in  $\ell$ . Formally, R represents the set<br>of MHA states  $\llbracket R \rrbracket = f(\ell, \nu) \mid \nu \in \llbracket R(\ell) \rrbracket$ . By abuse of notation, we assume that any of MHA states  $[[R]] = \{ (\ell, \nu) \mid \nu \in [[R(\ell)]] \}$ . By abuse of notation, we assume that any formula  $\Phi$  of  $(\mathbb{R} \cap 1 + \langle \cdot \rangle)$  denotes the function f such that  $f(\ell) - \Phi$  for all  $\ell$  Clearly formula  $\Phi$  of  $(\mathbb{R}, 0, 1, +, \leq)$  denotes the function f such that  $f(\ell) = \Phi$  for all  $\ell$ . Clearly, given symbolic states  $R_2 \vee R_2$  and  $R_3 \wedge R_2$ given symbolic states  $R_1$  and  $R_2$ , one can compute symbolic states  $R_1 \vee R_2$  and  $R_1 \wedge R_2$ representing resp.  $[[R_1]] \cup [[R_2]]$  and  $[[R_1]] \cap [[R_2]]$ ; and one can test whether  $[[R_1]] =$  $[R_2]$  [11]. It is also possible (see details in the appendix) to compute Post and Pre symbolically: we let post<sup> $\sharp$ </sup> and pre $\sharp$  be effective operators, returning symbolic states, s.t. for all symbolic states R:  $[\text{post}^{\sharp}(R)] = \text{Post}(\llbracket R \rrbracket)$  and  $[\text{pre}^{\sharp}(R)] = \text{Pre}(\llbracket R \rrbracket)$ .

<span id="page-13-0"></span>*Time-Bounded Forward and Backward Fixpoints.* Let H be an MHA with set of variables X, and let **T**  $\in$  N be a time bound. Let us augment H with a fresh variable t to measure time (hence the rate of t is 1 in all locations, and t is never reset). Let S be measure time (hence the rate of t is 1 in all locations, and t is never reset). Let S be<br>a set of states of  $\mathcal{H}$ . Then the sets Reach<sup>(T<sub>(S)</sub>)</sub> and coReach<sup>(T<sub>(S)</sub>) can be defined by</sup></sup> a *set of states* of H. Then the sets Reach<sup>≤T</sup>(S) and coReach<sup>≤T</sup>(S) can be defined by<br>means of fixed point equations: Reach<sup>≤T</sup>(S) – uV, ((S) | Post(V))  $\cap$  [0 < t < T]) means of fixed point equations:  $\text{Reach}^{\leq T}(S) = \mu Y \cdot ((S \cup \text{Post}(Y)) \cap [0 \leq t \leq T])$ <br>and coReach<sup> $\leq T(S) = \mu Y \cdot ((S \cup \text{Pre}(Y)) \cap [0 \leq t \leq T])$ . This observation forms</sup> and coReach<sup> $\leq$ **T**(S) =  $\mu$ Y · ((S ∪ Pre(Y)) ∩ [ $0 \leq t \leq$ **T**]). This observation forms the basis of our algorithm for computing symbolic states representing Reach<sup> $\leq$ **T**([R]])</sup></sup> the basis of our algorithm for computing symbolic states representing Reach<sup> $\leq$ T</sup>([R]]) and coReach<sup>≤T</sup>([R]]) for some symbolic state  $R(X)$ . Let  $(F_i)_{i\geq 0}$  and  $(B_i)_{i\geq 0}$  be the sequences of symbolic states defined as follows:  $F_0 = B_0 = R(\overline{X}) \wedge (0 \le t \le T)$ ; and for all  $i \geq 1$ :  $F_i = \text{post}^{\sharp}(F_{i-1}) \wedge (0 \leq t \leq T) \vee F_{i-1}$  and  $B_i = \text{pre}^{\sharp}(B_{i-1}) \wedge (0 \leq t \leq T)$ **T**)  $\vee$  B<sub>i−1</sub>. Note that, for all  $i \ge 1$ ,  $F_i$  (resp. B<sub>i</sub>) can be computed from  $F_{i-1}$  (B<sub>i−1</sub>).

**Proposition 10.** *For all MHA* <sup>H</sup>*, all symbolic states* R *and all time bound* **<sup>T</sup>***, there are* k and  $\ell$  *such th[at](#page-14-4)*  $0 \le k, \ell \le F(\mathcal{H}, \mathbf{T})$ ,  $\llbracket F_k \rrbracket = \llbracket F_{k+1} \rrbracket = \text{Reach}^{\leq \mathbf{T}}(\llbracket R \rrbracket)$  *and*  $R_k$  *takes at most doubly*  $[[B_\ell]] = [[B_{\ell+1}]] = \text{coReach}^{\leq T}([\![R]\!])$ *. Computing*  $F_k$  *and*  $\overline{B_\ell}$  *takes at most doubly* exponential time *exponential time.*

By Theorem 9, this deterministic algorithm can be considered optimal (unless NEXP-TIME=EXPTIME). Let us show, by two examples, the usefulness of our approach.

<sup>&</sup>lt;sup>3</sup> In practice, those formulas can be manipulated as finite unions of convex polyhedra for which there exist efficient implementations, see [3] for example.

*Example 1: Leakin[g g](#page-14-5)as burner* With this example, the *time-unbounded* forward fixedpoint computation does not terminate, in contrast to the time-bounded fixed-point computatio[n. T](#page-15-0)he gas burner in the example can be either *leaking* or *not leaking*. Leakages are repaired within 1 second, and no leakage can happen in the next 30 seconds after a repair. An MHA modeling this gas burner [1] is given in Fig. 4. Stopwatch  $y$  and clock  $t$  are

used resp. to measure the leakage time and the total elapsed time. One can show using *backward* analysis that, in any time interval of at least 60 seconds, the leakage time is at most 5% of the elapsed time [8]. The backward fixpoint is obtained after 7 iterations but the forward does not terminate.

<span id="page-14-5"></span>Using forward time-bounded reachability analys[is](#page-4-0) we can prove that, in all time intervals of fixed length  $T \ge 60$ , the leakage time is at most  $\frac{T}{20}$ . To prove that this property holds in all time intervals, we first compute using the algorithm described above (see holds in *all* time intervals, we first compute, using the algorithm described above (see Pr[op](#page-4-0)osition 10), Reach<sup>≤60</sup>([R]]), where  $\llbracket R \rrbracket = \{(\ell, v) \mid \ell =$  leaking implies  $0 \leq v(x) \leq 1$  i.e. R represents all possible states of the system HYTECH computes  $v(x) \leq 1$  $v(x) \leq 1$  $v(x) \leq 1$ , i.e. R represents all possible states of the system. HYTECH computes<br>Reach  $\leq 60$  ([R]] after 5 iterations of the forward time-bounded fixpoint. Then, we check Reach<sup>≤60</sup>([R]]) after 5 iterations of the forward time-bounded fixpoint. Then, we check<br>that  $t = 60$  implies  $u < 60 = 3$ ; holds in all states of Reach<sup>≤60</sup>([R]]) that ' $t = 60$  implies  $y \le \frac{60}{20} = 3$ ' holds, in all states of Reach<sup>≤60</sup>([R]]).

<span id="page-14-4"></span><span id="page-14-3"></span><span id="page-14-2"></span><span id="page-14-0"></span>*Example 2: bounded invariant* Let us come back to the RHA≥<sup>0</sup> of Fig. 1 (left). Notice that all variables have a bounded invariant  $[0, 1]$ . The forward reachability analysis of HyTech does not terminate here because the set of reachable states is not a finite union of polyhedra, see Fig. 1 (right). Yet, the time-bounded forward fixpoint terminates for all **T** by Proposition 10. This example shows that bounding the variables is not sufficient to obtain termination while performing time-bounded analysis is.
