A question which often arises is which patients should be tested. Numerous approaches to this issue have been proposed, and while ultimately such decisions are made by the treating oncologist, some general principles have emerged. First and foremost, for patients with advanced stage disease, testing for *EGFR* mutations and *ALK* rearrangements is the standard of care, because the results impact first-line therapy selection. Regardless of the determinations of which patients to test, it is critical that results be available in a timeframe to allow therapeutic decisions to be based on the test results. This leads to the question of whether to test concurrently or in sequence. Despite the low prevalence of *ALK* rearrangement in NSCLC and the finding that co-occurrence of *EGFR* mutation and *ALK* rearrangement is uncommon, in order to meet the goal of returning results in a clinically actionable timeframe, concurrent testing may be preferable from a clinical perspective.

One significant challenge of clinical molecular testing for NSCLC is the need to perform testing on diagnostic small

biopsy or FNA specimens. As the majority of NSCLC patients are not surgical candidates at the time of diagnosis, small samples are common for initial diagnosis. When considering the common need for IHC evaluation, which often requires multiple rounds of facing of a paraffin block, the residual material remaining after histopathologic diagnosis can be exceedingly limited. However, given appropriate methods, testing on such specimens can be accommodated. Implementation of appropriate tumor enrichment techniques is essential, as is evaluation of the specimen by a pathologist prior to testing, selection of an appropriate testing method, and reporting of results in an integrated format. Cytopathology specimens, including cell blocks and direct smears, are often adequate specimens for testing. Of paramount logistical relevance is the need to institute measures for maximal preservation of tissue from small diagnostic specimens to allow for molecular testing following histopathologic diagnosis. This includes efforts to limit the degree to which paraffin blocks are multiply faced and reduction in the use of IHC and duplicative controls. As the number of clinically validated molecular targets for testing grows, the need to preserve tissue will become ever more paramount. Part of the management of tissue for this purpose will be a growing recognition of the need to establish prioritization of clinical testing. While clinical parameters may be associated with some of the molecular subtypes of NSCLC, they are not sufficiently specific to dictate choice of testing. However, they may be useful in determining prioritization of testing for limited specimens.

Conclusions and Future Directions

As the number of defined targets for clinical molecular testing that drive therapy selection grows, the need to implement testing which evaluates as many of these oncogenic variants simultaneously is an inevitable necessity. The one-at-a-time model for testing for individual mutations has already been supplanted in some centers by multiplex testing for dozens of mutations simultaneously [104, 105]. As the clinical use of NGS advances, testing is likely to migrate to platforms which can accommodate the evaluation of dozens to hundreds of genes and variants concurrently.

Breast Cancer

33

Carolyn Mies

Abstract

Breast cancer treatment has evolved over the past 50 years, often as a direct consequence of molecular testing advances. In fact, molecular testing of predictive markers in breast cancer, including hormone receptors and HER2, is the model for personalized cancer treatment. Clinical practice guidelines specify that every primary invasive breast cancer and putative recurrence be tested for ER, PR, and HER2 expression to identify those cancers likely to respond to corresponding targeted treatments. The newest tests for breast cancer management are the tissue-based prognostic and/or predictive molecular assays, which identify patients with biologically indolent breast cancer who will not benefit from cytotoxic chemotherapy and those with intrinsically aggressive disease who may benefit. This chapter reviews clinically standard predictive marker and Oncotype DX® testing, as well as several emerging molecular testing systems.

Keywords

Breast cancer • Predictive markers • Estrogen receptor • HER2 • Immunohistochemistry In situ hybridization • Prognostic molecular assays • Intrinsic subtypes

Introduction

Breast carcinoma is the most common malignancy in women in the USA and occurs in two major forms: sporadic and hereditary. Sporadic breast cancer is the topic of this chapter; hereditary breast cancer, caused by mutations in *BRCA1* and *BRCA2* and other germline DNA mutation syndromes, is discussed in Chap. 22. Molecular assays for detecting circulating tumor cells are discussed in Chap. 39.

Molecular Pathogenesis of Breast Cancer

The cause of common, sporadic breast cancer and the reasons for its progression are unknown. What is amply clear is that no simple, single alteration is responsible for sporadic breast cancer. Putative oncogenic processes include impaired cell-number regulation, mutated oncogenes and tumor suppressor genes, dysfunctional epigenetic controls, and deranged intercellular interaction [1]. In addition, emerging evidence supports a theory that transforming epithelia communicate aberrantly with their surrounding mammary stroma, such that the entire tissue region is likely involved in the oncogenic process. Collectively, these processes determine the behavior of a specific breast cancer.

Two dominant models of mammary carcinogenesis are (1) the stochastic clonal evolution model and (2) the cancer stem cell model (both reviewed in Ref. 2). The stochastic clonal evolution model proposes that random mutational events occur in any mammary cell; uncontrolled cell division results when a cell accumulates a sufficient number

D.G.B. Leonard (ed.), *Molecular Pathology in Clinical Practice*, DOI 10.1007/978-3-319-19674-9_33

and type of mutations to gain a selective growth advantage. In this model, the expanding aberrant clone acquires additional DNA alterations that enable it to invade adjacent stroma and spread to distant sites via lymphatics and blood vessels. The clone "evolves" to an invasive and metastatic phenotype.

The cancer stem cell hypothesis derives from the theoretical normal breast parenchymal development pathway. A breast stem cell divides asymmetrically to produce a daughter stem cell (self-renewal) and a common progenitor cell, which can divide and differentiate into either a myoepithelial cell or a luminal progenitor cell. The latter is the parent of two more-differentiated lineages: luminal and ductal epithelia [2]. The cancer stem cell hypothesis posits that the initiating carcinogenic event occurs in one of the small number of mammary stem cells or their uncommitted progenitors but never in differentiated luminal or myoepithelial cells. Following initiation, clonal evolution may progress to the fully malignant phenotype. An appealing variation of the cancer stem cell hypothesis has cancer initiation restricted to the second generation common progenitor cell, usually a common luminal progenitor. If correct, this would explain why global gene expression profiling parses human breast cancers into four to five major molecular classes (intrinsic subtypes), which include luminal A and B groups [3–5].

Anatomic Classification of Breast Cancer

The vast majority of breast cancers arise in the hormonally sensitive, physiologically active, terminal duct lobular units; only a small percentage arise in the larger ducts. The two morphologic subtypes of breast cancer, ductal and lobular, are named for the histologic structures from which they appear to arise, the terminal ducts and the lobules, respectively. Both ductal and lobular carcinomas occur in invasive and in situ forms; this chapter focuses on invasive carcinoma.

Invasive ductal carcinoma (IDC) is the most common form of invasive breast cancer, accounting for approximately 85 % of cases. Several lines of evidence indicate that IDC directly evolves from ductal carcinoma in situ (DCIS). Invasive lobular carcinoma (ILC) accounts for fewer cases of invasive breast cancer (approximately 15 %). Like IDC, ILC appears to evolve from a morphologic precursor lesion, lobular carcinoma in situ (LCIS). At the genomic level, IDC is far more heterogeneous than ILC. While the two subtypes share some recurrent molecular alterations, they differ at many more loci. Invasive ductal and lobular carcinomas are managed clinically in the same way.

Overview of the Clinical Management of Breast Cancer

Breast cancer treatment has evolved over the past 50 years, often as a direct consequence of molecular testing advances. Currently, potentially curable, early invasive breast cancer (Stages I, II, and III) is treated both as local-regional and systemic disease. The goal of local-regional treatment is to eradicate cancer from the breast and regional lymph nodes, whereas systemic treatment seeks to eliminate occult microscopic deposits of cancer at remote sites in the body.

Treatment selection rests on two sets of clinicopathologic factors: (1) anatomic staging [6] to estimate prognosis, which is the likelihood that a person will survive the disease independent of systemic treatment, and (2) results of predictive marker tests, which estimate the likelihood a breast cancer will respond to specific targeted treatments. Only two targeted treatments are in current common use for breast cancer: antiestrogens (e.g., tamoxifen, aromatase inhibitors) and trastuzumab (Herceptin™; Genentech, South San Francisco, CA), a monoclonal antibody targeting the human epidermal growth factor receptor-2 protein (simplified to HER2 in this chapter). Currently, tests for these predictive markers are used to determine the use of these targeted therapies for breast cancer: estrogen receptor (ER) levels and progesterone receptor (PR) levels for the antiestrogens and HER2 overexpression for trastuzumab.

Molecular testing of prognostic and predictive markers in breast cancer has a long, successful history and is a paradigm for personalized cancer treatment. Clinical practice guidelines specify that every primary invasive breast cancer and putative recurrence be tested for expression of ER, PR, and HER2 [7, 8]. These are called predictive markers because they predict the likelihood a cancer will respond to antiestrogen and anti-HER2 treatment. The next sections describe the standard and emerging molecular tests for newly diagnosed breast cancer, including ER and PR tests, HER2 tests, molecular profiling for intrinsic breast cancer subtypes, and the commercially marketed prognostic and/or predictive tests for breast cancer management.

Hormone Receptors in Breast Cancer

Molecular Basis for Targeting Hormone Receptor Expression in Breast Cancer

Like normal mammary glandular tissue, most invasive breast cancers (75–80 %) express ER and/or PR [9]. These receptors, which bind endogenous estrogen and progesterone, are ligand-inducible transcription factors that bind to regulatory DNA sequences associated with target genes, activating a

variety of cellular events that give cancer cells a survival advantage [10, 11]. Aside from this direct DNA interface, ER also interacts with cytoplasmic proteins that have an indirect action on gene transcription [12]. Interfering with this key hormone-receptor interaction is a mainstay of ER-positive breast cancer treatment.

Estrogen receptor protein exists in two isoforms, ERα and ERβ, which are encoded by two highly homologous genes, *ESR1* and *ESR2*, respectively. ERα (*ESR1*) is the clinically important isoform of ER in breast cancer. Similarly, there are two PR isoforms (A and B), which are products of the same gene. PR isoform A is a truncated form of B [12]. Estrogen receptor-ligand complexes activate the transcription of PR; thus, nearly all ER-positive breast cancers also express PR. The ER test result dominates clinical decision-making. Antiestrogen treatment is recommended for all ER-positive (>1 % cells) cancers. The small fraction (approximately 3 %) of ER-negative, PR-positive cancers also are treated with antiestrogens because they are presumed to have partially intact ER transcriptional activity [13].

Three therapeutic approaches are used to nullify estrogen's ER-mediated effects on breast cancer: (1) remove the ovaries to reduce endogenous estrogen, (2) pharmacologically inactivate ER, and (3) medicate to prevent inactive forms of endogenous estrogen from converting to active molecules. Surgical oophorectomy, the oldest endocrine treatment for breast cancer, still has a role in some circumstances [14]. Inactivating ER directly is accomplished by treatment with tamoxifen (Nolvadex), one of the most commonly used targeted therapies. Tamoxifen is an oral medication that binds stably to the ER to form an unwieldy complex that is sterically incapable of binding to DNA to activate gene transcription. Lastly, aromatase inhibitors (AIs), such as anastrozole (Arimidex) and exemestane (aromasin), bind to the aromatase enzyme to prevent adrenal androgens, the main source of endogenous estrogen after menopause, from being converted to estrogen. AIs are most useful in postmenopausal patients, reducing circulating estradiol to near zero levels [13, 68].

Clinical Utility of ER/PR Expression Testing

ER/PR testing is critical because the ER content of a breast cancer is the strongest predictor of antiestrogen treatment efficacy, regardless of how the estrogen-reduced state is achieved (oophorectomy, tamoxifen, or AI). Breast cancers that entirely lack ER do not respond to antiestrogens and are omitted from the therapeutic plan [15]. All patients (women and men) with ER-positive invasive breast cancer based on ER/PR test results are offered antiestrogen treatment, unless contraindicated by specific comorbid conditions [9, 16]. The decision whether to use antiestrogen therapy is highly significant because adjuvant tamoxifen reduces mortality by at least 33 % at 15 years [15, 17].

Available Assays for Hormone Receptor Content Testing

Currently, immunohistochemistry (IHC) of formalin-fixed, paraffin-embedded (FFPE) tissue sections is the standard method for ER/PR testing. IHC testing for ER/PR expression has many advantages: ER/PR in invasive cancer cells can be assessed specifically and normal tissue expression ignored; results are not confounded by endogenous hormone levels; no requirement for fresh or frozen tissue, so that IHC can be applied retrospectively and to small (≤1.0 cm) invasive cancers, which are now commonplace; and lastly, IHC staining kits and instrumentation are widely available in nonacademic centers, where most breast cancers are diagnosed and treated. Any proposed new testing platform must retain or improve on these advantages to supplant IHC hormone receptor testing.

In late 2008, The American Societ of Clinical Oncology (ASCO) partnered with the College of American Pathologists (CAP) to convene a panel to determine best practices for ER/PR testing in breast cancer. The standardization effort was driven by academic oncologists who discovered significant discordances between local and central predictive marker testing results for patients entered in clinical trials. The panel analyzed numerous published studies and clinical trials' results correlating the ER/PR content to outcomes of antiestrogen treatment [8, 18]. The resulting 2010 ASCO/CAP Guideline Recommendations for IHC Testing of ER/PR in Breast Cancer were widely adopted and remain the standard practice [8].

The guideline recommends using IHC of FFPE tissue sections to test all primary invasive breast cancers and putative recurrences for ER/PR content, whenever tissue is available. The guideline defines how to control and document preanalytic, analytic, and postanalytic variables to ensure analytic and clinical validity and clinical utility [8].

Preanalytic Standardization

The 2010 ASCO/CAP Guideline Recommendations for IHC testing of ER/PR in Breast Cancer specify how to handle FFPE tissues that are likely to be tested (see summary below). The overall goal is to standardize three key preanalytic variables: tissue handling, fixation type, and fixation duration [8, 18]. Preanalytic factors are most easily controlled in the core biopsy setting which, therefore, is the preferred tissue for testing.

Documenting cold ischemia time requires cooperation between persons performing the breast cancer biopsies and resections with pathology personnel, which can be a challenge. Adding designated spaces for this biopsy or resection

timing data to the surgical pathology requisition form or in the electronic ordering process can aid clinicians in providing the data. Reporting templates help the pathologist to document the preanalytic factors in the report.

Summary of ASCO/CAP Guideline Recommendations for Preanalytic Variables for Hormone Receptor and HER2 Immunohistochemistry:

- Minimize cold ischemia time (time from excision to initiation of fixation) to 1 h or less.
- Use 10 % neutral buffered formalin (NBF) as the standard fixative.
- If nonstandard fixatives or those containing decalcifying agents are used, add a disclaimer to the report.
- Do not use microwave-type processors for ER/PR staining, because results have not been clinically validated.
- Fix the cancer in NBF for at least 6 h, but no more than 72 h, before paraffin embedding.

Analytic Standardization

Antibodies and controls are the key analytic variables for ER/PR testing. The 2010 ASCO/CAP Guideline Recommendations for IHC Testing of ER/PR in Breast Cancer advise using specific ER antibody clones (1D5, 6F11, SP1, and 1D5+ER.2.123), which have slightly different staining profiles but have been sufficiently validated to provide comparable results. Test kits with validated scoring schemes that are approved or cleared by the US Food and Drug Administration (FDA) are considered optimal. Laboratory developed tests (LDTs) are acceptable, if stringently validated [8].

The interpreting pathologist must verify that the internal and external controls stain appropriately. Internal controls consist of immunoreactive benign mammary epithelia in the same section or in another equivalently processed section from the same specimen [8]. Where appropriate internal controls are lacking, an apparently negative ER or PR stain is considered uninterpretable. Breast biopsies are rarely problematic, but lung and bone, which are common sites of metastasis, may be more difficult to interpret. In this context, the pathologist should add a disclaimer that a negative staining result cannot be confirmed as accurate in tissues that do not normally express ER/PR (no internal control). Also, bone from pathologic fractures due to metastatic cancer typically must be decalcified. With decalcification, an apparently negative ER/PR stain must be interpreted cautiously and a disclaimer added to the report for a negative result, noting that decalcification can adversely affect antigen preservation in tissue and result in a false-negative stain. Finally, it is essential for a laboratory initiating IHC for ER/PR to validate the assays; the CAP provides guidelines for validation [19].

Postanalytic Standardization

The 2010 ASCO/CAP Guideline Recommendations for IHC Testing of ER/PR in Breast Cancer allow the pathologist to choose a scoring system (Allred system, *H*-score, etc.) but recommend that the report indicates both the percentage of stained invasive carcinoma cell nuclei and the stain intensity (see below). Some FDA-approved or FDA-cleared staining systems mandate the use of a specific scoring system to ensure clinical validity. For example, the FDA 510(k)-cleared DakoCytomation ER/PR pharmDx™ (Dako Corp, Carpinteria, CA) staining kit requires pathologists to report stain results using the Allred scoring scheme [20]. Semiquantitative visual estimates of nuclear staining are sufficient for guiding clinical decisions. Computer-assisted imaging is more expensive and does not add value to testing, given that antiestrogen treatment is considered for any level of staining ≥1 %.

Interpreting ER/PR stains (adapted from Ref. 8):

- ER- or PR-positive cancer is one in which ≥1 % of invasive carcinoma cell nuclei are immunoreactive.
- ER- or PR-negative cancer is one in which <1 % of invasive carcinoma cell nuclei are immunoreactive.
- ER and/or PR status is not interpretable when no invasive carcinoma cell nuclei are immunoreactive and appropriately stained controls are lacking.

Laboratory and Regulatory Issues

The Clinical Laboratory Improvement Amendments (CLIA) of 1988 and the derived CLIA regulations provide the analytic validity standards for predictive factor assays such as ER, PR, and HER2 tests. Laboratories performing these high complexity tests must be surveyed semiannually, with defined criteria and actions required when performance is deficient [21]. Semiannual proficiency testing for ER/PR analysis is now a mandatory part of the CAP Laboratory Accreditation Program (LAP) (http://www.cap.org/web/home/lab/accreditation/laboratory-accreditation-program. Accessed 3/10/2015). Competence is assessed by periodic review of test performance against peers and failure mandates remediation.

Future Directions

Transitioning routine ER/PR expression testing to a molecular platform, for example, a reverse transcription-polymerase chain reaction (RT-PCR) analysis using paraffin tissues, would not be straightforward. IHC has many advantages, including wide availability, and a strong evidence base that allows ER/PR results to be used to triage cancers for additional molecular testing, as discussed later.

The 2010 ASCO/CAP Guideline Recommendations for IHC Testing of ER/PR in Breast Cancer require new ER/PR tests be validated clinically and operationally [8]. Although

ER/PR expression profiling results are provided with the Oncotype DX® Recurrence Score (Genomic Health™, Redwood City, CA), these may serve to confirm IHC stain results but have not been validated for clinical decision-making [8, 21]. It is likely that paraffin-IHC will remain the platform of choice for some time.

HER2 in Breast Cancer

Molecular Basis for Targeting HER2 Expression in Breast Cancer

The other important predictive marker in breast cancer is HER2, a cell-surface membrane glycoprotein involved in cell proliferation control. *HER2* gene amplification, leading to protein overexpression, is found in 15–20 % of invasive breast cancers [21]. Early investigations used Southern blot analysis to identify *HER2* gene amplification in fresh or frozen samples of breast cancer and showed that patients with *HER2*-amplified breast cancers had higher recurrence and death rates than those with *HER2*-normal cancers [22, 23]. Defining *HER2* as a possible prognostic marker drove the first laboratory testing efforts using monoclonal antibodies for IHC staining [24]. Later, as HER2 became far more important as a drug target, the goals of testing shifted to predicting therapeutic response to drugs targeting the HER2 protein.

The first anti-HER2-targeted treatment, trastuzumab (Herceptin™; Genentech, South San Francisco, CA), was developed in the mid-1990s and is now the standard treatment for HER2-overexpressing breast cancers. Trastuzumab is a recombinant humanized monoclonal antibody that specifically binds to the extracellular juxtamembrane domain of HER2 and inactivates its intracellular tyrosine kinase function by several possible mechanisms, resulting in reduced growth and reduced survival of HER2-dependent cancers [25]. Trastuzumab is most effective when combined with chemotherapy agents active against breast cancer, such as taxanes, doxorubicin, and cyclophosphamide, with trastuzumab monotherapy not being the standard care at this time (http://www.nccn.org/professionals/physician_gls/pdf/breast.pdf. Accessed 03/19/2015).

Following the landmark Genentech-sponsored trials that demonstrated the efficacy of trastuzumab in HER2-overexpressing metastatic breast cancer, trastuzumab was marketed with a companion diagnostic IHC assay, HercepTest™ (Dako Corp, Carpinteria, CA). In 1998, the FDA approved the HercepTest™ designed to identify HER2 overexpression in invasive breast cancer to select patients for trastuzumab treatment [26]. The FDA advocates the importance of companion diagnostic testing for all emerging targeted cancer treatments.

Other anti-HER2 agents (pertuzumab, lapatinib, and ado-trastuzumab emtansine [T-DM1]) are in the clinical trial pipeline. Testing for HER2 overexpression/amplification is also used to select patients for these newer agents [21].

Clinical Utility of HER2 Expression Testing

Following trastuzumab's introduction, HER2 joined ER/PR expression as a standard predictive marker in breast cancer management. The ASCO Tumor Marker Guidelines Panel added routine HER2 expression testing of all invasive breast cancers to its 2001 recommendations [7]. Because DCIS is never treated with chemotherapy and trastuzumab, DCIS should not be tested for HER2 amplification.

The goal of HER2 expression testing is to identify patients who are likely to benefit from trastuzumab treatment, i.e., those with breast cancers that overexpress HER2 protein and/or have *HER2* gene amplification by in situ hybridization (ISH). Trastuzumab can be lifesaving for patients with HER2-overexpressing breast cancer but requires a costly (approximately $100,000), yearlong course of intravenous therapy that is not risk-free. As is true for ER/PR expression testing, accurate, reliable, and reproducible testing is essential to direct anti-HER2 treatment to those who can benefit and spare those who will not.

Whether trastuzumab benefits patients with HER2-negative or HER2-equivocal cancers has been controversial, although the weight of evidence from early exploratory trials suggested little, if any, effect [21, 25]. A prospective randomized clinical trial (NSABP B-47; NCT01275677) will answer this question definitively, but current clinical practice is to treat only HER2-positive invasive breast cancer with trastuzumab [21, 27].

Available Assays for HER2 Overexpression/HER2 Amplification Testing

Clinical laboratories can use IHC to test for HER2 overexpression or ISH to detect *HER2* gene amplification. Gene amplification is the preponderant mechanism for HER2 overexpression in breast cancer. IHC and ISH share several advantages over Southern blot analysis: (1) the signals are interpreted in the context of the histopathology on tissue sections, permitting specific scoring in morphologically confirmed invasive cancer cells; (2) standard FFPE tissues are acceptable specimens, whereas Southern blot analysis requires fresh or frozen tissue to obtain intact DNA, not fragmented by the fixation and embedding processes; and (3) small cancer specimens, such as core needle biopsies, are acceptable for IHC and ISH, whereas larger specimens are needed for Southern blot analysis, which requires a large amount of DNA [21, 26]. ISH testing, especially fluorescence ISH (FISH), has the disadvantages of being more labor-intensive and costly than IHC;

because of expense, ISH is a second-line, confirmatory test in most clinical settings. Newer bright-field ISH platforms mitigate some of these disadvantages and may have a future in testing.

The optimal procedures for HER2 IHC testing, scoring, and reporting of results have been long debated. Some phase III clinical trials of trastuzumab found significant discordances between local and central laboratory results for HER2, highlighting the need to standardize HER2 testing [27]. Accurate testing for HER2 expression in the clinical trial context is critically important, because treating cancers with false-positive HER2 overexpression results can confound interpretation of treatment efficacy [21, 27]. Obviously, accurate testing in the patient care context is no less essential.

The ASCO and the CAP came together in 2006 to address HER2 testing inaccuracy (both false-positive and false-negative results) and develop guidelines for testing and interpretation. They convened an expert panel to (1) determine the optimal testing algorithm for HER2 testing, and (2) develop strategies to ensure optimal performance, interpretation, and reporting of results across US laboratories. The first ASCO/CAP HER2 Guideline Recommendations were published in 2007 [28]. An updated guideline in 2013 was informed by new clinical trial data and stakeholder suggestions and addresses newer testing platforms, such as FDA-cleared bright-field ISH assays ([21, 29]; http://www.asco.org/guidelines/her2; http://www.cap.org. Accessed 03/10/2015). Molecular pathologists can expect periodic guideline updates as investigators publish new clinical trial data for anti-HER2 agents.

Testing, Interpreting, and Reporting HER2 Test Results

The 2013 ASCO/CAP HER2 Guidelines recommend using IHC or ISH (FISH or bright-field ISH) on FFPE tissue sections to test all primary and recurrent invasive breast cancers for HER2 overexpression. Increasingly, oncologists biopsy suspected breast cancer recurrences to obtain tissue for accurate HER2 and ER/PR results to guide the treatment of metastatic disease.

The goal of the ASCO/CAP HER2 Guidelines is the same as for ER/PR testing: to standardize preanalytic, analytic, and postanalytic variables to ensure analytic and clinical validity and clinical utility [21, 28]. If available, a core biopsy sample of the primary cancer is used for the first HER2 test. If clearly positive, no further testing of the resected primary cancer is recommended. If the result is negative, no further testing is recommended, unless there are concerns about the core biopsy tissue handling, histopathologic discordance, or tumor heterogeneity, in which case testing can be repeated on the resection specimen [21].

Preanalytic Standardization

The 2013 ASCO/CAP HER2 Guidelines for tissue handling of primary invasive breast cancers and putative recurrences are identical to those for ER/PR expression testing [see section above and Refs. 8, 21].

Analytic Standardization

Antibodies and controls are the key analytic variables for IHC HER2 testing. ASCO/CAP, as well as the maker of trastuzumab and pertuzumab (Genentech, South San Francisco, CA), recommends using FDA-approved or FDA-cleared assays for HER2 testing. The FDA-approved HercepTest™ (Dako Corp, Carpinteria, CA) has validated scoring schemes and is considered optimal. As is true for ER/PR expression testing, LDTs are acceptable, if stringently validated [21].

Ideally, a new HER2 assay should be validated using well-annotated breast cancer specimens from prospective therapeutic trials of anti-HER2 therapy. This task is difficult to accomplish because such specimens are relatively rare and limited. As a substitute, ASCO/CAP will endorse HER2 assays that show high-level concordance with other established HER2 tests, as long as concordance studies use data sets with a representative distribution of HER2 overexpression/*HER2* amplification states.

The interpreting pathologist must verify that the controls stain appropriately. Benign mammary epithelia, which have normal *HER2* gene copy number and do not overexpress HER2 protein, function as negative controls. External controls are extremely important as positive controls and include known HER2-overexpressing and HER2-nonoverexpressing invasive breast carcinomas, which must be run concurrently. The HercepTest™ kit (Dako Corp, Carpinteria, CA) is an IHC test kit that includes three FFPE cell line controls with different HER2 copy numbers that stain negative (score 0), negative (score 1+), and positive (score 3+), respectively. Where appropriately stained controls are lacking, or nonstandard conditions have occurred, an apparently negative HER2 stain must be considered uninterpretable and be accompanied by a disclaimer noting the problem [21, 28]. HER2 staining results are interpreted as positive (3+), equivocal (2+), or negative (score 0 or 1+), as summarized below.

Interpreting IHC for HER2 overexpression status (adapted from Ref. 21):

1. IHC-positive (3+) carcinoma shows:
   - Circumferential complete, intense membrane staining in >10 % of contiguous and homogeneous cancer cells
2. IHC-equivocal (2+) carcinoma shows:
   - Complete, circumferential intense membrane staining in ≤10 % of cancer cells

- Circumferential membrane staining that is incomplete and/or weak/moderate intensity in >10 % of contiguous and homogeneous cancer cells

3. IHC-negative (1+) carcinoma shows:
   - Incomplete, faint/barely perceptible membrane staining in >10 % of cancer cells
4. IHC-negative (0) carcinoma shows:
   - No staining
   - Incomplete, faint/barely perceptible membrane staining in ≤10 % of cancer cells

The 2013 ASCO/CAP HER2 Guidelines indicate that ISH for *HER2* gene amplification may be single-probe (*HER2* alone) or dual-probe (*HER2* and chromosome 17 centromere, CEP17). The first FDA-approved, dual-probe FISH test for HER2 is the PathVysion *HER2* DNA Probe Kit (Abbott Molecular, Des Plaines, Illinois) and is used by most laboratories in the USA. Dual-probe FISH has been the standard method of detecting and semiquantitating *HER2* gene amplification in breast cancer since the late 1990s but has some disadvantages: suboptimal morphologic detail, which can make identification of carcinoma cells difficult; signals that fade quickly, not allowing for review; a 2–3-day turnaround time (TAT); and significant cost due to the need for a fluorescence imaging system and specially trained personnel. These drawbacks have stimulated development of more user-friendly bright-field approaches.

Bright-field ISH offers better microscopic detail, permanent signals that allow later review, less hands-on technician time, easier identification of tumor heterogeneity using low-power magnification, and lower cost (conventional light microscope) [30–32]. An important question has been whether bright-field ISH is as sensitive as FISH. While 15–20 % of invasive breast cancers have *HER2* amplification, among FISH-positive cases, nearly half (47 %) have only borderline or low levels of *HER2* amplification [33].

The most favored bright-field ISH platform is chromogenic ISH (CISH), which entails hybridizing DNA probe(s) to the target *HER2* DNA in tissue sections and then detecting the probe(s) using reagents similar to those used in IHC. Both single- and dual-probe approaches are feasible, and the signals appear as brown granules on tissue sections examined with a light microscope. Dual-probe approaches require two parallel cut sections, one for each probe; in this case, the two probes are to *HER2* and the chromosome 17 centromere.

Bhargava et al. [30] used tissue microarrays and a CISH *HER2* kit with a polymer detection system that enhances hybridization signals (Zymed Laboratories, South San Francisco, CA) to study 113 breast cancers selected from a much larger sample of tumors that had been tested previously for *HER2* amplification using FISH on tissue sections. The study set was designed to include ample proportions of negative and borderline-, low-, and high-amplified FISH-positive samples. Among 102 cases analyzed successfully for both probes ("dual-probe"), concordance between FISH and CISH was 100 % in categorizing a cancer as *HER2* amplified or not amplified. The use of a single *HER2* probe only resulted in discordant results (no amplification vs borderline or low-level *HER2* amplification) in three cases, 2.9 %, that were positive by FISH [30].

CISH has the same 2–3-day TAT as FISH but requires less hands-on technician time and the pathologist can interpret a CISH slide in approximately half the time, because it is easier to recognize carcinoma cells and count signals [30]. CISH may be especially useful in cases where morphologic detail is challenging: small invasive carcinomas; cases with an intimate admixture of in situ and invasive components; and cases where carcinoma insidiously invades benign parenchyma as single cells. Laboratories not currently set up for FISH but regularly performing IHC can consider CISH as a good alternative for HER2 expression testing [30].

Additional studies have shown good correlation between CISH and FISH for identifying *HER2* amplification [31]. Disadvantages are that not all signals appear crisply discrete and may be difficult to count against background. In addition, the CEP17 probe must be evaluated in a second reaction on a separate, parallel tissue section [30, 34].

Bright-field ISH should be interpreted on the basis of a comparison between normal breast and cancer cells. If the cancer cell pattern is neither normal nor clearly amplified, then expert opinion should be sought. Nonneoplastic cells in the same section serve as an internal control. A cancer should not be reported as "not amplified" unless one or two signals per nucleus are evident in benign cells. ISH criteria for *HER2* amplification status are summarized below.

ISH criteria for HER2 amplification status, based on counting at least 20 cells within the area (adapted from Ref. 21):

1. ISH-positive carcinoma fulfills one of the following criteria:
   - Dual-probe: HER2:CEP17 is >2.0, with average HER2 copy number >4 signals/cell.
   - Dual-probe: HER2:CEP17 is >2.0, with average HER2 copy number <4 signals/cell.
   - Dual-probe: HER2:CEP17 is <2.0, with average HER2 copy number >6 signals/cell.
   - Single-probe: Average HER2 gene copy number is >6 signals/nucleus.
2. ISH-equivocal carcinoma fulfills one of the following criteria:
   - Dual-probe: HER2:CEP17 is <2, with average HER2 gene copy number >4 but <6 signals/nucleus.
   - Single-probe: ISH average HER2 gene copy number is >4 and <6 signals/nucleus.

3. ISH-negative carcinoma fulfills one of the following criteria:
   - Dual-probe: HER2:CEP17 is <2, with average HER2 gene copy number <4 signals/nucleus.
   - Single-probe: Average HER2 gene copy number is <4 signals/nucleus.

Postanalytic Standardization

A HER2-positive (3+) breast cancer has evidence of protein overexpression by IHC or gene amplification by ISH. A HER2-negative (0, 1+) cancer lacks both. HER2-equivocal (2+) carcinoma has borderline features and requires confirmatory (reflex) testing by a second method. Most commonly, this refers to cases with equivocal IHC results, but some laboratories also do follow up testing of cancers that are IHC "triple-negative" (ER-, PR-, and HER2-negative) to ISH as further assurance that tissue quality has not led to spurious negative results. ISH-equivocal results should be confirmed by IHC, although many oncologists prefer to treat such patients regardless of the IHC staining results. Retesting using both approaches may be in order for results that seem discordant with clinical circumstances, e.g., HER2 overexpression in an ILC or a subcentimeter tubular ductal carcinoma, which usually do not overexpress HER2 [21].

Laboratory and Regulatory Issues

The CLIA requirements for laboratories performing HER2 expression testing are the same as for ER/PR expression testing. The 2013 ASCO/CAP HER2 Guidelines recommend that proficiency testing be through the CAP or another entity. Mandatory proficiency testing surveys for HER2 expression testing, identical to those for ER/PR evaluation, were added to the CAP LAP in 2007. The CAP has observed increased levels of proficiency testing and fewer deficiencies since the 2007 HER2 Guideline was published ([21], data supplement).

The 2013 ASCO/CAP HER2 Guideline recommendations allow the use of LDTs for HER2 expression testing, as long as the test has been prospectively validated clinically and operationally in the same clinical laboratory that will perform it, which entails demonstrating high concordance with a validated HER2 test on a sufficiently large and representative set of breast cancers [21]. This has been accomplished for bright-field ISH approaches such as CISH. Notably, HER2 expression profiling results provided with the Oncotype DX® Recurrence Score (Genomics Health™) may serve to confirm IHC stain results but have not been validated for clinical decision-making [8, 21].

Standard and Emerging Molecular Tests

Just as tamoxifen and trastuzumab and their corresponding predictive tests were "game changers" in breast cancer treatment, adjuvant systemic chemotherapy also has an important role in improving breast cancer survival. Berry et al. [35] note that breast cancer mortality declined 26 % between 1975 and 1990 and ascribe at least 50 % of the reduction to use of adjuvant systemic chemotherapy.

The persistent challenge has been to direct adjuvant systemic chemotherapy to those who can benefit most from the intervention and avoid treating those who will not. Overall, two groups of patients will *not* benefit from systemic chemotherapy: (1) those with biologically indolent cancer whose chances of survival are so good that the toxicities and risks of chemotherapy are greater than the benefits, and (2) patients with biologically aggressive cancers that will not respond to currently available chemotherapy agents. The new "game changers" in breast cancer management are the recently developed, tissue-based prognostic/predictive molecular assays, which aim to identify patients who do not need chemotherapy (prognostic) or who either will or will not respond to chemotherapy (predictive) [36].

Approximately 75–80 % of patients are diagnosed with ER-positive breast cancer. Without specific contraindications, these patients will be treated with antiestrogens and have an excellent outcome: 80 % of these patients will survive 10 years or more. Within this ER-positive group, however, 20 % recur within 10 years. The challenge has been to identify these patients at the time of diagnosis and add additional treatment to the antiestrogen treatment, in hopes of improving outcome. Thus, the second part of the challenge is to identify, within the ER-positive breast cancer patients, those who will benefit from added chemotherapy.

In this context of deciding whether chemotherapy will provide benefit for a patient, molecular tests have two actionable tasks:

1. Determine prognosis for the individual cancer patient with ER-positive cancer, which is either node negative (largest group) or node positive (second largest group), with the goal being to identify the low-residual risk group, in whom risks of adjuvant systemic chemotherapy outweigh predicted benefit
2. Among the patients with high residual risk, identify those who are likely to respond to systemic chemotherapy (and even better, a specific chemotherapy regimen).

The molecular profiling test endorsed by the major oncology and health-care organizations in the USA and abroad to date is the Oncotype DX® test (Genomic Health, Inc.). Several other tests are available, including MammaPrint®

(Agendia Inc., USA; Irvine, CA) and PAM50-based Prosigna Breast Cancer Prognostic Gene Signature Assay, simplified to Prosigna in this chapter (NanoString Technologies, Seattle, WA). All of these tests are LDTs that are validated and performed by a commercial reference laboratory.

Typically, oncologists and/or surgeons order one of the molecular profiling tests and pathologists select and ship FFPE tissue sections to the commercial laboratory, with estimated shipping/processing times of 7–10 days. The Prosigna test is the only one that has an option for local performance of the test through purchase of a testing system (http://prosigna.com/. Accessed 3/04/2015). All these tests presume that the test result will be used in the context of other clinicopathologic features (patient age, tumor size, lymph node status, standard predictive markers) and that women with ER-positive cancer will be treated with tamoxifen or aromatase inhibitors.

Oncotype DX®

The Oncotype DX® test provides a result as a 21-gene recurrence score (RS), which has been incorporated into ASCO, NCCN, St. Gallen, and NICE clinical practice guidelines ([37–39]; http://www.nccn.org/. Accessed 3/04/2015; https://www.nice.org.uk/. Accessed 3/04/2015). Oncotype DX® is a commercially available test that uses quantitative RT-PCR (qRT-PCR) to profile the expression of 21 genes (16 cancer-related; 5 reference) in FFPE breast cancer tissue.

The original clinical validation studies for Oncotype DX® examined archived tumors from patients enrolled in the National Surgical Adjuvant Breast and Bowel (NSABP) clinical trials B-14 and B-20, which compared different treatment outcomes in women with node-negative, ER-positive breast cancer [40, 41]. NSABP B-14 demonstrated the benefit of adjuvant tamoxifen compared to no adjuvant treatment, whereas the B-20 trial compared results of adjuvant tamoxifen plus chemotherapy to tamoxifen therapy alone. The investigators developed a high-throughput real-time RT-PCR method to quantitate gene expression levels in FFPE tissues and selected 250 candidate genes from prior publications, genomic databases, and intrinsic subtyping studies, discussed below [3]. Archived cancers were analyzed to assess the relationship between the expression of the candidate genes and breast cancer recurrence in patients with known outcome [40]. From these results, they further refined the candidate gene panel to 16 cancer-related genes and 5 reference genes, which were analyzed in prospective-retrospective studies of archived tumors from NSABP B-14 and B-20 trial patients. To quantitate the likelihood of distant recurrence in patients with node-negative, ER-positive breast cancer treated with adjuvant tamoxifen or not, they designed an algorithm based on the expression of the 21 genes. The test assigns a continuous RS between 1 and 100 and a risk category of low ($RS < 18$), intermediate ($18 \leq RS \leq 30$), or high ($RS \geq 31$) to each tumor [40]. The same strategy was applied to other clinical trial specimens from patients treated with either tamoxifen with systemic chemotherapy or tamoxifen only [41].

The RS quantitates the 10-year recurrence risk in tamoxifen-treated patients with node-negative, ER-positive breast cancer [40, 42]. In addition, the RS predicts the magnitude of chemotherapy benefit in this cohort: the higher the RS, the more likely that chemotherapy will be beneficial. Patients whose cancer has a low RS have minimal, if any, response to adjuvant systemic chemotherapy [41]. Further, the Oncotype DX® RS has clinical utility as a prognosticator for tamoxifen therapy for patients with ER-positive, node-positive (N1 = 1–3 nodes) breast cancer, as well as clinical utility for selecting patients likely to benefit from adjuvant systemic chemotherapy [43, 44].

Dowsett et al. [45] further validated the RS in the Arimidex, Tamoxifen Alone, or in Combination (ATAC) study, showing improved risk stratification in postmenopausal women treated with anastrozole or tamoxifen. A subsequent study showed that combining RS with clinicopathologic features could enhance the prognostic accuracy of the RS [43]. This group further showed that IHC4, an IHC panel consisting of ER, PR, HER2, and Ki67, a proliferation marker, provides risk information similar to that of the RS [46]. Further studies are needed to extend these early comparisons of the lower cost IHC4 method, which could be performed by many laboratories.

Two prospective, randomized clinical trials are in progress to assess the correlation between Oncotype DX and response to adjuvant systemic chemotherapy. The *T*rial *A*ssigning *I*ndividua*L*ized *O*ptions for Treatment (*Rx*) TAILORx trial is testing the value of adjuvant chemotherapy in tamoxifen-treated patients with ER-positive, node-negative breast cancer that yields an Oncotype DX® RS in the 11–25 range. The trial is now closed to accrual and is expected to yield the first mature data in 2015 (https://clinicaltrials.gov/ct2/show/NCT00310180?term=TailoRx&rank=2. Accessed 3/04/2015).

MammaPrint®

The MammaPrint® test began as a 70-gene prognostic signature developed by scientists at the Netherlands Cancer Institute [47, 48]. These investigators used gene expression microarrays to study archived snap-frozen breast cancers from a group of 117 patients with early breast cancer (tumors ≤5.0 cm size, node negative) who had not received adjuvant systemic chemotherapy. The expression of 231 genes was found to correlate with outcome at 5 years, identifying an

early recurrence subgroup of patients who had developed metastatic disease within the first 5 years after treatment and a larger group who remained disease-free at this endpoint. This group of genes was then further refined to a 70-gene classifier that could optimally parse the two groups [47].

The 70-gene classifier was assessed with another cohort of 295 patients composed of early breast cancer patients with both node-negative and node-positive diseases. The 70-gene classifier parsed the cancers into those with a "poor prognosis" signature ($N=180$) and those with a "good prognosis" signature ($N=115$). At 10 years, the overall survival of those patients with "poor prognosis" cancers was 54.6 % compared to 94.5 % for the patients with "good prognosis" cancers. Patients with node-negative and node-positive breast cancer were evenly distributed in the two groups, indicating the signatures were independent of lymph node status. The prognostic signature was a strong independent factor in predicting disease outcome and added to risk assessment [48].

The 70-gene classifier was clinically validated for node-negative breast cancer by a retrospective multi-institutional European TRANSBIG consortium (http://www.breastinternationalgroup.org. Accessed 03/09/2015) that examined archived frozen cancers from 302 patients who had not been treated with adjuvant systemic chemotherapy or endocrine therapy [49]. Microarray analysis was performed at Agendia Laboratories (Irvine, CA), a spin-off company of the Netherlands Cancer Institute, which custom-designed an array chip given the name MammaPrint™, which was manufactured by Agilent Technologies using their oligonucleotide microarray platform [49]. The aim of the validation study was to examine whether the 70-gene signature had prognostic value independent of the best clinical risk classifications in a patient cohort in which adjuvant treatment could not confound the results. The TRANSBIG consortium used Adjuvant! Online (AOL) (http://www.adjuvantonline.com. Accessed 03/09/2015) to classify patient risk using conventional clinicopathologic attributes. Results showed MammaPrint™ was a strong prognostic marker for time to distant metastasis and overall survival for the node-negative breast cancer patients who had received no adjuvant systemic treatment and the prognostic value of the result was independent of the clinical risk stratification. Further, where there were discordances between clinical risk category (low vs high) generated by AOL and the MammaPrint™ result, the latter provided stronger prognostic information [49].

The ability of MammaPrint™ to effectively parse node-negative breast cancer patients into low- and high-risk categories was prospectively tested in the observational microarRAy-prognoSTics-in-breast-cancER (RASTER) study conducted at 16 community hospitals in the Netherlands using archived frozen cancers from 427 patients. MammaPrint™ performance was again compared to AOL clinical risk categories [50]. Adjuvant systemic chemotherapy decisions were based on the Dutch CBO 2004 guidelines, the MammaPrint™ result, and doctors' and patients' preferences. After a median follow-up of 5 years, MammaPrint™ outperformed AOL in prognostication, but the study had a number of limitations including the inhomogeneous approach to adjuvant systemic treatment. Despite the design drawbacks, omitting chemotherapy for patients with a low-risk gene signature did not appear to compromise outcome, an important aspect of clinical utility. Another prospective randomized clinical trial to demonstrate the clinical validity and utility of MammaPrint™ is underway in the MINDACT trial, which expects to report results after 2019 [51].

One of the disadvantages of using MammaPrint™ in routine clinical practice is that it requires snap-frozen tumor for testing, a distinct inconvenience in the clinical setting and one that may restrict use to larger tumors, where there is sufficient excess tumor tissue after standard pathologic staging and margin assessment in breast conserving procedures. Agendia Inc., USA (Irvine, CA), is in the process of validating MammaPrint™ for use with FFPE breast cancer tissues.

Intrinsic Subtype Profiling

Virtually all of the prognostic and predictive molecular tests are in some way informed by seminal gene profiling studies that are now more than 10 years old. Perou et al. [3] studied gene expression profiles of a small set of frozen invasive breast cancers ($N=38$), normal breast tissues ($N=3$), and 17 breast cancer cell lines, looking for evidence of molecularly defined breast cancer subtypes. Using an 8,100-gene complementary DNA (cDNA) microarray, these investigators honed this gene expression set to a smaller "intrinsic" gene expression list, whose transcripts showed significantly greater variation in expression between tumors from different patients than between paired samples from the same patient's tumor [3]. Using unsupervised cluster array analysis to organize the data, the samples were segregated based on the overall similarity in their gene expression patterns [3].

Four molecular signatures or subtypes emerged: ER+/luminal-like, basal-like, HER2-enriched, and normal breast-like, with expression of genes related to ER, PR, and HER2 largely driving placement into one of these groups. Later work using the same methods parsed the original ER+/luminal-like group into two subgroups, luminal A and luminal B, that differed primarily in the expression of proliferation related genes [4, 5]. Most importantly, intrinsic subtypes correlated with different patient outcomes. The "normal breast-like" cancers, accounting for 3–6 % of cancers in most studies, lack a distinct signature; there is evidence that they are a spurious category caused by artifactual contamination by excessive normal tissue RNA [52, 53].

Intrinsic subtypes are biologically plausible, conforming to tumor biology as it is understood on the basis of the standard predictive markers (ER/PR/HER2) and treatments, and the signatures have proven robust across multiple genomic profiling platforms [5, 54–57]. Breast cancers from different racial/ethnic groups partition into the same five groups, although the signatures can vary in distribution. For example, African Americans enrolled in two population-based breast cancer cohorts had a lower prevalence of luminal A cancers and a higher prevalence of basal-like cancers relative to non-Hispanic Whites [58]. Similarly, male breast cancers have intrinsic profiles that skew largely to the luminal A/B subtypes [59].

Research studies have used three different strategies for intrinsic subtyping: (1) microarray gene expression assays, (2) IHC stains, and (3) quantitative RT-PCR (qRT-PCR) [3, 58]. Microarray gene expression profiling is the gold standard approach but requires fresh or frozen tumor, which is impractical for routine clinical use. Standard IHC predictive marker stains (ER/PR/HER2) supplemented with a proliferation marker stain (e.g., Ki67) can parse FFPE breast cancers of any size into four clinicopathologic groups that are reasonable, but imperfect, surrogates for the intrinsic subtypes [60]. Lastly, qRT-PCR classifiers that can be applied to FFPE tissues are more practical clinically than microarray gene expression profiling and more quantitative than IHC stains. One qRT-PCR classifier is PAM50-based Prosigna™, which is described below.

PAM50-Based Prosigna™ Breast Cancer Prognostic Gene Signature Assay

Parker et al. [52] adapted microarray-based gene expression profiling to a clinically applicable test by developing a qRT-PCR assay using RNA extracted from FFPE tissues as a substrate. An expanded "intrinsic" gene set was derived from previous microarray studies and narrowed down to a 50-gene expression profiling set, with special weighting given to a set of proliferation-associated genes that could reproducibly predict the intrinsic subtypes. The final classifier was constructed using the Prediction Analysis for Microarrays (PAM) algorithm, hence the name "PAM50" ([3, 4, 5, 52, 61]). The PAM50 test was developed using FFPE tumors and the nCounter® platform (NanoString Technologies, Seattle, WA). The test is now marketed as the PAM50-based Prosigna™ Breast Cancer Prognostic Gene Signature Assay and nCounter® Dx Analysis System (NanoString Technologies, Seattle, WA), simplified to Prosigna™ in this discussion.

The clinical utility of Prosigna™ was assessed using a cohort of patients with node-negative breast cancer who had not received adjuvant systemic chemotherapy and found that the intrinsic subtypes showed prognostic significance that remained valid in multivariable analyses that incorporated standard clinicopathologic variables. The subtype plus tumor size performed best among several models as a risk of relapse (ROR) predictor and classified patients into low-, intermediate- or high-risk categories. Prosigna™ estimates prognosis for all types of breast cancer, irrespective of the status of ER and lymph node metastases [62]. The lowest ROR group contained only luminal A cancers; thus, like what Oncotype DX® does for node-negative, ER-positive patients, Prosigna™ identified an excellent prognosis group of patients who can reasonably forgo chemotherapy.

The clinical value of Prosigna™ has also been assessed using independent cohorts of ER-positive, tamoxifen-treated patients and shown to be superior to clinicopathologic features (e.g., using AOL) in estimating residual risk after antihormonal treatment and its similarity to Oncotype DX® in identifying a very low-risk cohort for whom antiestrogens alone are adequate treatment [53]. In node-positive patients, Prosigna™ is a better predictor than IHC profiling of standard markers, but late relapses and death occur in even the lowest risk category of patients; thus, an outcomes prediction test for a node-positive cohort that is adequately treated by antiestrogens alone is not yet available [53].

The ATAC study looked at outcome in women with ER-positive breast cancer who had received either tamoxifen or Arimidex (an aromatase inhibitor) [63] and compared, head-to-head, the ability of the Prosigna™ ROR score, the Oncotype DX® RS, Prosigna™ ROR, and IHC4 (an expanded stain panel: ER, PR, HER2, Ki67), to predict the 10-year risk of distant recurrence after endocrine therapy. The Prosigna™ analysis was done on the same RNA sample as the Oncotype DX® analysis. A significant difference is that the Oncotype DX® test was performed in one central laboratory (Genomic Health Inc., Redwood City, CA), whereas the Prosigna™ test was done with instruments distributed to multiple testing sites. Investigators compared the three molecular predictors to standard clinicopathologic features (stage, grade, age, and type of endocrine treatment). Distant recurrence (DR) risks predicted by the Prosigna™ ROR score were distinctly different in node-positive and node-negative patients: a 10-year DR of 10 % was predicted by a ROR score 42 in node-negative patients, whereas it was predicted by a ROR score of 25 in node-positive (N1, 1–3 nodes) patients [63]. Prosigna™ ROR was more accurately prognostic than Oncotype DX® RS with respect to scores and their corresponding 10-year DR rate. The number of patients characterized as low risk was similar between ROR and RS, but ROR categorized more patients as high risk and fewer as intermediate risk [63].

The difference in Prosigna™ and Oncotype DX® test performance characteristics, however, has little impact on clinical decision-making at this time, because of the way scores and categories are used to recommend treatment: without specific

contraindication, all low-risk ER-positive breast cancer patients (Oncotype DX® or Prosigna™), by physician and patient preference, are treated with endocrine therapy alone following surgical resection. Most patients with intermediate-risk cancers and all with high-risk cancers, irrespective of specific score, are offered adjuvant systemic chemotherapy (ASCO treatment guidelines). The ATAC study showed the two tests performed similarly in this important regard [63]. Results from clinical trials to determine the benefit of adjuvant systemic chemotherapy for patients categorized as either intermediate or high risk by Oncotype DX® and/or Prosigna™ are eagerly awaited, since this prognostic/predictive classification has important impact on breast cancer patient management.

A second question is whether response to different types of chemotherapy will align with scores or with intrinsic subtype identified by Prosigna™. A phase III chemotherapy trial comparing response to three different chemotherapy regimens found that higher continuous ROR score was associated with worse outcome [64]. Although intrinsic subtypes did not predict treatment benefit, subgroup analysis suggested that subtype (nonluminal vs luminal) predicted taxane benefit [64]. Other clinical trials examining this question are in progress.

Prosigna™ was validated for analytical precision in a study testing five breast cancer RNA samples across three sites. Reproducibility was measured by testing replicate tissue sections from 43 FFPE tumor blocks across three sites [65]. Hospital laboratories have the option of sending tissue for the Prosigna™ test to a central commercial laboratory (Agendia Inc., USA; Irvine, CA) or purchasing an nCounter Dx Analysis System and performing and interpreting the assay.

Summary and Conclusions

The evolution of breast cancer testing and treatment has become the leading paradigm for personalized cancer treatment. In breast cancer, the first era began with the standardization of adjuvant tamoxifen treatment for ER-expressing breast cancers, which yielded dramatic improvements in survival. The next phase was dominated by the development and standardization of trastuzumab for HER2-overexpressing breast cancers. The third epoch, now 15 years old, began with global genome profiling and statistical algorithms for parsing molecular signatures into biologically distinct groups. Linking molecular profiles of archived FFPE cancers to outcomes from prospective-retrospective clinical trials translated gene profiling into clinically useful prognostic/predictive molecular tests that, combined with standard clinical and pathologic features, can better identify patients with biologically indolent cancer, who will not benefit from cytotoxic chemotherapy, and estimate the probability of chemotherapy response in patients with biologically aggressive cancer.

Molecular testing advances will continue to light the path leading to new and better breast cancer treatments. Research focus is now shifting to next-generation sequencing (NGS) and its ability to identify mutations that may be amenable to targeted treatments effective for similarly mutated non-breast cancer types. Moreover, genomic information derived from NGS also has the potential to drive new drug development and testing in breast cancer [66]. The translational task going forward is formidable because of the extreme genomic diversity of breast cancer and the daunting task of identifying and validating targets, as well as clinical response to treatments [67]. Because improvements in computational science have paralleled remarkable advances in the speed, precision, and affordability of genomic sequencing, many are optimistic that we are on the threshold of yet another new era of personalized breast cancer treatment.

Urothelial Carcinoma

34

Kevin C. Halling

Abstract

Our understanding of urothelial carcinoma (UC) has advanced significantly over the past three decades to provide a better understanding of the molecular basis of these tumors and the different clinical behaviors of low- and high-grade urothelial carcinoma. Fluorescence in situ hybridization is currently used to monitor UC patients for recurrent tumor and to detect new bladder tumors in patients with hematuria. The detection of cells with FGFR3 mutations in urine shows promise as a way to detect low-grade UC. Assessing upper urinary tract UC for defective mismatch repair with microsatellite instability testing or immunostains for MLH1, PMS2, MSH2, and MSH6 helps identify patients that may have Lynch syndrome. While targeted therapies are being investigated for use in advanced bladder cancer, progress has been slow and molecular profiling of urothelial carcinoma for guiding targeted therapy of UC is not currently clinically indicated.

Keywords

Bladder cancer • Urothelial carcinoma • UroVysion • Fluorescence in situ hybridization • FGFR3 • P16 • Microsatellite instability • Lynch syndrome

Introduction

The two main types of urothelial carcinoma (UC) are papillary UC (pTa) and "flat" UC (pTis), also known as carcinoma in situ (CIS). Approximately 80 % of UC are papillary and approximately 20 % are CIS. Most UC arise from the bladder, but UC also originate from the ureters and renal pelvis, and patients sometimes have tumor involving both the lower and upper urinary tract. Papillary tumors tend to recur but not progress to invasive cancer. CIS is aggressive and tends to progress to muscle-invasive cancer. UC tumorigenesis is a multistep process. Papillary UC may arise from areas of urothelial hyperplasia or from urothelial papillomas. Although most papillary tumors are low-grade and have little tendency to progress to invasive tumors, a small proportion are high grade and have significant potential to progress to invasive UC. Most invasive UC arise through the following sequence of events: normal urothelium to dysplasia to CIS to invasive cancer (Fig. 34.1). The schema used for staging UC of the bladder is shown in Table 34.1.

Molecular Basis of Disease

At the chromosomal level, the majority of low-grade papillary tumors are diploid or near-diploid, while the majority of high-grade papillary UC, CIS, and invasive UC (pTa tumors) are aneuploid. Based on array-based comparative genomic hybridization and fluorescence in situ hybridization (FISH) studies, noninvasive, low-grade pTa papillary UC have relatively few chromosomal abnormalities except for loss of all or part of chromosome 9, while CIS, high-grade pTa, and invasive UC (pT1 tumors) have a high number

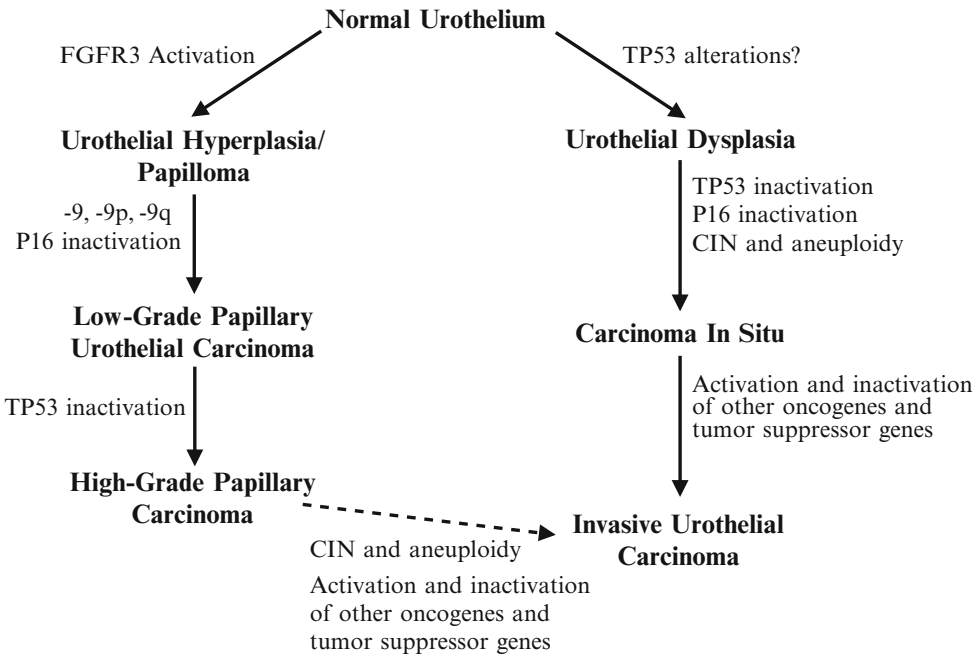

Figure 34.1 Genetic pathways for urothelial carcinoma tumorigenesis. Noninvasive papillary tumors are characterized by early activating mutations of the *FGFR3* gene, inactivating mutations or epigenetic alterations of the *P16* gene, and a diploid or near-diploid DNA content. Carcinoma in situ (CIS) and invasive tumors are characterized by early inactivating mutations within the *TP53* and *P16* genes, chromosomal instability (CIN), and an aneuploid DNA content. A small proportion of papillary tumors may acquire *TP53* alterations or alterations of other unknown genes that cause invasive potential of these tumors

Table 34.1 Pathologic staging of primary bladder urothelial carcinoma

Stage	Description
pTa	Noninvasive papillary
pTis	Carcinoma in situ
pT1	Invasion into lamina propria
pT2	Invasion into muscularis propria
pT3	Invasion through the muscularis propria and into bladder adventitia
pT4	Invasion into surrounding organs (e.g., colon)

of chromosomal gains and losses [1, 2]. The pT1 tumors also have loss of all or part of chromosome 9 but have numerous additional chromosomal abnormalities, which include whole or partial chromosomal losses and gains. Frequent sites of allelic imbalance (AI) in UC include 3p, 4p, 8p, 9p, 9q, 11p, 13q, 17p, and 18q based on microsatellite analysis (MA) [3–5]. Regions with high rates of AI are the sites of known or putative tumor suppressor genes. Many of the regions that show high rates of AI correspond to the areas of chromosomal gains and losses detected by aCGH.

Two important molecular genetic alterations that contribute to UC tumorigenesis are mutational and epigenetic alterations that inactivate the *P16* and *TP53* tumor suppressor genes. *P16* loss is one of the earliest events in the development of both papillary and flat/invasive UC [1, 5–7]. Mutations that inactivate *TP53* are found primarily in CIS and invasive UC and not low-grade papillary tumors and in part may be responsible for the aggressive behavior of these tumors [8, 9]. According to the Catalogue of Somatic Mutations in Cancer (COSMIC) database, other oncogenes and tumor suppressor genes mutated in decreasing order of frequency in UC include *FGFR3*, *PIK3CA*, *CDKN2A*, *HRAS*, *KRAS*, *PTEN*, *AKT1*, *APC*, *CTNB1*, and *NRAS* (http://www.sanger.ac.uk/genetics/CGP/cosmic/).

Defective DNA mismatch repair (MMR) is manifested as MSI at >30 % of microsatellite markers examined and in most cases is associated with a loss of expression of one of the DNA MMR proteins, hMSH2, hMLHl, hMSH6, or hPMS2. MMR is rarely observed in UC of the bladder but is found in approximately 20–30 % of upper urinary tract UC [10, 11]. The finding of defective MMR in an upper tract UC should prompt an investigation into the possibility that the patient may have hereditary nonpolyposis colorectal cancer (HNPCC) and a germline mutation of one of the DNA MMR genes.

Chromosomal instability (CIN) is present in invasive UC and CIS. It is likely that genes that maintain genomic stability are inactivated early during invasive UC tumorigenesis. CIN drives tumorigenesis and tumor progression by accelerating the mutation rate in tumor cells [12]. The genes responsible for CIN in invasive UC are not known, and the role of *TP53* inactivation in CIN has been a matter of debate. pTa tumors show little evidence of CIN but, as noted above, tend to be diploid or near-diploid tumors with relatively few chromosomal alterations. Chromosome 9 and *P16* alterations play a major role in the formation of low-grade pTa tumors.

In addition, most low-grade papillary UC and urothelial papillomas have missense mutations of the fibroblast growth factor 3 (*FGFR3*) gene, while mutations of this gene are less common in invasive UC and CIS [13].

Taken together, two genetic pathways lead to the development of UC [1, 7]. One pathway leads to the formation of noninvasive papillary UC and the other to the development of CIS/invasive UC (Fig. 34.1). The pathway for noninvasive papillary UC is characterized by the presence of *FGFR3* mutations and/or chromosome 9 alterations and *P16* inactivation. The pathway for invasive UC is characterized by early alterations in the *TP53* and *P16* genes, late alterations of other tumor suppressor genes and oncogenes, chromosomal instability, and aneuploidy. The genetic differences between noninvasive papillary and CIS/invasive tumors likely explain the markedly different behavior and prognosis of these tumors [14].

Clinical Utility of Testing

In general, clinical molecular tests for solid tumors can be categorized as being useful for predicting predisposition to developing tumor, aiding in a diagnosis of the tumor type, detecting the presence of tumor, predicting prognosis, or guiding therapy. Examples of assays that are currently being used or investigated for each of these indications for UC are presented below.

Available Assays

The most clinically useful clinical molecular tests, as described below, are the following:

- MSI analysis and DNA MMR protein immunohistochemistry (IHC) of upper urinary tract UC to assess for Lynch syndrome (LS)
- FISH for UC detection
- *FGFR3* mutation analysis for UC detection

Numerous assays with a variety of clinical purposes for UC have been investigated but have not yet transitioned into the clinical use. *TP53* mutations are common in UC, especially in high-grade UC [15]. Assays that assess for *TP53* status could potentially be used to assess prognosis and detect tumor recurrence. Some studies have shown that TP53 overexpression detected by IHC analysis of formalin-fixed, paraffin-embedded tumors is associated with worse prognosis and higher risk of muscle invasion [8, 16], while others have not [17]. IHC analysis of bladder tumors for TP53 expression has not been widely utilized by urologists or pathologists. A few studies have shown that the antiapoptotic protein survivin may be a sensitive and specific marker for the detection of recurrent UC [18], but blinded prospective studies are needed to further evaluate the clinical utility of this assay. Alterations in certain genes, such as glutathione S-transferase M1 and N-acetyltransferase that encode proteins that metabolize carcinogens, may increase an individual's risk of developing bladder cancer, especially among smokers, but assays for these alterations also have not been used clinically.

Interpretation of Results

MSI Analysis and DNA MMR Protein IHC of Upper Tract UC to Assess for LS

Defective DNA MMR is rarely observed in UC of the bladder but is found in approximately 20–30 % of upper tract UC [10, 11]. Patients with early onset upper tract UC or an upper tract UC and a family history of LS-related tumors should be evaluated for LS. This evaluation can consist of assessing the tumor for defective DNA MMR with MSI testing and/or DNA MMR IHC. Patients whose tumors exhibit high-level MSI (MSI-H phenotype) have defective DNA MMR and almost always show loss of expression of one or more of the DNA MMR proteins by IHC. Most histopathology laboratories perform immunostains for four DNA MMR proteins: MLH1, PMS2, MSH2, and MSH6. The most common pattern of protein expression loss in tumors that exhibit defective DNA MMR is loss of MLH1 and PMS2 with retention of staining for MSH2 and MSH6. This pattern of expression is most often due to epigenetic silencing of the *MLH1* gene through promoter hypermethylation. However, some patients with MLH1 and PMS2 loss have a germline mutation in the *MLH1* gene and consequently have HNPCC. Less common IHC staining patterns are loss of MSH2 and MSH6 with retention of MLH1 and PMS2, loss of MSH6 alone, or loss of PMS2 alone. These three patterns are strongly associated with the presence of a germline mutation in the *MSH2*, *MSH6*, and *PMS2* genes, respectively. Patients with genetically proven LS are at risk of developing various tumors such as colorectal cancer, endometrial cancer, upper tract UC, gastric cancer, and sebaceous skin tumors and should undergo regular surveillance for these tumors.

Fluorescence In Situ Hybridization for UC Detection

Urine cytology has been the primary laboratory method for diagnosing and monitoring UC for the past 50 years. Urine cytology has excellent specificity but poor sensitivity for the

detection of UC [19]. The problem with false-negative urine cytology test results, if combined with a negative cystoscopy, is that clinical surveillance regimens recommend rescreening in 3 months, allowing an undetected tumor to progress to a higher, potentially incurable state before it is detected. This is of particular concern for grade 3 UC, which routinely progress if not removed or treated. The suboptimal sensitivity of urine cytology has prompted the development of new tests with improved sensitivity for UC detection.

Most UC are characterized by numerical and structural chromosomal abnormalities and a marked degree of CIN with variation in the chromosomal abnormalities found from cell to cell. The finding of aneusomy (i.e., abnormal chromosome copy number) and CIN in a population of cells by FISH is strongly correlated with the presence of malignancy. UroVysion (Abbott Molecular, Des Plaines, IL) is a FISH assay that has been developed for the detection of UC in urine. This assay utilizes four FISH probes, CEP3, CEP7, CEP17, and LSI 9p21, that are labeled with red, green, aqua, and yellow fluorophores, respectively [2, 19]. UroVysion received FDA approval in 2001 for monitoring UC patients for tumor recurrence and FDA approval in 2005 for assessing patients with hematuria (gross or microscopic) for bladder cancer. Representative examples of patients with FISH-positive and FISH-negative findings are shown in Fig. 34.2.

Meta-analysis of the sensitivity and specificity of UroVysion was 72 % (69–75 %) and 83 % (82–85 %), respectively [20]. The sensitivity of UroVysion for the detection of CIS, invasive UC, and high-grade papillary tumors is > 95 % [21]. The sensitivity of UroVysion is lower for low-grade papillary tumors than other UC, but is still significantly better than cytology for low-grade tumors. Though further studies are needed, it is possible that the low-grade tumors not detected by FISH have lower invasive potential and the intervals between cystoscopy could be extended. Studies suggest that UroVysion can detect recurrent UC before it is clinically evident by cystoscopy [21–24]. In the trial that led to FDA approval [23], Sarosdy et al. reported that 36 patients had a negative cystoscopic examination but a positive FISH result. With continued follow-up, 15 (41.7 %) of these cases were found to have biopsy-proven tumor recurrence with time-to-tumor diagnosis of 3–16 months (mean 6.0 months). Conversely, among 68 patients who had a negative cystoscopy and a negative FISH result, only 13 (19.1 %) had a biopsy-proven recurrence at 3–19 months (mean 11.2 months). The time to recurrence was significantly less ($p = 0.014$) for the patients with a positive FISH result but a negative cystoscopy than for patients with a negative FISH result and a negative cystoscopy [23].

UroVysion FISH testing has several other clinical uses. The clinical management of patients with equivocal cytology results is challenging because fewer than half of these patients will have bladder cancer on clinical follow-up. Equivocal cytology results can lead to unnecessary and expensive clinical investigations. Patients with an equivocal cytology and positive FISH result are at higher risk for having bladder cancer and should be followed more aggressively [25, 26]. FISH is also useful for assessing noninvasive bladder cancer patients undergoing bacillus Calmette-Guerin (BCG) treatment for reduction of recurrence risk following therapy. A 2005 study by Kipp et al. found that patients with a positive FISH result following intravesical therapy were 4.6 times more likely to have recurrent bladder cancer and 9.4 times more likely to have follow-up muscle-invasive

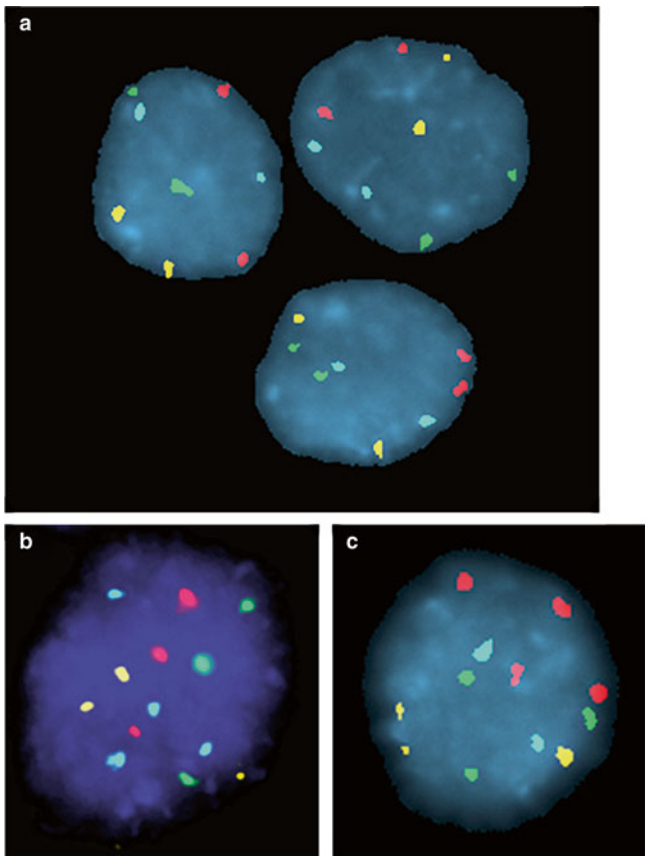

Figure 34.2 Representative examples of FISH results for nonneoplastic urothelial cells (*panel* **a**) and UC cells (*panels* **b** and **c**) using the UroVysion FISH assay (Abbott Molecular, Des Plaines, IL). Nonneoplastic cells generally have two signals for each of the four probes, though occasional nonneoplastic cells show only one signal for one or more of the probes due to random overlap of signals or imperfect hybridization efficiency. UC cells generally have gains for two or more of the probes (i.e., polysomy) of the UroVysion probe set. The finding of just a few cells with polysomy has high specificity for the presence of malignancy. *Panel* **b** shows UC cells with a gains of all four probe signals, CEP3(*red*), CEP7(*green*), CEP17 (*aqua*) and LSI 9p21 (*yellow*). *Panel* **c** shows UC cells with gain of CEP3 (*red*) and CEP7 (*green*) probe signals.

bladder cancer than patients with a negative FISH result [27]. Similar results were obtained by Mengual et al. [28] and Savic et al. [29], who found that patients with a positive post-BCG FISH result had 3.0 and 3.8 times higher risk of tumor recurrence, respectively.

Although other tumor markers are currently available for diagnosing bladder cancer (e.g. BTA stat [Polymedco, Inc., Cortlandt Manor, NY]; NMP22 [Alere, Orlando, FL]), the high sensitivity and specificity of the UroVysion FISH probe set makes this test one of the most commonly used molecular markers for detecting UC in urine cytology specimens. The primary disadvantage of the FISH assay is that it requires more effort than conventional cytology or point-of-care assays such as the BTA stat test. Typical turnaround time for the FISH assay is 1–2 days, though the test can be performed in a single day. Automated FISH enumeration instruments such as the Metasystems (Newton, MA), BioView (Billerica, MA), and Ikonisys (New Haven, CT) systems are used by some clinical laboratories. These systems may increase the ease of FISH test performance, reduce the cost of testing, and increase the throughput and sophistication of the data that can be obtained. Another shortcoming of the FISH test is its inability to detect some low-grade papillary tumors. An assay for UC cells that harbor *FGFR3* mutations (see *FGFR3* Mutation Analysis for UC Detection section below) may complement FISH and allow for the detection of virtually all UC.

FGFR3 Mutation Analysis for UC Detection

The detection of cells with *FGFR3* mutations in the urine is a promising way to detect the low-grade papillary tumors that are not detected by cystoscopy, cytology, or assays such as FISH [13, 30, 31]. FGFR3 is a tyrosine kinase receptor. Germline point mutations in various domains of *FGFR3* are associated with human skeletal disorders such as hypochondroplasia and achondroplasia, and somatic mutations of *FGFR3* have been identified in bladder cancer and myeloma. Interestingly, two groups have demonstrated a high frequency of somatic *FGFR3* point mutations in low-grade papillary UC and urothelial papilloma but not in high-grade papillary UC, CIS, or invasive UC [13, 30]. Billerey et al. found that the frequency of *FGFR3* mutations by stage was pTa 74 %, pTis 0 %, pT1 21 %, and pT2 to pT4 16 % [13]. UC of grade 1 showed 84 %, grade 2 showed 55 %, and grade 3 showed 7 %. The most common *FGFR3* mutation was an S249C mutation (33 of 48 tumors; 69 %), but R248C, G372C, Y375C, and K652E mutations also were identified. The difference in the frequency of *FGFR3* mutations between low-grade and high-grade tumors was highly significant ($p < 0.0001$) and is consistent with the current model of bladder tumor progression in which the most common precursor of invasive UC is CIS (Fig. 34.1). A commercial test kit for *FGFR3* mutation analysis is not available currently.

Laboratory Issues

Laboratory tests can be broadly divided into FDA-cleared/approved tests and laboratory-developed tests (LDT). Laboratories should verify that they can reproduce the performance characteristics that are published in the package inserts of FDA-approved tests. Laboratories that develop LDTs are responsible for establishing the performance characteristics of the LDT. Analytical validation of an LDT should include determining the accuracy, precision (reproducibility), reportable range, reference range, analytical sensitivity, and analytical specificity of the assay. In addition, the laboratory should conduct or be able to cite studies that demonstrate the clinical validity and utility of the LDT, including the positive and negative predictive values of the test. For a diagnostic assay, clinical validation would address the clinical sensitivity and specificity of the assay. For a prognostic assay, evidence of clinical validity would come from studies with Kaplan-Meier analyses and likelihood or hazard ratios.

As with all clinical tests, appropriate controls should be included with each run. For PCR-based tests, this would include positive, negative, and "no DNA" controls and analytical sensitivity and precision controls when a quantitative result is produced. Positive and negative controls for the UroVysion FISH test can be obtained from Abbott Molecular, Inc. These controls are non-hybridized slides prepared from cultured normal male lymphoblast cells and cultured bladder cancer cell lines. Each control slide consists of two separate target areas in which each of the different cell types has been applied. Clinical laboratories must enroll in proficiency testing when available and if not available establish internal methods to assess proficiency. Proficiency testing is available for UroVysion testing through the College of American Pathologists (CAP) Cytogenetics resource committee and for microsatellite instability (MSI) testing through the CAP Molecular Oncology resource committee.

Conclusions and Future Directions

Relatively few clinical molecular tests are used for the diagnosis and management of patients with UC. The main tests that are currently being used or developed are intended for bladder cancer detection in urine specimens. Messenger RNA expression profiling assays (e.g., Oncotype DX [Genomic Health, Redwood City, CA] and MammaPrint [Agendia, Inc., Irvine, CA]) have been used for prognosis and to guide therapy for patients for some tumor types such as breast cancer. Similar assays are not available for UC patients yet but could have clinical utility. Currently, no therapies are directed to specific molecular targets in UC. Therapies that target the FGFR3 tyrosine kinase receptor are being developed, and it is possible that the mutation status of the *FGFR3* gene may identify patients who are

most likely to respond to these therapies [32]. In the near future it is likely that next-generation sequencing of UC will guide targeted therapy.

Conflict of Interest Dr. Halling receives industry funding from Abbott Laboratories and royalties from the sale of the UroVysion probe set.

Prostate Cancer

35

Priti Lal

Abstract

The diagnosis and management of prostate cancer (PCa) was revolutionized by monitoring of prostate specific antigen (PSA), with a reduction in the mortality rate for men between the ages of 60 and 79 years, which correlates with a decrease in the incidence of metastatic disease. The monitoring of PSA levels also has led to overdiagnosis of clinically insignificant PCa, while highly aggressive PCa continues to be underrecognized. Over the last decade, advances in gene expression techniques and the introduction of sophisticated bioinformatics tools, have increased the momentum for discovery of more accurate clinicopathologic testing algorithms. Many potentially useful molecular biomarkers are using diverse specimen types, such as blood, urine, and tissue. This chapter describes the biomarkers used for diagnosis and prognosis for PCa.

Introduction

Prostate specific antigen (PSA), first isolated from prostatic tissue in 1970 [1], rapidly revolutionized the diagnosis and management of prostate cancer (PCa). According to the Surveillance, Epidemiology, and End Results Program of the National Institutes of Health, the mortality rate from PCa for men between 60–79 years of age has decreased to below that found before the introduction of serum PSA level testing. This decrease in mortality has been accompanied by a decrease in the incidence of metastatic disease [1, 2]. Multicenter trials have shown that patients with PSA values 3–10 ng/ml may have localized disease and may benefit from curative treatment [3]. However because of the low sensitivity of the PSA test, a negative biopsy rate of 70–80 % is noted in patients with PSA in the 3–10 ng/ml range. Several parameters, including prostate size, PSA density, PSA velocity, age-adjusted cutoff for PSA values, and free PSA have been added to improve the specificity of PSA. Despite these efforts, overdiagnosis of clinically insignificant PCa and underrecognition of a small proportion of highly aggressive PCa continue to be problems.

Despite its initial success as a screening tool, serum PSA is neither cancer-specific nor predictive of biological behavior. More specific tests that can enhance our ability to accurately predict disease progression, response to therapy, and survival are needed. Over the last decade, advances in gene expression techniques and the introduction of sophisticated bioinformatics tools have increased the momentum for discovery of more accurate clinicopathologic testing algorithms [2]. Many potentially useful molecular biomarkers using diverse specimen types, such as blood, urine, and tissue, are being evaluated.

Cancer biomarkers are either produced by the tumor or by the body in response to the tumor. Depending on their individual characteristics, biomarkers may be used as tools for early detection, specific diagnosis in difficult cases, prognosis, prediction of therapeutic response, and therapeutic targets, or as markers of surrogate end-points [3]. Biomarkers with proven clinical usefulness are designated by the College of American Pathologists (CAP) as Category I factors. In current clinical practice, PSA, TNM stage, Gleason grade, and surgical margins are defined as Category I factors. CAP Category II factors are those that have been studied extensively but await statistically robust trials and include tumor volume, histologic type, and DNA ploidy analysis. CAP Category III markers are those that need additional studies to ensure their clinical utility before undergoing further clinical trials. The majority of the currently emerging molecular markers fall into CAP Category III.

The advent of technologies such as next-generation sequencing [4–8] and proteomic platforms, together with advancements in computational and statistical tools, has led to an accelerated growth in our knowledge of the molecular changes in PCa. Significant progress made during the past few years has elucidated that the clinically heterogeneous entity of PCa is in fact a collection of homogeneous molecular subtypes. The ability to sequence many or all genes simultaneously has made comprehensive genomic classification of PCa possible. The completion of an accurate molecular classification is the first step towards development of biomarkers to distinguish aggressive from indolent disease and of targeted therapies. As high throughput technology has become more cost effective, gene panels for specific diagnoses, targeted treatment, and accurate prediction of prognosis are rapidly becoming mainstream, finally bringing the paradigm of comprehensive genomic medicine closer to routine practice of PCa management.

Multiple commercial molecular test kits are now available for PCa. Prostate cancer antigen 3 (PCA3) test (Progensa, Gen-Probe, San Diego, CA) and ConfirMDx (MDx Health, Irvine, CA) improve diagnostic specificity. Once PCa is detected, discrimination between clinically indolent and clinically significant disease is of paramount importance. Two multi-gene signature tests are used to stratify patients for definitive treatment and active surveillance: the cell cycle progression (CCP) score marketed as the Prolaris test (Myriad Genetics, Salt Lake City, UT), and the 17-gene RT-PCR panel algorithmically combined to calculate the Genomic Prostate Score (GPS) by Oncotype DX (Genomic Health, Redwood City, CA). Other tests differentiate patients who would benefit most from adjuvant treatment following prostatectomy. Decipher genomic classifier (Genome Dx Biosciences Vancouver, British Columbia, Canada) is designed to predict early metastasis and disease-specific mortality after radical prostatectomy using a 22-gene expression signature. The CCP (Prolaris) and GPS (Oncotype DX) scores show an association with adverse outcome following prostatectomy. In addition to RNA tests, a DNA test that uses copy number alterations (Genomic Evaluators of Metastatic Prostate Cancer) at 36 loci has been validated to predict biochemical failure in men at high risk of recurrence and is found to be better than clinical risk-stratification alone. This is the only test to be validated in a cohort of African-American patients with PCa treated by prostatectomy. This test was not commercially available at the time of writing this chapter.

Immense progress has been made in developing new prognostic and diagnostic tests for PCa. These tests need to be validated on a larger scale to truly empower patients and treating physicians to make well informed and scientifically sound decisions. Currently available models of risk-stratification at all stages of PCa management are limited in their ability to predict true aggressiveness. Ongoing evaluation of these tests and integration of genomic profiling into risk-assessment models will be critical to realizing the potential benefits for patients.

Molecular Basis of Prostatic Adenocarcinoma

PCa is driven by multiple genetic alterations. The majority of PCa harbor recurrent *ETS* gene fusions [2, 9–12]. Genomic and transcriptomic analyses of PCa have defined new PCa classifications based on gene-expression and somatic copy number aberration signatures [13–17]. Cardinal genetic alterations that activate oncogenes and inactivate tumor suppressor genes are now recognized as drivers of PCa (Table 35.1). Deletion of *NKX3.1* and the phosphatase and tensin homologue tumor suppressor gene (*PTEN*), and amplifications of the androgen receptor (*AR*) and *MYC* genes are some of the most common structural genomic alterations. Protein-altering mutations are rare in PCa. Genes with point mutations most commonly include *AR*, *PTEN,* and *AKT1* [18, 19], but mutations are rare and seen in approximately 1 % of primary PCa [14].

A significant percentage of PCa harbor gene-fusions involving androgen-regulated 5′ gene partners (*TMPRSS2*, *SLC45A3*, and *NDRG1*) and ETS transcription factors (e.g., *ETV1* and *ERG*) [5, 12].

While the implications of the ETS transcription factors as partners in gene fusion events in PCa are not currently understood, the fact that these gene partners are androgen-responsive may play a role in PCa development and progression. Numerous other genetic alterations, somatic mutations, and epigenetic changes occur during carcinogenesis and progression of PCa (see Table 35.1).

Table 35.1 Common genetic and epigenetic changes in prostate cancer

Change	Gene	Encodes	Location	Function
Tumor Suppressor Genes	*NKX3.1*	Prostate restricted homeobox protein	8p21.2	Suppresses cell proliferation
	PTEN	Phosphatase and tensin homolog	10q23.31	Suppresses cell proliferation and increases apoptosis
	CDKN1B	Cyclin-dependent kinase inhibitor p27	12p13.1-p12	Cell cycle inhibitor
	TP53	TP53	17p13.1	Many tumor suppressor functions:
				• Cell cycle arrest in response to DNA damage
				• Senescence in response to telomere dysfunction
				• Induction of apoptosis
Oncogenes	*MYC*	Transcription factor	8p24	Regulates cell proliferation, senescence, apoptosis and cell metabolism
	ERG	Proposed new oncogene in prostate cancer	21q22.3	Fusion transcript with androgen-regulated *TMPRSS* gene found in all stages of prostate cancer
	ETV1-ETV4	Proposed new oncogenes in prostate cancer	7p21.3; 19q13.12; 1q21-q23; 17q21.31	Fusion transcripts with androgen-regulated *TMPRSS* gene found in all stages of prostate cancer
	AR	Androgen receptor	Xq11-12	Protein over expressed in most prostate cancers
Other Changes	*GSTP1*	Glutathione S-transferase pi 1	11q13	Detoxifies carcinogens; inactivated in 90 % of cancers by hypermethylation
	Activation of telomerase			Activated via MYC leading to telomere shortening
	Telomere dysfunction			Shortening of telomere and chromosomal instability
	Multiple genes with hypermethylation of CpG islands			

Blood-Based Molecular Tests

Total PSA and PSA Isoforms

Total PSA

While Total PSA (t-PSA) has been used as a marker for PCa, the expression levels of t-PSA are highly variable across individuals and also in the same individual at different times. A single t-PSA result therefore has little clinical value [20]. Multiple factors account for the variations in t-PSA, including preanalytical specimen handling, different detection methods, biologic variations such as prostate size, and nonneoplastic processes such as hypertrophy and inflammation. In addition, no single t-PSA cutoff separates men at high risk for PCa from men at low risk.

The Prostate Cancer Prevention Trial demonstrated that as many as 15 % of men with a normal digital rectal examination (DRE) and a serum t-PSA of less than 4.0 ng/ml have PCa [21], and of these men, as many as 15 % may harbor a high Gleason grade disease. However, lowering the t-PSA threshold below 4 ng/ml did not improve early detection and long-term survival. Studies suggest that a rise in t-PSA level begins years or even decades before the diagnosis of PCa. Slowly rising t-PSA levels may reflect the long duration of PCa carcinogenesis.

Many efforts have focused on improving the performance of the t-PSA test over the years, including normalizing PSA to the size of the prostate gland, monitoring change in velocity (tPSAV) and PSA doubling time (tPSADT), and measurement of PSA isoforms (Pro-PSA) and alternate PSA forms. Given the limitations of t-PSA, targeting of the various molecular forms of PSA is being used to improve the predictive value of PSA testing and are discussed below.

Complex PSA vs Free PSA

Serum PSA exists in two forms, the bound form also known as complex PSA (c-PSA) and the unbound, enzymatically inactive form called free PSA (f-PSA). Serum c-PSA concentration correlates with the presence of PCa. Serum f-PSA levels are elevated in patients with benign prostatic hyperplasia (BPH) [22–25].

Large prospective studies have demonstrated that use of the percentage of f-PSA (%f-PSA) of total PSA improves the specificity of PSA screening for PCa in men with a normal DRE with serum PSA concentration in the "grey zone" of PSA (between 4 and 10 ng/ml) [26]. Based on these findings, the US Food and Drug Administration (FDA) approved the use of %f-PSA for PCa screening. In a recent meta-analysis of 66 studies, %f-PSA outperformed t-PSA and c-PSA as a predictor of biopsy outcomes [27]. This was more true in older men (≥50 years of age) than in younger men (44–50 years of age). Vickers et al. [28] found that the combined performance of %f-PSA, hK2 (human kallikrein-2), and t-PSA improved predictive ability when t-PSA was in the range of 1.2–2.0 ng/ml.

Subsequent studies noted a decrease in performance of %f-PSA. Explanation for these inconsistencies may lie in the limited stability of f-PSA in blood, particularly in stored sera [29, 30]. In addition performance of %f-PSA decreases with increased prostate size. In men with large prostates, %f-PSA increases even in the presence of cancer, thereby lowering the sensitivity of the test for PCa detection [31].

ProPSA and Prostate Health Index

ProPSA is a precursor form of PSA that contains a seven amino acid pro leader peptide that is cleaved by hk2 and trypsin to form active PSA. ProPSA is a component of free PSA (fPSA) and levels of proPSA are more closely associated with PCa. Truncated forms of proPSA in serum contain five, four, or two amino acids more than the total number of amino acids in PSA; the form with two additional amino acids is noted as proPSA (-2), [-2]proPSA, or p2PSA. FDA approved the Prostate Health Index (phi) developed by Beckman Coulter (Indianapolis, IN) in partnership with the NCI's Early Detection Research Network in 2012. Phi, a mathematical formula using three biomarkers ($[p2PSA/f\text{-}PSA] \times \sqrt{PSA}$), has been found to be useful in distinguishing men with PCa from those with benign prostatic conditions, when tPSA is in the grey zone (between 4 and 10 ng/ml) and the DRE is negative. Additionally, p2PSA levels and phi improve the detection of PCa with a Gleason score of 7 or higher; and in men with family history of PCa, phi score significantly outperforms tPSA and %fPSA for detection of aggressive PCa [32].

C-PSA remains to be evaluated as an alternative test. Currently the only c-PSA assay approved by the FDA is based on antibody-mediated elimination of all f-PSA followed by measurement of the remaining PSA (Bayer Immuno1 c-PSA Assay, Bayer Diagnostics, Tarrytown, NY).

Human Kallikrein-2

The human tissue kallikrein family of serine proteases consists of 15 members, known as kallikrein-related peptidases 1–15 (KLK 1–15) located together in a gene cluster at chromosomal region 19q13.3-13.4 [33–40]. The first identified kallikreins, the so-called classical kallikreins (KLK1, hK2, and PSA), contain a unique 11-amino acid-long kallikrein loop. Human Kallikrein-2 (hK2) shares 78 % homology with the amino acid sequence of PSA and has overlapping biological functions. Similar to PSA, hK2 occurs in two forms; one complexes with various plasma protease inhibitors, and the other occurs free in circulation. Unlike PSA, the majority of hK2 in serum is found in the free, unbound form. Total hK2 mRNA amounts to 10–50 % of t-PSA mRNA in the prostate tissue but in serum and seminal plasma, hK2 concentration is only 1–3 % of t-PSA. The highest concentrations of hK2 and PSA are found in seminal and prostatic fluid, but they are also present at lower concentrations in breast milk, breast cyst fluid, saliva, urine, and plasma [41–43]. Within the prostate, the expression of hK2 and PSA is regulated by androgens through the andro-

gen receptor (AR) [44, 45]. Androgen response elements are located in the PSA promoter region [46–48].

Serum levels of hK2 and its ratio to f-PSA and %f-PSA have been reported to outperform t-PSA for PCa detection [49, 50] and could improve the discrimination of men with PCa from men without PCa [49, 51]. Two large studies tested the ability of serum hK2 to improve PCa screening in men with PSA levels below 10 ng/ml [52, 53]. Although the ratio of hK2 to f-PSA did not outperform %f-PSA, these studies showed that the hK2: f-PSA ratio is an independent predictive factor compared to %f-PSA.

Additionally, preoperative serum levels of hK2 appear to better predict biochemical failure (BCF), which is defined as post-treatment elevation of PSA level predictive of PCa recurrence. The predictive value of preoperative serum hK2 in patients undergoing prostatectomy for clinically localized disease was estimated at 0.721 (concordance index) vs 0.691 for tPSA. This difference in predictive accuracy was more pronounced in men with a tPSA <10 ng/ml (0.739 for hK2 vs 0.599 for tPSA, $p < 0.0005$), a category of men where a more accurate predictor is clinically useful.

Histological studies suggest that unlike t-PSA, hK2 expression increases with higher-stage and-grade tumors. It has also been suggested that hK2 could predict poor differentiation, extra-prostatic extension (EPE), and biochemical recurrence (BCR) in patients treated with radical prostatectomy [51, 54]. While intriguing, these findings need further validation [55].

In the grey zone of t-PSA levels, hK2 may add statistically and clinically important information for PCa detection and more importantly for prognostication. This is especially true in the USA where, due to aggressive PSA screening, most men diagnosed with PCa have a t-PSA less than 10 ng/ml, at which level the risk stratification using only t-PSA is not accurate.

Because of the extensive overlap in their amino acid sequence, clinical assays specific for hK2 without cross reactivity to PSA, yet sensitive enough to detect picogram/ml concentrations of hK2, have been difficult to develop. Currently these assays are only available in research laboratories.

A panel of four kallikreins, total PSA, f-PSA, intact PSA, and hK2, were combined to generate the 4K score [26, 28, 56, 57]. Studies suggest that the 4K score could be used to distinguish between pathologically insignificant and aggressive disease and reduce unnecessary biopsies [26]. The 4K score test is anticipated to be available through OURLab Urologic Reference Laboratory (OPKO Health, Inc., Miami, FL) in the future.

Other Blood-Based Molecular Markers

Between 15–40 % of patients treated for localized PCa will experience BCR as evidenced by rising PSA levels [58]. Androgen deprivation therapy is an accepted standard of care for patients who develop metastasis after definitive treatment [59, 60]. Despite adjuvant therapy, the mortality rate in these patients is high (also known as castrate resistant prostate cancer). Currently available tools for predicting disease-free survival are statistical models such as the Kattan nomogram that use PSA, Gleason Score, Clinical and Pathologic stage, and other clinical parameters to predict the probability of BCR-free survival at 5 years after radical prostatectomy [61]. Integration of blood-based predictive biomarkers to the currently available nomograms will increase their predictive power.

The uroKinase plasminagen activator (uPA) pathway or axis includes potential markers for PCa by being involved in various phases of tumor development and progression through degradation of extracellular matrix. Elevated levels of circulating uPA [62] and its receptor (uPAR) are linked to PCa stage and bone metastasis. Large multi-institutional studies are ongoing to further validate these findings [63–65].

TGF-β1 is a growth factor which regulates several cellular mechanisms such as proliferation, immune response, differentiation, and angiogenesis [66]. Increased levels of TGF-beta1 have been associated with cancer progression, occult and documented metastasis, and BCR [67–69]. Serum levels of IL6, a cytokine, and its receptor (IL6R) are elevated in patients with metastatic and treatment refractory disease. Elevated levels of IL6 may thus predict progression PCa [70, 71].

Endoglin is a transmembrane glycoprotein that is associated with angiogenesis. Elevation of preoperative plasma Endoglin may be associated with metastasis to regional lymph nodes [72]. Taking these into account, preoperative plasma levels of a combination of TGF-beta1, soluble IL6R, IL6, Endoglin, vascular endothelial growth factor, and vascular cell adhesion molecule were found to improve the predictive accuracy of the Kattan preoperative nomogram [73] by approximately 15 % (71.6–86.6 %) [2, 74, 75]. Additionally the inclusion of preoperative serum levels of these biomarkers to the traditional base model (tPSA, surgical margin status, extracapsular extension, seminal vesicles invasion, lymph node involvement, and pathologic Gleason sum) statistically significantly improved prediction of BCR.

Urine-Based Molecular Markers

PCA3/*DD3*: A Cancer-Specific Marker

PCA3, also known as *DD3*, is a noncoding RNA that was initially identified by Bussemakers et al. [76], and is currently the most specific clinically available marker for PCa. *PCA3* RNA is highly overexpressed in PCa compared to normal or benign prostate tissue. Hessels et al. [77] reported a median of 66-fold upregulation of *PCA3* in PCa tissue compared with normal prostate tissue. No other normal tissue or cancer expresses *PCA3*. In addition, *PCA3* is upregulated in prostate

tissues with a low volume cancer load (less than 10 % PCa cells). Since PCa cells are shed into the urine, *PCA3* RNA can be measured not only in prostate tissue specimens but also in urine and in urine sediments after DRE. Given the specificity for PCa and the ease of analysis in urine sediments, *PCA3* is currently the most specific PCa marker. Several versions of *PCA3* urine tests are available [78].

In phase two of biomarker development for *PCA3*, a second generation reverse transcription-polymerase chain reaction (RT-PCR) assay was developed to detect *PCA3* transcripts in urinary sediments obtained after DRE from a cohort of men who were recommended for prostate needle biopsy based on a total serum PSA value above 3 ng/ml [77]. This study, and three subsequent independent studies [78–82], showed that *PCA3* had a high sensitivity and specificity using prostatic biopsies as the gold standard for the presence of a tumor (Table 35.2). DiagnoCure (Quebec, Canada) developed the first generation version of the *PCA3* RT-PCR test. Gen-Probe (San Diego, CA) acquired the exclusive worldwide diagnostic rights for the PCA3 test from DiagnoCure and developed a *PCA3* test using their APTIMA platform Progensa™ PCA3 test (Hologic, Inc., San Diego, CA).

Progensa™ PCA3 test (Hologic, Inc.) measures the concentration of *PCA3* RNA and *PSA* RNA molecules in serum and calculates the ratio of the two. The Progensa™ test was FDA-approved for use in men who have a suspicion of PCa based on elevated PSA level and/or an abnormal DRE and/or one or more negative biopsy results in the context of a clinical suspicion of PCa. A Progensa™ PCA3 score below 25 is interpreted as negative and is associated with a low likelihood of PCa [83–85]. Based on 11 clinical studies (including 6 multicenter studies and 5 from individual centers) that encompassed a total of 2,737 men, the Progensa™ PCA3 score had an area under the curve (AUC) ranging from 0.66 to 0.75. The average sensitivity and specificity for the Progensa™ PCA3 score quoted by various studies are 66 % and 76 %, respectively, compared to the sensitivity of 47 % for serum PSA alone [84, 86].

To increase the predictive accuracy of biopsy outcome and identify men at risk for PCa, novel biopsy nomograms that include *PCA3* levels have been created. Incorporation of *PCA3* test results improved the diagnostic accuracy of the Prostate Cancer Prevention Trial Risk Calculator [87, 88]. It is expected that inclusion of *PCA3* test results in future nomograms will be clinically useful for deciding whether to biopsy the prostate. Multiple studies [85, 89, 90] have suggested that PCA3 scores fulfill the criterion of being a valuable predictor of low-volume, insignificant cancer and could be of great help in selecting patients with PCa who are candidates for active surveillance.

PCA3 score predicts PCa risk independent from prostate volume, age, and the principal known non-neoplastic causes of increase in PSA, such as BPH and prostatitis. More than 90 % of high-grade prostate intraepithelial neoplasia (PIN) tissues express *PCA3* [91]. The PCA3 test score may therefore help monitor patients with high-grade PIN (HGPIN), such that increasing PCA3 scores may trigger a decision to biopsy the prostate.

TMPRSS-ERG Translocation: A Cancer-Specific Translocation

The combined use of a DNA microarray expression data and a novel bioinformatics algorithm called Cancer Outlier Profile Analysis (COPA) identified gene over-expression of two ETS family transcription factors, ERG and ETV1 in PCa [14, 15]. Further characterization of cases with ERG or ETV1 outlier expression subsequently lead to the identification of fusion of the 5′ untranslated region of the prostate specific androgen-induced trans-membrane protease serine 2 gene (*TMPRSS2*), to the 3′ end of an *ETS* family transcription factor gene [16]. *TMPRSS2* fusion with the *ETS* family member *ERG* is the predominant variant and is seen in 40–70 % (average 50 %) of patients with PCa, making the *TMPRSS2-ERG* gene fusion the most common genetic aberration described to date in human solid tumors [2]. *ERG* is regarded as a key PCa oncogene. Numerous other *ETS* member genes also can fuse to *TMPRSS2*, but are found at a much lower frequency in PCa. Similarly, variability in the 5′ gene fusion partner has been identified. Five major partners are known, and divided into classes based on their tissue-specificity and the sensitivity to androgens (Table 35.3) [9–12, 92, 93]. Class I is reserved for *TMPRSS2*; Class II includes other genes with prostate-specific, androgen-inducible 5′ UTR elements or endogenous retroviral elements; Class III includes the prostate-specific but androgen-repressed gene partners; Class IV includes the non-tissue-specific promoters that are ubiquitously expressed (housekeeping genes); and Class V consists of *ETV1*-specific rearrangements, including the localization of the entire *ETV1* locus to the prostate specific locus, 14q13.2-14q21.1. ETS fusion seems to be an early event in the development of PCa [4, 17]. To date none of the published literature has found this translocation to be present in benign prostate tissue, making it specific for PCa.

Use of ETS Fusion in the Diagnosis and Treatment of Prostate Cancer

The presence of the *TMPRSS2–ERG* translocation can be assessed by immunohistochemistry (IHC) and fluorescent in-situ hybridization (FISH). Mosquera et al. [94], using a

Table 35.3 Classification of 5′ partner of *ETV* associated translocations

[a]3′ partners that are not members of the *ETS* family
Numerous alternative *ETS* members can fuse to *TMPRSS2*, but at a much lower frequency. Variability in 5′ partners are divided into five classes: Class I, Reserved for *TMPRSS2*; Class II, Prostate specific androgen inducible 5′ UTR or endogenous retroviral elements; Class III, Associated with prostate specific but androgen repressed partners; Class IV, Non-tissue-specific promoters that are ubiquitously expressed; Class V, *ETV1*-specific rearrangements, including the localization of the entire *ETV1* locus to prostate specific locus 14q13.2-14q21.1

FISH assay for *ERG* gene rearrangements in PIN, found a strong correlation with the presence of cancer. Based on these findings *TMPRSS2–ERG* FISH study on isolated PIN may identify men with a high likelihood of having unsampled PCa. In addition, *TMPRSS2–ERG* FISH may help identify patients undergoing transition to invasive carcinoma and for the work-up of atypical small acinar proliferations which are suspicious for, but quantitatively insufficient for, a definitive diagnosis of PCa on needle biopsy. Assessment for the presence of the *TMPRSS2-ERG* gene fusion therefore may not only be useful for early diagnosis [17, 18] but also may help stratify diagnostically difficult cases.

Knockdown of *TMPRSS-ERG* in fusion-positive cells inhibits tumor growth in xenograft assays [95, 96]. ETS fusions are therefore attractive therapeutic targets. Evaluation for targeting ETS fusion and its downstream targets is ongoing. Most 5′ *ETS* fusion partners including *TMPRSS2* are androgen-responsive and it is likely that current and future therapeutic strategies that target androgen signaling may function at least in part through inhibition of ETS fusions [97, 98]. Phase 1 and Phase 2 trials analyzing the response to abiraterone, a small molecule inhibitor of cytochrome P, found evidence of *ERG* translocation in circulating tumor cells of 41 % men with castrate-resistant PCa prior to treatment [99]. After treatment with abiraterone, 80 % of the patients with *ERG* rearrangements had more than 90 % decline of PSA levels. In patients showing less than 90 % decline in PSA, only 30 % had a translocation [99, 100]. In this cohort of patients, a decline in PSA was associated with a decline in circulating tumor cells and an increased survival rate. Phase 3 trials incorporating fusion status are ongoing. The usefulness of *ETS* gene fusion status as a prospective marker of androgen-dependence in castrate-resistant PCa remains to be seen. In addition to the therapeutic implications, these studies provide evidence that castrate-resistant PCa may remain dependent on androgen signaling [101]. *TMPRSS2–ERG* translocation may predict tumor sensitivity to poly (adenosine diphosphate-ribose) polymerase 1 (PARP1) inhibition and in conjunction with *PTEN* deletion may add prognostic information [91, 102, 103].

While TMPRSS2–ERG translocation is very specific for prostate cancer, it is only present in approximately 50 % of cancer, and hence has limited use as a diagnostic tool on its own. Its use as a diagnostic test therefore lies in multiplexed assays with other biomarkers such as *PCA3* [104, 105]. A study of more than 1,300 men demonstrated that combined measurement of *PCA3* mRNA levels and *TMPRSS2–ERG* gene-fusion in urine outperformed serum PSA for PCa diagnosis [105].

Immunohistochemical Assays of TMRPSS2-ETS Fusion Protein

Multiple anti-ERG monoclonal antibodies standardized for IHC on formalin-fixed paraffin-embedded (FFPE) tissue are commercially available. Expression of ERG on IHC (Fig. 35.1) is considered a marker for the translocation with a sensitivity and specificity of approximately 86 % [106–109]. IHC expression of ERG can therefore be utilized as a surrogate marker for the translocation.

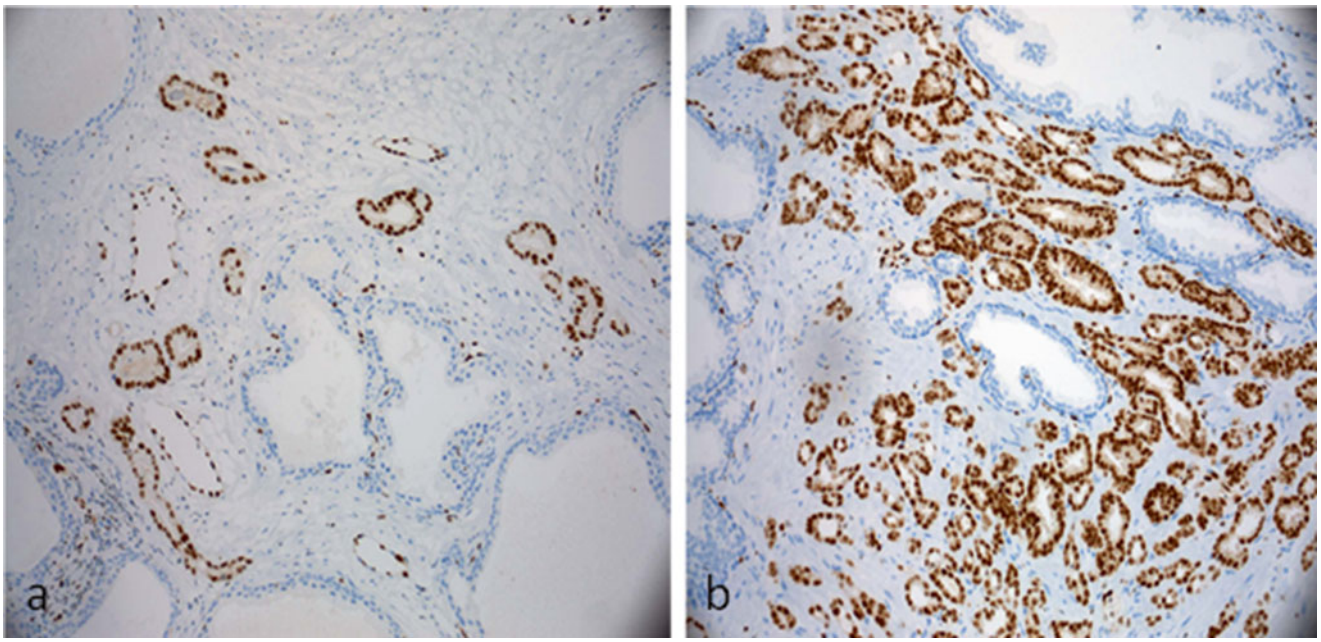

Figure 35.1 Immunohistochemical stain for ERG demonstrates negative staining of the stroma and normal glands. Normal endothelial cells are positive and act as internal controls. (**a**) Strong diffuse nuclear staining of a small cluster of atypical glands supports the diagnosis of prostatic adenocarcinoma. (**b**) Strong diffuse nuclear staining of ERG in prostatic adenocarcinoma. (Slides provided by Drs. Kyung Park and Mark A. Rubin, Department of Pathology and Laboratory Medicine, Weill Cornell Medical College, New York, NY)

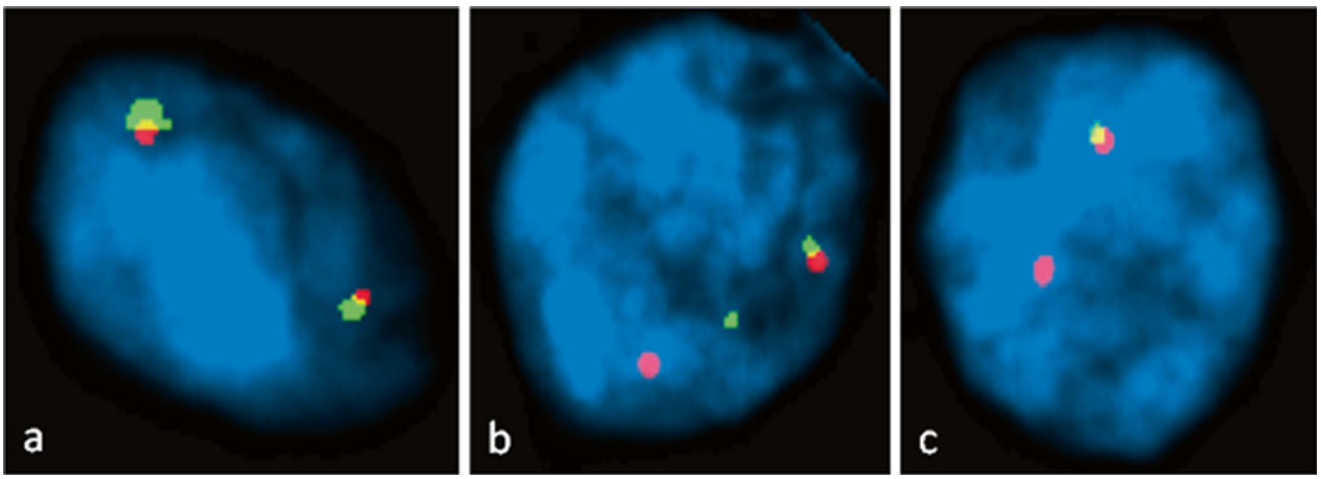

Figure 35.2 Dual Color *TMPRSS-ERG* FISH pattern in formalin-fixed, paraffin-embedded prostatic adenocarcinoma. A probe telomeric to the *ERG* gene is labeled green and a probe centromeric to *ERG* is labeled red. Overlapping green and red signals in normal cells produce a yellow color signal. (**a**) Normal cells without *TMPRSS-ERG* translocation with two overlapping red and green signals. (**b**) A cell positive for *TMPRSS-ERG* translocation with separation of one red and green signal. (**c**) Cell with *ERG* deletion resulting in loss of one green signal. (Slides provided by Drs. Kyung Park and Mark A. Rubin, Department of Pathology and Laboratory Medicine, Weill Cornell Medical College, New York, NY)

FISH Assays for Detection of *TMPRSS2–ETS* Gene Fusion

Traditionally, two strategies for FISH detection of *TMPRSS2–ERG* fusion included the two and three color break-apart assays. The two-color break-apart FISH assays (Fig. 35.2) are designed to identify rearrangements in specific *ETS* family gene partners [110, 111]. Probes were designed to label regions telomeric (green) and centromeric (red) of *ERG* locus on 21q22.3. This set of probes appears yellow due to the overlap of the red centromeric and green telomeric probe in the nontranslocated allele. If a break occurs between the two probes, each color can be separately detected indirectly supporting the *TMPRSS2–ERG* gene fusion [2]. By this

method, confirmation of fusion between two genes and identification of the specific 5′ partner is not possible because the probes are not specific for any single gene.

The three-color break-apart assay developed by Yoshimoto et al. [112] utilizes three probes. Two probes flank the *ERG* gene at the 3′ (BAC clone RP11-476D17 RED) and 5′ (BAC clone RP11-95121 GREEN) regions, and the third probe is specific for the 5′ region of *TMPRSS2* (RP11-535H11 BLUE) or for the transcriptional regulatory sequences (telomeric) of *TMPRSS2* (RP11-35C4; RP11-891L10; RP11-260O11). The use of this probe configuration not only enables detection of *ERG* rearrangement but also allows the detection of the mechanism of the rearrangement as explained below. With three color FISH, rearrangement as a result of deletion (Edel) results in co-localization of the 3′ *ERG* and *TMPRSS2* signals and an absence of the 5′ *ERG* signal. Less frequently a genomic rearrangement leading to insertion of those sequences elsewhere in the genome to an unknown chromosome location can occur resulting in the separation of the 5′ *ERG* signals from the co-localization of the 3′ *ERG* and *TMPRSS2* signals, thus described as ERG split or Class Esplit. In either scenario the unaffected chromosome 21 will display a class N (or normal) signal configuration. The presence of more than one copy of the *TMPRSS2–ERG* gene fusion is identified as Class 2+Edel. In summary, in Class N, where no *ERG* rearrangement has occurred, the two *ERG* signals (3′ BAC clone RP11-476D17 in RED and 5′ BAC clone RP11-95121 GREEN) co-localize and are visualized as a yellow signal and the 5′ *TMPRSS2* signal is a separate blue probe signal. In Class Edel, the 3′ *ERG* probe (RED) co-localizes with the *TMPRSS2* probe signals (BLUE) with absence of the 5′ *ERG* signal, representing rearrangement with the loss of the intervening sequence; the unaffected chromosome 21 will display a Class N configuration. In Class Esplit, the 3′ *ERG* signal (RED) co-localizes with the *TMPRSS2* signal (BLUE) with retention of 5′ ERG signal (GREEN) elsewhere in the nucleus; the unaffected chromosome 21 displays Class N configuration.

RT-PCR for Determining Gene Fusion Status

The RT-PCR technique is dependent on detection of hybrid transcripts; however RT-PCR assays do not differentiate between the different genomic mechanisms such as Edel vs Esplit. To date, up to 17 different fusion transcripts and splice variations have been characterized. The most commonly found fusion transcript is composed of exon 1 of *TMPRSS2* fused to exon 4 of *ERG* [109, 113]. Of the transcripts described, one produces a genuine TMPRSS2-ERG fusion protein and eight contain premature stop codons and are unlikely to result in ERG over-expression [12, 113–116].

Wang et al. [113] characterized in detail the expression of *TMPRSS2-ERG* fusion mRNAs and correlated the isoforms and their respective expression levels with clinical outcome in cancers from men undergoing radical prostatectomy. Significant variation was identified in the alternatively spliced isoforms expressed in different cancers. Expression of an isoform, in which the native ATG in exon 2 of the *TMPRSS2* gene is in frame with exon 4 of the *ERG* gene, was associated with clinical and pathologic variables of aggressive disease. Expression of other isoforms, in which the native *ERG* ATG in exon 3 was the first in-frame ATG, was associated with seminal vesicle invasion, which is correlated with poor outcome following radical prostatectomy.

Clark et al. [115, 116] have described the great diversity that exists in the precise structure of *TMPRSS2-ERG* hybrid transcripts found in human PCa. Fourteen distinct hybrid transcripts were characterized, each containing different combinations of sequences from the *TMPRSS2* and *ERG* genes. Distinct patterns of hybrid transcripts were found in samples taken from separate regions of individual cancer-containing prostates, suggesting that *TMPRSS2-ERG* gene fusions may arise independently in different regions of a single prostate.

Indirect Methods for Detection of *ETS* Rearrangement Status

Analysis of array comparative genomic hybridization (aCGH) data, specifically the 21q22.2.3 region, may permit identification of Class Edel *TMPRSS2-ERG* gene fusions [117, 118]. Class Esplit retains the intervening sequence within the nucleus, in a copy-neutral manner and consequently aCGH cannot identify this arrangement. Gene expression microarray may indirectly indicate the presence of an ETS rearrangement by identifying overexpression of *ETS* gene family transcripts. A novel multiplexing technology developed to detect disease-specific biomarkers, including differentiation of various fusion transcripts, uses nano-structured microelectrodes that are integrated into a chip [119].

Tissue-Based Molecular Tests

Several commercial laboratories have developed LDT tests which combine multiple biomarkers for PCa into a single molecular test with a prognostic or predictive score as the result. These tests are not cleared or approved by FDA, but are offered nationally under each laboratory's CLIA permit which requires demonstration of analytical and clinical validity. A concern in using these tests is uncertainty of the validation studies and the lack of demonstration of clinical utility.

Oncotype DX

Oncotype DX (Genomic Health Inc., Redwood City, CA) was developed to test small 1 mm PCa using FFPE needle biopsies. The test assigns a GPS [57] by measuring 12 genes related to four molecular pathways. The genes are *AZGP1*, *KLK2*, *SRD5A2*, and *RAM13C* of the androgen pathway, *FLNC*, *GSN*, *TPM2*, and *GSTM2* of the cellular organization pathway, *TPX2* of the proliferation pathway, and *BGN*, *COL1A1*, and *SFRP4* genes of the stromal response pathway. In addition, five reference genes are used to normalize and control preanalytical and analytical variability. Together with the National Comprehensive Cancer Network risk criteria [120–122], the GPS [123] provides a risk stratification of PCa into very low, low, and modified intermediate risk to help clinicians select appropriate candidates for active surveillance.

Prolaris Score

The Polaris score (Myriad Genetics, Salt Lake City, UT) focuses on tumor cell growth characteristics to stratify risk of progression. The test uses either biopsy or prostatectomy FFPE tissue and includes 46 genes including 31 cell cycle genes and 15 housekeeping genes. A low expression of these genes is associated with low risk of progression whereas high expression is associated with high risk of progression [124, 125]. Patients with a high risk of progression may be offered closer clinical follow-up or additional therapy.

ConfirmHDx

This multiplex polymerase chain reaction (PCR) assay from MDx Health (Irvine, CA) measures DNA methylation of three genes *GSTP1*, *APC*, and *RASSF1*. Methylation of these genes is associated with PCa but can also be seen in histologically normal prostate tissue adjacent to PCa in a "halo" effect. The ConfirmHDx test guides urologists in distinguishing patients who have a true negative biopsy from those who may have an occult cancer (false-negative biopsy). A multiplexed testing approach is useful for smaller tissue volumes and works well on older tissues with small quantities of poor quality DNA [126]. Core-specific methylation pattern-identification has been validated by ConfirMDx with an 80–90 % negative predictive value on follow-up biopsy [127, 128].

Emerging Prognostic Factors Amenable to FFPE Tissue Evaluation

In addition to the commercially available tests mentioned above, a number of emerging prognostic factors are amenable to FFPE tissue evaluation, including oncogenes (*BCL2*, *MYC*, *EZH2*, and *HER2*), a proliferation index marker (Ki-67), tumor suppressor genes (*TP53*, *P21*, *P27*, *NKX3.1*, and *PTEN*), adhesion molecules (CD44 and E-cadherin), and AR. These biomarkers can be assessed using FISH (DNA or mRNA expression) or IHC (protein expression). Once validated for clinical use on FFPE tissue sections, the tests are easy to perform and have the added advantage of interpretation of many glands maintained within their histologic context. The information can be gathered as an adjunct to histological prognostic parameters (such as Gleason score) during routine histopathologic evaluation. IHC assays, such as those for TP53 and Ki67, are poised for transition to clinical use if clinically significant evidenced thresholds are established.

Deletion of *PTEN* at 10q23.3 occurs in approximately 40 % of PCa and can lead to genomic instability [129]. The genomic instability induced by the loss of *PTEN* leads to acquisition of other genomic rearrangements, and continuing instability generates genotypic heterogeneity. Loss of PTEN function leads to accumulation of PIP3 that activates the AKT/PKB signaling pathway with selective advantage for tumor progression. PTEN-null tumors are associated with an aggressive metastatic potential, poor prognosis, and androgen independence [130–134]. Hemizygous loss of *PTEN* carries an unfavorable prognosis in human disease. Homozygous deletion of *PTEN* is strongly associated with metastasis and hormone refractory PCa. Abnormalities of PTEN have been observed not only in prostate carcinoma but also in pre-neoplastic lesions of the prostate [135, 136]. Multiple inhibitors of the PI3K/AKT/mTOR pathway are in clinical trials, with much attention focused on mTOR inhibition. Interestingly, Yoshimoto et al. [103] and Reid et al. [134] observed that in PCa with a *TMPRSS2-ERG* translocation, a loss of *PTEN* was associated with less favorable outcomes. Patients lacking both *PTEN* deletion and *ERG–ETV1* gene rearrangements comprise a good prognosis population with favorable cancer-specific survival. The loss of *PTEN* in the absence of *ERG–ETV1* gene rearrangements is associated with a patient population (6 %) with poorer cancer-specific survival as compared to the good prognosis group. *ERG* rearrangements and *PTEN* deletion can be studied using FFPE tissue by FISH and IHC (Figs. 35.1, 35.2, 35.3, and 35.4).

Chinnaiyan et al. [137] tested seven putative PCa biomarkers using a multiplexed quantitative real-time PCR test

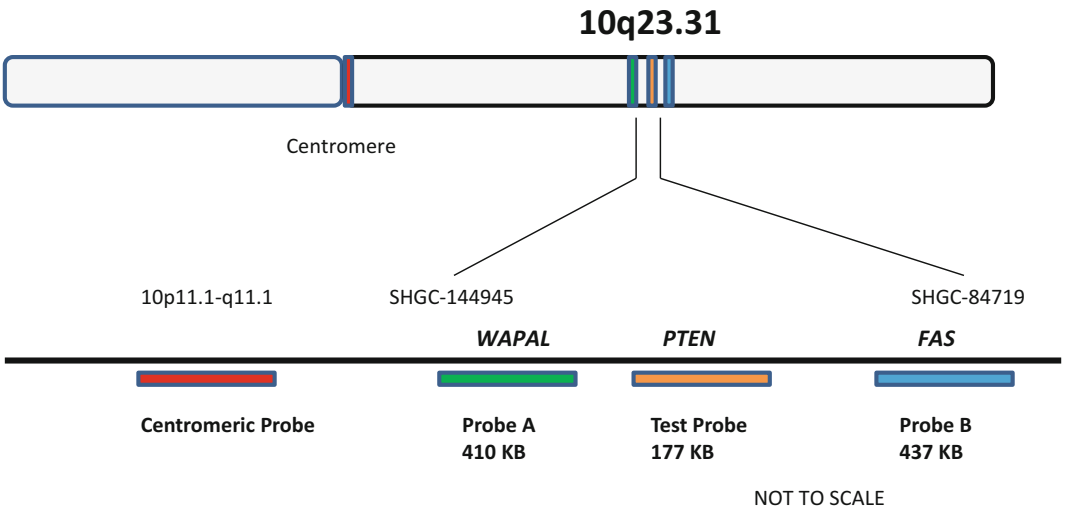

Figure 35.3 *PTEN* construct and ideogram. The localization of the four *PTEN* probes is shown above. The centromeric probe is labeled red and hybridizes to the centromere. The *PTEN* probe is labeled orange. A probe centromeric to *PTEN* is labeled green and hybridizes to *WAPAL*. A probe telomeric to *PTEN* is labeled aqua and hybridizes to the *FAS* gene. See Fig. 35.4 for examples of the signals with different *PTEN* mutations. (*PTEN* ideogram provided by Mohammed Harris, Director of Technical Service and Research, CymoGen Dx, New Windsor, NY)

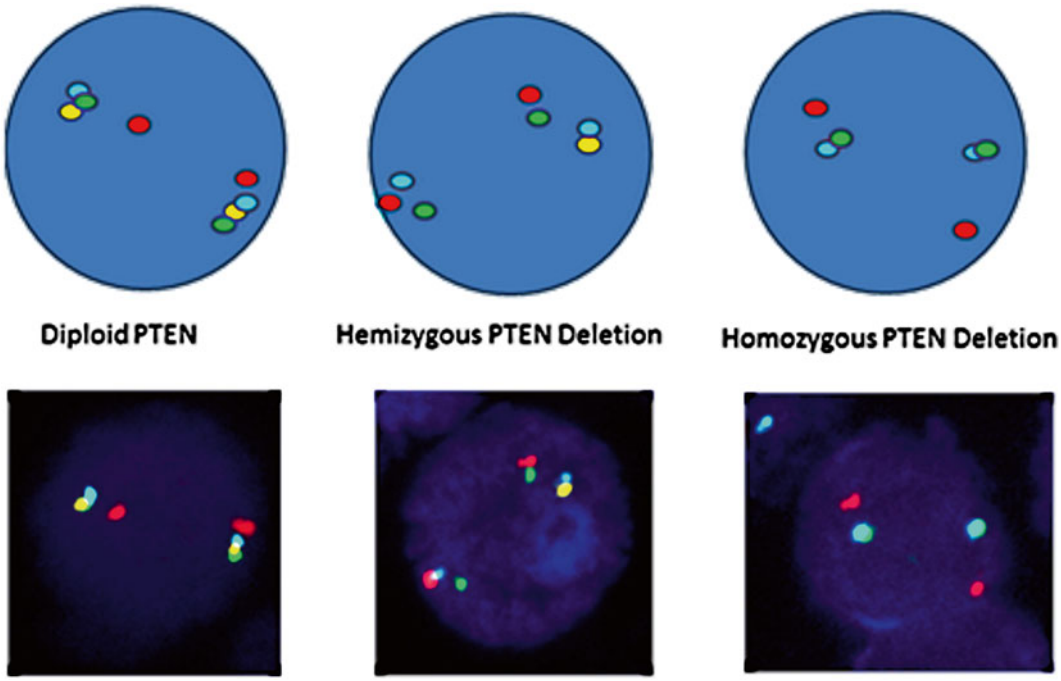

Figure 35.4 Four-Color *PTEN* FISH pattern in formalin-fixed, paraffin-embedded prostatic adenocarcinoma. *Left Panel*: Normal cell with preservation of all four signals, hence no evidence of TMPRSS2–ERG translocation. *Middle Panel*: Absence of gold/orange signal in one cluster and preservation in the other cluster, which indicates hemizygous deletion of *PTEN*. *Right Panel*: Absence of gold/orange signal in both clusters along with the absence of green, which is an example of homozygous deletion of *PTEN*. (*PTEN* FISH figures provided by Mohammed Harris, Director of Technical Service and Research, CymoGen Dx, New Windsor, NY)

in 138 patients with PCa and 96 patients with negative prostate needle biopsies. The biomarkers included those that are generally overexpressed in PCa such as *PCA3*, *AMACR*, and *GOLPH2*, as well as those that are overexpressed in subsets of PCa such as *ERG* and *SPINK1*. In the initial univariate analysis, *GOLPH2*, *PCA3*, *SPINK1*, and *TMPRSS2-ERG* showed significant discrimination between patients with and without PCa. Additionally, AUC analysis of these individual biomarkers for the ability to detect PCa showed that *GOLPH2*, *PCA3*, and *SPINK1* expression levels had better correlation with the presence of PCA than serum PSA.

Clinical Use of Prostate Cancer Tests for Patient Management

Compared to the other solid organ and hematologic malignancies, PCa diagnosis and management has been lagging far behind in utilization of molecular tools for diagnosis and personalized treatment. Only in the last 4–5 years have advances in our understanding of the genetic basis of PCa enabled scientists to design molecular panels for each step in the management of PCa. Integration of these novel molecular tools in routine clinical practice will help physicians better differentiate patients with PCa from those who have an elevated PSA secondary to other reasons. Currently available PCa molecular assays, including the PCA3 test, the phi, and *TMPRSS-ERG* translocation tests, are all standardized for use on urine samples. Integration of these cancer-specific tools as post-PSA screening tests can help identify patients at high risk of having PCa.

Despite their promise, the true ability of these newer tests to reduce the number of unnecessary biopsies has yet to be determined. A comparison of watchful waiting compared to treatment based on these test results would clarify their utility in routine clinical practice. Eventually the ability of these tests to reduce unnecessary biopsy procedures will depend on the tolerance of patients and physicians for the risk of occult cancer and also on the confidence index of the tests. Future tests may eventually include a panel of cancer-specific genes included in one test rather than individual biomarkers forming multiple individual tests.

Upon diagnosis of PCa on a needle biopsy, genomic tests such as Oncotype DX and Prolaris predict clinically indolent and clinically significant cancers. Integration of such tests into clinical algorithms will help confidently differentiate

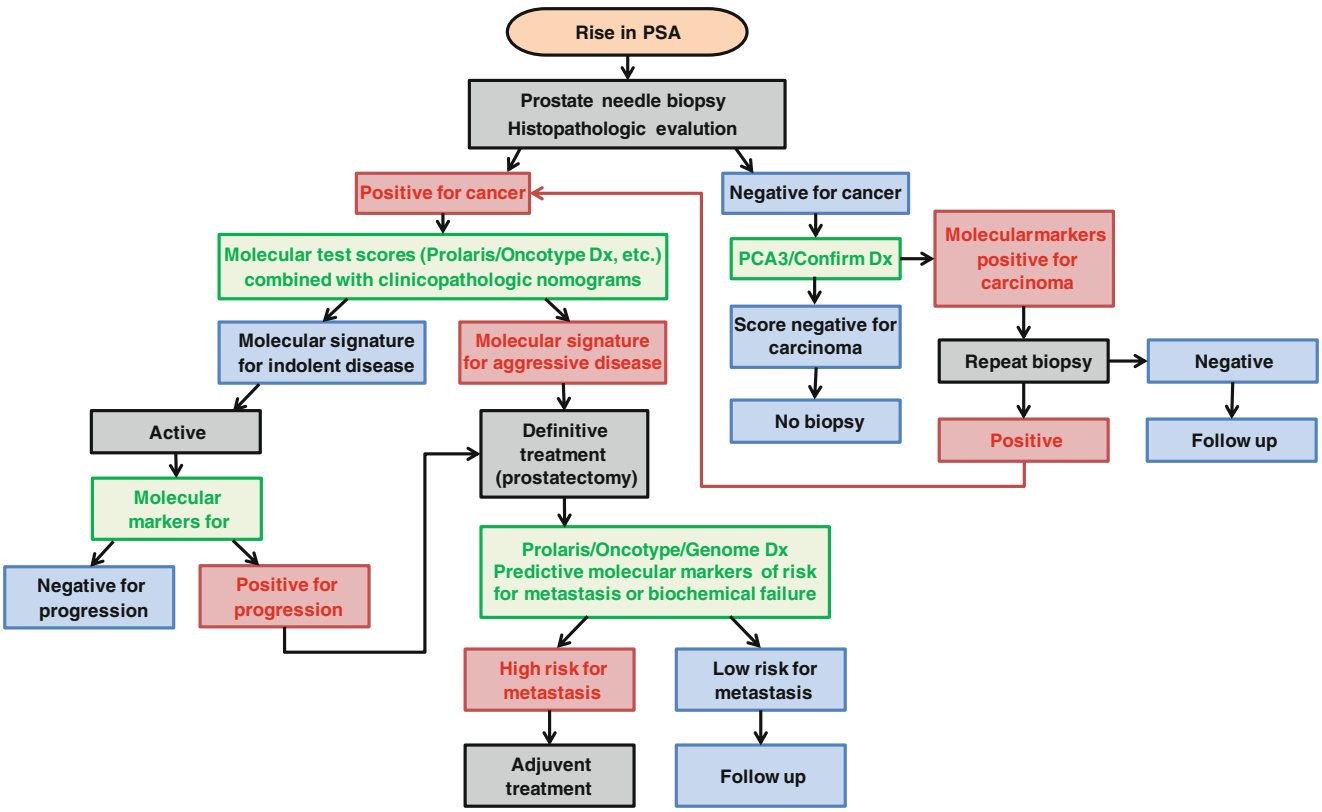

Figure 35.5 Potential algorithm for integration of molecular tests into clinical practice. Molecular tests can be integrated into each step of prostate cancer (PCa) diagnosis, treatment, and long-term management. Patients with an initial negative biopsy may be triaged further into those who have a high likelihood of cancer and hence in need of an early follow-up biopsy and those who are truly negative. Molecular tests can help stratify patients with a first time diagnosis of PCa into those who should get definitive treatment and those who should receive active surveillance. Patients who receive definitive treatment can then be further divided into those who are at low risk of metastasis and those who are at high risk of metastasis and hence need adjuvant therapy

patients who would benefit from active surveillance [138] from patients with more aggressive disease needing definitive treatment [139]. An algorithm for the use of molecular tests in clinical practice is shown in Fig. 35.5.

After radical prostatectomy, the currently available diagnostic models have predictive accuracies ranging from 78–89 % [140–143]. Use of recently discovered urine, blood, and tissue biomarkers may enhance the performance of currently available nomograms. The profiling of blood proteins, TGF-b1 and IL-6sR, in preoperative plasma improves the predictive accuracy of the Kattan [143] preoperative nomogram by a significant margin, but is not yet widely used in clinical practice.

Future Directions

From our current understanding of PCa, no single biomarker can provide high sensitivity and specificity to predict PCa behavior or aid in early diagnosis. Using single markers to predict the presence of PCa and outcomes does not take into account the genetic heterogeneity of PCa. The important issue in evaluating a new biomarker is not its independent predictive value, but its ability to improve the predictive accuracy for patients when combined with established biomarkers. An ideal test therefore will seek to identify the correct permutation and combination of the newly emerging biomarkers in association with established predictive factors. An extensive list of serum, urine, and tissue PCa biomarkers are currently in various phases of development. Multiplex assays that use a combination of biomarkers hold the most promise in the future. With advances in biotechnology, diverse techniques including a spectrum of "omics" are being explored. Future approaches may integrate proteomic, transcriptomic, and genomic approaches to identify the optimal combination of biomarkers for detection of PCa, differentiation of indolent from aggressive PCa, and for directing adjuvant treatment. The development of these future tests will require careful attention to the populations and clinical scenarios in which the tests are validated and used.

Thyroid Cancer

36

Marina N. Nikiforova and Yuri E. Nikiforov

Abstract

Thyroid cancer is the most common type of endocrine malignancy. Initiation and progression of thyroid cancer involves multiple genetic and epigenetic alterations, of which mutations leading to the activation of the MAPK and PI3K/PTEN/AKT signaling pathways are crucial for tumor initiation and progression. Common mutations found in thyroid cancer are point mutations of the *BRAF* and *RAS* genes, as well as *RET/PTC* and *PAX8/PPARG* chromosomal rearrangements. More recently, a number of other mutations have been characterized, which occur in this cancer type with significantly lower frequency, but are associated with specific phenotypic and biological properties. These somatic mutations are useful diagnostic and prognostic markers for thyroid cancer and are being incorporated into clinical practice, offering a valuable tool for management of patients with thyroid nodules and cancer.

Introduction

Thyroid cancer is the most common endocrine malignancy, with a steadily growing incidence in the USA and other industrialized countries [1, 2]. The vast majority of thyroid tumors originate from follicular epithelial cells. The follicular cell-derived cancers are further subdivided into well-differentiated papillary carcinoma and follicular carcinoma, poorly differentiated carcinoma, and anaplastic (undifferentiated) carcinoma (Fig. 36.1) [3, 4]. Papillary carcinoma is the most common thyroid malignancy (80–85 %). In addition to classic-type papillary carcinoma, common histopathologic variants are microcarcinoma, follicular variant, and tall cell variant. Follicular carcinomas account for approximately 15 % of thyroid cancers and are subdivided into conventional type and oncocytic (Hürthle) type. Follicular adenoma is a benign tumor that is considered a precursor for follicular carcinomas (Fig. 36.1). Less differentiated thyroid cancers, i.e., poorly differentiated carcinoma and anaplastic carcinoma, can develop de novo, although many arise through the process of stepwise dedifferentiation of papillary and follicular carcinomas (Fig. 36.1). Medullary thyroid carcinoma originates from thyroid parafollicular or C cells, accounts for 3–5 % of thyroid cancers, can be a manifestation of an inherited genetic disease, and, therefore, is not discussed in this chapter.

Thyroid cancer occurs in thyroid nodules. Thyroid nodules are common in adults, particularly with increased age, and are typically detected by palpation or imaging [5–7]. However, most nodules are benign, and the rate of cancer in medically evaluated thyroid nodules ranges from 5–15 % [7–9]. A clinical challenge is to accurately diagnose cancer in these nodules and to avoid unnecessary thyroid surgery for benign disease. Sampling of thyroid nodules using fine needle aspiration (FNA) under ultrasound guidance followed by subsequent cytologic examination is the most accurate

and widely used diagnostic tool at this time. FNA provides a definitive diagnosis of a malignant or benign nodule in the majority of cases. However, in about 25 % of nodules, FNA cytology cannot reliably exclude cancer, and such cases are placed in one of the indeterminate categories, hampering clinical management of these patients [6, 8, 10, 11]. By the current Bethesda System for Reporting Thyroid Cytopathology, the indeterminate categories include three specific cytologic diagnoses: atypia of undetermined significance/follicular lesion of undetermined significance (AUS/FLUS); follicular or oncocytic (Hürthle cell) neoplasm/suspicious for follicular or oncocytic (Hürthle cell) neoplasm (FN/SFN); and suspicious for malignant cells (SMC), with a predicted probability of cancer of 5–15 %, 15–30 %, and 60–75 %, respectively [12, 13]. Because FNA is unable to provide a definitive diagnosis for these indeterminate nodules, most patients with indeterminate cytology undergo diagnostic surgery to establish a histopathologic diagnosis. However, only 10–40 % of surgically resected indeterminate thyroid nodules are malignant [12]. The unneeded operations, with their attendant expenses and risks, may be avoided if the FNA procedure could reliably establish the presurgical diagnosis of a benign nodule. Additionally, since the standard of care is to offer a second surgery for total thyroidectomy if the diagnostic lobectomy confirms a cancer, a more optimal surgical management would be a single total thyroidectomy procedure that is planned when the diagnosis of cancer is established preoperatively.

Although well-differentiated thyroid cancer is a disease with an overall favorable outcome, some tumors entail a substantially worse prognosis and have to be treated more aggressively [14–16]. Multiple prognostic systems for differentiated thyroid cancer based on demographic and pathologic factors exist [17], but none of the systems accurately stratify thyroid tumors into appropriate risk categories. The rapidly expanding knowledge of the molecular genetics of thyroid cancer is being translated into clinical practice, offering significant improvement in the accuracy of the preoperative diagnosis of thyroid cancer and better tumor prognosis.

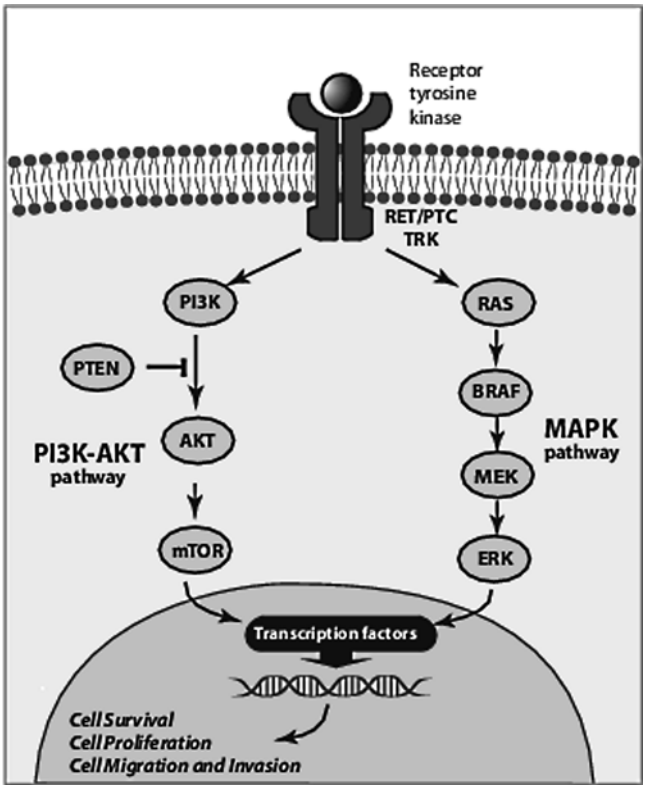

Figure 36.2 Thyroid cancer development and progression typically involves the activation of the mitogen-activated protein kinase (MAPK) and PI3K/PTEN/AKT signaling pathways. In thyroid cancer, the MAPK pathway is activated via point mutations of the *BRAF* or *RAS* gene, or chromosomal rearrangements involving the *RET* gene (known as RET/PTC rearrangement) or the *NTRK1* gene (TRK rearrangement). These non-overlapping genetic events are commonly found in well-differentiated papillary carcinomas and in some follicular carcinomas. Mutations in the genes coding for the effectors of the PI3K/PTEN/AKT pathway, such as *PIK3CA* (encoding a subunit of PI3K), *AKT1*, and *PTEN*, are found more frequently in follicular carcinomas and in more advanced and less-well-differentiated cancers

Molecular Basis of Disease

Thyroid cancer initiation and progression occurs through gradual accumulation of genetic and epigenetic alterations, including activating and inactivating somatic mutations, alteration in gene expression patterns, and miRNA dysregulation. Most mutations in thyroid cancer involve the effectors of the mitogen-activated protein kinase (MAPK) signaling pathway and the PI3K/PTEN/AKT signaling pathway (Fig. 36.2). Critical genes are frequently mutated in thyroid cancer via two distinct molecular mechanisms, point mutation or chromosomal rearrangement. MAPK activation frequently occurs via mutations in the cell membrane receptor tyrosine kinases RET and NTRK1, which are involved in chromosomal rearrangements, or through intracellular signal transducers BRAF and RAS, which are typically activated as a result of a point mutation. These mutually exclusive mutations occur in approximately 70 % of papillary thyroid carcinomas

(Table 36.1) [18–21]. In follicular carcinomas, mutations in the *RAS* genes are the most common, followed by *PAX8/PPARG* rearrangement. Thyroid cancer progression and dedifferentiation involves a number of additional mutations that affect the PI3K/PTEN/AKT signaling pathway and other cell signaling pathways (Table 36.1).

BRAF Mutations

BRAF is a serine-threonine kinase that is activated by RAS binding and protein recruitment to the cell membrane. BRAF phosphorylation leads to activation of MEK and other downstream targets along the MAPK signaling pathway (Fig. 36.2). In thyroid cancer, BRAF can be activated by point mutations, small in-frame deletions or insertions, or chromosomal rearrangement. The most common mechanism of activation is a point mutation of a thymine to adenine substitution at nucleotide 1799 (c.T1799A), resulting in a substitution of valine to glutamate at residue 600 (p.V600E) [19, 22]. The *BRAF* V600E mutation constitutes 95–99 % of all *BRAF* mutations found in thyroid cancer. Other alterations are *BRAF* p.K601E point mutation and small in-frame insertions or deletions surrounding codon 600 [23–26], as well as *AKAP9/BRAF* rearrangement [27]. The *BRAF* rearrangement seen in thyroid carcinomas is a paracentric inversion of chromosome 7q leading to the fusion of 3′ portion of the *BRAF* gene to the 5′ portion of the *AKAP9* gene and is more common in papillary carcinomas associated with radiation exposure [27]. More recently, several other fusion partners of *BRAF* have been identified in papillary carcinomas [28].

BRAF V600E is the most common genetic alteration in papillary thyroid carcinoma and is found in approximately 45 % of papillary thyroid tumors (Table 36.1) [29]. *BRAF* V600E also occurs in 10–20 % of poorly differentiated carcinomas and 30–40 % of anaplastic carcinomas arising from papillary carcinoma [30–33]. This mutation is typically found in papillary carcinomas with classic papillary histology and in the tall cell variant and is rare in the follicular variant of papillary carcinoma [18, 29]. In contrast, tumors with the *BRAF* K601E mutation are typically the follicular variant of papillary carcinoma [26]. *BRAF* V600E is not found in follicular carcinomas and benign thyroid nodules and therefore, among primary thyroid lesions, represents a specific marker of papillary carcinoma and related tumor types.

RAS Mutations

Point mutations of *RAS* are found in follicular carcinomas, papillary carcinomas, and follicular adenomas. Human *HRAS*, *KRAS*, and *NRAS* genes encode highly related G proteins that reside at the inner surface of the cell membrane and propagate signals arising from cell membrane receptors and G-protein-coupled receptors along the MAPK, PI3K/AKT, and other signaling pathways. Activating point mutations typically affect codons 12, 13, and 61 of the *RAS* genes. In thyroid cancer, *NRAS* codon 61 and *HRAS* codon 61 mutations are most common, followed by *KRAS* codon 12 and 13, although mutations have been found in different hot spots of all three genes. *RAS* mutations are present in 10–20 % of papillary carcinomas, 40–50 % of follicular carcinomas, and 20–40 % of poorly differentiated and anaplastic carcinomas [34–40]. Among papillary carcinomas, virtually all tumors with a *RAS* mutation belong to the follicular variant [18, 31]. *RAS* mutations also occur in 20–40 % of benign follicular adenomas [35, 36]. The finding of *RAS* mutations in benign adenomas as well as in follicular-patterned carcinomas suggests that *RAS* mutation positive follicular adenomas may serve as a precursor for *RAS* mutation positive follicular carcinoma and follicular variant of papillary carcinomas. Furthermore, *RAS* mutation may predispose well-differentiated cancers to dedifferentiation and anaplastic transformation [41–44]. Therefore, detection of this mutation at early stages may guide the therapy to prevent tumor progression.

RET/PTC Rearrangements

The *RET/PTC* chromosomal rearrangement is a characteristic of papillary thyroid cancer [45]. The rearrangement forms a fusion between the 3′ portion of the *RET* receptor tyrosine kinase gene and the 5′ portion of different partner genes. All chimeric genes contain the intact tyrosine kinase domain of *RET* fused to an active promoter of another gene that drives the expression and ligand-independent dimerization of the RET/PTC protein, leading to chronic stimulation of MAPK signaling (Fig. 36.2) [46–48]. The two most common fusions, *RET/PTC1* and *RET/PTC3*, are paracentric inversions since both *RET* and its respective fusion partners, *CCDC6* (*H4*) and *NCOA4* (*ELE1*), reside on the long arm of chromosome 10. In contrast, *RET/PTC2* and nine more recently discovered types of *RET/PTC* fusions are all interchromosomal rearrangements formed by *RET* fusion to genes located on different chromosomes (Table 36.2) [49].

RET/PTC is found in approximately 10–20 % of adult sporadic papillary carcinomas [18, 49] but occurs with higher incidence in patients with a history of radiation exposure (50–80 %) and in papillary carcinomas from children and young adults (40–70 %) [50–52]. The distribution of *RET/PTC* rearrangement within the tumor may be quite heterogeneous, varying from involving almost all neoplastic cells (clonal *RET/PTC*) to being detected only in a small fraction of tumor cells (non-clonal *RET/PTC*) [53, 54]. Although a low level of *RET/PTC* rearrangement has been

Table 36.1 Average prevalence of mutations in thyroid cancer

Tumor type	Genes	Prevalence of common mutations (%)
Papillary carcinoma		
	BRAF	40–45
	RET/PTC	10–20
	RAS	10–20
	NTRK1	<5
	NTRK3	<5
	ALK	<5
Follicular carcinoma		
	RAS	40–50
	PAX8-PPARG	30–35
	PIK3CA	<10

	AKT1	5–10
	PIK3CA	5–10
Anaplastic (undifferentiated) carcinoma		
	TP53	50–80
	CTNNB1	50–60
	RAS	20–40
	BRAF	20–40
	PIK3CA	10–20
	PTEN	5–15
	AKT1	5–10

reported in adenomas and other benign thyroid lesions in studies that used ultrasensitive detection techniques, the clonal *RET/PTC* (i.e., rearrangement that is found in most cells within the tumor) is specific for papillary thyroid carcinoma [49, 53]. Proper techniques for the clinically relevant detection of *RET/PTC* are discussed later in the chapter. Among different rearrangement types, *RET/PTC1* is typically the most common, followed by *RET/PTC3*, whereas *RET/PTC2* and other novel rearrangement types are rare (Table 36.2) [49].

NTRK1 and *NTRK3* Rearrangements

Chromosomal rearrangements involving the *NTRK1* and *NTRK3* receptor tyrosine kinase genes also occur in papillary thyroid carcinomas, although with a significantly lower prevalence. The *NTRK1* gene resides on chromosome 1q22 and can be fused to at least three different partner genes located on the same or different chromosomes, leading to the *TRK* rearrangement (Table 36.2) [55–57]. *NTRK* rearrangements occur in less than 5 % of papillary thyroid carcinomas [28]. Fusions involving another *NTRK* family gene, *NTRK3*, also occur in papillary thyroid cancer. *ETV6-NTRK3* fusions occur in approximately 2 % of sporadic papillary thyroid cancers and with a significantly higher prevalence (approximately 15 %) in tumors associated with exposure to ionizing radiation [28, 58].

ALK Rearrangements

Recently, rearrangements involving the *ALK* gene were identified in thyroid cancer. The most common fusion partner of *ALK* is the striatin (*STRN*) gene [59]. *ALK* fusions are found in 1–2 % of papillary carcinomas and with higher frequency (5–10 %) in poorly differentiated and anaplastic thyroid cancers [28, 59].

PPARG Rearrangements

PAX8/PPARG rearrangement is a t(2;3)(q13;p25) translocation that leads to fusion between a portion of the *PAX8* gene, which encodes a paired domain transcription factor, and the peroxisome proliferator-activated receptor (*PPARG*) gene [60]. *PAX8/PPARG* rearrangement leads to strong overexpression of the PPARG protein, although the mechanisms of cell transformation induced by this genetic event are not understood. Several types of *PAX8/PPARG* rearrangement occur, formed by the fusion of four *PAX8* gene regions (exons 1–7, 1–8, 1–9, or 1–7 plus 9) to *PPARG* exons 1–6. These different *PAX8* gene region fusions are apparently a result of the alternate splicing involving exons 8 and 9 known to affect the wild-type *PAX8*. The most commonly expressed *PAX8/PPARG* transcripts in follicular thyroid carcinomas contain exons 1–9 and 1–7 plus 9 of *PAX8*. In addition to *PAX8/PPARG*, the *PPARG* gene can fuse with the *CREB3L2* gene; however, this type of fusion is rare (Table 36.2) [61].

PAX8/PPARG is characteristically found in 30–35 % of follicular thyroid carcinoma [62–64]. This rearrangement also occurs in a small proportion (1–5 %) of the follicular variant of papillary carcinomas and in some (2–13 %) follicular adenomas [62–66]. Follicular adenomas with a *PAX8/PPARG* rearrangement typically have a thick capsule and show the immunohistochemical profile characteristic of thyroid cancer, suggesting preinvasive (in situ) follicular carcinomas or malignant tumors where invasion was overlooked during histological examination [63]. *PAX8/PPARG* rearrangements and *RAS* point mutations rarely occur in the same tumor, suggesting that they represent distinct oncogenic pathways in the development of follicular thyroid carcinoma [63].

Table 36.2 Common chromosomal alterations in thyroid cancer

	Tumor type	Fusion name	Fusion genes	Chromosomal alterations	Prevalence of subtypes
RET Fusions	PTC	*RET/PTC1*	*RET/CCDC6(H4)*	inv(10)(q11.2;q21)	60–70 %
		RET/PTC2	*RET/RIα*	t(10;17)(q11.2;q23)	<5 %

			CREB3L2/PPARG	t(7;3)(q33;p25.2)	2 %

FTC follicular thyroid carcinoma, *FV* follicular variant, *PTC* papillary thyroid carcinoma

TERT Mutations

Mutations of the telomerase reverse transcriptase (*TERT*) gene promoter were first described in melanoma at two specific hot spots (chr5:1295228C→T, termed C228T, and chr5:1295250C→T, termed C250T) and lead to increased transcriptional activity and expression of the gene [67, 68]. The C228T and C250T *TERT* promoter mutations occur with variable prevalence in different types of thyroid cancer and have strong association with tumor recurrence, distant metastasis, and tumor-related mortality [69–72]. *TERT* mutations are not found in benign thyroid nodules and therefore are useful diagnostically; they can also play a role in prognostication of thyroid cancer.

Mutations Associated with Tumor Dedifferentiation

Thyroid cancer progression and dedifferentiation is more frequent in tumors with *BRAF* and *RAS* mutations and typically involves the accumulation of additional genetic alterations (Table 36.1). Point mutations affecting the *TP53* gene are very common in anaplastic carcinomas (50–80 % of cases) [73–76] but less frequent in poorly differentiated carcinomas and extremely rare in well-differentiated thyroid cancer. *TP53* mutations are most common in exons 5–8 and lead to loss of function of this important cell cycle regulator. The *CTNNB1* gene frequently mutates in anaplastic carcinoma and encodes β-catenin that is involved in cell adhesion and the wingless (Wnt) signaling. Point mutations in exon 3 of *CTNNB1* occur in up to 60 % of anaplastic carcinomas and with lower prevalence in poorly differentiated thyroid carcinomas [77, 78]. In addition, mutations in *PIK3CA*, *PTEN*, and *AKT1* genes are found in anaplastic and poorly differentiated carcinomas, but they are less common [33, 79–82].

Gene Expression and miRNA Expression

Thyroid papillary carcinomas and other types of thyroid cancer have distinct alterations in gene expression [21, 83–86]. Gene expression changes include downregulation of genes responsible for specialized thyroid function such as thyroid hormone synthesis, upregulation of many genes involved in cell adhesion, motility, cell-cell interaction, and different patterns of deregulation of genes coding for cytokines and other proteins involved in inflammation and immune response. Among papillary carcinomas, different mRNA expression profiles correlate with classic papillary histology,

follicular variant, and tall cell variant [83, 87]. Moreover, presence of *BRAF*, *RAS, RET/PTC*, and *NTRK1* mutations correlates with different patterns of gene expression, providing a molecular basis for distinct phenotypic and biologic features associated with each mutation type [21, 83].

Many miRNAs are deregulated in thyroid cancer [88–91]. Generally, miRNA expression profiles are different between papillary carcinoma, follicular carcinoma, and other types of thyroid tumors [92]. Several specific miRNAs, such as miR-146b, miR-221, and miR-222, have increased expression in papillary carcinomas and may play a role in the development of these tumors [89, 91, 92]. Possible target genes for these miRNAs are the regulator of the cell cycle *p27(Kip1)* gene and the thyroid hormone receptor (*THRB*) gene [93, 94]. Several abnormally expressed miRNAs were found in follicular carcinomas (miR-197, miR-346, miR-155, miR-224) [90, 95] and anaplastic carcinomas (miR-30d, miR-125b, miR-26a, and miR-30a-5p) [96].

Clinical Utility of Testing

Preoperative Diagnosis of Thyroid Cancer

Molecular markers are helpful in improving the preoperative diagnosis of cancer in thyroid nodules. Despite the high diagnostic value of FNA cytology, it cannot reliably diagnose cancer in 20–30 % of nodules, and such cases are considered as indeterminate for malignancy. The inability to rule out cancer in these nodules leads to diagnostic lobectomy for most of these patients, although most surgically removed thyroid nodules are benign [12]. Additionally, those patients that are found to have cancer on surgery have to undergo a second surgery to complete thyroidectomy. Both the unnecessary surgeries and two-step surgical management can be avoided with more accurate preoperative diagnosis of cancer. The current American Thyroid Association's management guidelines recommend testing for mutational markers for nodules with indeterminate FNA cytology to help guide clinical management [97].

Mutational markers that have been most extensively validated and clinically used for preoperative diagnosis of thyroid cancer in FNA samples include *BRAF* and *RAS* point mutations and *RET/PTC*, *PAX8/PPARG*, and *NTRK1* rearrangements [98–101]. Finding of any of these mutations in thyroid FNA samples is a strong predictor of malignancy in thyroid nodules irrespective of the cytological diagnosis [98–100]. *BRAF* mutation has been studied most extensively, and in a meta-analysis of 22 studies of thyroid FNA samples, *BRAF* mutation correlated with malignant outcome in 99.3 % of cases [102]. The presence of a *RET/PTC* or *PAX8/PPARG* rearrangement also correlates with malignancy in close to 100 % of cases. Therefore, patients with these mutations would be candidates for total thyroidectomy irrespective of the cytologic diagnosis (Fig. 36.3). This would eliminate the need for intraoperative pathology consultation and subsequent second surgery for complete thyroidectomy, reducing costs and additional morbidity. Detection of a *RAS* mutation, which is the second most common mutation after *BRAF*, conferred a 74–87 % probability of malignancy [98, 99, 103]. Importantly, *RAS* mutations are found in tumors which are difficult to diagnose by cytology alone, i.e., follicular variant of papillary carcinoma and follicular carcinoma [104]. The remaining *RAS*-positive nodules are diagnosed as a benign follicular adenoma, which is most likely a precursor lesion for follicular carcinoma [63]. Therefore, surgical removal of follicular adenomas that carry this oncogenic mutation by lobectomy may be considered as justifiable to prevent tumor progression.

Testing for a seven-gene panel (*BRAF*, *NRAS*, *HRAS*, *KRAS*, *RET/PTC1*, *RET/PTC3*, and *PAX8/PPARG*) is particularly helpful in nodules with indeterminate cytology. In a prospective study of 1,056 consecutive thyroid FNA samples with indeterminate cytology, detection of any mutation in specific categories of indeterminate cytology, i.e., AUS/FLUS, FN/SFN, and SMC, conferred a risk of histologic malignancy in 88 %, 87 %, and 95 % of nodules, respectively [103]. The risk of cancer in mutation-negative nodules was 6 % in the AUS/FLUS group, 14 % in FN/SFN, and 28 % in SMC [103]. The clinical algorithm outlined in Fig. 36.3 recommends that any positive result in the mutational panel is an indication for total thyroidectomy in all categories of indeterminate cytology as the initial surgical approach [103]. This avoids a repeat of FNA and proceeds with optimal surgical management without delay. This clinical approach also eliminates the need for the current two-step surgery, i.e., diagnostic lobectomy followed by completion thyroidectomy for most patients with malignant nodules. In a series of 471 patients with thyroid nodules that had indeterminate cytology (AUS/FLUS or FN/SFN), patients with no access to mutation testing were 2.5-fold more likely to require a two-stage surgery [105]. A mutation-negative result of the seven-gene panel does not eliminate the risk of cancer, as expected based on its sensitivity of approximately 70 %. Therefore, diagnostic lobectomy is justified as the initial surgical intervention for mutation-negative nodules with FN/SFN and SMC cytology, whereas conservative management with ultrasound follow-up and repeat FNA can be considered for nodules with AUS/FLUS cytology (Fig. 36.3). Although larger gene panels are available, even the seven-gene panel, when applied routinely to thyroid FNA samples with indeterminate cytology, leads to an overall cost saving for patients with thyroid nodules due to the up-front offering of optimal surgical management [106].

The expansion of knowledge on driver mutations in thyroid cancer and the availability of new high-throughput tech-

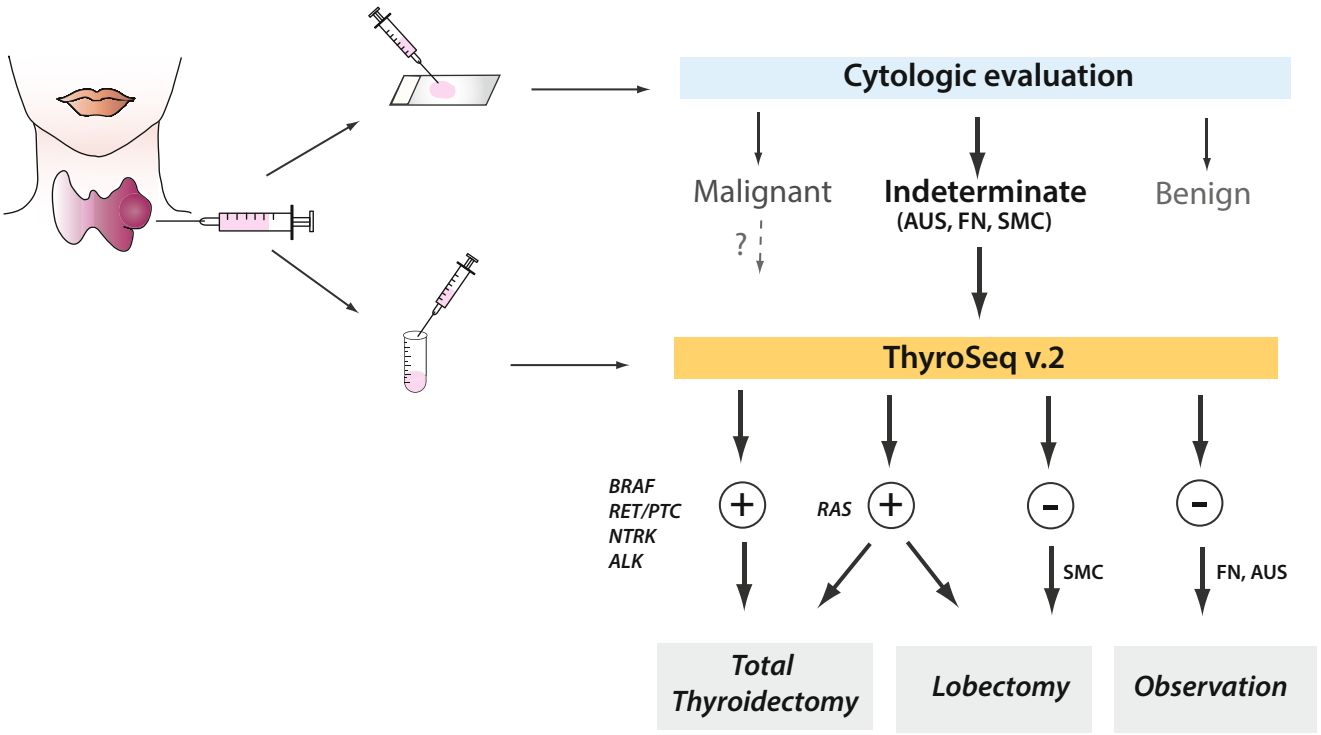

Figure 36.3 Clinical management of patients with thyroid nodules based on the combination of cytological examination and ThyroSeq v.2 mutational analysis of fine needle aspiration (FNA) samples. Molecular testing is particularly helpful for nodules with indeterminate cytology. Due to a high risk of cancer in nodules with *BRAF* mutations or *RET/PTC*, *PAX8/PPARG*, and *TRK* rearrangement, surgical treatment can proceed directly to total thyroidectomy. *RAS* mutations confer a 70–80 % risk of cancer, and these patients may benefit from either total thyroidectomy or lobectomy, depending on the additional clinical and imaging findings. Nodules without mutations found on ThyroSeq v.2 panel that have a cytologic diagnosis of follicular neoplasm/suspicious for follicular neoplasm (FN/SFN) or atypia of undetermined significance/follicular lesion of undetermined significance (AUS/FLUS) have a 4–5 % residual probability of cancer and may be followed conservatively. Nodules with suspicious for malignant cells (SMC) cytology and negative for mutations have approximately 20 % residual risk of cancer and should be managed by lobectomy.

nologies for simultaneous detection of multiple genetic mutations provided the basis for expanding gene panels for thyroid FNA samples. A 12-gene panel of selected gene regions from *AKT1*, *BRAF*, *CTNNB1*, *GNAS*, *PIK3CA*, *TP53*, *TSHR*, *PTEN*, *HRAS*, *KRAS*, *NRAS*, and *RET* (e.g., ThyroSeq [107]) utilizes next generation sequencing (NGS) to expand the original seven-gene panel and test for mutations in additional genes implicated in thyroid tumors. Detection of additional mutations together with higher sensitivity of detecting all mutations offered increased test performance. A study on 228 thyroid nodule samples including 51 FNA samples showed accurate detection of multiple mutations with a sensitivity of 3–5 % [107]. Common *BRAF* and *RAS* mutations were identified at low level in 27 tumors by NGS, which were not detected by the Sanger sequencing. This indicates that NGS-based panels not only can assess additional genes and hot spots mutations in a single test but also detect common driver mutations at a higher rate, thereby increasing the sensitivity and negative predictive value (NPV) of cancer detection in thyroid nodules [107]. Although most thyroid tumors had a single oncogenic mutation, this panel identified 2–3 mutations in each of the nine tumors, most of which presented at a higher stage, with dedifferentiation on histopathology [107]. As a result, identification of multiple mutations may be used to preoperatively identify those patients that need a significantly more aggressive treatment plan to maximize the chances for disease cure.

Commercially available NGS gene panels, such as AmpliSeq, contain many of the genes important to thyroid carcinogenesis. One study analyzed 34 indeterminate FNA samples using DNA obtained from cell blocks or from stained smears and tested them for mutations in 50 genes (AmpliSeq panel) [108]. Mutations in *BRAF*, *NRAS*, *KRAS*, and *PTEN* were detected in these samples, and the presence of a mutation in any of these genes was a strong indicator of cancer. In this study, the residual risk of cancer in nodules with indeterminate cytology and a negative molecular test result was 8 %.

Expansion of the gene panels to include additional and more recently discovered point mutations and gene fusions further increases the sensitivity and overall performance of gene tests for cancer diagnosis in thyroid nodules. An NGS gene panel that includes 56 genes and gene fusions (ThyroSeq®

v.2, UPMC/CBLPath, Rye Brook, NY) was validated with 143 thyroid nodules with FN/SFN cytology and known surgical outcome and showed both high sensitivity (90 %) and specificity (93 %) for cancer detection, with the NPV of 96 % [109]. Based on the high sensitivity and specificity, the NPV and positive predictive value (PPV) are expected to remain high in a broad range of cancer prevalence in the tested population.

Another approach to cancer detection in thyroid nodules is through the analysis of gene expression changes associated with cancer development. A commercial test, known as Afirma Thyroid FNA Analysis (Veracyte, South San Francisco, CA), utilizes the mRNA expression profiles of 142 genes to classify indeterminate thyroid nodules into a benign or suspicious category using a proprietary algorithm [110, 111]. This test was validated in a multi-institutional prospective double-blind study that included 265 nodules with indeterminate cytology [111]. The study showed high NPV in nodules with AUS/FLUS (95 %) and FN/SFN (94 %) cytology, whereas the PPV remained low (38 % for AUS/FLUS and 37 % for FN/SFN) [111]. High NPV suggests that this test is particularly helpful as a "rule-out" test, thereby helping to avoid unnecessary surgeries [112, 113].

Prognostic and Treatment Implications

Among prognostic markers, one of the best studied is the *BRAF* V600E mutation. *BRAF* V600E is associated with poor prognostic factors in papillary thyroid cancer such as extrathyroidal invasion, lymph node metastases, and tumor recurrence (reviewed in Ref. 114). In thyroid FNA specimens, preoperative testing that identifies a *BRAF* V600E mutation may be associated with disease persistence and recurrence [14], although some studies did not find such association [115–117]. A meta-analysis of multiple studies encompassing almost 2,500 patients demonstrated that a *BRAF* V600E mutation was significantly associated with tumor recurrence or persistent disease, which was found in 25 % of tumors with a *BRAF* V600E mutation compared to 13 % of *BRAF* mutation-negative tumors [118]. In addition, a large, multicenter study of 1,849 patients found the presence of the *BRAF* V600E mutation to be significantly associated with increased mortality from papillary thyroid cancer [119]. The overall mortality was 5 % in patients with a *BRAF* V600E mutation and 1 % in patients with a *BRAF* mutation-negative tumor. The results of these studies indicate that *BRAF* V600E is overall a sensitive but not specific marker of unfavorable outcome.

The presence of multiple driver mutations in thyroid cancer is associated with more aggressive tumor behavior. Coexisting mutations in the early driver genes, such as *BRAF* or *RAS*, with mutations in *PIK3CA*, *AKT1*, or *TP53* in the same tumor occur in poorly differentiated and anaplastic tumors [79, 81, 120]. More recently, an NGS-based mutation analysis demonstrated that approximately 4 % of well-differentiated papillary cancers have more than one mutation, and these tumors are aggressive and typically present with distant metastases [107].

TP53 mutation is a well-characterized genetic event governing thyroid tumor dedifferentiation and is found with high frequency in poorly differentiated and anaplastic thyroid cancer [73, 74]. However, *TP53* mutation also occurs in some well-differentiated cancers such as papillary thyroid carcinoma and oncocytic follicular carcinoma [107]. Well-differentiated cancers carrying a *TP53* mutation may have greater tumor dedifferentiation and a more aggressive clinical course.

Another prognostic molecular marker for thyroid cancer is a *TERT* mutation. The C228T and C250T mutations have a significantly higher prevalence in aggressive thyroid tumors including widely invasive oncocytic (Hürthle cell) carcinoma and anaplastic thyroid carcinoma [69–72]. In the largest study of thyroid cancer reported to date, *TERT* promoter mutations were an independent risk factor for persistent disease, distant metastases, and disease-specific mortality for well-differentiated thyroid cancer and separately for papillary carcinoma and follicular carcinoma [72]. Overall, testing for specific mutations and their combinations may provide important prognostic information and accurately identify patients who may benefit from more extensive initial thyroid surgery to prevent tumor recurrence and from more frequent monitoring of disease recurrence.

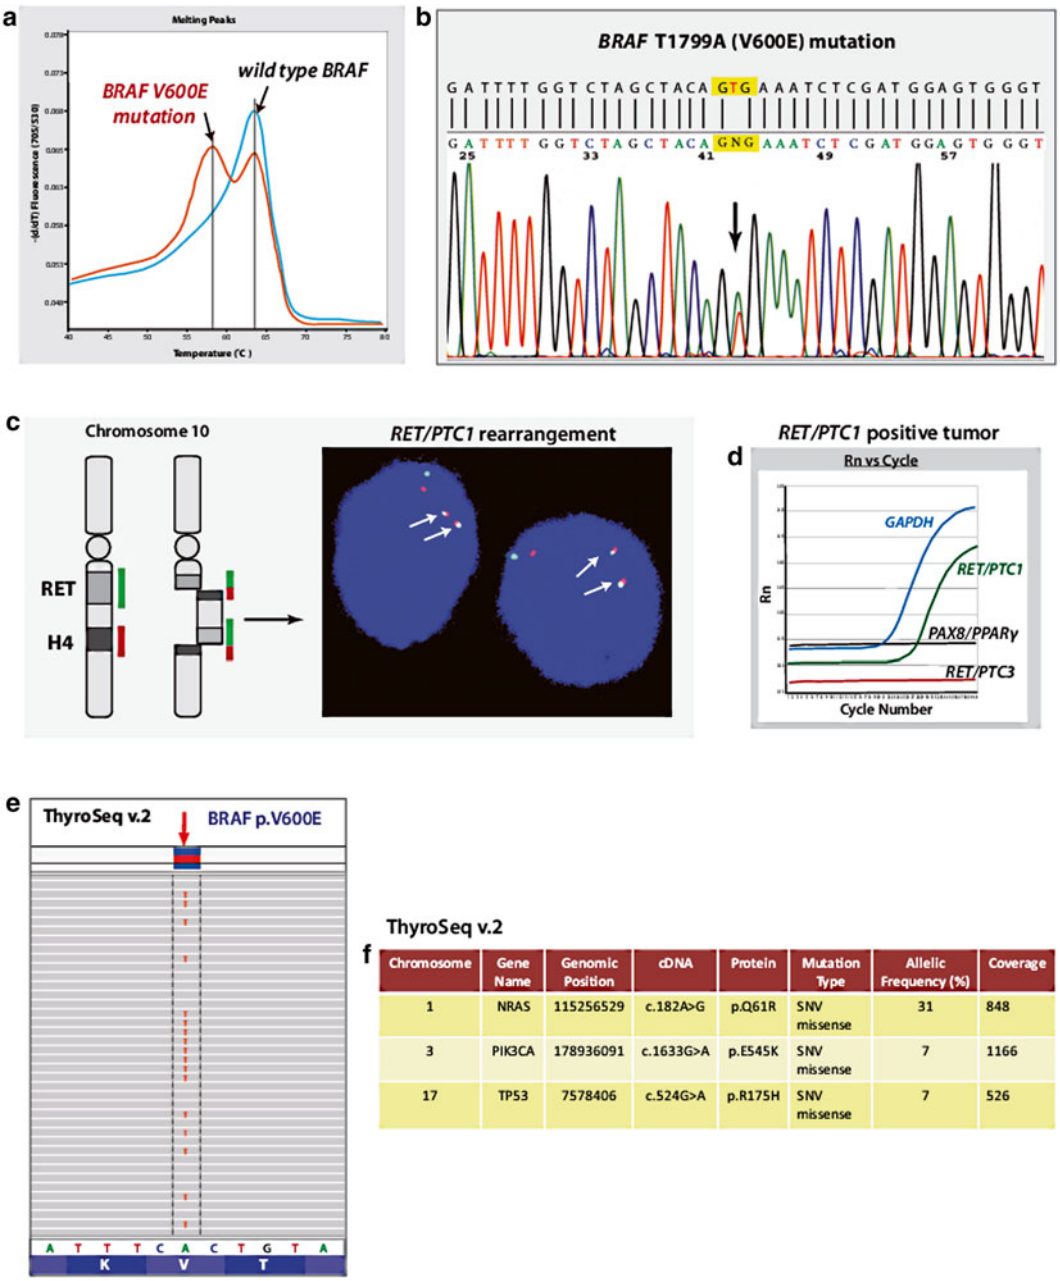
Patients with advanced thyroid cancer carrying activating mutations in the MAPK and PI3K pathways may benefit from treatment with tyrosine kinase inhibitors (sorafenib, vandetanib, axitinib, sunitinib) [121]. Also, selective inhibitors of the V600E mutant BRAF kinase (vemurafenib, PLX4032) showed promising early results in clinical trials, as well as inhibitors of ALK and NTRK kinases.

Available Assays

Testing for Mutations

For preoperative diagnosis of thyroid cancer, FNA samples can be tested for a shorter or broader panel of mutations. Those should contain most frequently occurring alterations including point mutations (*BRAF*, *HRAS*, *NRAS*, *KRAS*) and chromosomal rearrangements (*RET/PTC1*, *RET/PTC3*, *PAX8/PPARG*).

Detection of point mutations can be performed using many different methods, including Sanger sequencing, real-time PCR, pyrosequencing, allele-specific PCR, snapshot array, or restriction fragment polymorphism analysis



Chromosome	Gene Name	Genomic Position	cDNA	Protein	Mutation Type	Allelic Frequency (%)	Coverage
1	NRAS	115256529	c.182A>G	p.Q61R	SNV missense	31	848
3	PIK3CA	178936091	c.1633G>A	p.E545K	SNV missense	7	1166
17	TP53	7578406	c.524G>A	p.R175H	SNV missense	7	526

Figure 36.4 Laboratory techniques for detection of mutations in thyroid cancer. (**a**) Real-time PCR with post-PCR fluorescence melting curve analysis showing two melting peaks, one corresponding to a wild-type allele and the other to a mutant *BRAF* c.T1799A (p.V600E) allele. (**b**) Sanger sequencing detection of a *BRAF* c.T1799A (p.V600E) mutation, with vertical arrow indicating the heterozygous T and A nucleotides of the heterozygous wild-type and V600E alleles. (**c**) FISH detection of *RET/PTC1* rearrangement (arrows) using the fusion probe design. (**d**) Real-time RT-PCR analysis showing *RET/PTC1* rearrangement and no *RET/PTC3* and *PAX8/PPARG* rearrangements. (**e**) Detection of *BRAF* c.T1799A (p.V600E) mutation using targeted next generation sequencing gene panel. (**f**) Results of testing of a thyroid FNA sample using a 56-gene mutation panel showing the presence of three mutations involving the *NRAS*, *PIK3CA*, and *TP53* genes, which indicates a high risk of cancer in this nodule and suggests that the cancer may be prone to dedifferentiation and more aggressive biological behavior

(Fig. 36.4a, b) [19, 31, 122–126]. Other methods can be used for more sensitive detection of point mutations, e.g., coamplification at lower denaturation polymerase chain reaction (COLD-PCR), locked nucleic acids (LNA)-PCR, and others [103, 127]. In one study, detection of *BRAF* mutations was compared using probe-specific real-time PCR, real-time allele-specific PCR, direct sequencing, and a colorimetric assay and showed similar sensitivity in *BRAF* detection in archival FNA samples [125].

Real-time PCR methods are rapid, easy to perform, cost-efficient, and run in a closed PCR system that reduces the risk of PCR amplicon contamination. Real-time PCR followed by

fluorescence melting curve analysis is frequently used for detection of *BRAF* and *RAS* mutations [63, 128]. Two probes complementary to wild-type sequences are designed to span the mutation site for each mutational hot spot, including codons 12, 13, and 61 of the *RAS* genes and codons 600 and 601 of the *BRAF* gene. If no mutation is present, probes will bind perfectly to the sample DNA and melt at a higher temperature, showing a single peak on post-PCR melting curve analysis (Fig. 36.4a). In contrast, if a heterozygous mutation is present, probes will bind to mutant DNA imperfectly, i.e., with one nucleotide mismatch, and will melt (dissociate) earlier, producing two melting peaks (Fig. 36.4a). Each nucleotide substitution produces a melting peak at a specific melting temperature (T_m). This method detects all possible mutation variants at the interrogated hot spot using a minimal amount of DNA.

The two most common approaches for detection of chromosomal rearrangements (*RET/PTC*, *PAX8/PPARG*, and *TRK*) are reverse transcription PCR (RT-PCR) and fluorescent in situ hybridization (FISH). RT-PCR is a reliable and sensitive technique for detection of fusion transcripts in fresh FNA samples and frozen tissue specimens. Assays frequently use real-time RT-PCR with fluorescently labeled probes, which increase the specificity of transcript detection and allow quantification of the amplified product (Fig. 36.4c) [98]. Amplification of a housekeeping gene in each RT-PCR reaction monitors RNA quality and quantity. When RT-PCR is used for detection of rearrangements from formalin-fixed paraffin-embedded (FFPE) tissue samples, amplification of short PCR products can overcome poor-quality RNA and avoid false-negative results.

Highly sensitivity techniques (such as nested PCR amplification or blotting of PCR products with specific probes) are not optimal for detection of rearrangements due to an increased risk of false-positive results due to RT-PCR contamination or amplification of nonspecific sequences and require rigorous use of negative controls. In addition, ultrasensitive techniques may result in the detection of rearrangements that are present in a small fraction of the tumor. This is particularly problematic for the detection of the *RET/PTC* rearrangement, which can vary from involving almost all neoplastic cells (clonal *RET/PTC*) to involving only a small fraction of tumor cells (non-clonal *RET/PTC*) [53, 54]. Since only clonal *RET/PTC* rearrangement is specific for papillary carcinoma [45, 53], the sensitivity of detection will not be greater than 1 % of tumor cells (i.e., detection of 1 % or more tumors cells in the background of normal cells) to avoid detecting non-clonal rearrangements, which have no clinical implications at this time.

For detection of gene rearrangements in FFPE samples, where RNA is degraded, FISH is a reliable method (Fig. 36.4d). FISH utilizes fluorescently labeled DNA probes for targeted detection of gene rearrangements in interphase or metaphase nuclei. The FISH probes are relatively large in size, ranging from 20 to 200 kb. Currently, probes for detection of *RET/PTC* or *PAX8/PPARG* rearrangements are not commercially available, but bacterial artificial chromosomes clones are available [53, 54, 60]. Several positive and negative controls are required to validate the scoring criteria for accurate FISH results. For *RET/PTC* rearrangement, the cutoff level for positive test results is 7–30 % positive cells, depending on the probe design [53, 129].

Introduction of NGS technology has enabled high-throughput detection of multiple genetic alterations in both constitutional and cancer genomes. NGS has clear advantages over conventional sequencing techniques, such as Sanger sequencing, by allowing sequencing of large regions of the genome at lower cost and with higher sensitivity. NGS can be used to sequence the genome, exome, transcriptome (mRNA), and targeted multigene panels. While genome or exome analyses are essential for discovery projects, targeted gene panels are advancing into routine clinical testing of thyroid cancer. Targeted NGS gene panels include testing for common mutations in thyroid cancer and for multiple genetic alterations known to occur in thyroid cancer with low prevalence, such as mutations in the *PIK3CA*, *AKT1*, *PTEN*, and *TP53* genes [102, 108] and chromosomal rearrangements of the *BRAF*, *ALK*, and *NTRK* genes. An NGS-based panel that includes 56 genes and gene fusions (ThyroSeq v.2) has been recently validated for preoperative diagnosis of thyroid nodules [109]. Commercially available targeted NGS gene panels that offer sequencing for mutations in cancer-related genes or custom NGS thyroid panels can be used.

Testing for Gene Expression and miRNA Expression

In addition to gene mutations, changes in mRNA and miRNA expression have been explored for diagnostic use in thyroid samples. Search for a limited number of differentially expressed genes that can be used diagnostically appears to be promising. Upregulation of the *HMGA2* gene in malignant thyroid tumors has been found in several studies and may be of diagnostic utility for thyroid nodule FNA samples [130, 131]. Aberrant expression of *MET*, *TPO*, *TIMP1*, *DPP*, and other genes was observed in several studies and explored for diagnostic use [83–85, 131, 132]. At least one company is exploring the use of gene expression profiling of thyroid FNA samples as a tool for determining the benign or malignant potential of thyroid nodules [110]. The possibility of applying a combination of cytological evaluation, mutational analysis, and gene expression markers to improve the FNA diagnosis of thyroid nodules may improve clinical care for these patients.

The diagnostic utility of miRNA expression in thyroid FNA samples has been also explored [88, 92, 133, 134]. In one study, preoperative assessment of several miRNAs (miR-221, miR-222, miR-146b, miR-224, miR-155, miR-197,

miR-187) in thyroid nodule FNA samples demonstrated that upregulation of three or more of these miRNAs can predict papillary or follicular thyroid cancer with 98 % accuracy [92]. This demonstrates the feasibility of miRNA detection in thyroid FNA samples and provides initial evidence for its possible diagnostic use pending further validation.

Laboratory Issues

Collection of FNA Sample

Freshly collected and fixed FNA and resection specimens can be used for clinical molecular testing. Collection of fresh FNA samples during routine FNA procedures is simple, does not prolong the FNA procedure, and yields DNA and RNA of excellent quality. Typically, the FNA procedure is conducted under ultrasound guidance to ensure sampling of the nodule, with thyroid cells collected using a 23, 25, or 27 gauge needle and sent for cytological evaluation. In most cases, 3–4 FNA needle passes are performed. To collect a sample for molecular testing during an FNA procedure, either one entire pass is taken for molecular testing or most of the aspirated sample from the first two passes (the most representative sample) is used for direct cytology smears for cytological evaluation, with the residual material in the needle and the needle wash from both passes placed into a tube containing nucleic acid preservative solution, e.g., RNAlater (Qiagen) or Trizol (Invitrogen) (Fig. 36.3). The latter approach allows successful sampling of the nodule in 90–98 % of cases [98, 103]. After collection, the FNA specimen for molecular testing can be stored at −20 or −80 °C until molecular testing is performed. If collection of fresh FNA material is not possible, fixed cytology FNA material, i.e., stained cytology smear or cytology cell block, can be used for molecular testing. Use of a fixed specimen provides reliable detection of point mutations but is not ideal for detection of chromosomal rearrangements due to the suboptimal quality of the RNA.

Quality Assurance

The quantity and quality of nucleic acids isolated from FNA specimens can be assessed either by spectrophotometric measurements or by PCR amplification. Real-time PCR can be used to assess the quantity and quality of nucleic acids in a simple and cost-efficient way via evaluating PCR amplification of the *RAS* or *BRAF* genes for DNA and amplification of the *GAPDH* housekeeping gene for RNA.

Fresh FNA samples should be evaluated for sample adequacy prior to molecular testing to assess the proportion of thyroid epithelial cells and tumor cells within the sample. Thyroid FNA samples may contain a number of "contaminant" cells, i.e., lymphocytes, other white blood cells, and stromal cells. An abundance of these non-epithelial cells may decrease sensitivity of detection and lead to a false-negative result. Assessment of the proportion of thyroid epithelial cells within an FNA sample can be performed by comparing the expression of the universal housekeeping gene (i.e., *GAPDH*), which is uniformly expressed in all cell types, with the expression of a gene that is expressed only in thyroid cells or in several types of epithelial cells including thyroid cells, such as the thyroid peroxidase (*TPO*) gene, the thyroglobulin (*TG*) gene, and cytokeratin genes (*KRT7* and *KRT19*) [103, 135].

For assurance of quality of molecular testing, a set of positive and negative controls at different levels of allelic frequencies has to be used during each analytical run. Some controls are available through the commercial sources, e.g., Horizon Diagnostics (Cambridge, UK). In addition, the College of American Pathologists offers proficiency testing for several of the most commonly mutated genes in thyroid cancer, including *BRAF* and *KRAS*.

Conclusions

Our understanding of the molecular changes in thyroid cancers is improving the clinical management of patients with thyroid nodules. Molecular testing can enhance the accuracy of cancer diagnosis in thyroid nodules, cancer prognosis, and will likely be important for selection of targeted therapies for thyroid cancer. The most significant impact of molecular testing is the improved diagnosis of cancer in nodules with indeterminate cytology results. Research discoveries using NGS technologies will lead to identification of novel mutations and other genetic and epigenetic events in thyroid cancer with the potential for further improvement in the care of patients with thyroid cancer.

Sarcomas and Related Mesenchymal Tumors

37

Giovanni Tallini, Dario de Biase, and Pei Hui

Abstract

Understanding the molecular pathology of sarcomas and related mesenchymal lesions is often essential for their diagnosis. Cytogenetics and molecular cytogenetics have contributed significantly to the identification of recurrent chromosomal changes, fostering a continual refinement in the classification of these tumors. The recognition of distinctive rearrangements in tumor subsets is providing powerful tools to a field in which pathological diagnosis and clinical management are often difficult, due to both the variety of tumor phenotypes and their relative rarity. Novel technical approaches, including next-generation sequencing, are increasing the speed and throughput of molecular analysis and the application of genomic knowledge into clinical practice may radically change the management of patients with sarcomas.

Keywords

Sarcoma • Soft tissue tumor • Mesenchymal lesion • Chromosomal translocation • Chromosomal amplification • Gene rearrangement • Fusion transcript • Gene mutation • Oncogene • Real-time PCR • Reverse transcription-PCR • Next-generation sequencing • FISH • Karyotyping

Introduction

Oncologic molecular pathology focuses on identifying and understanding molecular and genetic alterations underlying the development and progression of neoplastic processes. Sarcomas and related tumors may be classified into two main pathogenetic types: sarcomas with complex genetic alterations and sarcomas with specific recurrent chromosomal translocations. The type with complex genetic alterations includes the majority of high-grade, pleomorphic mesenchymal malignancies, for example, undifferentiated pleomorphic sarcoma (malignant fibrous histiocytoma), osteogenic sarcoma, and leiomyosarcoma. In the second type, that accounts for approximately 20 % of the cases, tumors are translocation specific, with a recurrent chromosomal translocation leading to an in-frame fusion of coding sequences from each of the two rearranged genes [1]. The translocation typically results in the production of a chimeric transcript encoding a fusion protein with oncogenic activity. Histologically, the translocation-specific sarcomas are generally a monomorphic proliferation of neoplastic cells. This two-category pathogenetic classification of sarcomas is biologically relevant and is best illustrated by the sarcoma types observed in Li–Fraumeni syndrome. Li–Fraumeni patients, with a *TP53* germline mutation, are prone to sarcomas with complex karyotypes, such as osteogenic sarcoma and undifferentiated pleomorphic sarcoma, which constitute major mesenchymal cancers. On the other hand, translocation-specific sarcomas virtually never occur in Li–Fraumeni patients [2]. Other mesenchymal tumors that do not fall into these main pathogenic groups are

characterized by amplification of specific chromosomal regions or specific mutations.

Tremendous progress has been made in characterizing the molecular alterations of sarcomas. The identification of tumor-specific molecular changes has not only reshaped their classification, but in many instances is having an impact on patient therapy and prognosis. Chromosomal translocations and associated fusion genes can be so specific and occur in such a high prevalence in a given sarcoma type that they are essentially used to define the neoplasm at both the pathobiological and clinical diagnostic levels and are therefore the main focus of this chapter [3–7].

Molecular Basis of Disease

Chromosomal Translocations and Gene Rearrangements

Chromosomal rearrangements (translocations, inversions, deletions, and insertions) are associated with DNA recombination of the genes located at the DNA breakpoints. If the breakpoint occurs within the involved gene, an altered gene structure arises. If the breakpoint occurs outside the gene, it may involve control elements critical for gene expression. In either case, the result can be a dramatic change in the gene structure, expression levels, or both. Molecular analysis has identified two general mechanisms through which chromosomal translocations result in altered gene function (Fig. 37.1).

The first mechanism by which chromosomal translocations result in altered gene function is by gene fusion (Fig. 37.1), in which chimeric or fusion genes are the result of joining of two parent genes (one upstream, or 5′, and the other downstream, or 3′, to the breakpoint). Both genes are truncated by the translocation involving the coding portions of the parent genes. In general, translocation breakpoints are located in noncoding introns, and the normal splicing mechanism removes the chimeric intron sequence. The exons are spliced "in frame" for the translational reading frame and can be translated into a novel fusion protein. In rare instances, the breakpoints are located in the exons of the parent genes. This may result in a novel chimeric product if the translational reading frame is maintained, or it may produce a truncated protein (encoded by the 5′ gene sequence) if the reading frame is lost. Transcription of chimeric genes is usually under the control of the upstream parent gene promoter but may be influenced by DNA sequences in or close to the downstream gene.

The second mechanism through which chromosomal translocations result in altered gene function is promoter exchange, in which the breakpoint occurs at the 5′ end of the coding region of the involved gene (Fig. 37.1). This results in the replacement of the gene's promoter region with enhancer elements or with the promoter from the translocation partner. Promoter exchange leads to transcriptional activation with abnormal gene expression, but the protein is wild-type.

Numerous fusion genes have been identified in malignant tumors of the soft tissues and in mesenchymal tumors in general (Table 37.1). The majority of sarcoma translocations

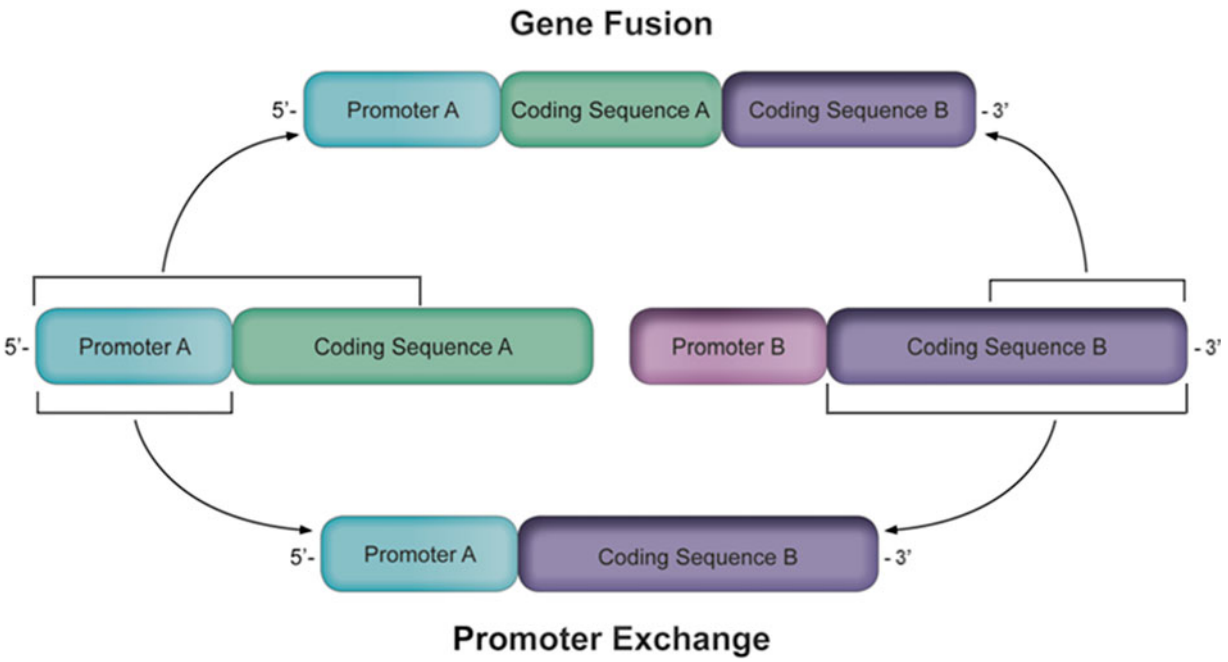

Figure 37.1 Mechanisms of chromosomal DNA rearrangement leading to altered gene expression by either gene fusion (*top pathway*) or promoter exchange (*bottom pathway*)

TKR tyrosine kinase receptor

[a]The overall proportion of inflammatory myofibroblastic tumors with *ALK* gene rearrangement is 35 %

[b]Percentages indicate the proportion of tumors with abnormal karyotypes which have 12q13–15 or 6p21 chromosomal alterations. (*Sources*: Heim S & Mitelman F: Cancer Cytogenetics, 3rd Ed., Wiley-Blackwell, New York, 2009; Mitelman Database of Chromosome Aberrations and Gene Fusions in Cancer (2012). Mitelman F, Johansson B and Mertens F (Eds.), http://cgap.nci.nih.gov/Chromosomes/Mitelman; Fletcher CD,Akerman M, Dal Cin P, et al. Correlation between clinicopathological features and karyotype in lipomatous tumors. A report of 178 cases from the Chromosomes and Morphology (CHAMP) Collaborative Study Group. Am J Pathol. 1996;148:623–630)

[c]Loss of *INI1* expression by immunohistochemistry occurs in malignant rhabdoid tumors (renal, soft tissue, central nervous system-atypical teratoid/rhabdoid tumor of the CNS), epithelioid sarcoma, and in a variety of other tumors, often with "rhabdoid" features, including renal medullary carcinoma, myoepithelial carcinoma, extraskeletal myxoid chondrosarcoma, and epithelioid malignant peripheral nerve sheath tumors. The link between INI1 expression loss and genomic alterations is strong only in the case of malignant rhabdoid tumors; in the other tumors, the link is not clear, where epigenetic silencing or other mechanisms are a likely cause of *INI1* loss of expression

[d]*EWSR1* rearrangement without an identified fusion partner has been reported by FISH in a significant proportion of myoepithelial tumors of soft tissue and bone (approximately 30 % of cases)

[e]Exostosin 1 (*EXT1*, at 8q24) or exostosin 2 (*EXT2*, at 11p11–13) gene inactivation causes the multiple osteochondroma (MO) syndrome (previously known as hereditary multiple exostoses, inherited as an autosomal dominant trait) in 65 % and 35 % of cases, respectively. The percentage in the table refers to non-syndromic cases

result in in-frame fusion genes, resulting in abnormal chimeric transcription factors [4]. In a few cases, the gene fusion results in an aberrant tyrosine kinase or an autocrine growth factor [8–10]. The der(17) associated with the nonreciprocal t(X;17)(p11.2;q25) of human alveolar soft part sarcoma produces a chimeric transcript between the transcription factor gene *TFE3* and *ASPL*, a novel gene at 17q25 [11]. *ASPL* encodes a UBX-like domain at the C-terminus of the encoded protein. In alveolar soft part sarcoma, the 5′ end of *ASPL* is fused to exon 3 or 4 of *TFE3*, resulting in a fusion protein retaining the C-terminal TFE3 DNA-binding domain, a possible aberrant transcriptional regulator.

A recurrent t(7;17)(p15;q21) has been identified in endometrial stromal tumors [12]. Two new zinc finger genes are fused as a result of the translocation: *JAZF1* and *JJAZ1*. Protein products of the zinc finger genes usually function as transcriptional regulators via specific DNA binding through the zinc finger motif. The chimeric protein in endometrial stromal tumors has a tumor-specific mRNA transcript containing 5′ *JAZF1* and 3′ *JJAZ1* sequences including the zinc finger encoding regions from both parent genes. Since gene expression of wild-type *JAZF1* is present in normal endometrial stromal cells, the *JAZF1–JJAZ1* fusion gene present in endometrial stromal tumors likely results in aberrant transcriptional regulation in a lineage-specific manner.

Oncogenic Nature of Fusion Transcripts

Sarcomas theoretically develop from mesenchymal stem cells that are present in all compartments of the body. Unlike many epithelial neoplasms, where diverse genetic alterations usually underlie the stepwise progression of precursor lesions leading ultimately to the emergence of malignant clones, soft tissue malignancies have no identifiable precursor lesions and usually have a single genetic alteration typical of a particular type of sarcoma. In addition, chromosomal fusions in soft tissue sarcomas do not seem to represent a form of generalized genomic instability, as occurs with germline *TP53* mutations [6] or with microsatellite instability associated with colon carcinoma [13]. Benign tumor counterparts of soft tissue sarcomas usually carry quite different genetic or chromosomal abnormalities or both. For example, the specific sets of chromosomal alterations found in soft tissue lipomas are not among those consistently observed in liposarcoma [14, 15]. Similar to leukemogenesis and lymphomagenesis, the fusion gene in a given sarcoma is speculated to be oncogenic only in a specific cell type at a specific differentiation stage [16] and explains why in some instances the same fusion transcripts can be identified in unrelated tumors. For instance, *FUS–ERG* is present in both Ewing's sarcoma (ES)/peripheral neuroectodermal tumor (PNET) and acute myeloid leukemia, while *EWSR1–CREB1* is present in both angiomatoid fibrous histiocytoma and clear cell sarcoma, two soft tissue tumors that are clearly distinct both histologically and clinically [17]. In general, the genes involved in sarcoma translocations are transcription factors or cofactors. Many of the chimeric proteins include a strong transcriptional activator N-terminal domain encoded by one partner gene fused with a DNA-binding domain encoded by the other partner gene. In fact, fusion of domains capable of activating transcription with other domains featuring specific DNA-binding function appears to be a common theme shared among neoplasms of mesenchymal derivation, such as soft tissue tumors and leukemia. EWSR1 (and its homologous FUS) is a powerful transcription activator [18] and provides a paradigm for this type of oncogenic mechanism, as also indicated by its "promiscuity" as a fusion partner (Table 37.1).

Available data indicate that the fusion genes produced in translocation-specific sarcomas are the initiating oncogenic events, although additional alterations are important for the genesis of the malignant tumor. The fact that fusion genes are early events is supported by the observation that in biphasic tumors like synovial sarcoma, *SS18–SSX* is present in both spindle cell and epithelial components of the tumor. In vitro and in vivo experiments have shown evidence of tumorigenesis with the expression of these fusion genes. The most common chromosomal translocation in myxoid liposarcomas, t(12;16)(q13;p11), creates a *FUS–DDIT3* (*TLS–CHOP*) fusion gene. Transgenic mice expressing the altered form of FUS–DDIT3 created by an in-frame fusion of the FUS domain to the carboxy end of DDIT3 develop liposarcomas. No tumors of other tissues were found in these transgenic mice despite widespread activity of the transgene. The results provided evidence that the FUS domain of *FUS–DDIT3* plays a specific and critical role in the pathogenesis of liposarcoma [19]. Alveolar rhabdomyosarcoma (ARMS) is consistently associated with the characteristic translocations t(2;13)(q35;q14) or t(1;13)(p36;q14), which encode the PAX3–FOXO1 (PAX3–FKHR) or PAX7–FOXO1 (PAX7–FKHR) fusion oncoproteins, respectively. PAX3–FOXO1 fusion protein contributes to oncogenesis through abnormal control of growth, apoptosis, differentiation, or cell migration [20].

Specific Amplification of Chromosomal Regions

Amplification of specific chromosomal regions may lead to the occurrence of ring or giant marker chromosomes in the context of a simple karyotype. Chromosomal region amplifications occur in atypical lipomatous tumors/well-differentiated liposarcoma and in low-grade osteosarcoma, including both low-grade central osteosarcoma and parosteal osteosarcoma [21, 22]. In both instances the amplified chromosomal region

Table 37.2 Specific oncogenic mutations in sarcomas and related tumors

is 12q13–15 where several genes with a role for tumor development are located, including *MDM2*, *CDK4*, *HMGA2*, *GLI*, and *SAS* [22–25]. *MDM2*, encoding a negative regulator of TP53, and *CDK4*, encoding a catalytic subunit of the protein kinase complex that promotes cell cycle progression, are the most consistently amplified genes [24, 25]. *HMGA2*, encoding a transcription cofactor, is often amplified and rearranged in atypical lipomatous tumors [25, 26].

Mutations

Specific and characteristic oncogenic mutations occur in mesenchymal tumors (Table 37.2). Gastrointestinal stromal tumors (GIST) are characterized by specific, mutually exclusive oncogenic mutations that affect primarily the receptor tyrosine kinase KIT or platelet-derived growth factor receptor-α (PDGFRA), in approximately 80 % and 5–10 %

of cases, respectively. In the remaining 10–15 % of GIST cases, mutations of other oncogenes, notably *BRAF*, have been identified [27]. The oncogenic role of *KIT* or *PDGFRA* mutations has been confirmed by numerous studies, and transgenic mice expressing mutated *KIT* develop stromal tumors with features of human GIST [28]. Mutations in GIST are in general heterozygous, but in 15 % of cases, the wild-type *KIT* allele is lost, an occurrence that has been associated with more aggressive behavior of the tumor [29]. GIST are mesenchymal neoplasms, thought to derive from the interstitial cells of Cajal, the pacemakers for peristaltic contractions in the gastrointestinal tract. Like their putative cell of origin, tumor cells express the KIT (CD117) protein that is detectable by immunohistochemistry in 95 % of cases, regardless of the presence of a mutation. Strictly speaking, GIST are gastrointestinal tumors, but because of their biologic and clinical features, they are included with other soft tissue sarcomas in the National Comprehensive Cancer Network guidelines [30]. GIST are relatively uncommon, but are very effectively treated with the tyrosine kinase inhibitor imatinib (STI571, Gleevec), developed to block the BCR-ABL tyrosine kinase of chronic myelogenous leukemia. Mutational analysis for *KIT* and *PDGFRA* genes is thus essential not only to define the diagnosis of GIST and to guide therapy [27, 31]; thus, mutation testing is included in the College of American Pathologists' protocol for GIST [32]. Correlation between genotype and phenotype is remarkable. *KIT* exon 11 mutations are associated with poor prognosis in untreated GIST [33]. Among exon 11 alterations, deletions, especially those involving codon 557 and/or codon 558, are a marker for poor outcome, when compared with other changes [34]. In contrast, GIST with mutations in *PDGFRA* generally have lower malignant potential, usually a gastric location, and variable, sometimes negative, immunohistochemical KIT expression [27]. Secondary resistance to imatinib treatment, which eventually develops in the large majority of patients, is usually caused by new mutations, which are almost always in the same gene and allele as the primary *KIT* or *PDGFRA* mutation. Unlike primary *KIT* mutations that predominate in exons 11 and 9, secondary mutations develop in specific regions of the KIT kinase domain that is the target of imatinib.

Mutations that prevent β-catenin degradation and activate Wnt signaling occur in a high proportion of desmoid tumors, including sporadic cases, not associated with the familial adenomatous polyposis syndrome [35]. Activating mutations of the *GNAS1* gene, encoding the stimulatory G protein α subunit (Gs-α) that couples receptor binding by several hormones to activation of the adenylate cyclase pathway, are present in most cases of fibrous dysplasia of bone and intramuscular myxoma [36, 37]. Inactivating *INI1* mutations are present in approximately 50 % of malignant rhabdoid tumors, a group of rare and highly aggressive cancers composed of large polygonal cells similar to rhabdomyoblasts. Like rhabdomyoblasts, rhabdoid tumor cells have vesicular nuclei with prominent nucleoli and aggregates of intermediate filaments resulting in intracytoplasmic eosinophilic inclusions. These tumors typically affect children and arise in the kidney, in soft tissue, or intracranially. Intracranial rhabdoid tumors are called atypical teratoid/rhabdoid tumor of the central nervous system. *INI1* encodes one subunit of an ATP-dependent chromatin remodeling complex that functions as a tumor suppressor, and biallelic inactivation through a combination of mutations, deletions, and loss of heterozygosity has been shown in more than 90 % of rhabdoid tumor cases [38].

Available Assays and Interpretation

A significant number of sarcomas have consistent abnormalities that are detectable by standard cytogenetics or molecular genetic approaches (Fig. 37.2) [4, 6, 7, 39]. Sarcomas in this group should be defined by their specific molecular and cytogenetic alterations, although determining the sensitivity and specificity of these translocations for specific sarcoma types and the relative roles of molecular and histological classification of each sarcoma will continue to be refined.

Karyotyping

Karyotyping is the classic cytogenetic approach for identifying chromosomal alterations including translocations in sarcomas [40]. Optimally, the procedure requires a substantial volume of viable, sterile tumor tissue, usually 1–2 cm^3. The specimen should be harvested, placed in culture medium as soon as possible, and transported to the laboratory. Specimens can be transported over a long distance at either room temperature or refrigerated for up to 48 h. Small samples (limited incisional or needle biopsies) can be successfully cultured and karyotyped, although they may require a longer incubation time (1–2 weeks) to obtain enough dividing tumor cells for analysis. Characteristic and diagnostic chromosomal alterations seen in human soft tissue tumors are listed in Table 37.1.

The major advantage of karyotyping over molecular genetic methods is the global assessment of the chromosome complement in a tumor cell in one assay, including both numerical and structural alterations. Moreover, primary and secondary chromosome alterations can be studied, and sarcoma translocations involving variant partner chromosome(s) can be easily identified. An obvious drawback of conventional cytogenetic analysis is the requirement of adequate tumor cell growth to obtain metaphase spreads. If tumor cells do not grow, a false-negative result of a normal karyotype

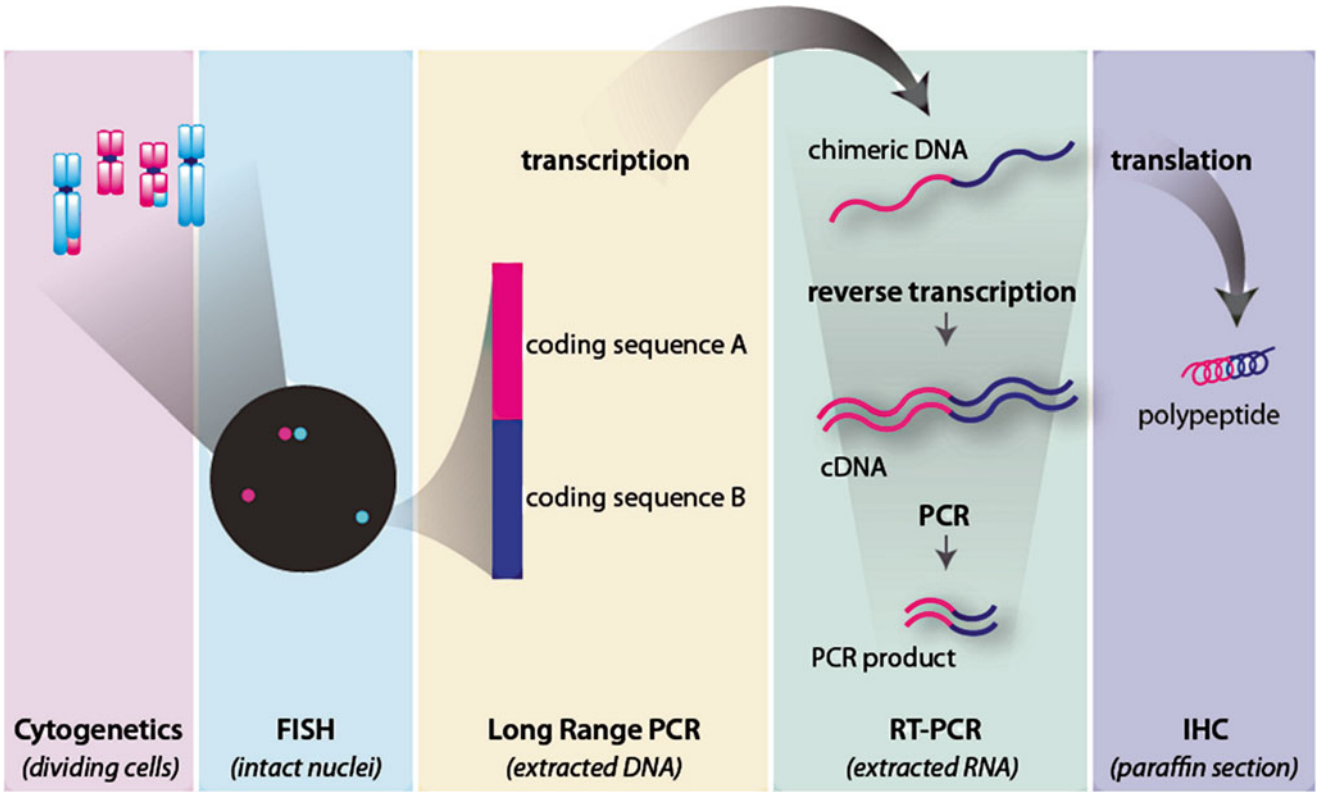

Figure 37.2 Methods to identify chromosomal translocation and fusion gene products (modified from Mertens et al. Semin Oncol 2009;36:312–323)

may occur due to the presence of normal fibroblasts in the specimen. Another pitfall of karyotyping is its limited resolution for identification of cryptic alterations, which may occur in sarcomas. Complex chromosomal changes also can make identification of sarcoma-specific translocations difficult. Furthermore, translocations involving specific chromosomal regions may not necessarily represent the characteristic gene fusion for a specific sarcoma. Confirmation by fluorescence in situ hybridization (FISH) or molecular testing, therefore, is recommended for questionable cases or to reach a definitive diagnosis.

Fluorescence In Situ Hybridization

FISH provides a powerful diagnostic method for demonstrating a specific gene fusion or chromosomal alteration. Metaphase chromosomal preparation from the tumor can be used to identify translocations by chromosomal painting using chromosome-specific probes or gene-specific probes. However, this is not always possible since cell culture of sarcoma tissue to obtain metaphase chromosomes may be unsuccessful. In these cases, interphase FISH provides an excellent alternative using touch preparations from fresh or frozen tumor specimens without the requirement for tissue culture. One major advantage of interphase FISH over traditional karyotyping is the ability to detect cryptic gene rearrangements. In fact, the chromosomes of interphase nuclei are much more extended than metaphase or prometaphase chromosomes. As a result, FISH analysis performed on interphase nuclei permits higher resolution and can help to determine the physical mapping order of large DNA probes. Dual-color DNA probes from the two rearranged genes (fusion probe) or breakpoint-flanking regions of one involved gene (break-apart probe) are most commonly used to assess sarcomas for the presence of a specific translocation (Fig. 37.3). Chromosomal centromeric probes and DNA probes spanning the translocation breakpoint also can be used. The interpretation of the FISH result depends on the types of hybridization probes.

The possibility of performing interphase FISH on formalin-fixed paraffin-embedded (FFPE) tissue, either on histology sections or on preparations of cell nuclei obtained from paraffin blocks, has recently increased its potential diagnostic applications [41, 42]. For interphase FISH of FFPE specimens, analysis of a nuclear preparation is superior to analysis of histological sections, although more labor intensive and seldom used in clinical practice. The most prevalent method for FISH detection of specific translocation in a sarcoma is the use of thin tissue sections of 4–5 μm

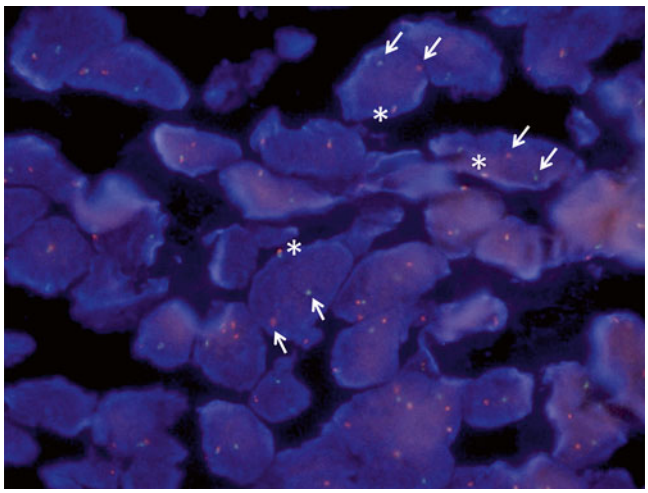

Figure 37.3 Interphase FISH detection of gene fusion in soft tissue sarcoma. Breakpoint-flanking probes of *SS18* (*SYT*), one red and one green, are hybridized to 4–5 μm thick sections from a formalin-fixed paraffin-embedded synovial sarcoma sample processed for routine histopathology. The juxtaposed *red* and *green* signals, which can appear *yellow* in some nuclei, represent undisturbed normal signal (*asterisks*). The translocation involving the *SS18* gene due to fusion with one of the *SSX* genes results in splitting the fused signal (juxtaposed *green* and *red*) into randomly disturbed single *red* and *green dots* (*arrows*)

thick. FISH detection of the specific translocation using the break-apart probes is most frequently used for the diagnosis of translocation-specific sarcomas (Fig. 37.3). Although dual-color fusion probe FISH can be used for the diagnosis of translocation-specific sarcomas, interpretation is not as easy as for break-apart probe FISH because of the presence of the truncation or overlap of tumor nuclei in a tissue section.

Other cytogenetic approaches like spectral karyotyping and comparative genomic hybridization (CGH), including conventional metaphase-based and array-based CGH, are suitable for genomic-wide analysis for detection of deletion, duplication, and copy-number changes. Although these methods may be diagnostically useful for the detection of specific regional chromosomal deletions, for example, the regional chromosomal loss of 22p11 in malignant rhabdoid tumor, they do not usually allow easy evaluation of balanced chromosomal translocations in sarcomas or other tumors.

Southern Blot

Southern blot analysis detects sarcoma-specific translocations using labeled DNA probes specific to the fusion genes. The procedure is highly specific and particularly useful in detecting translocations with frequently variable translocation breakpoints, as for ES/PNET. The main limitations of the Southern blot method are the labor intensiveness of the procedure and the requirement for fresh or frozen tissue to obtain high-molecular-weight genomic DNA. False-negative results may arise when DNA fragments surpass the upper limits of DNA length resolution (>15–20 kilobases [kb]) or with fusion genes encompassing large intron(s). Increasing the number of restriction enzymes to create shorter DNA fragments usually resolves this problem. False-positive results may be seen due to incomplete restriction enzyme digestion, contamination by a cloning vector or bacteria, structural polymorphism of the genes involved in the translocation, and restriction recognition site polymorphisms or variants.

Polymerase Chain Reaction

Polymerase chain reaction (PCR) amplification of the region encompassing the breakpoint of a fusion gene is often problematic. First, the breakpoint positions within the introns of the two rearranged genes are often variable, requiring selection of PCR primers within the adjacent exon and resulting in a variable size of the PCR product from case to case. Also, the introns can be very large, resulting in very large PCR products that may not be completely amplified and reducing the sensitivity of the test. Therefore, PCR of sarcoma-specific translocations using genomic DNA is not used for clinical testing.

Reverse Transcription-PCR

Chromosomal translocations in sarcomas give rise to aberrant fusion transcripts that are highly specific to a given tumor type (Table 37.1). More importantly, the structures of these fusion transcripts are highly consistent. Although the translocation breakpoint may involve various nucleotide positions of an intron at the DNA level, the resulting fusion transcript structure is the same due to RNA splicing. In a given sarcoma type, the gene fusion point at the messenger RNA (mRNA) level is highly precise to the single ribonucleotide. The tumor specificity and structural consistency of the fusion transcripts make reverse transcription-PCR (RT-PCR) the preferred method for molecular detection of specific translocations [43].

After reverse transcription of tumor mRNA into complementary DNA (cDNA), PCR primers complementary to the exons that flank the translocation breakpoint are used to amplify fusion transcript-specific RT-PCR products. Variations of RT-PCR methods have been used for the detection of sarcoma-specific fusion transcripts. Since the fusion-joining point may be far away from the poly(A) tail of the aberrant transcript, random hexamers or gene-specific downstream primers usually are used instead of oligo d(T) for the

reverse transcription of RNA into cDNA. Instead of the traditional two-step RT-PCR method, reverse transcription and PCR can be performed in a single reaction, a procedure called one-step RT-PCR. The reverse transcriptase works first at low temperature to convert mRNA into cDNA, while the Taq DNA polymerase is inactive. The temperature is then raised to inactivate the reverse transcriptase, to activate the Taq DNA polymerase, and to initiate the amplification reaction at the same time. Reactions with multiple primer sets are difficult to optimize, but are very convenient for molecular testing of sarcomas with numerous fusion gene variants such as ES/PNET [44]. Nested PCR using an additional pair of primers to further amplify the first-round RT-PCR product can greatly increase sensitivity, although it also increases the likelihood of amplicon contamination.

Identification of a positive RT-PCR result usually relies on detection of the expected-sized product on a DNA-separating gel, such as agarose or acrylamide, or by capillary electrophoresis. When fresh or frozen tissue is the starting material, the target size of the RT-PCR product is designed carefully to be less than 500 bp and preferably around 200 bp. For fusion genes that have little size variation, such as *SS18–SSX* fusion of synovial sarcoma, the presence of a single RT-PCR product of the expected size generally is considered adequate for positive identification, although post-PCR confirmatory analysis of the product sequence can be performed. For fusion genes with molecular size variability, such as *FUS–DDIT3* in myxoid liposarcoma, additional analysis of the PCR products is mandatory to confirm the specificity of the PCR products. Confirmatory methods include blot transfer with subsequent hybridization with a fusion gene-specific probe, DNA sequencing of the PCR product, restriction endonuclease digestion, or an additional nested PCR step. Inclusion of positive, negative, and no-template (water) control reactions is necessary because of the high sensitivity of the amplification process and the risk of amplicon contamination with RT-PCR detection of fusion transcripts for clinical diagnosis.

Soft tissue tumor FFPE blocks may be used as the source of RNA, although with some caution [45]. As a result of the fixation and embedding processes, the RNA from tissue blocks is substantially degraded. RNA degradation requires that the size of the amplification product(s) be designed to be considerably smaller (around 100 bp) compared to assays designed for use of fresh or frozen tissue. RT-PCR from FFPE tissue blocks usually requires more amplification cycles, and a nested approach may be necessary for the detection of the aberrant transcript, both of which increase the risk of false-positive results due to carryover amplicon contamination. Very stringent conditions and additional control reactions are necessary to ensure test specificity.

Consideration must be given to the variability of fusion gene transcripts for each type of sarcoma (see Table 37.1) when interpreting RT-PCR test results. For instance, in ES/PNET, considerable variations occur among the different exons involved in the gene fusion [44]. Although the tumors may be cytogenetically indistinguishable, differences in the exon composition of the final fusion transcript can only be detected by a PCR-based method. Variant chromosomal translocations involving different chromosomal and gene partners also give rise to variability in up to approximately 10 % of ES/PNET cases. In fact, the t(21;22), instead of the far more common t(11;22), results in the fusion of *EWSR1* with *ERG* [46]. Very rarely, EWSR1 is fused with other loci including *ETV1* or *E1AF* in ES/PNET [47]. Awareness of these variants is very important when a negative RT-PCR result for the more common *EWSR1–FLI1* rearrangements occurs.

Real-Time RT-PCR

Although designed for quantitative measurements, real-time RT-PCR has become a reliable detection method for fusion gene transcripts [48, 49] because of three major advantages over the conventional endpoint RT-PCR. First, real-time RT-PCR greatly enhances the specificity of detection by incorporating a probe that is complementary to the region of the gene internal to the PCR primers. Second, real-time PCR measures the geometric (exponential) phase of a PCR reaction (cycles 20–25), allowing quantification of the fusion transcript. Third, the PCR product accumulation is measured in real time by fluorescence detection through the semitransparent plastic cap of the reaction tube, and therefore, post-PCR manipulation and possible PCR contamination are reduced. Real-time RT-PCR conclusively has very high specificity and sensitivity, which are important when analyzing very small samples or target genes with very low expression levels [48]. Simultaneous amplification of multiple targets by multiplex real-time RT-PCR is possible by using target-specific probes labeled with different fluorescent labels [50].

With careful optimization, real-time RT-PCR can be highly reliable for detection of fusion transcripts, using all types of tissue sources [49]. The early geometric-phase detection with enhanced specificity and elimination of post-PCR manipulation makes real-time RT-PCR ideal for detection of sarcoma fusion transcripts, even if the RNA source is FFPE tissue [51]. The specific and quantitative detection power of real-time RT-PCR for FFPE tissue is illustrated in Fig. 37.4, in which amplification of the *SS18–SSX* fusion transcript of synovial sarcoma is shown. Positive identification of fusion transcripts can be achieved using as little as 20 ng of RNA extracted from one paraffin block, making small specimens, such as core needle biopsies, suitable for definitive molecular diagnosis. The operating cost profile

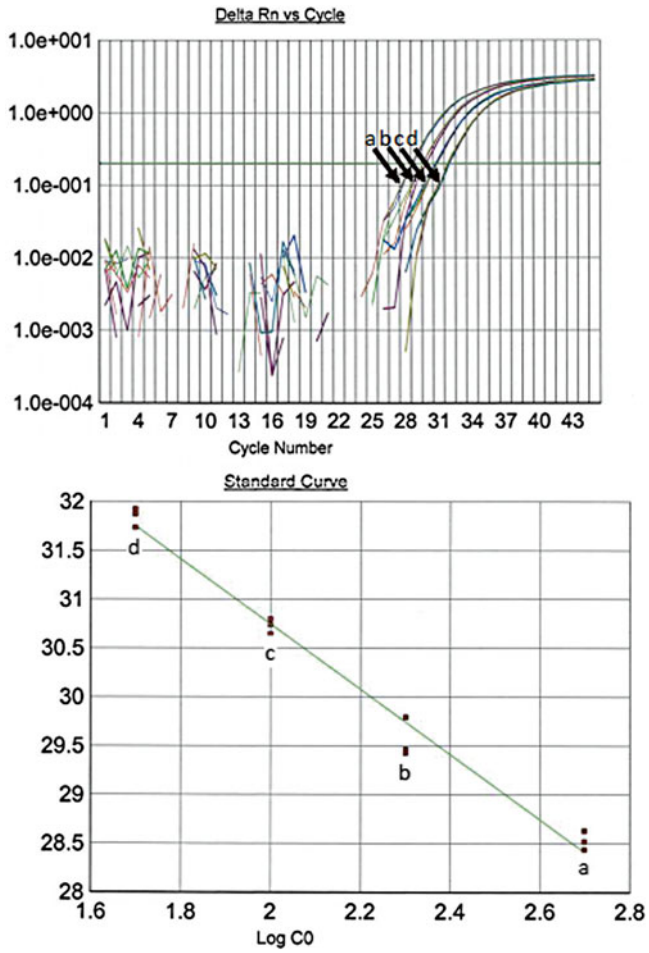

Figure 37.4 Real-time RT-PCR detection of *SS18–SSX* fusion transcripts in a synovial sarcoma. *Top panel*: Real-time RT-PCR plot of PCR cycle number vs fluorescence signal for *SS18–SSX* fusion transcript amplification in a synovial sarcoma with (a) 500 ng, (b) 200 ng, (c) 100 ng, and (d) 50 ng of total input RNA, each amplified in triplicate. The RNA was extracted from formalin-fixed paraffin-embedded tissue. *Bottom panel*: Log gradient plot of the data from the top panel, demonstrating linear quantitative amplification consistent with the amount of input RNA template. The *y*-axis represents the threshold cycle number, and the *x*-axis is the log of the RNA concentration (Log C0). The quantity of the specific RNA measured by real-time RT-PCR is inversely proportional to the threshold cycle number

and time to reporting also are in favor of real-time RT-PCR over conventional RT-PCR, and real-time RT-PCR is now commonly used for the routine diagnosis of sarcoma and minimal disease detection [48].

DNA Sequencing and Next-Generation Exome Sequencing

Sanger sequencing with capillary electrophoresis platforms will likely remain in significant use for targeted sequencing projects (biomarker identification and pathway analysis) and clinical molecular testing applications until next generation sequencing platforms become more standard for clinical molecular laboratories (see below). Technical advances in high-throughput next-generation sequencing (NGS), also known as massively parallel or multiplex cyclic sequencing, are key elements that are enabling the application of genomic knowledge into clinical practice, including the diagnosis of translocation-specific sarcomas [52]. NGS technologies have increased the speed and throughput capacities over Sanger sequencing while reducing cost and have significantly increased the possibility of detecting new gene fusions [7]. Detection of the sarcoma fusion genes may be accomplished by NGS platforms targeting the transcriptome in sarcoma cells. Through combination of hybridization capture of cDNAs and next-generation sequencing, targeted RNA sequencing (RNA-seq) provides an efficient and cost-effective method to analyze specific subsets of the transcriptome of a tumor simultaneously for mutations, fusion transcripts, and gene expression levels [53]. NGS technologies with appropriate assembly algorithms have facilitated the reconstruction of the entire transcriptome in the absence of a reference genome [54]. Targeted RNA-seq is also a powerful tool suitable for a wide range of large-scale tumor-profiling studies to identify sequence variations and novel fusion gene products [55].

Gene Expression Profiling

Gene expression profiling of many cancers, including sarcomas, has produced inconsistent results in predicting clinical drug or management response and prognosis and is not used

for the detection of sarcoma-specific transcripts as an aid to the histological diagnosis. One constraint of gene expression profiling is the preference for use of fresh or frozen tissue. The limited availability of fresh or frozen tissue represents a drawback compared with other methods that can utilize routinely processed FFPE tissue. Nevertheless, gene expression profiling definitely represents a potentially powerful tool for molecular grading of sarcomas, and specific gene expression profiles predict metastatic outcome. Refinement of the methods to select the relevant genes and validation of the expression signatures proposed for clinical use may open new avenues to the management of patients with sarcoma [56].

Immunohistochemistry

Fusion protein-specific antibodies are not available for routine diagnostic purposes, but the detection of aberrant protein expression can be used to infer the occurrence of a tumor-specific translocation. Expression can be altered because by immunohistochemistry the protein is (1) no longer present (e.g., lack of expression of INI1 in malignant rhabdoid tumor); (2) detected in a cell type that does not normally express that protein (e.g., ALK expression in a mesenchymal cell in the case of inflammatory myofibroblastic tumor with *ALK* rearrangement or expression of MDM2 in atypical lipomatous tumors with 12q13–15 amplification); (3) detected at higher levels compared to normal tissues (TFE3 in alveolar soft part sarcoma); and (4) present in an inappropriate cellular compartment (e.g., nuclear localization of β-catenin in desmoid tumors with mutated *CTNNB1*).

Clinical Utility of Testing

The molecular characterization of human sarcomas has significantly changed, is still reshaping sarcoma classification and diagnosis, and is promoting rapid progress in disease monitoring, prediction of outcome, and design of novel therapeutic strategies.

Establishing a Definitive Diagnosis and Redefining Tumor Entities

Soft tissue tumors comprise a vast and heterogeneous group of neoplasms. Because different tumors often have different biological behaviors and respond differently to therapeutic strategies, precise classification is of great clinical importance. The majority of soft tissue tumors were first delineated on the basis of morphologic and clinical findings into homogeneous groups. However, many tumors with similar histological and pathological characteristics actually are heterogeneous groups that differ in their clinical behaviors and underlying pathogenesis. Correlation of cytogenetic and molecular characteristics with pathologic findings is essential for understanding both the biological significance and the clinical value of specific molecular changes.

A surprising correlation has emerged among chromosomal alterations, gene rearrangements, and distinct histopathologic entities. Morphologic and cytogenetic/molecular observations in fact have been validating each other, and a combined approach has resulted in a more rational classification of soft tissue tumors. This combined morphologic and molecular classification has been particularly helpful in understanding the so-called small round blue cell tumors. ES and PNET are essentially a single-tumor type defined by the characteristic translocation between chromosomes 11 and 22, resulting in an *EWSR1* gene rearrangement. Despite the morphologic similarities, typical olfactory neuroblastoma lacks *EWSR1* rearrangement that argues against the previously proposed inclusion of this tumor in the ES/PNET group [57]. The finding of *PAX3–FOXO1* chimeric products is of considerable value in defining ARMS. In fact, the small proportion of primitive embryonal-like RMS containing a *PAX3–FOXO1* gene fusion likely represents unrecognized solid ARMS [58]. Molecular testing also allows the identification of previously unrecognized variants of known tumors. One such example, illustrated in Fig. 37.5, is a poorly differentiated synovial sarcoma with rhabdoid features.

Another group of tumors that has significantly benefited by a combined morphologic and molecular approach is adipose tissue neoplasms. The finding of ring or giant marker chromosomes cytogenetically defines the group of atypical lipomatous tumors (well-differentiated liposarcoma) and justifies the distinction of atypical lipomatous tumors from spindle cell and pleomorphic lipomas. The finding of *FUS–DDIT3* fusion transcripts in both myxoid liposarcoma and round cell liposarcoma demonstrates that they represent a continuum, an observation nicely correlating with the not infrequent observation of cases with mixed histology [59]. The t(17;22), which produces the *COL1A1–PDGFB* fusion, is present in both dermatofibrosarcoma protuberans (DFSP) and giant cell fibroblastoma, indicating that these are adult and pediatric presentations, respectively, of a single tumor entity [10, 60]. Similarly, the identification of the t(7;16)(q34;p11), resulting in the *FUS–CREB3L2* fusion gene, in both low-grade fibromyxoid sarcoma and hyalinizing spindle cell tumor with giant rosettes has clarified that these tumors represent variants of the same biological entity [61]. The *FUS–CREB3L2* fusion gene is highly specific for this tumor type, since it is present in low-grade fibromyxoid sarcoma, but not in other sarcomas with similar histologic features [62] and is uncommon in sclerosing epithelioid fibrosarcoma [63].

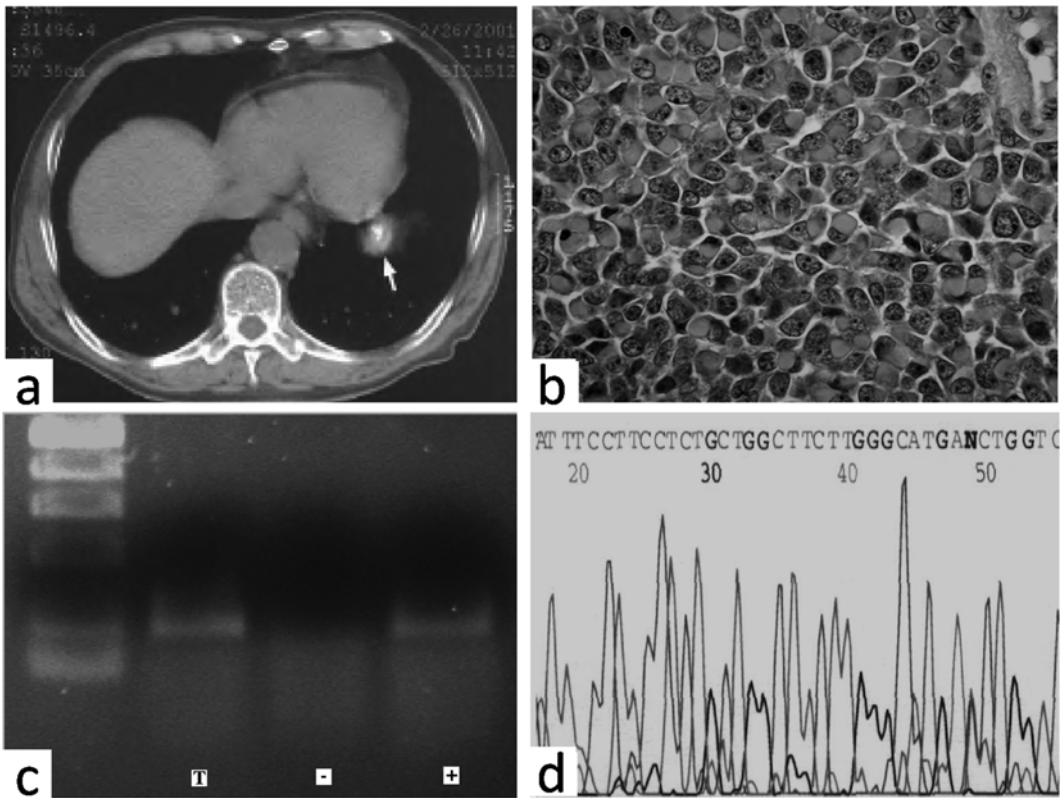

Figure 37.5 RT-PCR detection of *SS18–SSX2* fusion transcript in a primary poorly differentiated synovial sarcoma of the lung with rhabdoid features (courtesy of Dr. Thomas Ciesielski). (**a**) CT scan of a 72-year-old patient with a subpleural 2 cm nodule (*arrow*). An extensive physical and radiographic examination failed to reveal a separate primary lesion. (**b**) Proliferating tumor cells with rhabdoid cytoplasm. This histological variant of synovial sarcoma may be difficult to diagnose without molecular testing. (**c**) RT-PCR of formalin-fixed paraffin-embedded tumor tissue shows the presence of a 97 bp RT-PCR product from the *SS18–SSX2* fusion transcript in *lane 2* (*T* tumor). *Lanes 3* and *4* are the negative (−) and positive (+) controls, respectively. (**d**) Direct DNA sequencing of the RT-PCR product from *panel* (**c**) shows a *SS18–SSX2*-type fusion transcript

Providing Prognostic and Predictive Information

By allowing accurate diagnosis, molecular testing greatly contributes to defining both the therapy and prognosis for a patient with sarcoma. For patients with GIST, the mutational status correlates with both prognosis and response to treatment. GIST with *KIT* exon 11 mutations are more aggressive, but also respond better to treatment with imatinib, compared with tumors that have an exon 9 *KIT* mutation, no *KIT* mutation, or a *PDGFRA* mutation, and therefore have longer progression-free and overall survival [27, 31]. Specific mutations, like the *PDGFRA* D842V mutation, predict a lack of response (primary resistance) to imatinib. Other mutations, clustered in specific regions of the KIT kinase domain that is the target of imatinib, have been associated with disease progression after an initial treatment benefit (secondary resistance) [27]. Imatinib reduces the growth of *COL1A1–PDGFB*-transformed animal cells as well as primary cultures of DFSP tumor cells in vitro and in vivo [9, 64] and is an effective treatment for DFSP with the *COL1A1–PDGFB* fusion gene, including cases that have undergone progression to fibrosarcoma, with a response rate close to 50 % [65]. The *PAX3–FOXO1* fusion is an adverse prognostic factor in ARMS [66]. Therefore, not only is *PAX–FOXO1* fusion transcript the defining feature of ARMS, but also the specific type of gene fusion present in the tumor identifies a high-risk subgroup (with *PAX3–FOXO1*) and a favorable-outcome subgroup (with *PAX7–FOXO1*). The *SS18–SSX* fusion type is not prognostically significant [67–69]. Intensive treatment protocols for fusion-negative sarcomas have eliminated the better outcome previously reported in patients with *EWS–FLI1* fusion transcripts [70].

High-throughput analysis of gene expression can provide valuable prognostic information, even though this testing is not routinely used in clinical care yet. One example is the Complexity Index in Sarcoma (CINSARC) study that has produced a panel of 67 genes related to mitosis and chromosome management to define patient outcome. Remarkably, in this study, gene expression analysis performed better than

conventional tumor grading in the identification of patients with a high risk of metastatic disease [56].

Minimal Disease Detection

Molecular detection of occult tumor cells can be a prognostic indicator important for clinical staging and selection of therapeutic strategies. Detection of low-level expression of *EWSR1–FLI* fusion transcripts in bone marrow and blood has been reported for patients with sarcomas [71, 72]. Micrometastases were detected in 31 % of patients with localized disease and 50 % of patients with clinically metastatic tumors. RT-PCR detection of specific fusion transcripts has been used to study the marrow and body fluids of patients with ES, ARMS, and desmoplastic small round cell tumors (DSRCT). Molecular evidence of metastasis was detected in all patients with clinically evident metastatic tumors but not in the patients with localized disease [73]. Although correlative studies are needed to validate the prognostic significance of occult tumor cells, molecular staging is an emerging field that may change the approach to the clinical management of patients with soft tissue sarcomas.

Developing Tumor-Specific Therapy

High-throughput molecular analysis integrating test results on DNA sequence, copy number, and mRNA expression has revealed genetic alterations in major types of sarcoma that can be used to identify specific targets for patient treatment [74]. The therapeutic implications of sarcoma-specific gene fusion events are tremendous, since each fusion is a potential target for tumor-specific therapies. A tumor-specific cytotoxic T cell response can be induced by peptides derived from the fusion point of the SS18–SSX chimeric protein in synovial sarcoma that may function in vitro as a neoantigen [75]. Other forms of tumor-specific immunotherapies are under development, and the opportunity exists to design tumor-specific drugs against specific fusion proteins present in soft tissue sarcomas, which may include targeting by RNA interference or other gene therapy approaches [76, 77].

Quality Control and Laboratory Issues

The availability of two or more unrelated test methods for the diagnosis of each sarcoma type can facilitate the confirmation of unexpected results or the resolution of discrepant results. One key issue regarding the accurate molecular diagnosis of sarcomas is the selection of the appropriate test. This is largely determined by the type of sarcoma under consideration, the specimen type, and the specimen quality and quantity. For fusion genes with limited structural variations, such as synovial sarcoma, ARMS, clear cell sarcoma of soft parts, extraskeletal myxoid chondrosarcoma, DSRCT, alveolar soft part sarcoma, and inflammatory myofibroblastic tumor, RT-PCR and real-time RT-PCR are the method of choice. Interphase FISH is the best testing method for sarcomas having fusion genes with chromosomal and intramolecular variations, such as myxoid/round cell liposarcoma, DFSP, and ES/PNET. Ideally, all specimens with a preliminary diagnosis of sarcoma should have viable tissue for karyotyping. A portion of the diagnostic specimen can be temporarily stored in culture medium at room temperature or 4 °C until a provisional histological diagnosis is made and then sent for karyotyping, if appropriate. Whenever possible, a portion of the tumor specimen should be frozen and stored, to provide the best source of nucleic acid suitable for virtually all types of molecular tests used for soft tissue sarcoma testing. Unfixed, fresh, or frozen tissue also is suitable for protein analysis, although this is rarely used clinically. Touch preparations for FISH should be made and stored for possible use. When only paraffin-embedded archival material is available, interphase FISH and real-time RT-PCR are the best testing choices.

Turnaround time varies significantly for the different testing methods. Cytogenetic karyotyping requires short-term culture (3–10 days). The length of time for culturing reflects the quality and the quantity of the specimen source, as well as the tumor proliferation rate in vitro. Turnaround time for interphase FISH also depends on specimen type. Touch preparation and frozen sections allow for rapid FISH analysis (1–2 days). For archival tissue sources, an additional 1 or 2 days are required to obtain the nuclear suspension or the tissue sections. RT- PCR has a 2- or 3-day turnaround time for common fusion gene detection but requires a longer time for more complex fusion variant detection. Real-time RT-PCR offers a shorter turnaround time (1 or 2 days) because it does not require post-PCR manipulation steps or confirmatory testing. Longer turnaround times may be expected if the laboratory batches specimens and only runs the test once per week, for example.

Conclusion

Cytogenetics and molecular cytogenetics have contributed significantly to the study of the pathobiology of soft tissue tumors. Identification of recurrent chromosomal changes has resulted in the definition of an increasing number of tumor-related molecular changes and is fostering a continual refinement of the classification of sarcomas and related mesenchymal tumors. The recognition of distinctive rearrangements in tumor subsets is providing powerful tools to refine the histological diagnosis in a field in

which pathological diagnosis and clinical management are often difficult, due to both the variety of tumor phenotypes and their relative rarity. In this respect, interphase FISH, real-time RT-PCR, and multiplex RT-PCR testing for the detection of fusion products specific for different tumor types offer practical and cost-effective methods for complementing conventional histological diagnosis. Novel technical approaches, including NGS, may increase speed and throughput of molecular analysis, and the application of genomic knowledge into clinical practice may radically change the management of patients with sarcomas [7, 52, 56, 74].

Gliomas

38

Ehud Lavi

Abstract

Many advances have been made in evaluating the molecular genetics of gliomas. For example, the presence of 1p and 19q deletions is associated with gliomas of oligodendroglial lineage, with oligodendrogliomas that have a better survival, and with oligodendrogliomas that respond to chemotherapy and radiation therapy. While prospective data are needed to confirm these associations, 1p and 19q deletion testing has become a part of routine neurooncology practice. Alterations of chromosome 10, *EGFR*, *PTEN*, *IDH1*, *MGMT*, *ATRX*, and *TP53* are associated with different grades of astrocytic gliomas and with patient survival. While their clinical utility requires further investigation, these markers (and others) will be increasingly used to stratify patients to current and new therapeutic approaches. In the future, it is likely that the survival rate of primary gliomas will be lengthened using molecularly targeted therapies.

Keywords

Astrocytoma • Oligodendroglioma • Glioblastoma • MGMT • EGFR • IDH-1 • IDH-2 • ATRX • p53 • PTEN

Introduction

Approximately 28,320 people in the US were diagnosed with malignant nervous system tumors in 2010 [1]. Primary brain tumors constitute approximately 2 % of all malignancies [2]. The most common of the primary brain tumors are gliomas. Depending on the grade and morphologic type of glioma, newly diagnosed patients are treated by watchful waiting, surgical resection, radiotherapy, or chemotherapy or some combination of these. Regardless of therapy, most gliomas will progress and patients with glioma have a high risk of mortality and reduced quality of life. Thus, there has been intense interest in understanding the biology and genetics of gliomas, to provide better diagnostic tools and new therapeutic approaches. Molecular pathology markers are being identified that have been or will soon prove to be clinically useful in the practice of clinical neurooncology (see Table 38.1).

Pathology Considerations

Gliomas are classified into tumors of astrocytic, oligodendroglial, ependymal, and mixed lineage. "Diffuse gliomas" is a descriptive general term that applies to all diffusely infiltrating tumors of glial lineages before a more specific determination of lineage can be determined based on molecular and immunohistochemical markers. Diffuse astrocytic tumors are divided into three different grades by the World Health Organization (WHO) system [3]: grade II (or astrocytoma [A]), grade III (or anaplastic astrocytoma [AA]), and grade IV (or glioblastoma, previously known as glioblastoma multiforme [GBM]). These tumors occur predominantly in adults. Diffuse astrocytic tumors can be subclassified

Table 38.1 Molecular markers of gliomas used in clinical practice

Marker	Indication
1p/19q deletion	Oligodendroglioma diagnosis and prognosis Prediction of oligodendroglioma therapeutic response Confirmation of an oligodendroglial component in oligoastrocytomas
MGMT promoter methylation	Response of glioblastoma to alkylating drugs (temozolomide) Small cell glioblastoma diagnosis Prognostic marker
IDH1 mutation	Diagnostic tool for low- and intermediate-grade astrocytomas and oligodendrogliomas Distinction from primary glioblastomas, pilocytic astrocytomas, and ependymomas Neoplastic glioma vs reactive gliosis Prognostic marker
EGFR amplification (overexpression)	Differentiation from oligodendroglioma Therapeutic response to novel EGFR pathway inhibitors
Chromosome 10 loss/*PTEN* mutation	Prognosis of anaplastic astrocytomas Response to EGFR pathway inhibitors
TP53 mutation	Secondary glioblastoma vs primary Neoplastic glioma vs reactive gliosis

into several histological types, including fibrillary, gemistocytic, small cell, and giant cell subtypes. Several of these histological types can be found within a single diffuse astrocytic tumor. Pilocytic astrocytomas are nondiffuse, well circumscribed, and localized. Pilocytic astrocytomas are often WHO grade I, and predominantly occur in children and young adults. Glioblastomas can be subclassified into two groups based on the duration of symptoms [4]. Primary glioblastoma presents de novo with a short duration of symptoms (often less than 3 months). Secondary glioblastoma presents with a longer duration of symptoms or with a preceding grade II or III glioma. Primary and secondary glioblastomas usually present in patients greater than 60 and less than 40 years of age, respectively.

Oligodendrogliomas most commonly are divided into two grades: grade II (oligodendroglioma) and grade III (anaplastic oligodendroglioma), although some neuropathologists have described a grade IV oligodendroglioma [5]. Ependymomas are also classified as low (WHO grade II) and high grade (anaplastic or WHO grade III).

One of the problems with the neuropathologic diagnosis of gliomas is their histologic heterogeneity. AA exhibits increased cellularity, nuclear atypia, and mitotic activity. Microvascular proliferation and necrosis are additional features of glioblastomas. Depending on the extent of surgical sampling, some of the histologic elements that distinguish AA and glioblastoma may not be present in the specimen submitted for pathological diagnosis, and some gliomas may be undergraded. Thus, molecular markers that assist in tumor grading are clinically useful.

In addition to histologic heterogeneity, diffuse gliomas often exhibit cell type heterogeneity. Both astrocytic and oligodendroglial elements may be present in diffuse gliomas. When both of these elements comprise a significant proportion of the tumor, the glioma used to be classified as a mixed oligoastrocytoma (MOA). However, this term no longer exists based on recent recommendations of the International Society of Neuropathology [6].

Molecular Pathology Tools for Glioma Analysis and Grading

Gliomas have been extensively characterized by cytogenetic, molecular cytogenetic, and molecular genetic methods (reviewed in Refs. 4, 7, 8). Figure 38.1 summarizes the major genetic alterations found in diffuse gliomas. Some of these alterations are highly correlated with the grade of gliomas, especially for astrocytic tumors.

Several genetic alterations have been associated with gliomas, especially primary glioblastoma and oligodendrogliomas. These alterations include chromosomal deletions of chromosome arms 1p and 19q, *MGMT* promoter methylation, loss of chromosome 10, *PTEN* mutations, *IDH1* mutations, and amplification of *EGFR* with resulting overexpression of the EGFR protein. While the clinical use of these markers has been validated only partially, growing evidence supports the usefulness of these molecular markers for glioma grading, prognosis, and treatment decisions. The presence of *EGFR* amplification, chromosome 10 loss, or *PTEN* mutation, or some combination of the three, in a glioma indicates that the tumor is likely a glioblastoma. Importantly, a small but significant proportion of tumors with the histologic features of AA have one or more of these alterations [9–13]. It is reasonable to hypothesize, though needs to be proven, that since patients with glioblastoma have a poor prognosis, then patients whose AA shares molecular characteristics with glioblastoma also may have poor survival.

One of the first and most significant molecular developments in the study of gliomas was the discovery of chromosomal alterations in chromosomes 1 and 19. Cairncross et al. demonstrated in 1994 that some anaplastic oligodendrogliomas respond to combination chemotherapy and radiation therapy [14]. Simultaneously, several investigators observed that approximately 70 % of oligodendrogliomas have deletions of 19q, 70 % have deletions of 1p, and 60 % have deletions of both 1p and 19q [7]. Usually, the entire chromosomal arms are deleted [15]. In contrast, about 40 %, 20 % and 10 % of astrocytomas have deletion of 19q, 1p, and both 1p and 19q, respectively [15]. The proportion of MOA with 1p and 19q deletions is intermediate, suggesting that some of these tumors can be grouped with oligodendrogliomas [15, 16]. A significant proportion of MOA also has *TP53*

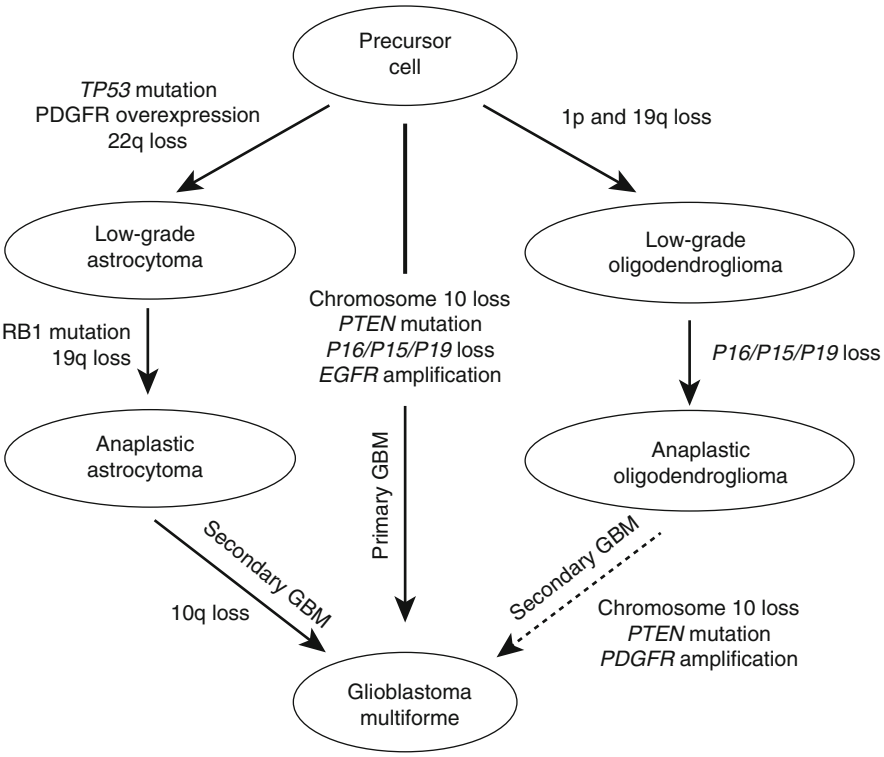

Figure 38.1 Possible genetic pathways of diffuse glioma formation and progression (modified from Refs. 7 and 8). Histologic classification is based on current WHO guidelines [3]. Although the molecular genetic evidence is increasing, it is still controversial whether anaplastic oligodendroglioma progresses to glioblastoma (GBm) (*dashed arrow*)

mutations and other genetic anomalies, suggesting that these tumors can be grouped with the astrocytomas [15, 16].

Two retrospective studies have provided evidence that the oligodendrogliomas with 1p deletions, 19q deletions, or both have a better prognosis and respond better to chemotherapy and radiation therapy [17, 18]. The data strongly suggest that 1p/19q deletions are associated with tumors of oligodendroglial lineage, with oligodendrogliomas that have a better prognosis, and with oligodendrogliomas that respond to chemotherapy and radiation therapy. Additional prospective studies provided evidence that the presence or absence of 1p/19q deletions suggests different treatment recommendations for oligodendrogliomas that require adjuvant therapy, especially anaplastic oligodendrogliomas [19, 20]. Patients with the deletion may receive chemotherapy first and delay radiation treatment, while patients without the deletion may receive radiation as first-line treatment.

Other alterations occur in oligodendrogliomas that lack 1p and 19q deletions. *CDKN2A–CDKN2B–ARF* (*P16*, *P15*, *P19*), *PTEN*, and chromosome 10 are frequently deleted in anaplastic oligodendrogliomas. The expression of *CDKN2A* and *CDKN2B* often is inactivated by promoter methylation. While the presence of these alterations is associated with a poorer prognosis [17, 21, 22], their detection has not become a part of standard clinical neurooncology.

MGMT is a DNA repair enzyme that normally counteracts the cell death effect of alkylating chemotherapy agents such as temozolomide, which is widely used in the treatment of glioblastoma. MGMT activity is downregulated and not fully expressed in about half of patients with glioblastoma due to *MGMT* gene promoter methylation and decreased gene expression and enzyme production. Thus, the presence of *MGMT* promoter methylation determines that the patient will be more responsive to chemotherapy. *MGMT* promoter methylation also correlates with better prognosis in general, suggesting that it might indicate a prognostically favorable molecular phenotype of the disease. In a study by Hegi et al., 46 % of the patients with *MGMT* methylation were alive at 2 years, while only 23 % of the patients with unmethylated *MGMT* were alive at 2 years [23]. Temozolomide provides some beneficial effect even in patients with unmethylated *MGMT* promoter; thus, both groups receive the same treatment. Since the methylation pattern might change over time, repeated testing at each tumor resection is justified.

Several growth factors are upregulated and involved in the pathogenesis of gliomas, especially the most malignant forms of glioblastoma. EGFR signaling is upregulated in approximately 30 % of gliomas and 60 % of glioblastomas. An even higher percentage of "small cell glioblastoma," which can be misdiagnosed and possibly confused for oligodendroglioma, has upregulated EGFR signaling. The presence of EGFR upregulation as opposed to 1p/19q deletion may help to distinguish between glioblastoma and malignant oligodendroglioma, respectively. Another scenario in which EGFR overexpression is diagnostically useful is when a biopsy is taken from the edge of a tumor that appears to be

histologically consistent with a grade III glioma but radiographically appears as glioblastoma. The presence of EGFR overexpression in these tumor specimens may support a diagnosis of glioblastoma instead of AA.

In glioblastomas that overexpress EGFR, mutant forms of EGFR are present in about half of the cases. The most common variant is EGFR vIII, which has deletion of exons 2–7 of the *EGFR* gene and results in an EGFR protein that is active independently of ligand binding (reviewed in Ref. 24). Several other amplified and mutated EGFR proteins also have been identified (e.g., the C958 variant is truncated after amino acid 958), some of which remain ligand dependent. Current translational studies are investigating the prevalence of these different amplified and mutated EGFR variants in primary and secondary glioblastoma and in glioblastoma from patients of different ages [25].

Many glioblastomas have dysregulation of EGFR downstream signaling, such as *PTEN* tumor suppressor gene mutations, phosphoinositide 3-kinase pathway, and AKT. These findings suggested a rationale for drug treatments that target these pathways. Mellinghoff and colleagues showed that gliomas with an EGFR vIII mutation in the presence of an intact PTEN-AKT pathway had increased sensitivity to erlotinib, whereas tumors with loss of the PTEN-AKT signaling did not. However subsequent trials showed less response to EGFR-targeted therapies, so the use of these drugs remains controversial.

Mutations in the *IDH1* and *IDH2* genes occur in high frequency in primary low- and intermediate-grade diffuse gliomas (both in astrocytomas and in oligodendrogliomas) [7, 20, 26, 27], as well as secondary glioblastomas. The most common mutation is the R132H mutation of *IDH1*, with a frequency of over 80 % in grade II astrocytomas, oligodendrogliomas, anaplastic oligodendrogliomas, and mixed oligoastrocytomas, close to 70 % of AA, but only less than 0.5 % in primary glioblastoma. *IDH1* mutations also serve as a tool to distinguish astrocytomas and oligodendrogliomas from low-grade tumors that usually do not express this mutation such as ependymomas, pilocytic astrocytomas, and dysembryoplastic neuroepithelial tumors, as well as neoplastic glial proliferation from reactive gliosis. Gliomas with *IDH1* mutations have a better prognosis, with or without adjuvant therapy. Therefore, *IDH1* mutation serves as a prognostic and diagnostic marker (Fig. 38.2).

A Mayo Clinic/North Central Cancer Treatment Group (NCCTG) study indicated that AA with chromosome 10 loss or *PTEN* mutation, using full sequencing of the *PTEN* gene and exons 5–8 of the *TP53* gene, behaves like glioblastomas [10]. The median survival of patients with AA and chromosome 10 loss or *PTEN* mutation was approximately 4 months, a survival worse than that of patients with glioblastoma (median survival of approximately 12 months). The median survival of patients whose AA lacked these alterations was 34 months. This difference in survival was statistically significant even after adjustment for patient age, performance score, and extent of resection, all of which are important prognostic variables for patients with gliomas. Importantly, the patient survival for glioblastoma with and without chromosome 10 loss or *PTEN* mutations was very similar [10]. It is possible that sampling bias (in terms of the tissue available for histologic and molecular analysis) may have accounted for the differences. However, sampling bias is a difficult problem to overcome in routine clinical practice, and molecular testing for chromosome 10 loss or *PTEN* mutations in a sample of a tumor with the features of AA indicates that the tumor may be a glioblastoma.

Interestingly, the Mayo Clinic/NCCTG study did not show that AA with *EGFR* amplification behaved like

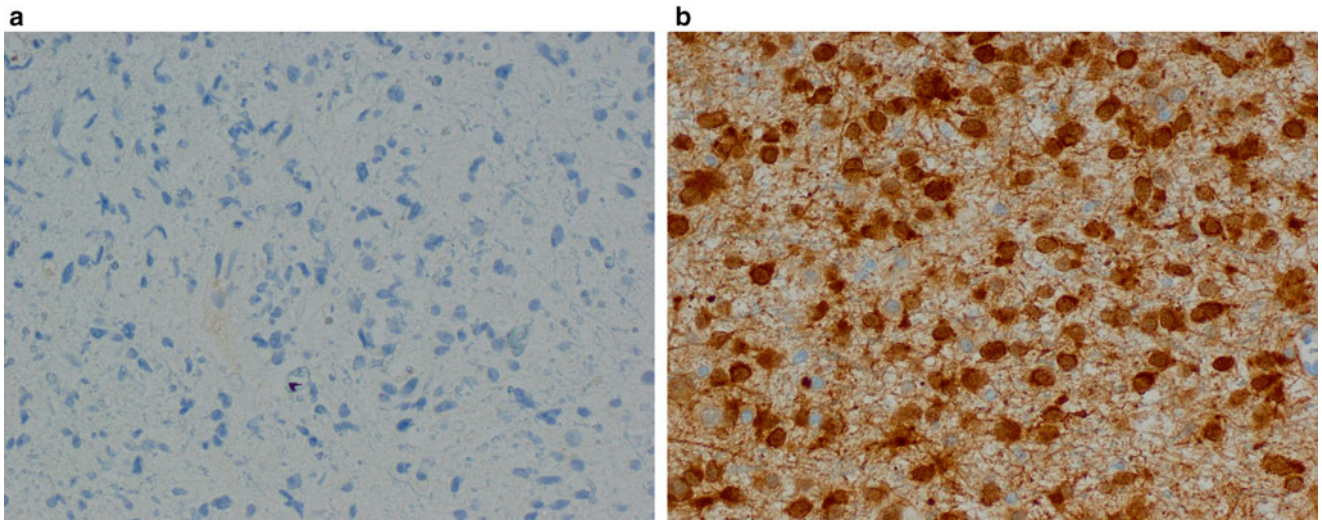

Figure 38.2 Immunohistochemistry images of low-grade glial neoplasms with negative (**a**) and positive (**b**) staining with antibody against the R132H mutations in *IDH1*

glioblastoma [10]. However, careful stratification indicated that AA and glioblastoma with *EGFR* amplification in young patients (i.e., <40 years old) progress much faster than AA and glioblastoma without *EGFR* amplification in this age group [10]. Conversely, AA and glioblastoma with *EGFR* amplification in older patients (i.e., >60 years old) had a better prognosis than those without this alteration. Importantly, this result has been confirmed by another group [28]. These differences in age-related prognosis may reflect the different biology of primary and secondary high-grade astrocytic tumors.

TP53 mutations are found in about half of astrocytomas and AA. About one quarter of glioblastomas have *TP53* mutations, and these tumors often have the clinical presentation of a secondary glioblastoma. Since *TP53* alterations usually are associated with low-grade tumors, it has been hypothesized that high-grade astrocytic tumors with *TP53* alterations may have a better prognosis. Except for the rare giant cell and gemistocytic variants (in which *TP53* mutations are especially prevalent) [29, 30], the presence or absence of *TP53* alterations does not seem to correlate with survival for glioblastoma [31–34]. However, in the Mayo Clinic/NCCTG series, the median survival of patients with AA with *TP53* mutations was 5 years [10]. This survival was significantly longer than for patients whose tumors did not have *TP53* mutations [10].

Although *PTEN*, chromosome 10, *TP53*, and *EGFR* alterations have been found to be correlated with clinical grade and thus with patient prognosis, they have yet to be routinely used in clinical practice for two reasons. First, the studies require broader validation. Second, and more importantly, the presence or absence of such alterations does not currently change the clinical management for these patients. High-grade glioma trials designed to specifically evaluate the clinical usefulness of these markers are needed to move these molecular markers into clinical practice.

A recent development in the field of molecular markers of gliomas has been the use of genetic mutations of the alpha-thalassemia/mental retardation syndrome X-linked (*ATRX*) gene. Loss of ATRX expression by immunohistochemistry, representing the presence of a mutated *ATRX* gene, is present in about half of all diffuse astrocytomas. *ATRX* mutations are essentially mutually exclusive with chromosomal deletions of 1p/19q and therefore indicate an astrocytic lineage. ATRX loss in glioma tumor cells also provides an indication of better prognosis than a preserved unmutated ATRX [35].

Available Assays

Despite intensive effort, the target genes on 1p and 19q that cause the differential treatment response have not been identified. However, molecular testing for 1p/19q deletion can be performed by loss of heterozygosity (LOH) analysis (currently by polymerase chain reaction [PCR] analysis of microsatellite loci or by high-throughput analysis of single-nucleotide polymorphisms) and by fluorescence in situ hybridization (FISH) with locus-specific bacterial artificial chromosome (BAC) probes. FISH can be performed on two formalin-fixed paraffin-embedded (FFPE) tissue sections and does not require microdissection, which is an advantage over the other methods. An advantage of FISH is that 1p/19q deletion can be focal [36], and normal cells are frequently present in gliomas. FISH can directly evaluate lesions and tumor cells of interest. An advantage of LOH analysis is detection of mitotic recombination (which is not detected by FISH). However, this LOH mechanism has been shown to be rare in gliomas [15].

FISH detection of 1p and 19q deletions has been described [15, 18]. Figure 38.3 illustrates typical 1p/19q FISH results for two anaplastic oligodendrogliomas, one with and one without 1p/19q deletion. Approximately 60 % of the nuclei in the tumor with 1p and 19q deletion contain one 1p36 or 19q13.3 probe signal and two 1q24 or 19p13 control probe signals (Fig. 38.3a). The remaining cells with two signals for each probe are likely contaminating normal glial, neuronal, or endothelial cells or tumor cells that lack deletion. The mean 1p/1q and 19q/19p signal ratios per nucleus are 0.62 and 0.71, respectively. Normal value studies and an evaluation of a large series of tumors by multiple methods indicate that ratios less than 0.80 are associated with 1p or 19q deletion. By comparison, approximately 60 % of the nuclei in the tumor without 1p and 19q deletion contain two signals for all four probes (Fig. 38.3b). The mean 1p/1q and 19q/19p signal ratios per nucleus are 1.04 and 1.01, respectively. The nuclei with one signal for each probe are likely a result of truncation of signals by paraffin sectioning. The nuclei with three or more signals are likely a result of nuclear overlap.

When used with appropriate control probes (e.g., the BAC probes on 1q42 and 19p13), FISH is able to detect 1p and 19q deletions in polyploid or aneuploid tumors. In addition, trisomy 19 is detected by this FISH method, an alteration long known to be associated with high-grade astrocytic tumors [37]. Based on normal value studies, chromosome 1 or 19 aneusomy is not reported unless the proportion of nuclei with three or more signals for each probe exceeds 30 % of the nuclei evaluated. Quantitative analysis of microsatellite alleles (QuMA) also detects 1p and 19q deletions (and trisomy 19) [38]. Both QuMA and current LOH analysis methods have the capacity for automation and rapid throughput. However, both require microdissection for accurate deletion detection, which increases turnaround time.

For similar reasons, FISH is the optimal method for the detection of chromosome 10 loss and *EGFR* amplification. In a careful method comparison study, semiquantitative PCR analysis and Southern blot analysis did not detect small foci

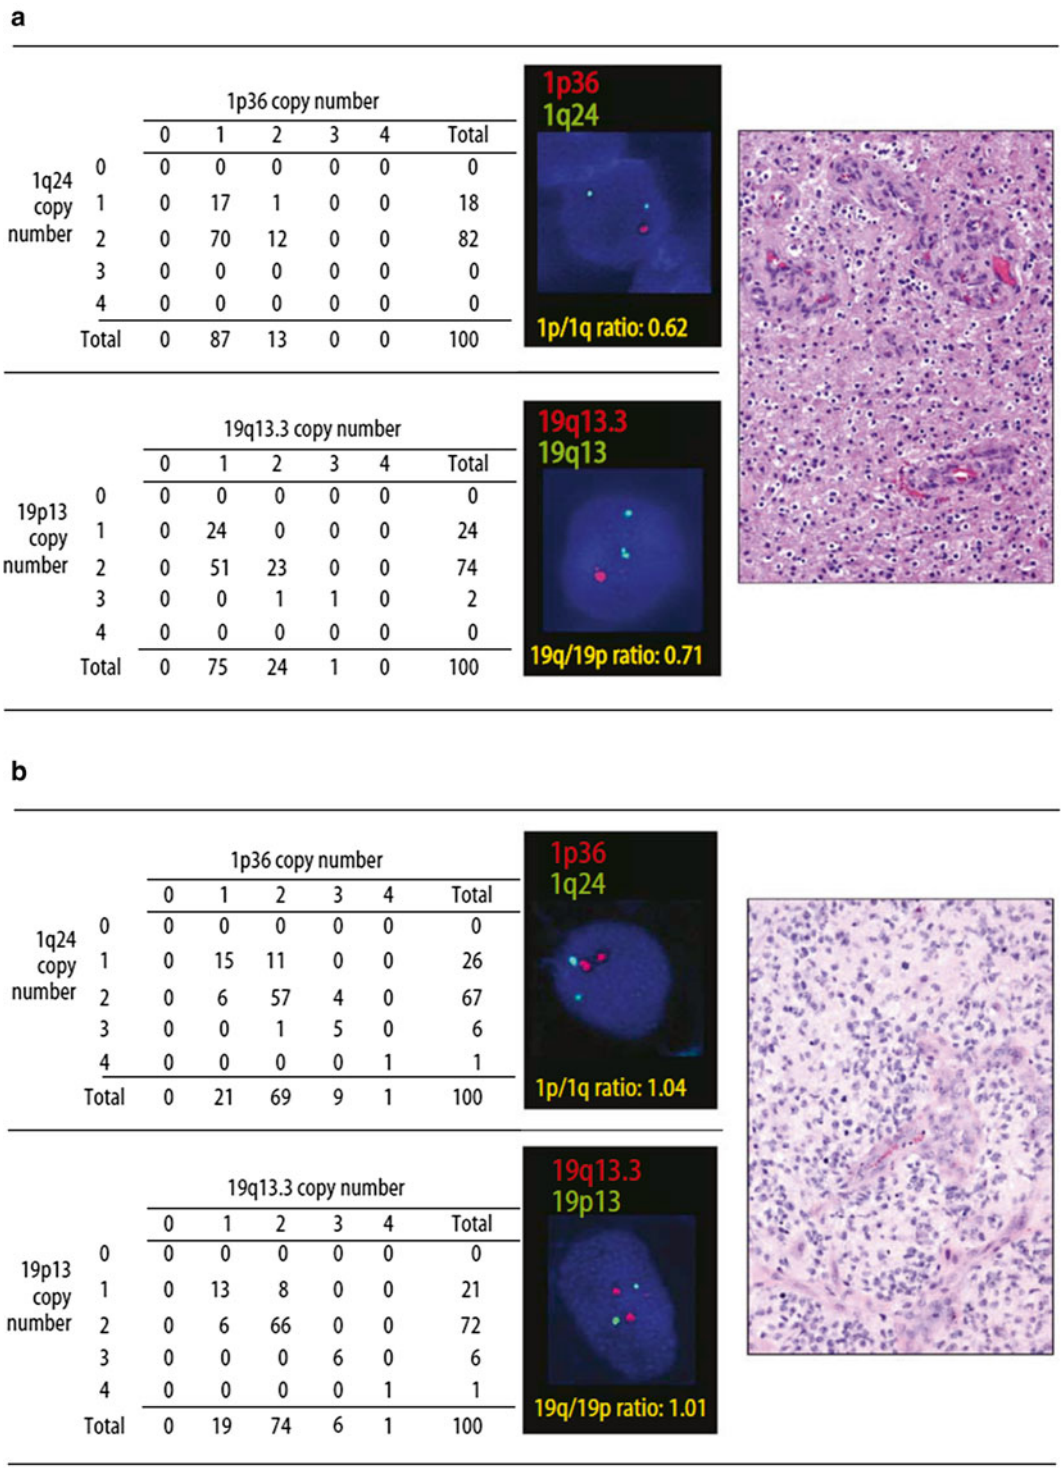

Figure 38.3 Representative histology and FISH results for two primary grade 3 anaplastic oligodendrogliomas. (**a**) An anaplastic oligodendroglioma with 1p and 19q deletion. (**b**) An anaplastic oligodendroglioma without 1p and 19q deletion. The values in the tables summarize the percent nuclei with the indicated number of 1p36 and 1q24 or 19p13 and 19q13.3 signals

of *EGFR* amplification compared to FISH [10]. The most accurate means to detect the EGFRvIII variant in gliomas is by immunohistochemistry with variant-specific antibodies [39]. The other *EGFR* variants can be detected by DNA sequencing of tumor specimens.

The *MGMT* promoter methylation test is currently done by PCR analysis using fresh, frozen, or FFPE tissue. Immunohistochemistry for assessment of MGMT expression, as a marker for *MGMT* promoter methylation, is inconsistent and currently not recommended. *TP53* and *PTEN*

mutation detection is best performed by high-throughput DNA sequencing/alteration methods (see Chaps. 2, 59, and 60). TP53 immunohistochemistry is a surrogate marker for *TP53* mutations by analyzing the level of expression of the protein in tissue sections. Immunohistochemistry is now the standard tool for analyzing reliably the expression of IDH1 with the R132H mutation in tissue sections due to the development of useful antibodies that selectively recognize this mutation [27]. Immunohistochemistry is a reliable tool for detection of nuclear expression of ATRX. Immunohistochemistry is less reliable for the protein level of PTEN in tissue sections.

Laboratory Issues

The use of molecular markers in gliomas is heavily dependent on the availability of sufficient lesional tissue for the different immunohistochemical and molecular studies. Stereotactic needle biopsies may not always be able to provide the amount of tissue necessary for such studies, and therefore open biopsies may be required for these studies. The accuracy of the tests is also dependent on the use of proper controls as well as proficiency testing to assure continued proper performance.

Future Directions

Array-based gene expression, gene dosage analyses, and the cancer genome atlas have the potential to identify new molecular markers for many cancers, including gliomas. Several groups are currently evaluating these methods of analysis in selected gliomas. Using a 1,100-gene expression array, Watson et al. identified 196 transcripts associated with oligodendrogliomas of different grades [40]. Similarly, two groups have used 12,000-gene expression arrays to discover differential expression of a limited number of transcripts that can be used to classify high-grade gliomas [41, 42]. Array-based comparative genomic hybridization (aCGH) likely will lead to the discovery of novel gene dosage alterations that can be used to classify gliomas [43, 44]. Importantly, the markers (and marker panels) ascertained by these methods will have to be carefully validated. However, there is the exciting possibility that a limited number of protein or molecular markers could be developed to enhance the molecular identification of gliomas and potentially to standardize neuropathologic diagnosis.

Much of the current translational research in gliomas is focused on developing therapeutic approaches that target specific protein and/or molecular alterations. The aCGH studies described above have, as one goal, the identification of new drug targets, with several promising targets for novel therapeutic approaches already identified. For example, several components of the receptor tyrosine kinase pathway are altered in gliomas: EGFR is overexpressed, *PTEN* is mutated, and AKT2 is activated. Small-molecule inhibitors, immunotherapeutics, and viral therapeutic agents are being developed that target this pathway (for examples, see Refs. 45, 46) and are being tested in glioma patients.

The design of current and future trials will need to develop the concept that therapeutic approaches will be customized to the molecular alterations found in specific tumors. Clinical molecular pathology will play an important role in this customization of clinical neurooncology practice.

Molecular Detection of Circulating Tumor Cells and Cell-Free Nucleic Acids

39

Nirali M. Patel and Karen Kaul

Abstract

One of the key roles performed by pathologists is determination of the presence or absence of tumor in clinical samples. This is the basis for most approaches to staging, monitoring response to treatment, and detecting relapse of neoplasia and, as such, is a critical step in determining the course of patient management. Pathologists have utilized a variety of methods, continually seeking to improve assay performance and thus patient outcome. The literature reflects this quest, including reports assessing the increased sensitivity afforded by immunohistochemistry (IHC), flow cytometry, and, more recently, molecular approaches for the detection of tumor cells and nucleic acids in blood and bone marrow samples. The goal is, of course, the more accurate detection of disease spread and, ultimately, better patient care.

This chapter addresses some of the recent work in tumor detection, focusing on molecular and, to some degree, immunofluorescent approaches for the detection of circulating tumor cells and free nucleic acids in clinical samples. A synopsis of the hundreds of articles published to date is beyond the scope of this chapter; instead, more general issues and findings are addressed, along with presentation of selected work. Several reviews are available for more detailed reading (Alix-Panabières and Pantel, Clin Chem 59:110–118, 2013; Pinzani et al., Methods 50:302–307, 2010; Pratt et al. Chem Eng Sci 66:1508–1522, 2011; Schwarzenbach et al., Nat Rev Clin Oncol 11:145–156, 2014).

cells and nucleic acids in blood and bone marrow samples. The goal is, of course, the more accurate detection of disease spread and, ultimately, better patient care.

This chapter addresses some of the recent work in tumor detection, focusing on molecular and, to some degree, immunofluorescent approaches for the detection of circulating tumor cells and free nucleic acids in clinical samples. A synopsis of the hundreds of articles published to date is beyond the scope of this chapter; instead, more general issues and findings are addressed, along with presentation of selected work. Several reviews are available for more detailed reading [1–4].

Circulating Tumor Cells

Cancer metastasis occurs when tumor cells acquire the ability to escape their local environment, enter the circulation to reach distant sites, attach at the distant site, and proliferate to form a metastatic cancer lesion. Depending on the type of tumor, cells enter either the venous or lymphatic circulation (or both) and thus are spread to distant tissues (such as the lung, liver, or bone marrow) or local lymph nodes, respectively, prior to the development of clinically detectable metastatic lesions. The fact that significant proportions of patients with organ-confined tumors who undergo theoretically curative surgery later have recurrence of their disease argues that current approaches to cancer staging are, to some degree, inadequate. Sensitive detection of circulating tumor cells could lead to improved staging and monitoring of cancer patients. Such techniques can also be applied to the study of stem cell harvests and assessment of body fluids.

Available Assays

Methods for detection of circulating tumor cells (CTCs) incorporate multiple technologies and platforms. At their most basic, information can be obtained about the quantity of tumor cells in blood and the antigens they express. Some systems also allow for captured CTCs to be examined morphologically, be cultured in vitro, or be used for cytogenetic or molecular analysis. While only one assay is currently FDA-approved for CTC enumeration, work is being done to create simpler and more sensitive instruments for CTC detection that allow for additional analysis to be performed on isolated CTCs and their extracted nucleic acids.

Immunohistochemistry

IHC methods for tumor cell detection have been applied to preparations of cells from the bone marrow, lymph node aspirates, and peripheral blood mononuclear cells. Cells can be smeared or centrifuged by cytospin onto slides, or sections taken from frozen or formalin-fixed, paraffin-embedded (FFPE) tissue. IHC is performed using antibodies to specific proteins associated with tumor type and standardized methods. Slides can be scanned under the light microscope by the eye, though to achieve a high level of sensitivity, thousands to millions of cells must be screened, which is tedious and time consuming. Thus, image analysis has become a popular approach for screening [5]. Alternatively, flow cytometry is utilized to achieve assessment of high numbers of cells rapidly [6].

In general, the interpretation of occult disease detection assays consists of either a positive or negative result, given that the assay controls are appropriate. For IHC markers, nonspecific or aberrant expression of protein markers requires that careful evaluation of the cytologic characteristics of the positive cells be performed. The ability to visualize cell morphology with IHC can reduce false-positive results because the interpretation of a positive result can be limited to IHC positive cells with appropriate tumor cell morphology.

Reverse Transcription-Polymerase Chain Reaction

Reverse transcription-polymerase chain reaction (RT-PCR) was the earliest molecular method by which detection of circulating tumor cells was explored [7]. RT-PCR assays rely on the detection of mRNA transcripts specific to a tumor type, such as tyrosinase in melanoma [8] or prostate-specific antigen for prostate cancer [9]. Unfortunately, such methods detect all cells expressing the marker of interest, which may include benign circulating epithelial cells [10]. More specific RT-PCR detection of CTCs may be possible through detection of markers of malignancy such as chromosomal translocations or point mutations. However, translocations are more common in sarcomas and hematologic malignancies such as lymphoma and leukemia, limiting their utility when applied to the detection of carcinoma CTCs.

Antibody Capture

Normal hematopoietic cells do not express the surface epithelial cell proteins, such as epithelial cell adhesion molecule (EpCAM), seen on carcinoma-derived CTCs. Therefore, many methods rely on positive selection strategies based on CTC expression of antigen markers such as BER EP4 to facilitate separation and identification, as well as increase the sensitivity and specificity of detection. The most common techniques use magnetically labeled antibodies. While automated immunomagnetic cell separation is currently used clinically for applications such as chimerism testing after stem cell transplant [11], CTC detection requires a higher level of sensitivity due to the small numbers of CTCs present. The only assay currently FDA approved, the CellSearch® System (Janssen Diagnostics, LLC, Raritan, NJ) (Fig. 39.1) [12], utilizes antibody-coated ferrofluids to separate CTCs

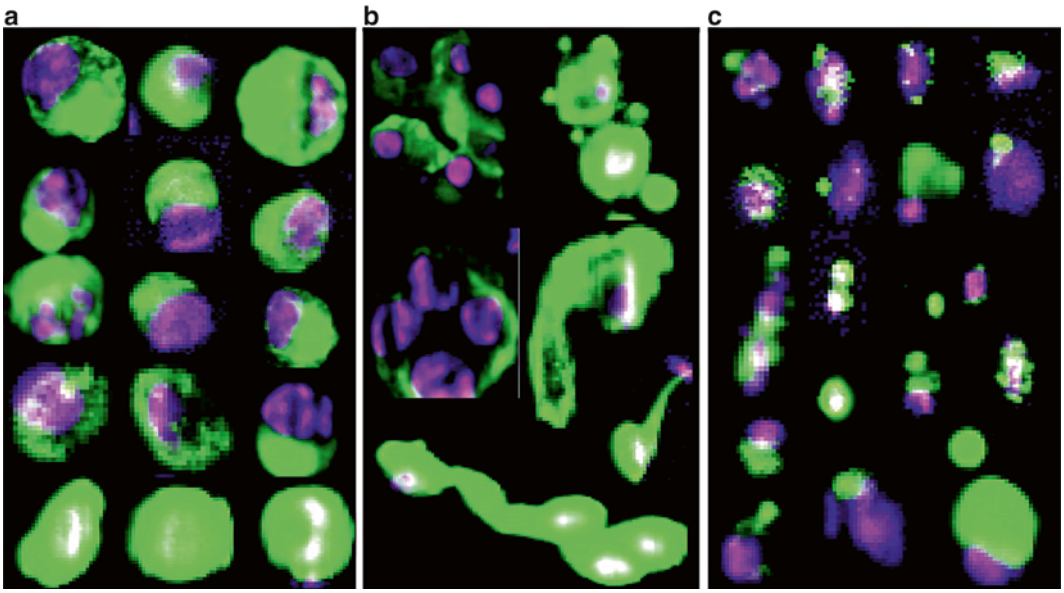

Figure 39.1 Gallery of CTC images from the CellSpotter Analyzer (Janssen Diagnostics LLC, Raritan, NJ) Diagnostics obtained from 7.5 mL of blood from cancer patients. (**a**) Examples of typical intact CTCs. (**b**) Examples of intact CTCs present as clusters or with odd shapes that are present less frequently. (**c**) Examples of CTC fragments and apoptotic CTCs. Images presented in **c** were not included in the CTC counts but are frequently observed in CTC analysis of carcinoma patients. From Allard WJ, Matera J, Miller MC et al. (2004) Tumor cells circulate in the peripheral blood of all major carcinomas but not in healthy subjects or patients with non-malignant diseases. Clin Cancer Res. 47:6897–6904. Reprinted with permission from American Association for Cancer Research

from normal blood components. To increase specificity, the isolated cells are then stained with 4′,6-diamidino-2-phenylindole (DAPI) and a fluorescently-labeled antitumor antibody prior to imaging. Automatically captured images are reviewed by a pathologist to determine the number of tumor cells present, based on a combination of fluorescent immunostaining and morphology [13].

To increase sensitivity, alternative methods of detection are being explored. One recently described ultrasensitive CTC detection device relies on detection of changes in electrical conductance caused by the presence of magnetic immunoparticles on cells instead of image analysis of separated cells to detect CTCs. Similar to flow cytometry, this system could allow multiple antigens to be simultaneously bound by multiple fluorescently labeled antibodies and detected on the same cell for increased specificity [14]. Such methods would require rigorous quality control and validation prior to clinical usage.

Negative cell selection strategies have successfully utilized CD45 immunomagnetic labeling to remove hematopoietic cells and enrich for CTCs in head and neck cancer patients [15]. These methods have possible advantages in that CTCs may express cytokeratins or other epithelial-specific markers weakly or not at all, limiting the ability to adequately tag CTCs for positive selection. Negative cell selection methods would allow for a wider spectrum of CTCs to be captured, including those that have undergone epithelial-to-mesenchymal transformation and thus might lack typical epithelial markers.

Size-Based Selection

CTCs of interest from solid tumors are often larger in size than normal blood components. This has led to the development of filter-based methods which collect larger cells for use in targeted analysis. One such device utilizes a parylene membrane to isolate possible CTCs from diluted blood. Once the blood has been passed through the filter, the trapped cells are analyzed directly on the membrane via light or electron microscopy, as well as by IHC [16]. These captured cells also are viable for cell culture, which is not possible for cells that have been fixed and stained [17]. Additional devices utilizing the principles of microfluidics have been successfully used to isolate CTCs [18, 19].

CTC chips combine the principles of both antibody capture and filter devices. Patient blood samples are filtered through silicon chips made up of microposts coated with antibodies to EpCAM; the chips are engineered to reduce cellular shear forces and allow a reasonable volume of blood to be analyzed. The captured epithelial cells are analyzed similarly to those captured on a filter and also remain viable for cell culture [20].

Clinical Utility

Blood

Many studies evaluating CTCs have been published. In a variety of tumor types, a correlation between the detection of blood-borne cells and tumor stage has been demonstrated [21–25]. Unfortunately, the data do not support the conclusion that the absence of CTCs indicates absence of metastatic disease with enough precision for clinical application [26]. Ultimately, the presence of CTCs may provide valuable information on the systemic spread of tumor in a manner different from conventional staging approaches. Small but aggressive tumors may shed cells into the circulation, while a more indolent but larger tumor may not; such a situation may appear to correlate poorly with tumor stage but may more accurately reflect tumor aggressiveness. The detection of circulating breast cancer cells is correlated with vascular invasion in the primary tumor. Larger studies using appropriate markers are needed to determine how to integrate these molecular test results for CTCs into cancer staging strategies.

While a relationship between CTCs and tumor stage is evident, studies demonstrating a correlation between circulating cells and cancer recurrence or progression have shown mixed results. A correlation between blood-borne cells and disease-free survival following radical prostatectomy has been reported [27]. Early studies correlated the presence of CTCs in patients with metastatic breast cancer to progression-free survival and overall survival [13]. However, in newly diagnosed breast cancer patients, the presence of CTCs prior to surgery was associated with an increased risk of cancer-associated death, but not a decreased risk of recurrence free survival [28]. Similar relationships have been established in colorectal [29] and prostate [30] cancers. These findings support the use of CTCs as prognostic markers that can help stratify patients into risk categories based on multiple clinical parameters.

CTC characterization may also be used to monitor response to chemotherapy. Prostate cancer patients treated with androgen deprivation therapy demonstrating the continuing presence or re-emergence of CTCs with androgen receptor signaling have poorer outcomes than those patients whose CTCs do not demonstrate androgen receptor signaling [31].

Bone Marrow

In general, better correlation has been observed between patient outcome and molecular or IHC detection of tumor cells in the bone marrow compared to blood [24, 25, 32, 33]. It is possible that circulating cells have the ability to get into the bloodstream but lack the ability to survive at a metastatic site, while cells in the marrow are at an "advanced" stage in the metastatic continuum, having acquired the capacity to survive in the circulation, attach, and grow in a remote environment. This, however, is a speculation until the molecular events underlying the metastatic process are better understood.

While few studies using single markers have shown results that correlate with clinical or pathologic parameters, correlation with survival/outcome was observed using IHC to detect cytokeratin-positive cells in bone marrow samples from breast cancer patients [32]. Similar findings have been reported for prostate [33] and colorectal cancer [34]. In the USA, such studies can be hampered by clinical practices that do not include bone marrow sampling as part of routine staging for many tumors.

Circulating Epithelial Cells in Benign Disease

While detection of CTCs has prognostic value when identified in cancer patients, CTC detection methods may show positivity in patients with benign diseases, particularly in disease processes in which the vascular integrity may be compromised, such as by inflammation, or by surgery. Patients with benign colonic diseases, including diverticulosis, Crohn disease, ulcerative colitis, endometriosis, and benign polyps, showed the presence of circulating epithelial cells identified as "circulating tumor cells" by the CellSearch (Janssen Diagnostics, LLC) and CK19-EPISPOT (Mabtech, Cincinnati, OH) assays in up to 18.9 % of patients. Up to 41 CTCs were detected in these patients, compared to no CTC detection in any of the healthy controls. Both platforms use antibodies to cytokeratin expression to identify circulating epithelial cells; again, these markers are not specific to malignant cells [35]. Further work is needed since patients with cancer may also be affected by benign disease of any organ and be falsely classified into poor prognosis groups based on circulating benign epithelial cells that are falsely identified as CTCs, regardless of the method used.

Circulating Nucleic Acids

Circulating tumor nucleic acids have multiple origins. They can exist as cell-free nucleic acids (cfNA) or be extracted from intact circulating tumor cells (see previous section). The presence of circulating nucleic acids has long been noted from peripheral blood samples [36], and the presence of circulating fetal DNA is routinely used for prenatal diagnosis [37, 38]. Increased levels of cfNA are often seen in patients with cancer [39]. In addition, since the advent of massively parallel sequencing, the molecular characterization of tumors has greatly expanded. Studies suggest that the majority of tumors carry somatic alterations [40, 41] that could be used to identify cfNA originating from tumors. This raises the possibility of "liquid biopsies," where peripheral blood is

analyzed for the presence of tumor-specific mutations. This is particularly significant as cell-free tumor DNA can originate from the patient's primary tumor, metastases, and CTCs that have undergone apoptosis within vessels. The contribution of cfNA from each would then provide information about tumor heterogeneity that would be unable to be obtained from a traditional biopsy and at lower risk to the patient [42].

Detection Methods

Compared to CTCs, cfNA are relatively easy to extract. The cellular component of the blood is spun down and the acellular plasma or serum used for extraction of nucleic acids, using either manual or automated methods. However, this apparent ease of isolation may adversely impact the implementation of cfNA analysis. Because of the ubiquity of blood-based specimens, a wide variety of extraction methods are available, each with its own performance characteristics. While general increases in cfNA are observed in patients with cancer [43], no standards are available to determine the efficiency of a specific cfNA extraction process. In addition to varying quantities of cfNA, the length of cfNA varies, from 20 bp-long microRNAs to DNA fragments over 80,000 bp long [44].

Exosomes

A more recent finding of relevance to the detection and isolation of cfNA is the existence of exosomes, which are small membrane-encoated vesicles ranging from 40 to 100 nm in diameter. Exosomes contain mRNA, miRNA, and proteins and are able to influence cell function when taken up by the cells [45, 46]. Exosomes have been shown to be stable in various body fluids and can be separated intact from serum and their contents used for subsequent analysis [47]. Exosomes appear to have important functions in normal immune regulation and also appear to have a role in regulation of immunoreactivity to cancer cells, as well as intercellular communication between cancer cells and stroma [46]. A better understanding of exosomes will be critical to understanding the metastatic process as well as the potential use of exosomes as cancer biomarkers.

Clinical Utility

Three main categories of cfNA are being explored for utility in patients with cancer: DNA, mRNA, and microRNA.

Cell-Free DNA (cfDNA)

If tumor-specific mutations are known, the presence of detectable point mutations in patient plasma over time could be used to monitor relapse and/or progression. The percentage of total cfDNA that is derived from tumor has been seen to track with the amount of disease present [42, 48]. A recent study showed that the percentage of cfDNA with TP53 mutation detectable in ovarian carcinoma patients tracked over time with CA125 levels. The same study also demonstrated that levels of cfDNA with tumor-specific mutations tracked with clinical presentation in a breast cancer patient with relapsed disease [42]. Tumor-derived cfDNA may be present in large amounts, as up to 52 % of cfDNA from a patient with a 13 cm hepatocellular carcinoma originated from the tumor. In this study, patients with smaller tumors had lower fractional concentrations of tumor-derived DNA. When the tumors were resected, the amount of tumor DNA in the circulation decreased [48].

High-sensitivity assays could also be used to look for mutations to help guide therapy, as demonstrated by the ability to detect 56 % of patients positive for *BRAF* V600 mutations using amplification refractory mutation system (ARMS) PCR in cfDNA [49]. Copy number changes and chromosomal rearrangements can be detected in cfDNA by genome sequencing (Fig. 39.2) [50], as noted in case reports of maternal malignancies detected by the presence of multiple aneuploidies on noninvasive prenatal testing using cfDNA [51].

Cell-Free mRNA (cfmRNA)

Because cfmRNA must be transcribed from DNA, it may provide more specific information about the pathways activated in a patient's tumor. Multiple studies have associated cfmRNA detection with clinical outcomes. The presence of cyclin D1 mRNA in the plasma of tamoxifen-treated breast cancer patients has been associated with poorer overall survival and lack of response to tamoxifen [52]. Expression levels of circulating hTERT cfmRNA have been studied in multiple tumor types. Increased levels above those seen in healthy individuals are associated with reduced disease-free and overall survival in patients with gastric cancer [22]. Elevated values have also been associated with shorter recurrence-free survival in patients with prostatic carcinoma [53].

Cell-Free microRNA (cfmiRNA)

MicroRNAs are involved in regulation of gene expression and are frequently dysregulated in cancer [54], and miRNA expression profiles have been established for many tumor types, increasing their potential clinical utility [55]. While most biomarker studies utilize multiple cell-free microRNA (cfmiRNA) targets, such as the combination of miR-21, -210, -155, and 196a in pancreatic adenocarcinoma [56], a recent study found that patients with stage IV breast cancer had higher concentrations of miR-21 [57]. Of note, miR-16, which is often used as a normalizer when evaluating expression levels of cfmiRNA, is present in high quantities in red blood cells. Therefore, the presence of hemolysis may interfere with the interpretation of cfmiRNAs in the plasma [58]. While measurement of cell-free miRNA has

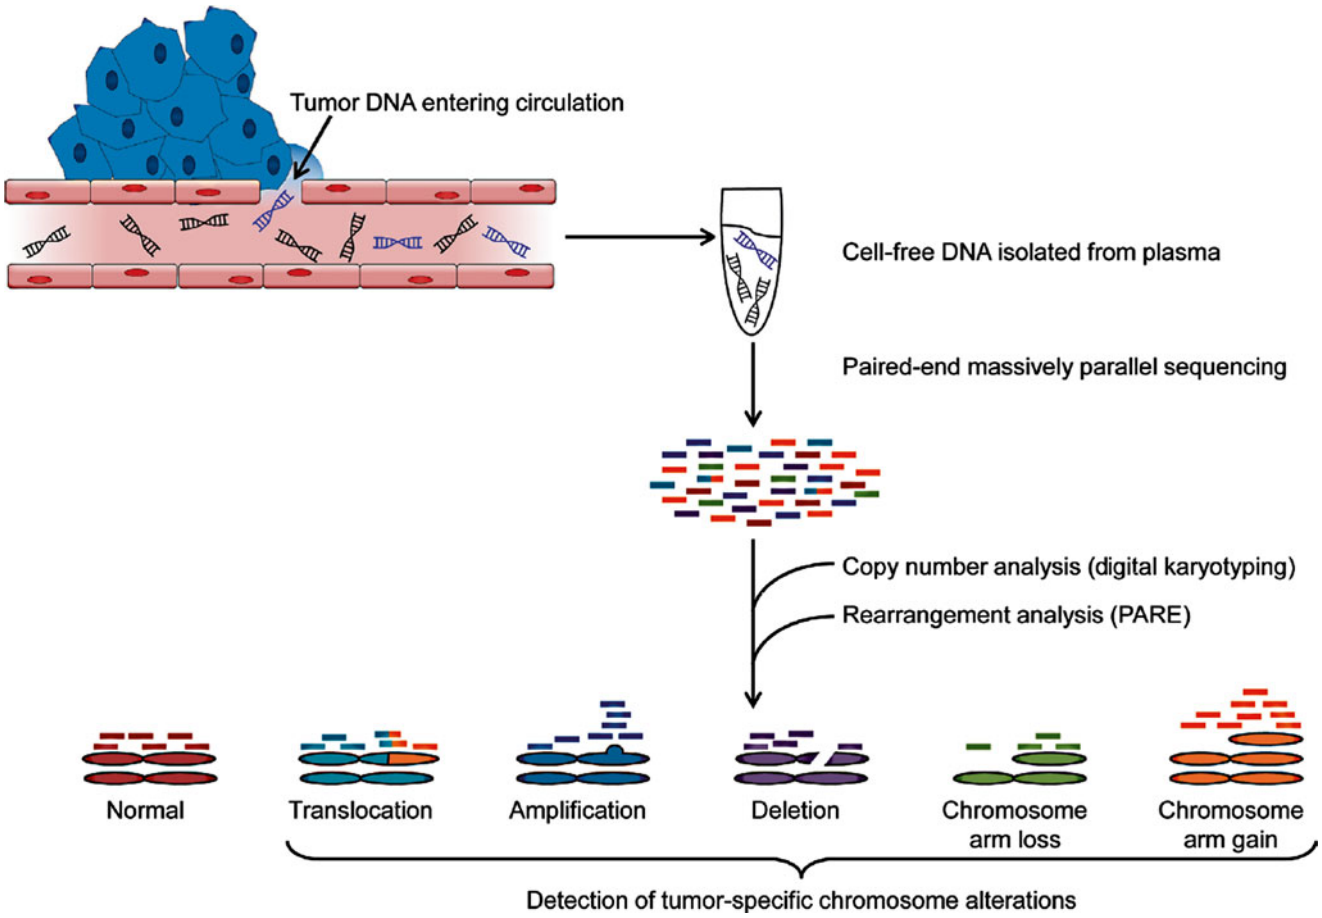

Figure 39.2 Schematic of analyses for direct detection of chromosomal alterations in plasma. The method uses next-generation paired-end sequencing of cell-free DNA isolated from plasma to identify chromosomal alterations characteristic of tumor DNA. Such alterations include copy number changes (gains and losses of chromosome arms) as well as rearrangements resulting from translocations, amplifications, or deletions. From Leary RJ, Sausen M, Kinde I, et al. (2012). Detection of chromosomal alterations in the circulation of cancer patients with whole-genome sequencing. *Sci Transl Med.* 4:162ra154. Reprinted with permission from AAAS

great potential, a more thorough understanding of normal and disease-related miRNA variation, as well as more straightforward analytic methods, will be needed.

Conclusions and Future Directions

Since 1991, when the first report of detection of circulating cells in melanoma was published [7], investigation of the clinical relevance of CTCs has been pursued by teams of investigators. To date, the only well-developed clinical parameter is the number of CTCs present in breast, colon, and prostate cancer patients, to be used for risk stratification. However, as the technology used for molecular analysis becomes capable of utilizing ever smaller quantities of input nucleic acids, the information that can be gained from cfNAs and isolated CTCs will continue to increase. In addition, these alternative tumor detection methods are beginning to be directly compared. For example, a recent study demonstrated a relationship between the amount of cfDNA in the serum of patients and overall survival, with those patients with higher levels of cfDNA demonstrating poorer survival. In addition, both levels of cfDNA and detection of CTCs are tracked with disease progression (Fig. 39.3) [30]. In addition, these more sensitive analysis methods will allow for elucidation of tumor heterogeneity, and it may therefore become possible to combine targeted therapies which block all of the oncogenic pathways utilized by a specific patient's cancer, much like antiretroviral therapies are currently tailored to the group phenotype of all HIV virions present in a patient, rather than one specific subclone.

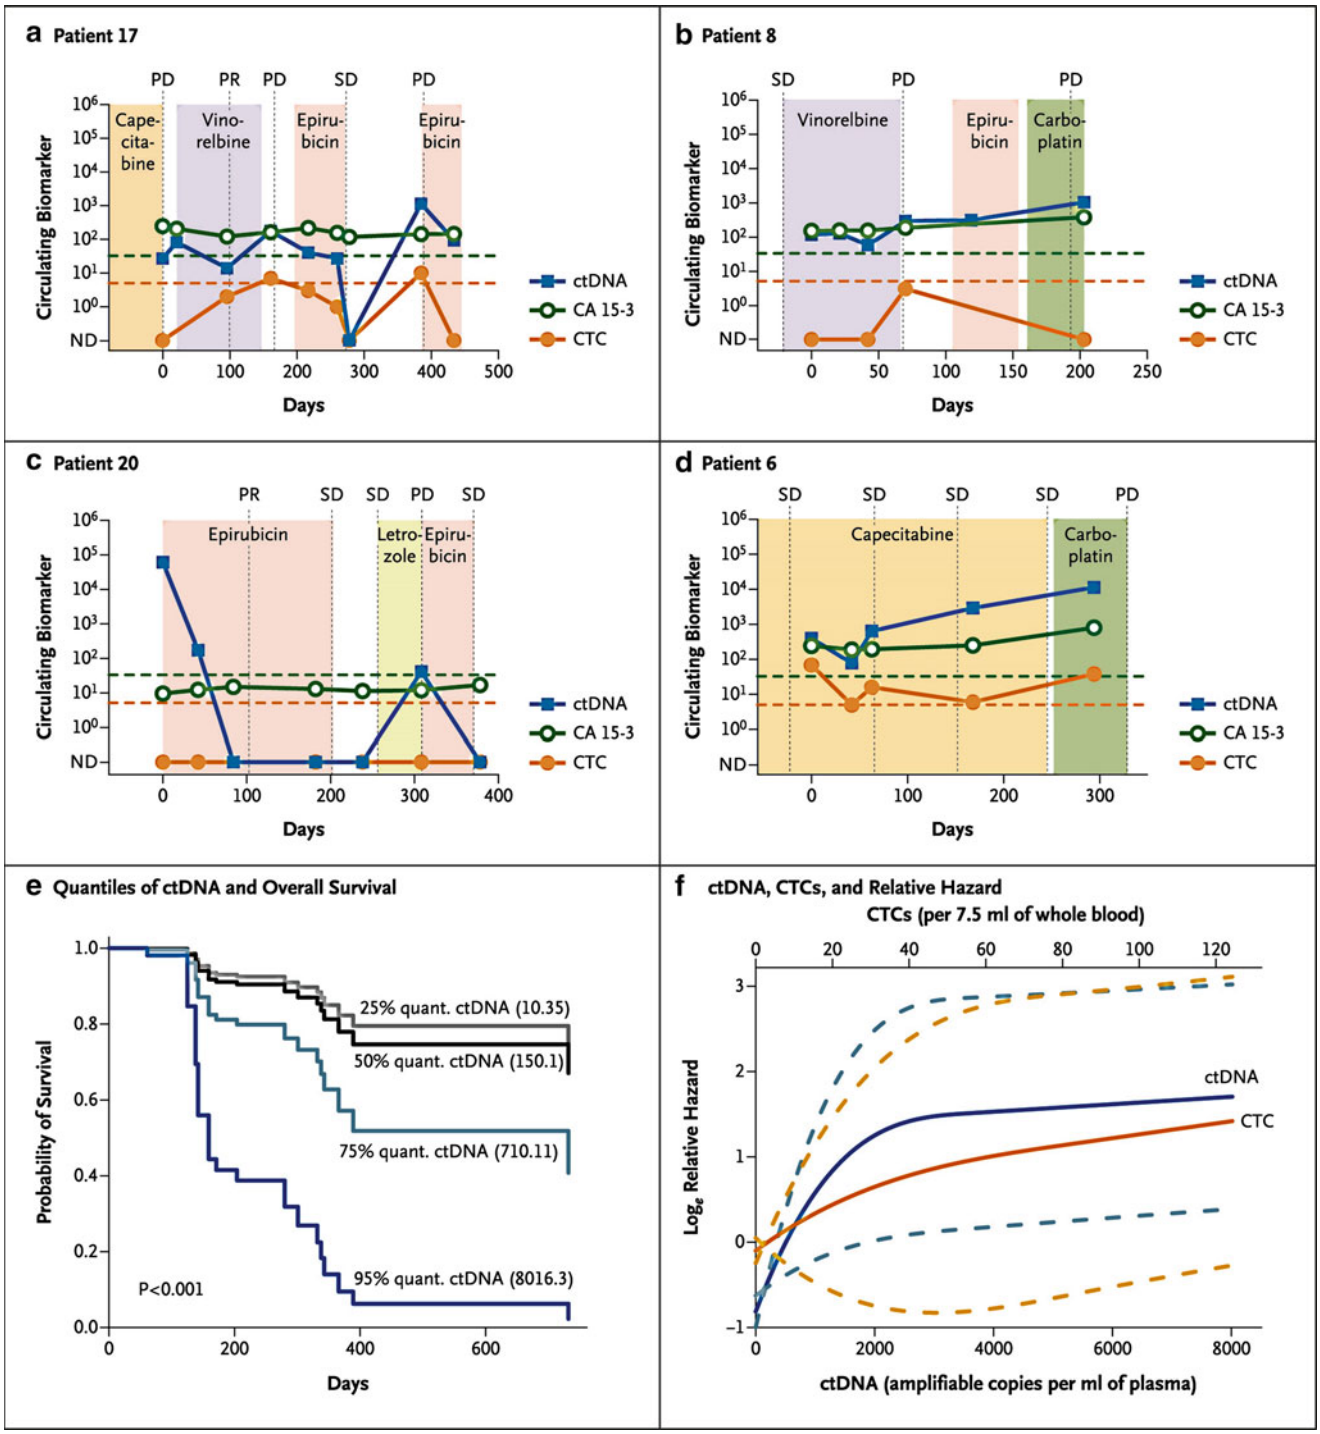

Figure 39.3 Comparison of circulating biomarkers to monitor tumor dynamics and predict survival. Panels **a**–**d** show serial circulating tumor DNA (ctDNA) levels (number of copies per milliliter of plasma), circulating tumor cell (CTC) numbers (per 7.5 ml of whole blood), CA15-3 levels (U per milliliter), and disease status as ascertained on computed tomography (*vertical dashed lines*) for four patients (one in each panel). Details of endocrine or cytotoxic therapy are indicated by *colored shading*. The *orange dashed line* indicates the threshold of five CTCs per 7.5 ml of whole blood. The *green dashed line* indicates the CA15-3 threshold of 32.4 U per milliliter. *ND* not detected, *PD* progressive disease, *PR* partial response, and *SD* stable disease. Panel **e** shows the results of a Cox regression model, which identified an inverse relationship between quantiles (quant.) of ctDNA (indicated in copies per milliliter of plasma) and overall survival, with increasing levels significantly associated with poor overall survival ($P<0.001$). At 200, 400, and 600 days, a total of 23, 8, and 3 patients were at risk, respectively. Panel **f** shows that increasing ctDNA levels (copies per milliliter), as indicated on the *bottom x* axis, and increasing numbers of CTCs (per 7.5 ml of whole blood), as indicated on the *top x* axis, were associated with an increased log*e* relative hazard. The prognostic discrimination power of circulating tumor DNA level was greatest with levels up to 2,000 copies per milliliter. Patients with levels of more than 2,000 copies per milliliter were uniformly found to have the worst prognosis. The prognostic power of CTCs increased according to the number of cells. *Dashed lines* represent 95 % confidence intervals. Abstract

The diagnostic entity of acute myeloid leukemia (AML) encompasses a heterogeneous group of diseases whose prognosis differs substantially according to the nature of the underlying molecular lesions and the age of the patient. AML is predominantly a disease of the elderly with a dramatic increase in incidence in individuals over 60 years of age. Traditionally, cases of AML have been classified as primary (de novo) or secondary including those arising following exposure to radiation and various chemotherapeutic agents (therapy-related AML), or occurring on a background of an antecedent hematologic disorder, particularly myelodysplasia.

Keywords

Acute myeloid leukemia • Cytogenetics • Fluorescence in situ hybridization (FISH) • FLT3 CEBPA • NPM1 • Risk stratification • Minimal residual disease (MRD) detection

Introduction

The diagnostic entity of acute myeloid leukemia (AML) encompasses a heterogeneous group of diseases whose prognosis differs substantially according to the nature of the underlying molecular lesions and the age of the patient. AML is predominantly a disease of the elderly with a dramatic increase in incidence in individuals over 60 years of age. Traditionally, cases of AML have been classified as primary (de novo) or secondary including those arising following exposure to radiation and various chemotherapeutic agents (therapy-related AML), or occurring on a background of an antecedent hematologic disorder, particularly myelodysplasia (Table 40.1).

Molecular Basis of Disease

Considerable progress has been made in understanding the cytogenetic and molecular basis of AML over the course of the last four decades. This has had a major impact on the laboratory workup of patients with suspected AML, with definition of the karyotype and mutational profile of the leukemic cells being of critical importance by serving to identify biologically distinct subsets of disease and predicting likely response to therapy and overall survival. Age of presentation has an important bearing on disease features, with balanced chromosomal translocations being relatively common in children and younger adults, while AML in older patients is characterized by a more common picture of whole chromosome losses (monosomy) and gains (e.g., trisomy) and losses (deletion) or gains (duplication, unbalanced translocation) of chromosomal segments that often occur in the context of a complex karyotype.

Cytogenetic Classification of AML

Balanced Chromosomal Rearrangements

Improved understanding of the molecular basis of AML was incorporated into the 2008 revision of the World Health Organization (WHO) Classification of Tumours of Haematopoietic and Lymphoid Tissues [1, 2], which necessitates application of a range of laboratory tests including cytogenetics and molecular testing to complement morphological and immunophenotypic assessment for disease diagnosis and categorization. The WHO classification is organized in a hierarchical fashion, with the first group being AML with particular balanced translocations or inversions (and their molecular counterparts), which are defined as "AML with recurrent genetic abnormalities" (Table 40.2). These include t(15;17)(q22;q12~21), the diagnostic hallmark of acute promyelocytic leukemia (APL), which accounts for approximately 12 % of AML cases. Cloning of the translocation breakpoints in the early 1990s [3–5] showed that t(15;17) leads to fusion of the gene that encodes the myeloid transcription factor, *r*etinoic *a*cid *r*eceptor *a*lpha (*RARA*), with a previously unknown gene designated *PML* (for promyelocytic leukemia), which has subsequently been found to be involved in growth suppression and regulation of apoptosis [6]. While the vast majority of APL cases have an underlying *PML–RARA* fusion, in approximately 1–2 % *RARA* is fused to an alternative partner [7] and classified as "AML with a variant *RARA* translocation." These rare subtypes of APL include involvement of *ZBTB16* (*PLZF*), *NPM1*, *NUMA*, *FIP1L1*, and *BCOR*, as a result of the t(11;17)(q23;q21), t(5;17)(q35;q21), t(11;17)(q13;q21), t(4;17)(q12;q21), and t(X;17)(p11;q21), respectively, and *PRKAR1A* and *STAT5B* in rearrangements involving 17q [8–14]. The nature of the fusion partner has an important bearing on disease biology, particularly the response to molecularly targeted therapies, i.e., all transretinoic acid (ATRA) and arsenic trioxide (ATO) [15]. ATRA targets the ligand-binding domain of the RARα moiety in the C-terminal region of the fusion proteins (as well as wild-type RARα). Sensitivity to ATRA has been documented in APL subtypes

Table 40.1 Factors predisposing to the development of AML

Genetic predisposition
Down syndrome
Fanconi anemia
Other inherited bone marrow failure syndromes:
Shwachman-Diamond
Diamond-Blackfan
Dyskeratosis congenita
Kostmann's
Familial platelet disorder (*RUNX1* mutation)
DNA repair defects, e.g., Bloom syndrome
Other germline mutations e.g., involving *CEBPA*, *DDX41*, *GATA2*
Prior hematologic disorder
Chronic myeloid leukemia
Myeloproliferative neoplasms
Myelodysplastic syndrome
Paroxysmal nocturnal hemoglobinuria
Exposure to environmental or therapeutic agents
Chronic exposure to benzene and derivatives
Ionizing radiation
Chemotherapeutic agents:
Alkylating agents
Topoisomerase II-targeting drugs

Table 40.2 Cytogenetic abnormalities used in the WHO classification of AML

Cytogenetic abnormalities used to define entities within the WHO category: "AML with recurrent genetic abnormalities"	
t(8;21)(q22;q22); *RUNX1-RUNX1T1*	t(6;9)(p23;q34); *DEK-NUP214*
inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*	inv(3)(q21q26.2) or t(3;3)(q21;q26.2); *GATA2-EVI1*[b]
t(15;17)(q22;q12); *PML-RARA*	t(1;22)(p13;q13); *RBM15-MKL1*
t(9;11)(p22;q23); *MLLT3-MLL*	
Cytogenetic abnormalities sufficient to diagnose WHO category: "AML with myelodysplasia-related changes"	
Complex karyotype	
Defined as three or more unrelated abnormalities, none of which can be a translocation or inversion associated with "AML with recurrent genetic abnormalities"	
Unbalanced abnormalities	**Balanced abnormalities**
–7 or del(7q)	t(11;16)(q23;p13.3)[a]
–5 or del(5q)	t(3;21)(q26.2;q22.1)[a]
i(17q) or t(17p)	t(1;3)(p36.3;q21.1)
–13 or del(13q)	t(2;11)(p21;q23)[a]
del(11q)	t(5;12)(q33;p12)
del(12p) or t(12p)	t(5;7)(q33;q11.2)
del(9q)	t(5;17)(q33;p13)
idic(X)(q13)	t(5;10)(q33;q21)
	t(3;5)(q25;q34)

Data from Vardiman et al. (Blood 2009;114(5):937–51) [2]

[a]A translocation commonly occurring in therapy-related AML. Before this translocation can be used as evidence for diagnosis of "AML with myelodysplasia-related changes," therapy-related disease should be excluded [b]Based upon Gröschel et al. [231] and Yamazaki et al. [232]

involving PML, NPM1, NUMA, and FIP1L1 [15], whereas PLZF-RARα and STAT5B-RARα have both been associated with primary resistance to retinoids and a poorer prognosis [14, 16, 17]. To date, sensitivity to ATO has only been demonstrated in *PML-RARA*-positive APL, reflecting the capacity of ATO to bind directly to the PML moiety of the fusion protein inducing its degradation via the proteasome [18]. Therefore, ATO should not be used for the treatment of APL as part of front-line therapy or in the context of suspected relapse, unless positive for *PML–RARA*.

Approximately 10 % of patients with AML are classified as having core-binding factor (CBF) leukemia with balanced chromosomal rearrangements that disrupt genes that encode components of the heterodimeric transcription factor complex, comprising RUNX1 (AML1, CBFα) and CBFβ, which plays a critical role in hematopoiesis [19]. The CBFα subunit is targeted by the t(8;21)(q22;q22), which fuses *RUNX1* (*AML1*, *CBFA2*) to the gene encoding the RUNX1T1 (formerly *ETO* for *e*ight *t*wenty *o*ne) transcriptional repressor, thereby potentially silencing RUNX1 target genes [19, 20]. The β-subunit is targeted by the inv(16)(p13.1q22) or the less common t(16;16)(p13.1;q22), in which *CBFB* is fused to the gene encoding myosin heavy chain (*MYH11*). *RUNX1* is a recurrent translocation target in non-CBF acute leukemias, with fusions to *ETV6* (*TEL*) as a result of the cytogenetically cryptic t(12;21)(p13;q22) in pediatric acute lymphoblastic leukemia (ALL), or to a range of partners in AML [21, 22], including *MECOM* (*EVI1*/*MDS1*) as a result of t(3;21)(q26;q22) in "AML with myelodysplasia-related changes" (Table 40.2). *RUNX1* also has been implicated in therapy-related leukemias arising following exposure to drugs targeting topoisomerase II [23, 24].

The *MLL* (for *m*yeloid/*l*ymphoid or *m*ixed-*l*ineage *l*eukemia, at present named *KMT2A*) gene located at 11q23 is a further recurrent translocation target in acute leukemia, with almost 80 partner genes now characterized [25]. MLL is an epigenetic regulator that plays a critical role in hematopoiesis, modulating *HOX* gene expression [26]. The most common *MLL* translocation observed in AML is the t(9;11)(p22;q23), which occurs in approximately 2 % of cases and leads to fusion of *MLL* with *MLLT3* (formerly known as *AF9*). AML with t(9;11)(p22;q23) has been associated with a relatively favorable outcome in some pediatric [27] and adult [28] AML studies and is distinguished as a separate entity in the 2008 WHO classification. Apart from the t(9;11), the most frequent other *MLL* translocations observed in AML are t(6;11)(q27;q23) involving *MLLT4* (*AF6*), t(11;19)(q23;p13.3) involving *MLLT1* (*ENL*), t(11;19)(q23;p13.1) involving *ELL*, and complex rearrangements between 10p12 and 11q23 (e.g., a reciprocal translocation and an inversion of an 11q segment translocated to 10p12 or inverted insertion of an 11q segment into 10p12 or a 10p segment into 11q23), in which the fusion partner is *MLLT10* (*AF10*) [29, 30]. While translocations involving *MLL* are observed in de novo leukemia and account for the majority of leukemias presenting in infancy, the locus is also a recurrent translocation target in therapy-related leukemias [31], particularly those arising following exposure to the epipodophyllotoxin class of topoisomerase II inhibitors [32]. Such cases are classified within the WHO as "therapy-related AML."

The remaining subtypes of AML distinguished as separate disease entities on the basis of cytogenetics are those characterized by the t(6;9)(p23;q34), inv(3)(q21q26.2) or t(3;3)(q21;q26.2), and t(1;22)(p13;q13). The t(6;9)(p23;q34) is found in approximately 1 % of AML and leads to fusion of *DEK* at 6p23 with *NUP214* (*CAN*) at 9q34, which encodes a component of the nuclear pore complex [33, 34]. The inv(3) or t(3;3) occurs in a similar proportion of AML cases and is associated with upregulation of the zinc finger transcription factor MECOM (EVI1), which is involved in normal hematopoiesis. AML with inv(3) or t(3;3) may present de novo, or secondary to prior myelodysplastic syndrome (MDS), and is characterized by a normal or elevated presenting platelet count and abnormal megakaryopoiesis with micromegakaryocytes in the bone marrow (BM) [35]. *MECOM* has long been implicated in leukemogenesis, having been identified as a recurrent integration target in murine retroviral mutagenesis screens [36, 37]; further evidence has been provided by characterization of MDS associated with insertional activation of *MECOM* occurring as a complication of gene therapy for chronic granulomatous disease [38]. Interestingly, these have provided important insights into potential mechanisms underlying acquisition of additional cytogenetic abnormalities in AML, with both cases showing monosomy 7, which is well recognized as a frequent secondary abnormality in cases with inv(3) or t(3;3). Forced overexpression of *MECOM* was found to disrupt normal centrosome duplication, suggesting that activation of *MECOM* as a result of retroviral insertion or chromosomal translocation leads to genomic instability, giving rise to acquisition of additional changes such as monosomy 7 involved in progression to MDS and AML.

AML with t(1;22)(p13;q13) is extremely rare (only approximately 40 cases reported worldwide [39]) and is associated with acute megakaryoblastic leukemia occurring in infants and young children (<3 years of age), particularly those without Down syndrome. The translocation fuses *RBM15* (for RNA-binding motif protein 15, also known as *OTT*) with *MKL1* (for MegaKaryoblastic Leukemia [Translocation] 1, or *MAL*) [40, 41], which is involved in normal megakaryocyte maturation [42].

AML with Myelodysplasia-Related Cytogenetic Changes

Apart from distinguishing AML with recurrent genetic abnormalities (as described above) from cases lacking one of these aberrations (or their molecular counterparts), cytogenetics is

also used in the 2008 WHO classification as a criterion (in conjunction with ≥20 % leukemic blasts in the bone marrow [BM]) to define a subgroup of "AML with myelodysplasia-related changes" (Table 40.2). Some of these cytogenetic entities are relatively common, such as monosomy 5 and 7 (−5 and −7) or deletion of the long arms of these chromosomes [del(5q) and del(7q)], which often occur as part of a complex karyotype. Noteworthy is the observation that while −7 is recurrently present both as a sole chromosome aberration and as part of a complex karyotype, −5 is very rare in patients with noncomplex karyotypes [43]. Moreover, most patients with a complex karyotype, with −5 detected using banding techniques (e.g., G-banding), do not harbor true monosomy 5, because segments from a seemingly missing chromosome 5 can be found using spectral karyotyping [44] or fluorescence in situ hybridization (FISH) [45] in marker chromosomes or unbalanced structural aberrations only partially identified by G-banding. While balanced translocations such as t(11;16)(q23;p13.3) involving *MLL*, t(3;21)(q26.2;q22.1) involving *RUNX1*, and t(3;5)(q25;q34) that generates the *NPM1–MLF1* fusion [46] may be initiating lesions in the development of leukemia, many of the changes considered as "myelodysplasia related" entail loss of chromosomal segments or whole chromosomes, which are poorly understood at the molecular level and may represent secondary and cooperating lesions in AML pathogenesis. Some of the aberrations designated "myelodysplasia related," especially balanced translocations and idic(X)(q13), are extremely rare [47], making characterization of their biological features and establishment of their impact on the clinical outcome challenging.

Mutations Involved in the Pathogenesis of AML

While balanced chromosomal rearrangements are considered to be primary lesions involved in the pathogenesis of AML, they are insufficient to mediate the full leukemic phenotype, requiring acquisition of additional cooperating mutations. Work is currently in progress to define the spectrum of such mutations in cytogenetically defined subsets of AML (Table 40.3), particularly using high-throughput sequencing technologies. In addition, a major focus of research in recent years has been the deciphering of the molecular events underlying the pathogenesis of AML with normal karyotype (CN-AML). Such strategies also carry the potential of generating important targets for molecular approaches to disease therapy.

Fms-Related Tyrosine Kinase 3 (*FLT3*)

The FLT3 tyrosine kinase has been an intense focus for research. Groups working in Japan in the late 1990s identified two major classes of receptor-activating mutations of *FLT3* that, cumulatively, are found in approximately 30 % of AML patients [127, 128]. In normal hematopoiesis, the membrane-spanning FLT3 receptor is expressed on early progenitor cells including CD34+ hematopoietic stem cells and plays an important role in proliferation, survival, and differentiation. High levels of abnormal FLT3 expression are seen in 70–100 % of AML [129].

FLT3 internal tandem duplication mutations (*FLT3*-ITDs) are in-frame palindromic duplications of exons 14 and 15 of the *FLT3* gene, between three and 400 bp in length, that disrupt the autoinhibitory function of the FLT3 juxtamembrane domain, leading to activation of signaling pathways downstream of FLT3. Pooled data show an overall *FLT3*-ITD incidence of 23 % in newly diagnosed AML, with a lower incidence in children [130]. Although ITD length has previously been thought not to influence prognosis, some longer ITDs, which integrate within the first tyrosine kinase domain of the receptor, are associated with lower complete remission (CR) rate and poor relapse-free survival [131]. *FLT3*-ITDs are accompanied by *NPM1* mutations in a significant proportion of CN-AML patients (see below) [58]. *FLT3*-ITDs are predominantly seen in CN-AML, being associated with proliferative disease with a high presenting white blood cell (WBC) count and poor prognosis in terms of significantly increased relapse rate and decreased survival in both adults and children [48, 132]. *FLT3*-ITD mutations at diagnosis are highly heterogeneous with respect to *FLT3*-ITD allelic ratio, ITD length, and cooperating partner mutations. Patients with a high "ITD mutant-to-wild-type *FLT3* allelic ratio," sometimes due to mitotic recombination leading to partial uniparental disomy, have an especially poor prognosis and usually relapse within 12 months of initial treatment [57]. Relapsed *FLT3*-ITD-mutated AML carries a particularly dismal prognosis; blasts in this setting are highly dependent on FLT3 kinase signaling, carrying a particularly high *FLT3*-mutant allelic burden with the wild-type *FLT3* allele often virtually absent [133].

A further 7–10 % of AML patients have mutations involving the activation loop within the tyrosine kinase domain of the FLT3 receptor (*FLT3*-TKDs), usually single base substitutions (most frequently D835Y) or small deletions. Although similarly FLT3 activating and associated with high presenting WBC levels, prognostic implications of *FLT3*-TKDs are less clear; patient series describe conflicting adverse, intermediate, and even favorable prognostic associations [51, 56, 134]. In contrast to *FLT3*-ITD mutations, *FLT3*-TKD mutations appear to frequently be "late genetic hits," are often lost at relapse, and have subtly different effects than ITDs on FLT3 downstream signaling [135].

Whether or not allogeneic stem cell transplantation (SCT) in first CR improves outcomes in *FLT3*-ITD AML patients remains controversial [136], although the presence of the mutation in the context of wild-type *NPM1* is considered an indication for SCT in the consensus document by the European LeukemiaNet [137]. The high incidence and clear

Table 40.3 Genes and their recurrent mutations in AML, with associated clinical characteristics and outcomes

Gene symbola/chromosome location	Gene name	Overall mutation frequency	Mutation frequency in CN-AML	Mutation frequency in other cytogenetic subsets	Associations of mutations with clinical and molecular characteristics	Clinical significance of the presence of mutations
FLT3 (*CD135*, *STK1*, *FLK2*)/13q12	Fms-related tyrosine kinase 3	*FLT3*-ITD: 21–30 % [48–50]	*FLT3*-ITD: 28–39 % [51–54]	*FLT3*-ITD: t(15;17): 30–37 % [48, 53, 54] t(8;21): 5–15 % [51, 53, 54] inv(16): 0–7 % [51, 53, 54] t(6;9): 90 % [54] inv(3)/t(3;3): 9 % [54] t(11;v)(q23;v): 3 % [51, 53] +8: 7–23 % [51] del(7q): 4 % [51] −5/del(5q): 3 % [54] CK: 2–3 % [51, 53, 54]	*FLT3*-ITD is associated with high WBC and high % of blood and BM blasts [48, 54, 57]	Pts with *FLT3*-ITD have worse DFS, EFS, and OS than those with no *FLT3*-ITD, but *FLT3*-ITD does not impact significantly on the CR achievement probability [53, 54] Outcome is particularly poor for pts with high *FLT3*-ITD mutant-to-FLT3-WT allelic ratio [54, 57, 58]
		FLT3-TKD: 5–11 % [49–51]	*FLT3*-TKD: 5–14 % [52, 54, 55] <60 years 9 % [56] 12 % [51]	*FLT3*-TKD: t(15;17): 8–9 % [54, 55] t(8;21): 2–7 % [51, 54, 55] inv(16): 14–24 % [51, 54] t(11;v)(q23;v): 6–7 % [51, 55] +8: 7–12 % [51, 54] del(5q): 9 % [51] −7: 5 % [51] del(7q): 9 % [51] −7/del(7q): 2–5 % [54, 55] CK: 1–4 % [51, 54, 55]	*FLT3*-TKD is associated with high WBC, % of blood, and BM blasts; rare in secondary AML [51, 56]	The prognostic significance of *FLT3*-TKD differs among studies [51, 55, 56]
CEBPA/19q13.1	CCAAT/enhancer-binding protein (C/EBP) alpha	7.5–9 % overall [49, 59] 3 % single mutations [59] 4 % double mutations [59]	13–18 % overall [52, 60, 61] 6–8 % double mutations [59, 60] 4–5 % single mutations [59, 60]	MRC favorable – 0 % mutation [59] MRC intermediate – 3 % single mutations – 5 % double mutations [59] MRC adverse – 3 % single mutations – 0 double mutations [59]	*CEBPA* double mutations are associated with younger age, FAB M1 and M2 BM morphology, low frequency of *FLT3*-ITD, and virtual absence of *NPM1* mutations [59, 62]	Among all AML pts, double *CEBPA* mutations are associated with better OS and RFS than those of pts with single *CEBPA* mutations and *CEBPA*-WT. On MVA, double *CEBPA* mutations have been an independent favorable prognostic factor for OS, RFS, and CIR. Double *CEBPA* mutations bestow longer OS also among pts in the MRC intermediate cytogenetic-risk group [59] In CN-AML pts, OS of pts with double *CEBPA* mutations was longer than OS of *CEBPA*-WT and single *CEBPA*-mutated pts. On MVA, double *CEBPA* mutations were an independent favorable factor for OS [62] In younger (<60 years) CN-AML pts, both single and double *CEBPA* mutations conferred longer OS than OS of *CEBPA*-WT pts, but only double *CEBPA* mutations retained favorable prognostic significance in MVA for OS, EFS, and RFS [60]

(continued)

Table 40.3 (continued)

Gene symbola/chromosome location	Gene name	Overall mutation frequency	Mutation frequency in CN-AML	Mutation frequency in other cytogenetic subsets	Associations of mutations with clinical and molecular characteristics	Clinical significance of the presence of mutations
NPM1 (*NPM*, *B23*)/5q35.1	Nucleophosmin (nucleolar phospho-protein B23, numatrin)	29–35 % [49, 63]	46–62 % [52, 63–65]	t(15;17): 0 % [66, 67] t(8;21): 0–3.5 % [66, 67] inv(16): 0–3 % [66, 67] +8: 10–21 % [66, 67] −7/del(7q): 0–4 % [66, 67] −5/del(5q): 3 % [67] t(11;v)(q23;v): 6 % [66] CK: 0–2 % [66, 67]	*NPM1* mutations are more frequent in women, associated with higher WBC, % of BM blasts and platelet counts; low or absent CD34 and high CD33 expression on blasts. *NPM1* mutated pts twice as often have *FLT3*-ITD and *FLT3*-TKD than *NPM1*-WT pts. *NPM1* mutations almost never coexist with double *CEBPA* mutations, *MLL*-PTD, R172 *IDH2*, and *BCOR* mutations [63–67]	In younger adults (<60 years), *NPM1* mutations confer superior CR rates, EFS, DFS, and OS in the absence of *FLT3*-ITD [52, 64–67] In older pts (≥60 years), *NPM1* mutations alone are an independent favorable prognostic factor [68]
IDH1/2q32-qter	Isocitrate dehydrogenase 1 (NADP+), soluble	7–10 % [49, 69, 70],	13–16 % [69–71],	CBF AML: 1.5 % [70] t(15;17): 1 % [69]	Among all AML pts, *IDH1* mutations are associated with higher platelet counts, higher % of BM blasts [69], FAB M1 BM morphology [70], and CN-AML [69, 70] In CN-AML, *IDH1* mutations are associated with higher platelet counts, lower frequency of *FLT3*-ITD [71] and *NPM1* mutations [70]	In CN-AML overall, *IDH1* mutations are not associated with outcome [70, 71] In CN-AML pts with *NPM1* mutations and no *FLT3*-ITD, *IDH1* mutations are associated with a higher relapse risk, shorter OS [70] and DFS [71]

IDH2/15q21-qter	Isocitrate dehydrogenase 2 (NADP+), mitochondrial	3–10 % [49, 69, 70, 72],	11–19 % [69, 71],	t(8;21): 0 % [69, 70] inv(16): 0 % [69, 70]	Among all AML pts, *IDH2* mutations are associated with older age, MRC cytogenetic intermediate-risk group and *NPM1* mutations [72]. Pts with *IDH2* mutations involving residue R172 have lower WBC and an abnormal, MRC intermediate-risk karyotype more often than pts with *IDH2* mutations involving R140, most of whom have CN-AML In CN-AML, *IDH2* mutations are associated with older age and higher platelet counts [69, 71] *IDH2* mutations involving R140 are associated with FAB M1 BM morphology [73] *IDH2* mutations involving R172 do not or very rarely occur together with *FLT3*-ITD, *FLT3*-TKD, *MLL*-PTD, or *NPM1*, *WT1*, and *CEBPA* mutations [70–72]	Among all AML pts, *IDH2* mutations involving R172 are associated with low CR rates and increased CIR *IDH2* mutations involving R140 constitute an independent favorable prognostic factor for relapse risk and OS [72] In CN-AML, *IDH2* mutations involving R172 are associated with lower CR rates [70, 71], increased relapse risk, and shorter OS [70]. *IDH2* mutations involving R140 are not associated with outcome [71]
TET2 (*FLJ*20032)/4q24	Tet methylcytosine dioxygenase 2	8–27 % overall [49, 74–76] 7 % in younger pts (≤60 years) [74] 24 % in older pts (>60 years) [74]	18–30 % overall [74, 76, 77] 15 % in younger pts (<60 years) [77] 29 % in older pts (≥60 years) [77]	+8: 35 % [74]	*TET2* mutations are associated with older age, higher WBC, lower platelet counts, and absence of *IDH1* and *IDH2* mutations [74–77]	*TET2* mutations have no impact on outcome of all AML pts [75] In CN-AML, *TET2* mutations are associated with lower CR rates and shorter DFS, OS, and EFS in the ELN Favorable Genetic Group [76, 77]

(continued)

Table 40.3 (continued)

Gene symbola/chromosome location	Gene name	Overall mutation frequency	Mutation frequency in CN-AML	Mutation frequency in other cytogenetic subsets	Associations of mutations with clinical and molecular characteristics	Clinical significance of the presence of mutations
DNMT3A/2p23	DNA (cytosine-5-)-methyltransferase 3 alpha	23 % [49, 78] 18 % in younger pts (<60 years) [79]	34 % overall [80] 27–35 % in younger pts (<60 years) [79–81] 33 % in older pts (≥60 years) [80]	CBF AML: 1 % [79]	Among all AML pts, *DNMT3A* mutations are associated with older age, higher WBC, % of BM blasts and platelet counts, CN-AML, *FLT3*-ITD, *NPM1*, and *IDH1* mutations, and higher *MLL5* expression [79] In CN-AML, *DNMT3A* mutations are associated with higher WBC and % of BM blasts and are found more often in pts with *NPM1* mutations, *FLT3*-ITD and *CEBPA*-WT [80]	In all AML pts, *DNMT3A* mutations independently predict a shorter OS, but are not associated with RFS or CR rate [79] *DNMT3A* mutations are associated with shorter OS and RFS in all pts and an intermediate cytogenetic-risk subset without *FLT3*-ITD and *NPM1* mutations [78] In CN-AML overall, *DNMT3A* mutations are associated with shorter DFS (but not OS [80]), with lower CR rates and shorter OS on MVA [79] and shorter EFS and OS, which remain significant on MVA [81] In CN-AML pts <60 years, non-R882-*DNMT3A* mutations confer shorter DFS and OS [80] In CN-AML pts ≥60 years, R882-*DNMT3A* mutations are associated with shorter DFS and OS [80]
ASXL1 (*KIAA*0978)/20q11	Additional sex combs like transcriptional regulator 1	3–19 % [49, 82–84]	5–10 % overall [82, 83] 3 % in younger pts (<60 years) [85] 16 % in older pts (≥60 years) [85]	t(15;17): 0–5 % [82, 83] t(8;21): 8–20 % [82, 83] inv(16): 0 % [82, 83] sole +8: 32 % [82]	*ASXL1* mutations are more frequent in men [82, 85], relatively rare in younger adults (<60 years) Among all pts, *ASXL1* mutations are associated with lower WBC [83], FAB M1 BM morphology, expression of HLA-DR and CD34 [82] and very rarely coexist with *NPM1* mutations and *FLT3*-ITD [83, 84] In CN-AML pts, *ASXL1* mutations are associated with lower WBC, % of BM and blood blasts, *CEBPA* mutations and low incidence of *NPM1* mutations and *FLT3*-ITD [85]	In all AML pts, *ASXL1* mutations confer lower CR rates and worse OS in univariable analyses and worse OS in MVA [83] In CN-AML pts ≥60 years, *ASXL1* mutations confer lower CR rates and worse DFS, OS, and EFS [85]

BCOR (*FLJ*20285, *KIAA*1575)/Xp11.4	BCL6 corepressor	2.5 % [86]	4 % [86]	None found among 131 pts with abnormal karyotypes [86]	In CN-AML, *BCOR* mutations very rarely coexist with *NPM1* mutations and *FLT3*-ITD; ~45 % of *BCOR*-mutated pts harbor *DNMT3A* and *RUNX1* mutations [86]	In CN-AML, *BCOR* mutations are associated with a shorter OS and EFS [86]
BCORL1 (*FLJ*11362)/Xq25-q26.1	BCL6 corepressor-like 1	6 % [87]	2 % [87]	NA	*BCORL1* mutations have not been detected together with *TP53*, *CEBPA*, or *NPM1* mutations [87]	Prognostic significance is not yet established
PHF6/Xq26	PHD finger protein 6	2–3 % [49, 88, 89],	NA	NA	*PHF6* mutations are seven times more common in men than women; associated with FAB M0, M1, and M2 BM morphology, detected mostly in pts with CN-AML and +8 [88]	Prognostic significance is not yet established
MLL (*ALL-1, CXXC7, HRX, HTRX1, TRX1, MLL1A, KMT2A*)/11q23	Myeloid/ lymphoid or mixed-lineage leukemia (trithorax homologue, *Drosophila*)	5–7 % [49, 50]	5–11 % [52, 90–92]	sole +11: 91 % [93]	In younger (<60 years) CN-AML pts, *MLL*-PTD is associated with lower WBC and less extramedullary involvement and negatively associated with *NPM1* mutations [52, 94] and mutually exclusive with *CEBPA* mutations [52] In older (≥60 years) CN-AML pts, *MLL*-PTD is associated with lower hemoglobin and incidence of *NPM1* mutations and absence of *CEBPA* and R172 *IDH2* mutations [95]	In earlier studies on CN-AML, *MLL*-PTD were associated with shorter CRD (but not CR rates or OS) [90–92] No prognostic significance was found in intensively treated younger (<60 years) [94] and older (≥60 years) CN-AML pts [95]

(continued)

Table 40.3 (continued)

Gene symbola/chromosome location	Gene name	Overall mutation frequency	Mutation frequency in CN-AML	Mutation frequency in other cytogenetic subsets	Associations of mutations with clinical and molecular characteristics	Clinical significance of the presence of mutations
RUNX1 (*AML1, CBFA2, AMLCR1, PEBP2A2*)/21q22.3	Runt-related transcription factor 1	5 % [49] 6 % in younger pts (<60 years) [96]	13–26 % overall [97, 98] 6–8 % in younger pts (<60 years) [96, 98] 16 % in older pts (≥60 years) [98]	t(15;17): 0 % [96] t(8;21): 0 % [96] inv(16): 0 % [96] +13: 90 % [97] +8: 30 % [97] +11: 31 % [97] +21: 36 % [97] –7/del(7q): 29 % [97]	Among all pts, *RUNX1* mutations are associated with FAB M0 and M2 BM morphology, *MLL*-PTD and *IDH1–IDH2* mutations and wild-type *NPM1* and *CEBPA* [96] In CN-AML, *RUNX1* mutations are associated with older age, lower hemoglobin, WBC and % blood blasts, *ASXL1* mutations, and wild-type *NPM1* and *CEBPA* [98]	Among all pts, *RUNX1* mutations associated with resistant disease and worse RFS, OS, and EFS [96, 97] In CN-AML, *RUNX1*-mutated pts had lower CR rates and worse DFS, OS, and EFS than wild-type *RUNX1* pts [97, 98]
KIT (*PBT, C-Kit, CD117, SCFR*)/4q11-q12	v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homologue	6 % [49] 2 % (only *KIT* D816 mutations) [50]		t(8;21): 12–47 % [99–102] inv(16): 22–47 % [99, 101–103]		In t(8;21) pts, *KIT* mutations associated with inferior OS, EFS, RFS, RI, and CIR [99–102] In inv(16) pts, *KIT* mutations associated with worse RI, higher CIR, and shorter OS [102, 103]
TP53 (*p53, LFS1*)/17p13.1	Tumor protein p53	2–14 % [49, 104]	1 % [104]	CK-*TP53* mutation: 60–69 % [104, 105] CK-*TP53* mutation/loss: 70–78 % [104, 105] t(8;21): 7 % [104] t(15;17): 0 % [104] inv(16): 0 % [104] t(11;v)(q23;v) : 0 % [104] +13 sole: 10 % [104] +8 sole: 7 % [104] –7 sole: 0 % [104]	*TP53* mutation and loss are associated with older age and larger number of chromosome aberrations in CK pts [105]	*TP53* mutations and loss confer lower CR rates and worse EFS, RFS, and OS in pts with a complex karyotype [105]

WT1 (*GUD, AWT1, WAGR, WIT-2*)/11p13	Wilms tumor 1	5–8 % [49, 106]	8–10 % [106, 107] 11–13 % in younger pts (<60 years) [108, 109] 7 % in older pts (≥60 years) [110]		Among all AML pts, *WT1* mutations found in younger pts and those with *FLT3*-ITD [106] In CN-AML pts, *WT1* mutations are almost twice as common in younger (<60 years) than in older (≥60 years) pts, associated with higher WBC and % of blood blasts and lower hemoglobin [109, 110]. Mutually exclusive of *TET2* and *IDH1/2* mutations [233, 234]	In CN-AML pts, *WT1* mutations confer: worse DFS and OS (but not CR probability) [109] worse CR probability, CIR, DFS, and OS [106, 107] no impact on RFS or OS [108] CN-AML pts with *WT1* mutations and *FLT3*-ITD have lower CR rates and worse RFS and OS than pts with *WT1* mutations without *FLT3*-ITD [108]
NRAS (*N-ras*)/1p13.2	Neuroblastoma RAS viral (v-ras) oncogene homologue	10–11 % [49, 50, 112],	9–14 % [52, 113]	inv(16): 18–38 % [112, 113] t(8;21): 6–10 % [112, 113] t(15;17): 2–5 % [112, 113] inv(3): 18–27 % [112, 113] t(3;5): 63 % [112] t(11;v)(q23;v): 4–20 % [112, 113] +8: 17 % [112] −7/del(7q): 8 % [112] CK: 2–4 % [112, 113]	No significant associations, except for lower WBC in one study [113]	No significant impact on outcome [112, 113] *RAS* mutations reported to increase sensitivity of AML blasts to higher doses of cytarabine [114]
KRAS (*KRAS1, KRAS2*)/12p12.1	v-Ki-ras2 Kirsten rat sarcoma viral oncogene homologue	2–5 % [49, 112]	4 % [112]	inv(16): 17 % [112] t(8;21): 5 % [112] t(15;17): 4 % [112] inv(3): 10 % [112] t(3;5): 0 % [112] t(11;v)(q23;v): 6 % [112] +8: 3 % [112] −7/del(7q): 7 % [112] CK: 3 % [112]	No significant associations [112]	No significant impact on outcome [112]

deleterious prognostic impact of *FLT3*-ITD mutations, however, coupled with the tangible clinical gains achieved through targeting dysregulated tyrosine kinase activity in other malignancies, such as chronic myeloid leukemia (CML) and breast cancer, have provided a strong rationale for the development of FLT3-targeted therapy in AML. Several multi-kinase inhibitors with FLT3-inhibitory activity, the most developed of which being midostaurin (PKC412), lestaurtinib (CEP701), and sorafenib, have been assessed in combination with chemotherapy in international phase III clinical trials, with results currently awaited. Newer and more potent FLT3-inhibitory molecules, most notably quizartinib (AC220) and ASP2215, are in earlier stages of clinical development [138].

Other molecular abnormalities that have been consistently shown to confer a poorer prognosis include mutations in the *RUNX1* gene [96–98, 139] and partial tandem duplications of the *MLL* gene (*MLL*-PTD) [52, 90–92], although recent data indicate that intensive consolidation therapy that includes autologous transplant in first CR may improve the outcome of CN-AML patients with the latter rearrangement [94].

CEBPA and *NPM1*

Major steps forward in understanding the molecular pathogenesis of AML were the discoveries of mutations in the genes encoding CCAAT/enhancer-binding protein-α (*CEBPA*) and nucleophosmin (*NPM1*) that serve to identify subsets of patients with relatively favorable prognosis [63, 140] and which were recognized as provisional disease entities in the 2008 WHO classification [1]. Mutations in *CEBPA*, which encodes a myeloid transcription factor, were first described in 2001 and occur in approximately 10 % of cytogenically normal AML (CN-AML) [141]. Mutations cluster in both the amino- and carboxy-terminal regions, with the former leading to expression of a truncated 30 kDa isoform of CEBPA (p30) and loss of the 42 kDa full-length protein (p42) [142]. Carboxy-terminal mutations affect regions involved in mediating dimerization and DNA binding. Interestingly, in the majority of patients with *CEBPA* mutations, both alleles are involved, combining an upstream mutation in one allele with a downstream mutation in the other [141, 142]. The analysis of patient samples has shown that *CEBPA* mutations can be inherited, with progression to AML in later life being associated with acquisition of additional mutations, which can include involvement of the other *CEBPA* allele [143, 144]. Significant insights into the biology of *CEBPA* mutations have been provided by murine models, which have shown how loss of p42 expression (mimicking biallelic N-terminal *CEBPA* mutations), or compound heterozygous mutations affecting amino- and carboxy-terminal regions in combination, affects hematopoiesis and gives rise to AML [145, 146]. While early studies reported that *CEBPA* mutation predicts a relatively favorable outcome in AML [52, 147–149], subsequent studies have shown that the more favorable prognosis is seen in the subset of patients with biallelic mutations, especially those who lack *FLT3*-ITD [59, 60, 150–152].

Mutations in *NPM1*, discovered by Brunangelo Falini and colleagues in 2005 [63], represent the most common molecular lesion identified in AML to date, occurring in a third of cases, including 50–60 % of those with CN-AML. Over 30 different mutations have been described, which involve the C-terminal region of the protein. These lead to loss of tryptophan residues and generation of a nuclear export signal resulting in delocalization of nucleophosmin from the nucleoli to the cytoplasm [153]. *NPM1* mutation is considered, an AML-defining lesion, being stable in the vast majority of cases over the disease course [154, 155]. Indeed, *NPM1* mutation has been shown to enhance self-renewal of hematopoietic progenitors, associated with expanded myelopoiesis leading to the development of AML in a murine model [156]. Patients with AML harboring an *NPM1* mutation in the absence of a *FLT3*-ITD have a relatively favorable prognosis [64–66]. *NPM1* mutations also have been shown to be strong, independent predictors of better outcome in older patients, especially those aged 70 years and older [68]. Whereas most studies have focused on CN-AML [157], patients with AML with cytogenetic abnormalities that would be considered to have a standard risk but who harbor an *NPM1* mutation also have a better outcome in the absence of *FLT3*-ITD; however, those with *FLT3*-ITD in the absence of the protective effect of an *NPM1* mutation have a very poor prognosis [43, 158]. Whether the combined *FLT3*-ITD/*NPM1*-mutated genotype is itself associated with an intermediate or adverse outcome remains open to debate.

Mutations Identified in Epigenetic Modifiers

Using a variety of high-throughput technologies, recurring mutations that affect regulation of gene expression, directly or through more indirect mechanisms, have been identified in recent years. In a landmark study, genome sequencing was undertaken to identify the presence of biologically relevant mutations in a case of *NPM1*-mutated CN-AML [159]. A mutation was identified in codon 132 of isocitrate dehydrogenase 1 (*IDH1*), which was already known to be involved in the pathogenesis of gliomas, with *IDH1* mutations predicting a relatively favorable prognosis in this group of solid tumors [160]. In the cytoplasm, IDH1 catalyzes the conversion of isocitrate to α-ketoglutarate, generating NADPH. The *IDH1* mutation that affects the arginine amino acid at codon 132 (R132) reduces α-ketoglutarate formation, but in addition alters enzyme function leading to generation of 2-hydroxyglutarate (2-HG), associated with increased reactive oxygen species (ROS) levels, HIF1α induction, and upregulation of VEGF [161, 162]. IDH1 mutations at R132 occur in approximately 7 % of AML, particularly in those with a normal karyotype and *NPM1* mutation (reviewed by

Löwenberg [163]). Based upon these findings, AMLs were screened for mutations in the mitochondrial homologue *IDH2*, which were identified in an additional 10 % of AML cases. The *IDH2* mutations cluster at codons R140 (8 %) and R172 (2 %) [69, 71, 163, 164]; these mutations are prognostically distinct, with the latter predicting a poor prognosis [71–73]. Interestingly, an inverse relationship has been observed between mutations occurring in the *IDH* genes and *TET2* [74–77, 165]. The latter was found to be a recurrent mutation target in a range of myeloid neoplasms including AML by array-based comparative genomic hybridization (aCGH) and single nucleotide polymorphism (SNP) profiling. TET2 has subsequently been shown to be involved in the regulation of hydroxylation of 5-methylcytosine, with disruption of TET2 leading to myeloid transformation in murine models [166, 167]. Methylation profiles of *IDH*- and *TET2*-mutated AMLs were found to be highly comparable, with evidence to suggest that accumulation of 2-HG secondary to *IDH* mutation inhibits TET2 function [165]. Moreover, it has recently been shown that TET2 binding to DNA is regulated by WT1, providing an explanation why WT1 mutations are also mutually exclusive of TET2 and IDH mutations [233, 234]. Consequently, this pathway is deregulated in a third of AML cases.

Studies examining the clinical significance of *TET2* mutations have yielded somewhat conflicting results. Gaidzik et al. [75] found no impact of *TET2* mutations on outcome of a cytogenetically heterogeneous patient population, and this was also true for the whole cohort of CN-AML patients analyzed by Metzeler et al. [77]. However, another study determined that *TET2* mutations confer worse outcome in AML patients with intermediate-risk cytogenetic findings (defined using the Southwest Oncology Group [SWOG] criteria) [74], and two studies demonstrated adverse impact of *TET2* mutations on the outcome of those CN-AML patients who are classified in the Favorable Genetic Group of the European LeukemiaNet (ELN) classification (i.e., CN-AML with mutated *CEBPA* and/or mutated *NPM1* without *FLT3*-ITD) [76, 77].

Re-sequencing of the index *NPM1*-mutated CN-AML case with *IDH1* mutation originally characterized by Mardis and colleagues [159] identified an additional acquired alteration in another gene involved in epigenetic regulation, namely, the DNA methyltransferase *DNMT3A* [168]. This gene was confirmed to be mutated in approximately 20 % of all AML patients and in approximately 30 % of those with a normal karyotype [79–81, 168–171]. Mutations in *DNMT3A* are associated with the presence of *NPM1* mutation and *FLT3*-ITD and are distributed throughout the gene, with a mutational hotspot at position R882. The presence of a *DNMT3A* mutation predicts a poorer outcome (Table 40.3).

High-throughput technologies have identified mutations in additional epigenetic modifiers in AML. These include *ASXL1* (*a*dditional *sex* combs *l*ike transcriptional regulator 1), which is involved in the regulation of histone methylation [82, 83, 85, 172], with mutations occurring 3–5 times more often in patients aged 60 years or older [83, 85] than in younger patients and being associated with the presence of *RUNX1* or *CEBPA* mutations, the absence of *NPM1* and *FLT3*-ITD mutations, and poorer clinical outcome [85]. Using exome sequencing, mutations in genes located on the X-chromosome encoding the related transcriptional repressors BCOR and BCORL1 have been identified [86, 87]. The former is a rare translocation target in APL [12]; is mutated in approximately 4 % of CN-AML, detected in cases with wild-type *NPM1*; and may also confer a poorer prognosis [86]. There are few data on *BCORL1* mutations, which were first identified in older adults with secondary AML and subsequently found to be mutated in 6 % of a cohort of unselected AML patients [87]. In addition, approximately 3 % of AML have mutations in the *PHF6* gene, which encodes a homeodomain protein and is frequently mutated in T-cell ALL [49, 88].

Indications for Testing

Thorough laboratory investigation of AML is fundamental to the optimal clinical management of the disease and is not only critical to establish the diagnosis but also to identify patients who may benefit from targeted therapies, to inform risk stratification and to guide post-remission therapy including the need for stem cell transplantation. Prognostic factors in AML can be subdivided into those defined at diagnosis (pretreatment) or following the start of antileukemic therapy (post-treatment) (Table 40.4). With the exception of age, patient performance status, and type of AML (de novo vs secondary), pretreatment determination of the likely outcome to therapy is dependent on laboratory investigation, with karyotype, *NPM1*, *CEBPA*, and *FLT3* mutation status being the most important factors identified to date. Predicting the likely outcome following initiation of therapy falls entirely within the realm of the laboratory and, for patients achieving morphological complete remission (CR), is dependent on the detection of minimal residual disease (MRD), for which flow cytometry and molecular diagnostic strategies have been developed.

Establishing a Diagnosis of AML

Morphological analysis of peripheral blood and BM smears stained with Wright Giemsa or May-Grünwald Giemsa is clearly the first step in establishing a diagnosis in patients with suspected leukemia. After confirmation that a patient has AML on the basis of morphology, cytochemistry, and immunophenotyping (for which standardized antibody panels have been published [173, 174]), cases may be classified further according to blast characteristics and degree of dif-

Table 40.4 Prognostic factors for relapse in patients with newly diagnosed AML

Pre-treatment predictors	
Major	**Other**
Age	Elevated WBC
Cytogenetics	Elevated LDH
Molecular:	Secondary disease[a]
FLT3-ITD	Dysplastic features[a]
NPM1 mutation	BCL2/BAX ratio
Biallelic *CEBPA* mutations	Resistance protein expression e.g., PGP[a]
	TP53 mutation[a]
	Autonomous growth of AML blasts in culture[a]
	Immunophenotype e.g. CD34 expression[a]
	Expression of chemotherapy metabolizing enzymes
	High expression of BAALC, MN1, MECOM, and ERG
	Mutations in WT1, DNMT3A, RUNX1, ASXL1
	MLL-PTD
	Absence of IDH2 mutation at R140
Post-treatment predictors	
Initial response (% BM blasts)	
MRD assessment	

BM bone marrow, *LDH* lactate dehydrogenase, *MRD* minimal residual disease, *PGP* P-glycoprotein, *WBC* presenting white blood cell count

[a]Many factors previously considered to confer adverse risk have been shown to be closely related to cytogenetic risk group

ferentiation in the BM. This initial workup may reveal features that are helpful in predicting the presence of particular cytogenetic and/or molecular subtypes of disease [e.g., APL with t(15;17)/*PML–RARA*, AML FAB-type M4Eo with inv(16)/t(16;16)/*CBFB–MYH11*], and may be especially valuable in situations in which the expected cytogenetic abnormality is lacking, yet the predicted fusion gene is formed as a result of a cryptic rearrangement, for example, an insertion event (Fig. 40.1), which may be detected by FISH or reverse transcription PCR (RT-PCR) [7, 175].

Rapid examination of the peripheral blood smear (and BM, once available) with immediate communication of results to the clinical team is essential for patients with a possible diagnosis of APL, which represents a medical emergency. A rapid and accurate diagnosis is critical for appropriate patient management, allowing ATRA and supportive care measures to be initiated promptly, to reduce the risk of induction death due to hemorrhage. Indeed, international disease guidelines recommend that ATRA therapy be initiated as soon as a diagnosis of APL is suspected and not delayed until the results of cytogenetic, FISH, or PCR analyses are available [176]. For the rapid diagnosis of APL, immunofluorescent methods using antibodies directed against the PML protein are of value, with the conversion from a normal pattern of 5–20 discrete dots to a microparticulate nuclear staining pattern (>30 microspeckles, Fig. 40.2) being indicative of expression of the PML-RARα fusion protein. Even if the diagnosis of APL is confirmed by the PML antibody test or other methods (i.e., cytogenetics, FISH), RT-PCR should still be performed on diagnostic samples to confirm the PML-RARα isoform type, which is important to define the most appropriate assay for subsequent monitoring for MRD [176].

Immunophenotyping is a valuable component of the routine workup of acute leukemia for a number of reasons, serving to (1) establish, confirm, and further refine a diagnosis of AML and (2) identify aberrant *l*eukemia-*a*ssociated *i*mmuno*p*henotypes (LAIPs), which can be used to monitor response to therapy. Although immunophenotypic studies are assuming a more important role in assessing remission status by informing risk-adapted treatment approaches in AML (reviewed by Freeman et al. [177]), they are not discussed in any great detail in this chapter, which is restricted to the role of molecular genetic analyses.

Role of Karyotype Assessment

Karyotype analysis is a mandatory component of the workup for all patients with AML, as emphasized in international ELN disease guidelines, by providing important diagnostic and prognostic information [173]. Apart from identifying patients with particular subtypes of AML who may benefit from molecularly targeted therapies [e.g., ATRA/ATO in t(15;17)/*PML–RARA*-associated APL and tyrosine kinase inhibitors for patients with t(9;22)(q34;q11.2)/*BCR–ABL1*-associated AML], karyotype analysis has been used to distinguish groups of patients with substantially different probabilities of achieving a remission and risks of relapse, particularly as a tool to guide SCT in first CR.

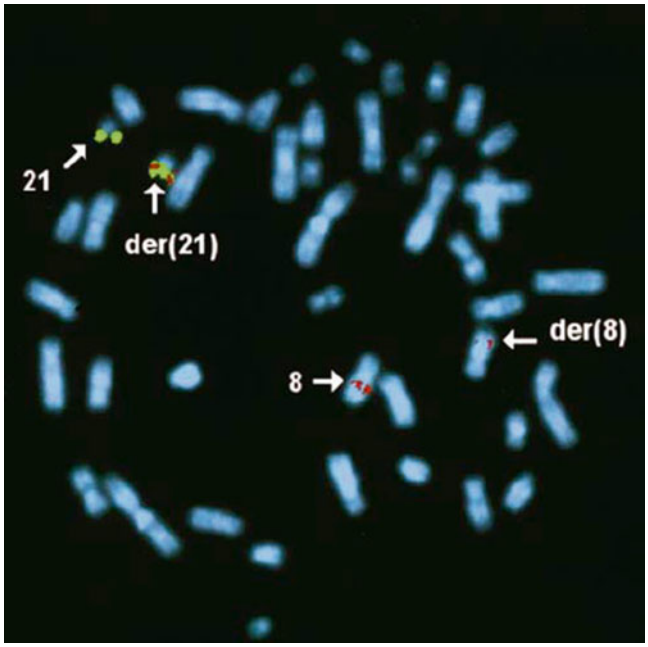

Figure 40.1 Characterization by FISH of AML with fusion gene formation due to cryptic rearrangements. Cryptic (8;21) rearrangement in an AML M2 case demonstrated by FISH with *RUNX1* (*green*) and *RUNX1T1* (*red*) probe set (Vysis, Downers Grove, IL). Fusion signals are seen on the derivative 21, and *RUNX1T1* signals are diminished on the derivative 8 (Figure prepared by Marina Lafage-Pochitaloff, Institut Paoli Calmettes, Marseille. From Grimwade D. The clinical significance of cytogenetic abnormalities in acute myeloid leukaemia. Baillieres Best Pract Res Clin Haematol. 2001;14:510. Reprinted with permission from Elsevier)

In multivariable analyses that take into account age, type of AML (de novo or secondary), and presenting WBC, the diagnostic karyotype emerges as the most significant prognostic factor and provides the framework for current risk-stratified treatment approaches applied in younger adults (reviewed by Grimwade and Hills [178]). Large multicenter studies have consistently reported that patients with APL with the t(15;17)(q22;q12~21) treated on ATRA- and anthracycline-based protocols, together with core-binding factor (CBF) AML with t(8;21)(q22;q22) or inv(16)(p13.1q22)/t(16;16)(p13.1;q22) treated with intensive chemotherapy involving high-dose cytarabine, are characterized by relatively favorable prognoses [176, 179, 180]. In this favorable risk group, relapse rates are too low and salvage rates too high for there to be any survival benefit for the routine application of allogeneic SCT in first remission [181–183]. Conversely, adults with adverse risk cytogenetics (Table 40.5) [43], including abnormalities of 3q [other than t(3;5)], del(5q), −5/−7, abnormalities of 17p, translocations involving 11q23 [apart from t(9;11)(p22;q23) and t(11;19)(q23;p13)], t(9;22)(q34;q11.2), and complex karyotype, have a very poor prognosis with conventional chemotherapy and therefore are considered candidates for SCT and experimental treatment approaches. The definition of a complex karyotype is inconsistent [178], with the WHO adopting a cutoff of three or more unrelated cytogenetic abnormalities [2]. However, subsequent large studies from the UK Medical Research Council (MRC) and Munich Leukemia Laboratory provide evidence that a threshold of four or more unrelated abnormalities is most prognostically relevant [43, 184]. Considering the outcome of cases of AML with more than one cytogenetic abnormality, in which the karyotype includes features that in their own right would confer favorable or adverse risk, respectively, has led to the definition of hierarchical risk groups, which are used to inform risk-stratified treatment approaches (Table 40.5).

Approximately half of the patients with adverse risk cytogenetic features have a so-called monosomal karyotype (MK+), as defined by the Dutch-Belgium Hemato-Oncology Cooperative (HOVON) group based on loss of an autosomal chromosome (i.e., excluding −Y and −X) in combination with at least one other autosomal monosomy (e.g., 44,XY,-7,-18) or one or more structural abnormality [e.g., 45,XY,inv(3)(q21q26.2),-7] [185]. Monosomal karyotypes almost invariably include at least one chromosomal abnormality that would independently be associated with adverse risk. Moreover, since up to 75 % of complex karyotypes are hypodiploid (i.e., have ≤45 chromosomes) and some pseudodiploid (46 chromosomes) and hyperdiploid complex karyotypes (≥47 chromosomes) also include at least one monosomy (Fig. 40.3) [186], the vast majority of patients with a complex karyotype are considered to have a monosomal karyotype. The MK+ cases have a particularly poor prognosis [43, 184, 187], which potentially could be improved by allogeneic SCT [188]. Although hitherto there has been little evidence that MK+ AML is biologically distinct from cases with other adverse risk cytogenetic abnormalities, a recent study has revealed that monosomal karyotype was more frequent among patients with a complex karyotype who also had *TP53* alterations (i.e., mutations and/or *TP53* gene losses) than among those who did not [105]. In multivariable analysis for overall survival (OS) of patients with a complex karyotype, *TP53* alterations constituted the most important prognostic factor, which outweighed other variables, including monosomal karyotype [105].

Prognostic Significance of Cytogenetics in Pediatric AML

Cytogenetics also comprises part of the routine workup for AML arising in children, although few large studies have considered its prognostic significance in the pediatric population. The Pediatric Oncology Group (POG) considered a cohort of 478 patients aged less than 21 years, reporting the best outcomes in those with inv(16), t(8;21) and normal karyotype [189]. Poorer outcome was reported in patients with 11q23 abnormalities and APL patients with t(15;17),

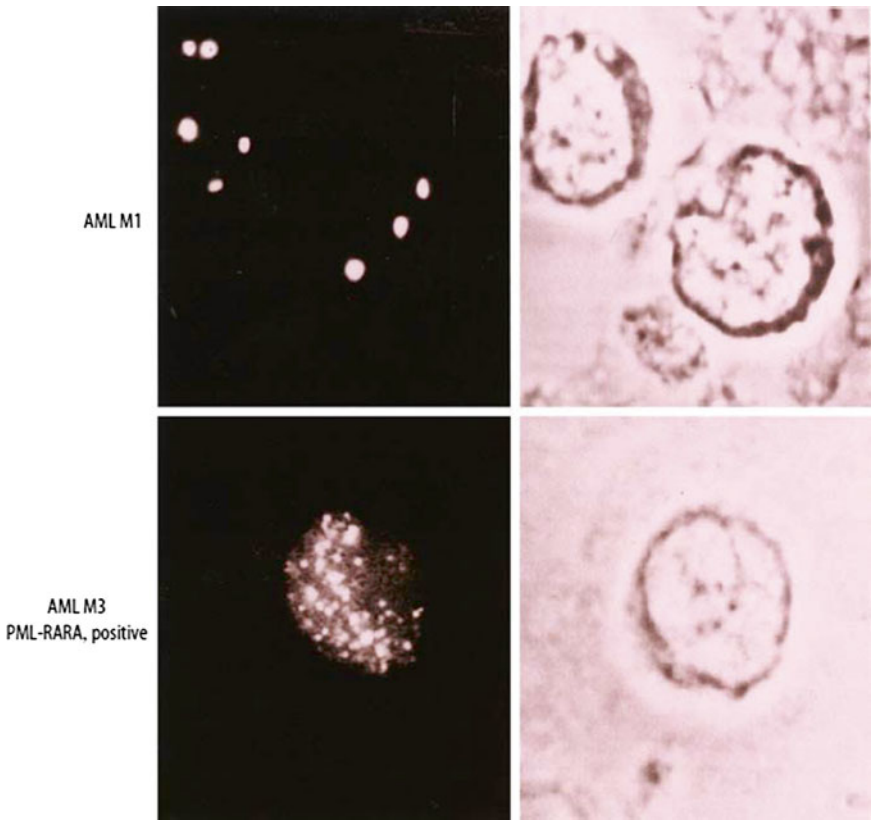

Figure 40.2 Rapid diagnosis of acute promyelocyte leukemia with the PML-RARα fusion by PML immunostaining. In leukemic blasts from cases of PML-RARα-negative AML and in normal cells, PML protein is localized within nuclear body structures (PML nuclear bodies). In such cells PML antisera detect a wild-type staining pattern comprising fewer than 30 (typically 5–20) discrete nuclear dots, e.g., a case of AML M1 (*upper left panel*). Whereas in APL cases with the PML-RARα fusion, PML nuclear bodies are disrupted, leading to a characteristic microspeckled/microparticulate nuclear staining pattern (>30 nuclear dots) with PML antisera, which detects PML-RARα and wild-type PML proteins (*lower left panel*). Nuclear integrity is confirmed by a nuclear stain or in this case by phase contrast microscopy (*right-hand panels*). These studies were performed with a PML polyclonal antibody, with FITC-conjugated secondary antibody

Table 40.5 Revised Medical Research Council AML cytogenetic classification applied in younger adults [43]

Risk group	Cytogenetic abnormality
Favorable	t(15;17)(q22;q12~q21) t(8;21)(q22;q22) inv(16)(p13.1q22)/t(16;16)(p13.1;q22)
Intermediate	Normal karyotype Cytogenetic abnormalities not classified as favorable or adverse
Adverse	In the absence of favorable risk cytogenetic abnormalities: abn(3q) [excluding t(3;5)(q21~25;q31~35)] inv(3)(q21q26.2)/t(3;3)(q21;q26.2) add(5q)/del(5q), –5 add(7q)/del(7q), –7 t(11q23) [excluding t(9;11)(p21~22;q23) and t(11;19)(q23;p13)] t(9;22)(q34;q11.2) –17/abn(17p) Complex karyotype (≥4 unrelated abnormalities other than favorable or adverse abnormalities)

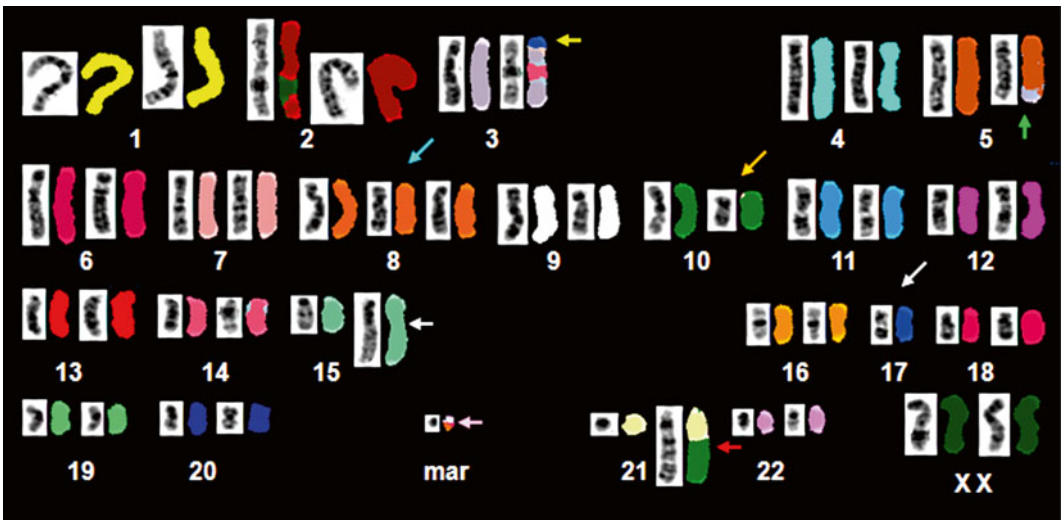

Figure 40.3 Complex karyotype containing eight chromosome abnormalities detected in a patient with AML, analyzed using spectral karyotyping (SKY). Each chromosome is represented twice, by G-banding-like inverted and contrast-enhanced 4′,6-diamidino-2-phenylindole (DAPI)-stained image on the left and SKY image shown in classification colors on the *right*. This karyotype contains several chromosome abnormalities relatively common in AML with a complex karyotype: an unbalanced translocation between chromosomes 3 and 17 leading to loss of material from 3p and chromosome 17 (*yellow arrow*), an unbalanced translocation between chromosomes 3 and 5 resulting in partial loss of 5q (*green arrow*), trisomy of chromosome 8 (*blue arrow*), loss of one copy of chromosome 17 (*gray arrow*), and a complex rearrangement between chromosomes 10 and 21 leading to gain of material from 21q (*red arrow*). Also present is a complex rearrangement of chromosome 15 resulting in amplification of 15q material (*white arrow*), abnormal chromosome 10 (*orange arrow*), and a small marker chromosome whose origin could not be established reliably by SKY technique (*pink arrow*). Had this case been analyzed using G-banding method only, the karyotype would have been classified as monosomal because chromosome 17 appeared to be lost entirely, with its part translocated to chromosome 3 not being recognizable without SKY. From Mrózek K. Cytogenetic, molecular genetic, and clinical characteristics of acute myeloid leukemia with a complex karyotype. Semin Oncol 2008;35(4):365–77. Reprinted with permission from Elsevier

with the caveat that most of the latter group did not receive ATRA. The findings of a more recent, similarly sized study (454 patients <18 years of age) published by the Berlin-Frankfurt-Münster (BFM) group were in accordance with most adult series, showing the best outcomes in patients with inv(16), t(8;21), and t(15;17) [190]. Significantly poorer outcomes were observed in patients with −7 and 11q23 aberrations [apart from t(9;11) as the sole abnormality and t(11;19)]. The largest study to date was conducted by the UK MRC group and considered the prognostic significance of 22 cytogenetically defined subgroups within a cohort of 729 children aged 0–15 years [191]. In this study, in which APL patients were excluded, the best outcomes were observed in CBF AML, with 10-year overall survival rates of approximately 80 %. In contrast to the POG and BFM studies, patients with 11q23 abnormalities ($n=104$) had an intermediate prognosis (61 % OS at 10 years), with no evidence of heterogeneity according to the translocation partner. While this study did not analyze the prognostic significance of secondary aberrations accompanying 11q23 abnormalities, a recent large international effort identified trisomy 8 as an independent favorable prognostic factor and trisomy 19 as an adverse prognostic factor in pediatric 11q23/*MLL*-rearranged AML, whereas complex karyotype was found to be an unfavorable prognostic factor in univariable analysis only [192]. Interestingly, in the MRC series, some of the abnormalities that have been associated with adverse risk in adult patients, i.e., −5, 3q abnormalities, and complex karyotype, were not predictive of a worse outcome in children. However, significantly poorer survivals were observed in pediatric AML with 5q abnormalities, t(6;9), −7, trisomy 13, and 12p abnormalities, including translocations involving *ETV6*, with only 36 % of patients alive after 10 years [191].

Prognostic Significance of Cytogenetics in Older Adults with AML

The outcome of AML presenting in older adults is much poorer (7–15 % 5-year survival for adults >60 years), as compared to when the disease presents in younger individuals (with cure rates of 40–45 %). Nevertheless, cytogenetics is still prognostic in this age group and therefore recommended as part of the diagnostic workup. The largest study to date was conducted by the MRC group, studying 1,065 patients (aged >55 years) treated in the AML11 trial [193]. The best outcome was observed in APL patients with the t(15;17) and CBF AML patients, with a superior CR rate (72 %) associated with low rates of resistant disease, although favorable risk cytogenetics only accounted for 7 % of patients in this age group, as compared to 24 % of younger adults [193]. Overall survival rates were much poorer in the older age

group than those observed in younger adults with the same cytogenetic abnormalities (only 34 % OS at 5 years vs >60 %). While the relapse rate in APL patients with the t(15;17) was low (26 % at 5 years), the relapse rates in the CBF AML patients were substantially higher (>80 % relapse risk at 5 years), as compared to 33 % in younger patients, which may reflect differences in disease biology as well being a consequence of less intensive therapy in older patients. Older patients with a complex karyotype (defined as five or more abnormalities) had an extremely poor prognosis, with relatively few achieving CR (26 %) due to high rates of resistant disease (56 %). The small proportion of elderly patients achieving remission almost invariably relapsed, leading to OS rates of only 2 % at 5 years [193]. Similar data have been published by other groups [194–196], raising the question as to whether elderly patients with high-risk cytogenetics might be most appropriately offered palliative non-intensive treatment approaches or supportive care. On the other hand, recent preliminary data indicate that at least some patients aged 60–70 years who achieve a CR may benefit from reduced-intensity allogeneic SCT [197]. Moreover, alternative, novel therapies are being investigated in older adults with AML [198]. In the MRC series, patients with normal karyotypes or noncomplex cytogenetic aberrations had marginally less poor outcomes, with 5-year survivals of 15 % and 10 %, respectively. The slightly better outcome in CN-AML occurring in older patients may reflect the influence of cases with *NPM1* gene mutation. Most recently, the Groupe Ouest -Est d'étude des Leucémies Aiguës et autres Maladies du Sang (GOELAMS) reported, in a study involving 186 older adults (>60 years) with unfavorable cytogenetic abnormalities, that the presence of a monosomal karyotype (found in 59 %) predicted a particularly poor prognosis [199].

Detection of Chromosomal Aberrations by Molecular Testing: Fluorescence In Situ Hybridization

Although karyotype assessment provides a valuable framework for design of risk-adapted treatment of AML, it has limitations as a means of determining the most suitable treatment approach for individual patients. Indeed, molecular analyses can serve to further refine the diagnosis of AML, reliably identify subgroups of patients that require a specific treatment approach (e.g., molecularly targeted therapies), and define targets for subsequent MRD assessment. Critical limitations of cytogenetic analysis include false-negative results due to sampling of residual normal BM elements and test failure in approximately 10 % of patients, with rates differing according to whether samples are analyzed in local or more remote laboratories, entailing substantial differences in transit time. In such cases, RT-PCR and/or FISH can be used to detect the presence of fusion genes corresponding to the favorable cytogenetic-risk group.

Even in AML with evaluable metaphases at diagnosis, patients may not necessarily be assigned to the most appropriate risk group on the basis of karyotype assessment alone due to cryptic rearrangements. Studies conducted by the European Working Party and UK MRC have established that almost 10 % of cases with morphologic APL and successful karyotype analysis actually lack the classical t(15;17) but nevertheless have an underlying *PML–RARA* fusion [7, 200]. This is most commonly the result of insertion events, in which chromosomes 15 and 17 are typically of normal appearance. Such cases share the beneficial response to targeted therapies, i.e., ATRA and ATO. This is supported by outcome data from the UK MRC ATRA trial, which showed that patients in whom *PML–RARA* was identified solely by molecular means had a comparable outcome to those with t(15;17) documented by karyotype [200]. This would suggest that cases of AML with cryptic rearrangement of *CBF* genes (i.e., with cryptic *RUNX1–RUNX1T1* or *CBFB–MYH11*) also are likely to be biologically equivalent to and share the favorable prognosis of those with karyotype-documented t(8;21) or inv(16)/t(16;16) [175]. This supports the adoption of routine molecular testing for *CBF* fusions in AML, which is most efficiently undertaken by RT-PCR. In CBF AML, testing for *KIT* mutations, which predict a poorer outcome, may be merited (reviewed by Döhner et al. [173]). Approximately 5 % of cases of CBF AML have a cryptic rearrangement and such cases cannot be reliably identified on the basis of distinct morphological features [175]. Where evidence of CBF AML is identified by RT-PCR testing in the absence of the typical cytogenetic lesion, the result should be independently confirmed using FISH to document fusion gene formation, for example, as a result of an insertion event (Fig. 40.1).

The most appropriate strategy for molecular screening for fusion genes depends upon the age group of the patient, with CBF AML representing a greater proportion of AML arising in children (approximately 17 %) and younger adults (approximately 12 %) than in the elderly, where they comprise less than 5 % of cases [193]. Molecular testing for CBF AML enables identification of additional patients informative for MRD assessment using a fusion gene marker, as well as distinguishing individuals who can potentially be spared an allogeneic SCT in first CR. Apart from undertaking molecular analysis for the *PML–RARA* fusion in cases with M3/M3v morphology, screening for this abnormality also is merited in patients presenting with severe coagulopathy (hemorrhage and/or thrombosis), an APL-like immunophenotype, or cases with cells suggestive of APL morphology even if occurring in a minor population.

In patients lacking molecular evidence of *PML–RARA*, CBF AML, or other favorable risk genotype (i.e., *NPM1*-mutated/*FLT3*-ITD-negative, biallelic *CEBPA* mutation), FISH may prove helpful in screening for chromosomal losses

(e.g., −5/del(5q), −7/del(7q), −17/del(17p)) or complex patterns of losses and gains characteristic of the adverse cytogenetic group. In addition, RT-PCR and/or FISH can be used to diagnose rearrangements, which may distinguish subgroups of patients at different risk of relapse and identify targets for subsequent MRD testing. This includes the detection of cases with 11q23/*MLL* rearrangements, as well as those with the *BCR–ABL1* fusion, who could benefit from tyrosine kinase inhibitors. FISH and reverse transcription quantitative PCR (RT-qPCR) can be used to distinguish AML cases with cryptic 3q abnormalities associated with overexpression of *MECOM* (*EVI1*), which are characterized by very poor prognosis [201]. In addition, in children and younger adults, molecular analysis for the cytogenetically cryptic t(5;11)(q35;p15.5), which leads to the *NUP98–NSD1* fusion, may be clinically useful, occurring in approximately 4 % of pediatric AML, including 16 % of those with normal karyotype. These patients appear to have a poor prognosis, but may benefit from allogeneic SCT [202, 203].

Detection of Mutations Implicated in Leukemogenesis and/or Predictive of Outcome: An Integrated Approach to Molecular Testing in AML

Over the last two decades, increased understanding of the molecular basis of AML has resulted in marked improvements in the risk stratification of patients. In the late 1990s, the risk of relapse was defined largely in terms of pretreatment cytogenetics, with approximately 25 %, 60 %, and 15 % of younger adults falling within favorable, intermediate, and adverse risk groups, respectively. With refinement of cytogenetic classification and recognition of a wide spectrum of prognostically relevant molecular markers, the relative proportions of patients assigned to each group have markedly changed, with expansion of the favorable risk group to 45 % by inclusion of cases with the *NPM1*-mutated/*FLT3*-ITD-negative genotype and with biallelic *CEBPA* mutations (Fig. 40.4). As recognized by inclusion of these patients in the ELN genetic reporting system [173], this is important clinically, since the outcome of these molecularly defined subtypes of AML is comparable to that of CBF AML (Fig. 40.5). Hence, they represent a further group of patients who can be spared routine allogeneic SCT in first CR. Conversely, recent studies have led to better definition of patients with adverse risk cytogenetic and molecular genetic features, who now comprise over a third of AML arising in younger adults and in whom allogeneic SCT in first CR is the favored treatment approach, if feasible.

Taking into account the mutual exclusivity of *NPM1* mutations with balanced chromosomal rearrangements or biallelic *CEBPA* mutations, efficient algorithms for the diagnostic workup can be used to guide management of AML. However, it is anticipated that these algorithms will continue to evolve as more prognostically relevant biomarkers are identified and further targeted therapies become available that are specific to the various molecular subtypes of disease.

Rationale for Minimal Residual Disease Monitoring

Relapse remains a major cause of treatment failure for patients with AML. Since the group of patients destined to relapse cannot be reliably identified on the basis of pretreatment characteristics, MRD testing allows more accurate tailoring of therapy according to individual patient requirements. MRD assessment may prove useful in several clinical scenarios. Assessment of kinetics of response relatively early in the treatment course using RT-qPCR (e.g., detecting *WT1* transcripts) or flow cytometry provides independent prognostic information, distinguishing subgroups of patients with different risks of relapse, with an inverse relationship between decline in MRD and risk of subsequent disease recurrence (reviewed by Grimwade et al. [204]). While this remains to be formally tested, patients at low risk could potentially be spared excessive therapy with its inherent additional risk of treatment-related morbidity and mortality, including that related to subsequent development of secondary MDS or AML. Conversely, the outcome of patients at high risk of relapse could potentially be improved with the administration of additional consolidation therapy, possibly in the form of allogeneic SCT or more novel approaches. MRD assessment also may be of potential value in the management of patients undergoing allogeneic SCT, as a means of determining the most suitable type of transplant, as well as identifying the need for additional therapy in the posttransplant setting.

Various methods have been evaluated for the detection of MRD, including cytogenetics, FISH, immunophenotyping, and molecular approaches. Cytogenetics is too insensitive for MRD monitoring, although it may be of interest as a complement to morphological assessment to determine remission status following induction therapy [205–207]. Although FISH is applicable in at least half of AML cases, the number of nuclei or metaphases available for scoring limits its sensitivity, and interphase FISH is affected by the capacity to distinguish low levels of disease from background. Even with hypermetaphase FISH, which is extremely labor intensive, sensitivities achieved are inferior to immunophenotype or PCR-based methods, and hence, attention has been focused on these approaches.

The use of multiparameter flow cytometry to detect MRD takes advantage of differences between normal and leukemic BM, with the majority of AMLs characterized by an abnormal pattern of markers (designated LAIP) which distinguishes them from their normal counterparts. The technique is relatively sensitive (capable of detecting one leukemic cell

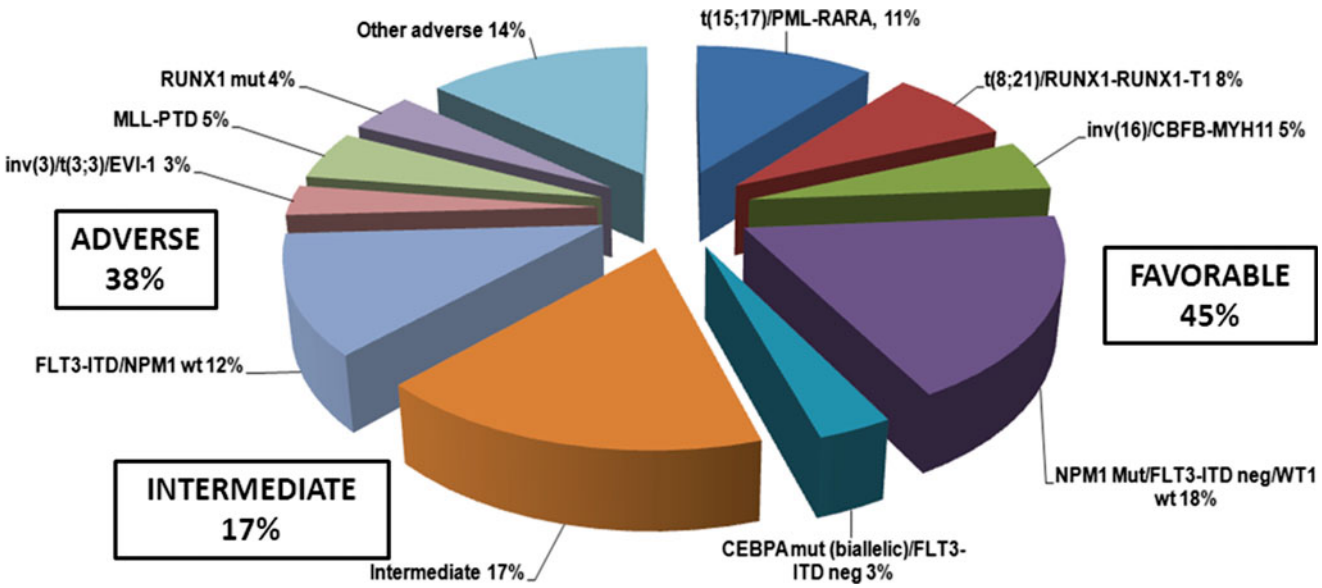

Figure 40.4 Integration of cytogenetic and molecular markers to refine risk groups in AML. From Smith ML, Hills RK, Grimwade D. Independent prognostic variables in acute myeloid leukaemia. Blood Rev 2011;25(1):39–51. Reprinted with permission from Elsevier

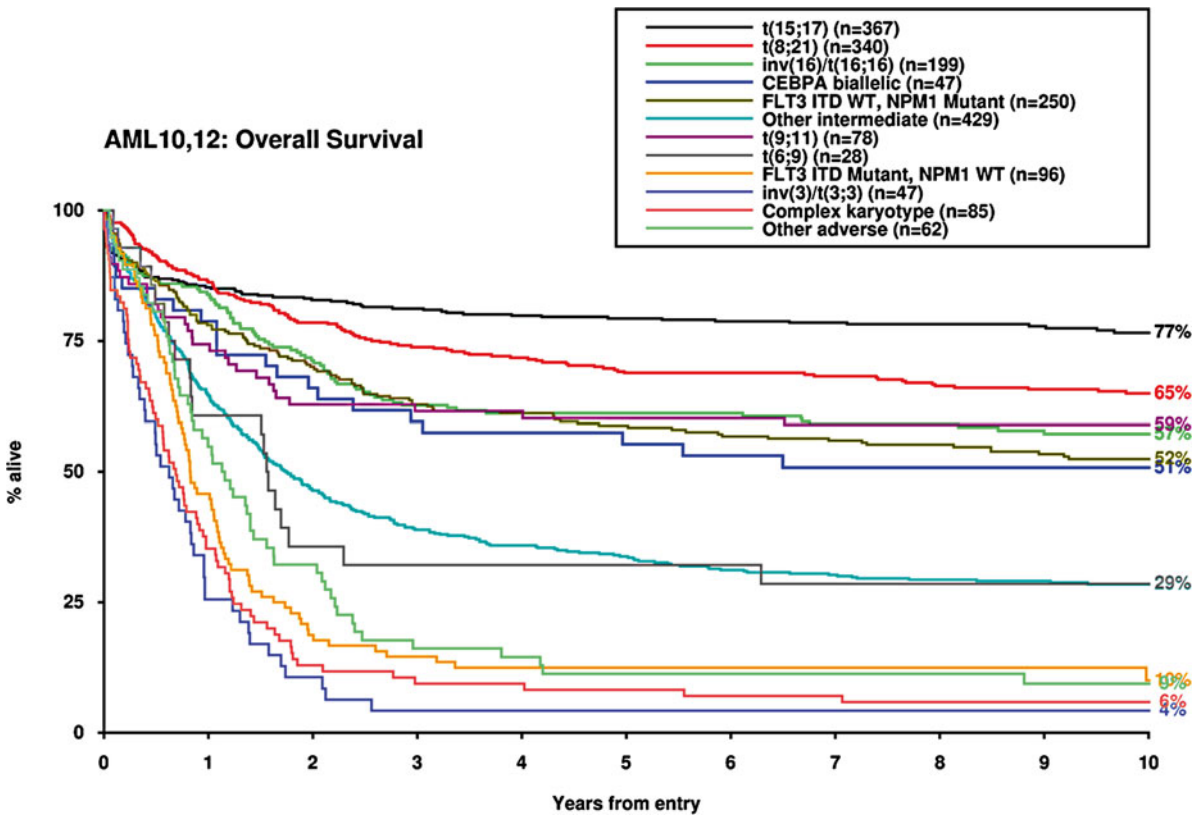

Figure 40.5 Outcome of younger adults with AML according to cytogenetic and molecular abnormalities. Overall survival for younger adults treated in the MRC AML10 and AML12 trials screened for *NPM1*, *CEBPA*, and *FLT3*-ITD mutations [58, 59] for whom cytogenetic data were available. Cases were classified in hierarchical fashion with t(15;17)(q22;q12~q21), t(8;21)(q22;q22), inv(16)(p13.1q22)/t(16;16)(p13.1;q22), t(9;11)(p21~22;q23), t(6;9)(p23;q34), and inv(3)(q21q26.2)/t(3;3)(q21;q26.2) at the top of the hierarchy, then *CEBPA* biallelic mutations, and *NPM1*-mutated/*FLT3*-ITD-negative, *NPM1*-wild-type/*FLT3*-ITD-positive, and other intermediate cytogenetic abnormalities, complex karyotypes, and other adverse cytogenetic abnormalities

in 10^3–10^5 normal BM cells) and has served to highlight the dynamic nature of disease response, which may differ between phenotypically distinct subclones, in which the surface markers that characterize leukemic blasts at relapse in some instances represent only a very minor population at the time of diagnosis [177]. These phenomena make the use of flow cytometry to track MRD extremely challenging and suggest that this approach is likely to be most informative relatively early during the disease course, rather than during longitudinal testing beyond completion of consolidation therapy. Flow cytometry has been used to inform risk-stratified therapy in pediatric AML [208]. Importantly, patients with evidence of MRD at the end of therapy, who otherwise have a very poor prognosis due to a high risk of relapse, can be salvaged by allogeneic SCT conducted in first CR [209]. Moreover, flow cytometric approaches may be used to identify and track leukemic stem cells which may prove more informative in measuring response to therapy compared to the use of LAIPs [204].

For AML characterized by chimeric fusion genes, numerous early studies investigated the use of nested RT-PCR assays for MRD detection to improve outcome prediction. Achievement of molecular remission (CRm) in the BM is a prerequisite for disease cure in APL, prompting inclusion of MRD assessment in standardized response criteria in this subset of AML patients [176, 210]. Importantly, patients in whom *PML–RARA* fusion transcripts are detectable at the end of consolidation, or reappear at a later stage, are destined to relapse rapidly unless additional therapy is given (reviewed by Sanz et al. [176]). Given the significant risk of fatal hemorrhage as a complication of clinical relapse of APL, there is a strong rationale for serial molecular MRD monitoring to identify patients with subclinical levels of leukemia, thus enabling early intervention to prevent progression. Studies conducted by the Gruppo Italiano Malattie EMatologiche dell'Adulto (GIMEMA) and Programa Español para el Tratamiento de Enfermedades Hematológicas (PETHEMA) suggested a benefit for administration of preemptive therapy at the point of molecular relapse as compared to patients treated in frank hematologic relapse [211, 212], although these studies predated the availability of ATO.

MRD monitoring is helpful in guiding treatment of relapse. APL patients with persistent evidence of MRD, in whom harvested stem cells or BM are also PCR positive, are unlikely to benefit from autologous transplant procedures, due to a high rate of relapse [213]. Nevertheless, if a suitable donor is available, such patients can potentially be cured by allogeneic SCT [214]. MRD assessment is also of value in the posttransplant setting to direct the need for additional therapy. While nested RT-PCR assays are still used by some laboratories for MRD detection in APL, they have been largely superseded by RT-qPCR assays, which afford significant advantages (see below). Importantly, the use of a housekeeping gene to normalize results indicates whether there is a falling or rising trend in disease-related transcripts, which is critical to determine whether patients are responding to therapy or are destined to relapse. The lack of capacity of conventional endpoint assays to assess a trend in transcript levels was particularly problematic in *RUNX1–RUNX1T1-associated* CBF leukemia, in which PCR positivity of patients in long-term remission limited test utility for clinical decision making (reviewed by Yin and Grimwade [215]).

Over the last 15 years, optimized RT-qPCR assays designed to detect a wide range of leukemia-specific transcripts (e.g., fusion genes, *NPM1* mutations) have been established through extensive international collaborative efforts, such as the Europe Against Cancer (EAC) [216] and European LeukemiaNet programs [217]. Studies using such assays have significantly extended those previously involving conventional nested RT-PCR, showing that MRD monitoring provides an independent prognostic factor among patients with a defined molecular lesion, who could not otherwise have been distinguished on the basis of pretreatment characteristics. The data are strongest in APL where MRD monitoring can be used to guide molecularly targeted therapies for a more tailored treatment approach. In the UK MRC AML15 trial, serial MRD monitoring with the standardized EAC assay predicted impending relapse of APL on the basis of a rising *PML–RARA* transcript level, and disease progression could be prevented in the majority of patients with early intervention with ATO [218]. This strategy led to a significant reduction in the frank relapse rate as compared to the previous MRC AML12 trial, in which patients received comparable therapy, but were not subject to MRD monitoring. Moreover, early intervention with ATO in the context of subclinical disease was associated with fewer treatment-related complications as compared to treatment in hematological relapse, with no induction of hyperleukocytosis or the associated differentiation syndrome. The analysis of the MRC AML15 data set has shown that longitudinal MRD monitoring beyond the posttreatment time point to direct preemptive therapy is most cost-effective in high-risk patients (i.e., presenting WBC $> 10^{10}$/l), associated with 10 % survival benefit at 5 years. However, in low-risk patients, documented to be in molecular remission following rapid clearance of *PML–RARA* fusion transcripts (i.e., PCR negative in BM following course two of ATRA + anthracycline therapy), there may be less clinical benefit in routine MRD monitoring beyond the posttreatment time point.

The MRC study also demonstrated that BM is the best sample source for MRD monitoring in APL patients. Peripheral blood (PB) had a 1.5 log inferior sensitivity compared to BM, thereby limiting its reliability to detect submicroscopic levels of disease and therefore significantly

reducing the chance to successfully deliver preemptive therapy to prevent progression to overt relapse. In order to develop optimal molecular monitoring schedules, apart from measuring the maximal sensitivity with which MRD can be detected in any given patient (determined by the relative level of expression of leukemic transcripts in AML blasts as defined at diagnosis) and establishing the most appropriate sample source (PB vs BM), it is important to characterize the kinetics of disease relapse. In APL, *PML–RARA* transcripts typically rise by approximately one log per month in relapsing patients; therefore, taking into account the median assay sensitivity of approximately 1 in 10^4, patients registered in the UK National Cancer Research Institute (NCRI) trials are monitored by BM assessments every 3 months until 36 months post-consolidation, at which point MRD monitoring is discontinued (due to the low risk of subsequent relapse). The optimal sampling schedule for other molecularly defined subtypes of AML remains to be firmly established; however, some work has already been conducted in terms of defining the kinetics of disease relapse in CBF and *NPM1*-mutated AML [219].

Available Assays

Mutation Screening and Analysis

Many methods are available for the detection of mutations. The optimal testing method depends on the location and distribution of mutations within the gene of interest and the number of genes to be analyzed. Ideally, genomic DNA, RNA, and viable cells from the diagnostic specimen are stored for testing, once the testing needs are determined. Mutation analysis within the coding sequence of genes can be conducted using genomic DNA or complementary DNA (cDNA) generated from RNA, although for genes in which splice-site mutations have been described, genomic DNA may be preferable. Denaturing high-performance liquid chromatography (DHPLC) of PCR products from genes of interest has been widely used for mutation screening, followed by sequence analysis of amplicons with an abnormal DHPLC pattern suggestive of a mutation. Rapid screening for the presence of an *NPM1* mutation can now also be undertaken by antibody staining of NPM1 using cytospin preparations of leukemic blasts, with the presence of a mutation being indicated by delocalization of NPM1 to the cytoplasm [220]. However, the identification of the specific mutation is particularly useful in *NPM1*-mutated AML, to allow the use of an appropriate mutation-specific assay to track MRD by RT-qPCR. Clinical tests for *CEBPA* must take into consideration the high GC content of the gene sequence and should be able to distinguish biallelic mutations, which predict a relatively favorable outcome [59, 60, 150–152]. Tests to detect *FLT3*-ITD should include the capacity to quantify the relative level of the mutant allele, because patients with high mutant allele ratios associated with acquired disomy have a particularly poor prognosis [57, 58, 133]. Typically, *FLT3*-ITD mutations are detected by PCR using fluorescently labeled primers and GeneScan analysis software (Applied Biosystems). A major advance has been provided by targeted sequencing technology, which is becoming increasingly available, allowing the mutational profile of multiple genes to be rapidly tested in parallel with relatively little DNA. These assays can also provide information on clonal architecture of AML, based on the relative variant allele frequencies of the different mutations.

RT-PCR and RT-qPCR

RT-PCR is widely used for the detection of leukemia-associated fusion transcripts, by PCR amplification of cDNA. For diagnostic samples, a single round of PCR may suffice to detect the fusion transcript; however, to optimize specificity and sensitivity, two rounds of PCR with nested primers may be used. Some laboratories avoid nested RT-PCR due to concern about increased risk of PCR contamination. Standardized methods for the detection of AML-associated fusion transcripts by RT-PCR, most notably *PML–RARA*, *RUNX1–RUNX1T1*, *CBFB–MYH11*, and *BCR–ABL1*, have been developed by the European BIOMED1 group [221].

For the detection of leukemia-associated transcripts by RT-qPCR for MRD monitoring, RNA is initially converted to cDNA using RT protocols identical to those involved in conventional RT-PCR. However, in contrast to the latter technique, in which two rounds of PCR amplification are routinely performed, RT-qPCR approaches involve only a single round of PCR. Importantly, as compared to nested RT-PCR, RT-qPCR assays are more readily standardized and less labor intensive and yield more reproducible results with much shorter turnaround times. SYBR Green I detection during RT-qPCR is not favored for MRD detection, given its lack of sensitivity or specificity in comparison to the use of specific probes, which are, however, significantly more expensive.

RT-qPCR methods allow measurement of leukemic transcripts relative to the expression of endogenous control gene transcripts, which enables exact evaluation of the kinetics of molecular response to treatment and documentation of rising leukemia-associated transcripts prior to frank relapse. The method also allows identification of poor-quality samples (e.g., hypocellular, delayed shipment to the laboratory) or problems with initial sample processing (e.g., red cell lysis), RNA extraction, or the RT step which could give rise to "false-negative" results had conventional endpoint assays been used. Changes in leukemic target transcript level normalized to an endogenous control gene may be calculated on the basis of

differences in cycle threshold (Ct) values, provided the efficiencies of the PCR reactions are comparable. Alternatively, normalized MRD data may be reported in terms of absolute copy numbers derived from plasmid standard curves run in parallel (reviewed by Flora and Grimwade [222]).

For reliable performance of RT-qPCR for MRD detection, testing of diagnostic material is critical to identify the optimal assay to use for each patient. For MRD detection in *NPM1*-mutated AML, in which over 30 different mutation types have been described [153], a mutation-specific reverse primer can be used in conjunction with a common probe and forward primer, which have been extensively tested [155, 223]. Variable breakpoints are observed in many balanced chromosomal rearrangements, e.g., t(15;17) and inv(16)/t(16;16) [216]. In some instances, a common primer and probe can be used in conjunction with a breakpoint-specific primer [216]. However, for patients with rare breakpoint patterns, design of a patient-specific assay may be required for subsequent MRD testing. Apart from molecular characterization to define the most appropriate assay for MRD detection, the analysis of diagnostic BM samples provides information on the maximal achievable sensitivity for MRD detection, based on the expression of leukemic transcripts relative to the endogenous control genes in the blast population, which has been shown to vary markedly both within and between molecular subtypes of AML [177]. Assay sensitivity for the detection of *PML–RARA* fusion transcripts is typically approximately 1 in 10^4, which is significantly lower than for cases with *RUNX1–RUNX1T1* and *NPM1*-mutated AML, in which MRD can be detected with at least one log greater sensitivity. In some patients with the latter subtype of AML, the *NPM1*-mutated allele is so highly expressed that sensitivities may reach 1 in 10^{6-7}.

Laboratory Issues

Transit of Samples to the Laboratory

A key issue in the provision of reliable molecular testing results relates to sample collection procedures and transit time to the laboratory. Heparin can potentially interfere with PCR, and PB or BM samples are more appropriately collected in ethylenediaminetetraacetic acid (EDTA). For assays that involve PCR amplification of genomic DNA, e.g., detection of *FLT3*-ITD/D835 mutations, relatively prolonged transit times are less problematic. However, for RNA-based assays, RT-qPCR has revealed degradation equivalent to approximately 0.5 log per 24 h delay in sample processing. Appropriate quantitation of fusion transcripts is feasible if endogenous control transcripts with a comparable degradation rate are amplified in parallel. However, it is important to bear in mind that the control transcript will not correct for the loss in sensitivity resulting from lower transcript levels due to degradation. Hence, there is interest in the use of RNA-stabilizing agents that reduce RNA degradation during specimen transit, which have been most extensively evaluated in MRD monitoring for CML.

Molecular Testing Using PCR-Based Methods

An important concern with RT-PCR is the potential for false-positive results due to PCR contamination. Specific steps to avoid PCR contamination include stringent process and sample controls as described elsewhere in this book. Less well appreciated is the potential of false-negative results in the presence of rare or atypical breakpoints. False-negative results are also a potential problem in the presence of poor-quality RNA or inefficiency of the RT step.

Quality Assurance and Reporting of RT-qPCR Results

Adherence to rigorous internal quality control (QC) and participation in external proficiency testing (PT) programs are essential for provision of high-quality and reliable clinical results. The College of American Pathologists PT surveys are available for myeloid malignancy genotyping, including *CBFB–MYH11*, *FLT3*-ITD and *FLT3*-TKD, *NPM1*, *PML–RARA*, and *RUNX1* testing. In Europe, initiatives including the BIOMED-1, Europe Against Cancer (EAC), and European LeukemiaNet programs have led to improved standardization of methods for the detection of leukemia-associated fusion transcripts by RT-PCR and RT-qPCR [216, 217, 221]. These programs are important to ensure reliability of diagnostic molecular testing and are absolutely fundamental if MRD data are to be used to predict outcome and to modify treatment approach.

The EAC QC exercises have highlighted variations in performance between laboratories that are ostensibly carrying out RT-qPCR assays according to a standardized protocol [216], which highlights the importance of developing and adhering to standard operating procedures for RT-qPCR tests and generating clear guidelines for reporting of RT-qPCR results. Such guidelines are established for the detection of *BCR–ABL1* transcripts for CML, with standardization efforts including the development of WHO reference reagents [224]. Ideally, RT-qPCR assays are performed in triplicate, so that the degree of reproducibility of individual results may be readily appreciated and outlying results disregarded. The EAC program [216] revealed that, in some instances, fusion gene assays yield an amplification signal in one of the triplicate wells of negative control samples. Given that, in many instances, the participating laboratories had not previously

amplified the specific transcript; such results most likely reflect nonspecific amplification or cDNA carryover between adjacent wells. This is an intrinsic shortcoming of platforms using the 96-well plate format and has led to reporting of MRD analyses in which amplification is restricted to one of the three wells as PCR negative (but recommending earlier repeat testing, should the result reflect possible residual disease at the limits of assay detection). According to the criteria established by the EAC consortium [216], PCR positivity is defined by presence of specific amplification in at least two of the three replicate wells, with Ct values ≤40 (i.e., equivalent to at least one plasmid copy). Since PCR amplification of primary patient samples is less efficient than plasmid controls, reproducible amplification at Ct values of 40–45 occasionally can be observed in follow-up patient samples, which most likely indicates low-level MRD; however, these low-level positive results are of uncertain clinical significance and again would be seen as an indication for earlier repeat MRD assessment.

Conclusions and Future Directions

Over the course of the last few years, next-generation sequencing (NGS) has led to the identification of many gene mutations and fusions not previously identified in AML [117]. NGS can be applied to determine which lesions are likely to represent initiating events in the development of AML, as well as to decipher the spectrum of cooperating mutations involved in the pathogenesis of particular molecularly defined subsets of the disease. A key challenge is to distinguish the "driver" mutations from "passenger" mutations in the process of leukemic transformation, which will require further investigation using in vitro functional assays and in vivo models. It is hoped that establishing the mutational profile using high-throughput sequencing across a large number of AML cases will provide insights into common pathways that act in concert to induce the AML phenotype and to the development of new targeted therapies. For example, drugs targeting IDH mutations are now in clinical trial; moreover, a study that involved screening for interaction partners of MLL fusion proteins identified BET proteins as potential therapeutic targets [225]. Very encouraging results have been obtained with BET inhibitors in established murine models of leukemia with *MLL* fusions, providing a strong rationale for the evaluation of these compounds in early phase clinical trials in patients [225]. Likewise, very promising results have been seen using pharmacologic targeting of the lysine-specific demethylase KDM1A (also known as LSD1 or AOF2) by tranylcypromine analogs alone or in combination with ATRA, which are capable of abrogating clonogenic potential and inducing differentiation of both murine and human AML cells in vitro and in vivo [226, 227]. Another potential target for therapeutic intervention is autocrine activation of MET and compensatory upregulation of HGF expression [228]. The capacity for rapid molecular testing is crucial to identify patients who could benefit from such targeted treatment approaches. Clinical trials involving evaluation of FLT3 inhibitors in AML harboring *FLT3*-activating mutations or dasatinib in CBF leukemias with *KIT* mutations have shown that this is feasible.

AML is highly heterogeneous at the molecular level, with the average case harboring over ten mutations [117]. This degree of complexity presents a major challenge to establish the most informative and clinically relevant mutations; however, through advances in NGS, the analysis of extensive panels of genes is feasible in a single test [49]. The Interlaboratory Robustness of Next-generation sequencing (IRON) study demonstrated high rates of concordance for mutation detection using NGS platforms (testing for mutations in *TET2*, *CBL*, and *KRAS* genes) in leukemia samples analyzed in ten laboratories in eight countries [229]. As rapid sequencing methods become more affordable with appropriate bioinformatic methods and standards, as well as provision of constitutional DNA for comparison, high-throughput sequencing will be used in routine clinical testing, which would allow leukemia-specific mutations to be identified in any patient. This may help refine outcome prediction and inform management. The capacity to identify a range of novel somatic mutations presents a significant opportunity, providing potential targets for MRD detection using RNA- or DNA-based real-time quantitative PCR assays and digital PCR. Indeed, molecular methods may be useful to track treatment response in the majority of patients with AML in the future.

Wider availability of MRD monitoring, using molecular approaches in conjunction with advances in multicolor flow cytometry to define LAIPs and better definition of the leukemic stem cell population, may allow more informed decisions on the use of allogeneic SCT in first remission, distinguishing patients who are most and least likely to benefit. MRD monitoring may be helpful in identifying patients who are unlikely to be cured without dose intensification, as well as sparing patients from ineffective excessive therapy. In relatively favorable subsets of AML, deintensified protocols are being explored, which could achieve disease cure with less treatment-related toxicity, lower cost, and improved quality of life. In this context, MRD assessment may play an important role to guide therapy but also to rapidly identify those patients who need additional therapy to prevent disease relapse. MRD-based deintensified treatment approaches have been widely investigated in pediatric ALL and subsequently in *PML–RARA*-positive APL, taking advantage of available molecularly targeted therapies, i.e., ATRA and ATO [111, 230, 235]. Similar strategies will hopefully be investigated in other subsets of AML in future clinical trials.

Research developments, in terms of our understanding of the biology of AML and the clinical evaluation of novel targeted therapies, are clearly going to have an impact on the range of clinical tests that will need to be developed and offered by molecular laboratories in the future. Indeed, the pathology laboratory is set to play an increasingly important role in optimizing and individualizing the management of patients with AML.

Acknowledgments We are indebted to Alan Burnett, Nigel Russell, Robert Hills, Rosemary Gale, David Linch, and members of the UK National Cancer Research Institute (NCRI) AML Working Group for their assistance in providing relevant data. DG gratefully acknowledges the National Institute for Health Research (NIHR) for the support for molecular diagnostics and assessment of minimal residual disease in the UK NCRI AML17 trial. This paper presents independent research funded by the National Institute for Health Research (NIHR) under its Programme Grants for Applied Research (Grant Reference Number RP-PG-0108-10093). The views expressed are those of the authors and not necessarily those of the NHS, the NIHR, or the Department of Health. In addition, D.G. grateful acknowledges research funding from Leukaemia & Lymphoma Research of Great Britain, the Guy's and St. Thomas' Charity, and the MRD Workpackage (WP12) of the European LeukemiaNet. K.M. thanks Clara D. Bloomfield for her continuous help and encouragement and gratefully acknowledges the support from the Coleman Leukemia Research Foundation.

Acute Lymphoblastic Leukemia

41

Andrea Biondi, Carlos Alberto Scrideli, and Giovanni Cazzaniga

Abstract

Acute lymphoblastic leukemia (ALL) comprises a heterogeneous group of disorders which originate from various important genetic lesions in B and T progenitor cells, including mutations that lead to stage-specific developmental arrest and those that impart the capacity for unlimited self-renewal, resulting in clonal expansion of immature progenitor cells (Pui et al. Lancet 371:1030–43, 2008; Pui et al. Blood 120:1165–74, 2012; Morgolin et al. 2011). Different B- and T-cell ALLs can be recognized according to immunologic and molecular criteria (Pui et al. Blood 82:343–62, 1993; Yeoh et al. Cancer Cell 1:133–43, 2002; Pui et al. J Clin Oncol 29:551–65, 2011). The identification of the molecular events underlying the process of leukemia transformation has provided not only important biological information but also clinically significant genetic markers for the identification of prognostically relevant ALL subgroups and for the molecular monitoring of minimal residual disease (MRD). For ALL, immunoglobulin (*IG*) and T-cell receptor (*TCR*) gene rearrangement studies are used as markers of clonality and for MRD detection. In addition, the identification of different genetic variations is used to define different ALL subgroups and to refine treatment protocols tailored to the risk of relapse.

Introduction

Acute lymphoblastic leukemia (ALL) comprises a heterogeneous group of disorders which originate from various important genetic lesions in B and T progenitor cells, including mutations that lead to stage-specific developmental arrest and those that impart the capacity for unlimited self-renewal, resulting in clonal expansion of immature progenitor cells [1–3]. Different B- and T-cell ALLs can be recognized according to immunologic and molecular criteria [4–6]. The identification of the molecular events underlying the process of leukemia transformation has provided not only important biological information but also clinically significant genetic markers for the identification of prognostically relevant ALL subgroups and for the molecular monitoring of minimal residual disease (MRD). For ALL, immunoglobulin (*IG*) and

T-cell receptor (*TCR*) gene rearrangement studies are used as markers of clonality and for MRD detection. In addition, the identification of different genetic variations is used to define different ALL subgroups and to refine treatment protocols tailored to the risk of relapse.

Molecular Basis of Disease

IG and *TCR* Gene Rearrangements in ALL

The immune system can specifically recognize and distinguish an enormous variety of specific antigens and antigenic epitopes (at least 10^{10}). Each lymphocyte has a unique membrane receptor, the immunoglobulin receptor (IG) on B lymphocytes and the T-cell receptor on T lymphocytes, that recognizes specific antigens [7–10].

Rearrangements of gene segments that encode the variable regions of the *IG* and *TCR* genes are responsible for the enormous diversity of antigen-specific lymphocyte receptors. This great variability of *IG* and *TCR* is mediated by several mechanisms: (1) the number of variable (V), diversity (D), and joining (J) segments (germline genome diversity); (2) the number of possible V(-D)-J combinations (combinatory diversity); (3) deletions of nucleotides at the ends of rearranging V, (D), and J gene segments, as well as random insertion of noncoded nucleotides (N-region nucleotides) between V–D and D–J segments (junctional diversity); and (4) somatic mutations in the V gene segments of the *IG* genes. This last process has not been observed for *TCR* genes [7–11]. The V, (D), and J segments of B and T precursor cells are rearranged during their differentiation, and each lymphocyte, in this way, contains a specific V-(D-)-J combination. Additional variability can be generated in the junctions V–D and D–J through the loss of nucleotides, as well as through insertion of new nucleotides. Insertion of nucleotides (insertion of N regions) in the junctional sites is mediated by the enzyme terminal deoxynucleotidyl transferase (TdT), which is present in the nucleus of immature B and T cells. N-region insertion occurs in rearranged immunoglobulin heavy chain genes (*IGH*), but is limited or absent in the immunoglobulin kappa and lambda light chain genes (*IGK* and *IGL*). Junctional diversity also occurs in *TCR* genes, primarily the T-cell receptor delta and gamma genes (*TRD* and *TRG*). The potential diversity introduced by the addition of N regions is very high and can increase the total combinatorial diversity to more than 10^{10} for the IGH molecules, 10^{12} for T-cell receptor alpha and beta (TRAB), and more than 10^{9} for T-cell receptor delta and gamma (TRDG) [8–10].

During the earliest stages of the B-cell differentiation, the *IGH* genes rearrange before the *IGL* genes, and of the light chain genes, *IGK* is the first to rearrange. If the *IGK* rearrangement is not functional, the *IGL* gene will rearrange. Another type of rearrangement of the *IGH* gene that can occur is class switching, from IgM and IgD to IgG, IgA, or IgE [8–10, 12]. During the earliest stages of the differentiation of T cells, the *TRD* gene is the first to rearrange, followed immediately by rearrangement of the *TRG* gene and in many cells also the rearrangement of the *TRB* gene. The *TRD* gene can be deleted when *TRA* rearrangement occurs [8–10, 13].

Because ALL is derived from a single transformed lymphoid precursor cell, all ALL cells of a patient should have the same *IG* and *TCR* gene rearrangements with identical junctional region sequences that can be regarded as leukemia-specific fingerprints. Such targets can be identified at initial diagnosis in more than 95 % of patients with ALL by using various polymerase chain reaction (PCR) primer sets [11, 14–17]. Studies of rearrangements of the *IG* genes in B-lineage ALL by Southern blot and PCR have shown that, despite an immature phenotype, more than 95 % of B-precursor ALL contain *IGH* rearrangements, approximately 60 % have *IGK* rearrangements or deletions, and approximately 20 % have *IGL* rearrangements [8, 9, 14, 18]. Cross-lineage rearrangements of the *TCR* gene also have been observed in approximately 90 % of B-lineage ALL pediatric patients [17]. Rearrangements of *TRA*, *TRB*, *TRD*, and *TRG* are found in 46–61 %, 29–35 %, 54–80 %, and 49–70 % of B-lineage ALL, respectively [19–25]. In B-precursor ALL, approximately 80 % of all *TRD* rearrangements are due to incomplete gene rearrangements *VD2-DD3* and *DD2-DD3* [20, 26, 27]. These *VD2-DD3* rearrangements also are prone to continuing rearrangements, particularly with *JA* gene segments. *V2-JA* rearrangements are detected in approximately 40 % of childhood B-precursor ALL and are rare or absent in normal lymphoid cells [23].

In T-lineage ALL, *TRA*, *TRB*, *TRD*, and *TRG* gene rearrangements have been described in 17–67 %, 85–89 %, 68–90 %, and 90–100 % of cases, respectively [8–10, 18, 21, 24, 25]. Cross-lineage *IG* gene rearrangements are not very common in T-lineage ALL, occurring in less than 20 % of cases, and involving only the *IGH* gene [8–10, 21].

Cross-lineage rearrangements of the *IG* and *TCR* genes in non-B and non-T cells, respectively, are probably due to the fact that the leukemic cells originate from a less-committed lymphoid precursor or even a more primitive pluripotent cell (lymphoid/myeloid), in which both *IG* and *TCR* genes are accessible to a common recombinase enzyme. Such rearrangements occur before the final determination of lineage; as soon as this determination for the B, T, or myeloid lineage occurs, the cell adopts the lineage-specific phenotype with expression or differentiation of the lineage-specific antigen, while the gene of cross lineage persists as an "artifact." Due to this, rearrangements in the *TCR* gene are relatively common in B- precursor cell ALL; however, they are very rare in B-ALL and mature B-cell neoplasia (B-cell chronic lymphocytic leukemia, multiple

myeloma, and B-cell non-Hodgkin lymphoma. Similarly, rearrangements of *IG* genes are rare in mature T-cell neoplasms (T- cell chronic lymphocytic leukemia and T-cell non-Hodgkin lymphoma [8, 9, 17].

Chromosomal and Genetic Abnormalities in ALL

The genes involved in the most frequent leukemia chromosomal abnormalities have been identified, providing important insights into disease pathogenesis and normal cellular physiology. Molecular assays for leukemias have been developed and now permit a more accurate diagnosis of the leukemia subtypes with frequently recurring genetic and chromosomal alterations. Essentially, two types of chromosomal aberrations occur in ALL: alterations in the number of chromosomes and structural abnormalities. In childhood ALL, high hyperdiploidy (51–65 chromosomes) is associated with a favorable outcome, while hypodiploidy (fewer than 45 chromosomes) is associated with poor prognosis. Trisomies of each chromosome has been observed in ALL, but the most common are trisomy 4, 6, 14, 17, 18, 21, and X. Combined trisomies between chromosomes 4 and 10 and between chromosomes 10 and 17 are associated with good prognosis and low risk of relapse. Intrachromosomal amplification of chromosome 21 (iAMP21) has been identified as a recurrent abnormality in childhood ALL and is associated with older children, common/pre-B immunophenotypes, low white blood cell (WBC) count, and poor prognosis [3, 28–31].

Somatically acquired chromosomal translocations or inversions occur in up to 65 % of ALL. In most instances, the genes disrupted by these abnormalities have been identified, thus providing important insights into disease pathogenesis and normal cellular physiology. Chromosomal translocations have two main consequences: activation of a protooncogene brought under the regulation of the promoter and enhancer elements of another gene that normally is active in the leukemia progenitor cell, and creation of a fusion gene from two distinct genes with expression of a chimeric protein (Fig. 41.1). The products of the latter aberrant genes are most often transcription factors or tyrosine kinases [32]

These genetic alterations have important prognostic implications that can be used to classify precursor lymphoid neoplasms and to guide the selection of therapy [33] (Table 41.1).

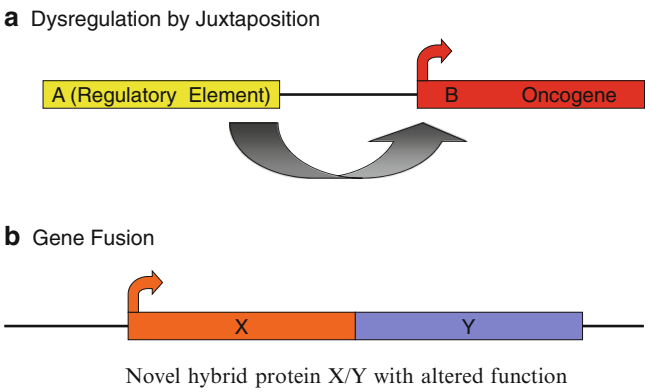

Figure 41.1 Schematic representation of two types of gene alterations generated by chromosomal translocations. (**a**) A protooncogene (B) is activated by the promoter and enhancer elements of a distinct translocation gene partner (A, Regulatory Element). (**b**) Discrete segments of two different genes (X and Y) are joined as a result of a translocation, creating a fusion gene that encodes a chimeric protein

Genetic Abnormalities in B-Lineage ALL

B-lineage ALL is the most frequent acute leukemia in children, corresponding to 80–85 % of cases with about 80 % of these having cytogenetic alterations and characteristic genetic translocations (Table 41.2). The chromosomal translocation t(12;21)(p13;q22) results in the *ETV6/RUNX1* (*TEL/AML1*) fusion gene. This is a cryptic translocation, which cannot be detected by karyotyping. Thus, fluorescence in situ hybridization (FISH) or PCR must be used for detection. It is the most common chromosomal rearrangement in childhood ALL, occurring in about 25 % of cases [34]; by contrast, it is rarely found in adult ALL (1–3 %) [35]. The t(12;21) translocation is almost exclusively associated with a young age (<10 years) and a precursor B-cell phenotype [34]. Both *ETV6* and *RUNX1* are important regulators of normal hematopoiesis, and are involved in other translocations in both lymphoid and myeloid leukemias, which suggests

Table 41.2 Main genetic alterations involving B-lineage ALL

Translocation	Involved gene(s)	Frequency
Pre-B cell/early pre-B cell		
t(12;21)(p13;q22)	*ETV6/RUNX1*	20–25 % children/1–3 % adults
t(1;19)(q23;p13)	*TCF3/PBX1*	5 % children
t(4;11)(q21;q23)	*AF4/MLL*	2 %
t(11;19)(q23;p13)	*MLL/ENL*	<1 %
t(9;11)(p21;q23)	*AF9/MLL*	<1 %
t(9;22)(q34;q11)	*ABL1/BCR*	3–5 % children/25 % adults
t(17;19)(q22;p13)	*HLF/E2A*	<1 %
t(12;v)(p12-p13;V)	*ETV6* or *KIP1*	5–10 %
Dic(9;12) (9p11-p12;p12)	Unknown	1 %
Dic(9;20) dic(9;20) (p11-13;q11)	Unknown	2 %
t(5;14)(q35;q32)	*IL3/IGH*	<1 %
B-cell ALL		
t(8;14)(q24;q32)	*MYC/IGH*	95 %
t(8;22)(q24;q11)	*MYC/IGL*	<5 %
t(2;8)(p11;q24)	*IgK/MYC*	<5 %
New recurrent abnormalities		
Del9p	*CDKN2A/B*	30–35 %
Del9p	*PAX5*	30–35 %
iAMP21	*AML1*	2 %
CRLF2	*CRLF2*	5–7 % (50 % with Down syndrome)
IKZF1	*IKZF1*	15 %

that the resulting fusion proteins could deregulate normal hematopoietic development leading to leukemia [1, 31]. ETV6-RUNX1 also causes overexpression of the erythropoietin receptor and activation of JAK-STAT signaling [36, 37]. The t(12;21) can be present in blood cells at birth, 5–10 years before the leukemia becomes evident, as demonstrated by studies using neonatal blood spots. The leukemias induced by ETV6-RUNX require a second genetic event for their development. The loss of function of normal TEL protein, through the loss of the normal *TEL* allele as observed in patients with t(12;21), appears to be this second event [1, 38].

Whether t(12;21) is associated with a good prognosis or with only a marginally better outcome compared to other cytogenetic ALL subgroups remains controversial [34]. *ETV6/RUNX1* rearrangement has been observed in about 25 % of relapsing cases treated within European Berlin-Frankfurt-Munster (BFM) group protocols. These patients tend to have a longer duration of remission (>2 years) compared to other childhood ALL cytogenetic groups; however, early relapses have also been observed, illustrating a heterogeneous pattern of clinical behavior in this group of patients [34, 39].

The t(1;19)(q23;p13) translocation is one of the most frequently observed translocations in childhood ALL, occurring in approximately 25 % of pre-B cytoplasmic IG-positive cases and in 1 % of early pre-B cytoplasmic IG-negative cases. This translocation most frequently creates a fusion of *TCF3* (*E2A*), a helix-loop-helix (bHLH) protein-coding gene on chromosome 19, with *PBX1*, a homeobox-containing gene located on chromosome 1 [36, 37, 40]. A few molecular variants of the t(1;19), leading to different species of *TCF3/PBX1* mRNAs, have been described [41]. Both genes play a critical role in lymphocyte development and alteration of *HOX* genes has a clear role in leukemogenesis. Although this translocation has been associated with a poor clinical outcome, the current chemotherapy protocols have improved prognosis for this subgroup of patients [31, 36, 37, 42].

Another rare translocation, found in 1 % of B-precursor ALLs, is t(17;19)(q22;p13.3), which also involves the *TCF3* gene but creates a fusion with the *HLF* gene, resulting in a chimeric transcript and protein that could contribute to leukemogenesis by aberrant regulation in genes that control the fate of early lymphoid progenitors. This translocation has been associated with poor prognosis [3, 36, 37, 43].

Abnormalities of the q23 region of chromosome 11 are seen with relative frequency in childhood ALL (5 %), infant acute leukemia (70 %), and secondary leukemias in patients who received topoisomerase II inhibitors (85 %). Leukemias with translocations involving 11q23 have an early pre-B phenotype and express myeloid antigens. More than 40 different chromosomal loci have been identified as fusion partners in 11q23 translocations. In the majority of cases, the translocation partner is chromosome 4, and less frequently chromosome 1, 10, or 19. At the molecular level, the t(4;11) fuses *MLL* at 11q23 to *AF4* at 4q21, resulting in an *MLL/AF4* chimeric gene. *MLL*-rearranged leukemias exhibit an upregulation of HOX Class I genes. The ability of MLL to regulate expression of the *HOX* genes suggests a role in hematopoiesis and also in leukemogenesis [36, 37]. This translocation is related to aggressive clinical features such as hyperleukocytosis, organomegaly, frequent central nervous system involvement, and poor outcome [3, 6, 36, 37, 44–49].

The t(9;22) translocation is identified in 3–5 % of childhood ALL and approximately 25 % of adult ALL [47, 48, 50]. This translocation creates a novel chromosome (the Philadelphia chromosome, Ph+) and a fusion between the protooncogene *ABL1* on chromosome 9 and the "breakpoint cluster region" gene (*BCR*) on chromosome 22. Whereas the *ABL1* breakpoint on chromosome 9 is consistently between exons a1 and a2, the *BCR* breakpoints on chromosome 22 can occur in two different gene regions. The "minor" breakpoint cluster region (m-bcr), between exons e1 and e2, is present in approximately 90 % of childhood Ph+ ALL; by contrast, a "major" breakpoint cluster region (M-bcr), between exons 13 and 14 or 14 and 15 (formerly called b2 and b3 or b3 and b4, respectively), is a usual finding in chronic myelogenous leukemia [50] and occasionally present in Ph+ ALL. The m-bcr generates a fusion protein of

190 kDa (p190), whereas the M-bcr results in a fusion protein of 210 kDa (p210) [47, 48, 50–53]. The presence of t(9;22) is associated with a high risk of treatment failure in children and adults with ALL. However, Ph+ childhood ALL is a heterogeneous disease with regard to treatment response. High leukocyte count, old age, and poor response to prephase treatment with prednisone and intrathecal methotrexate influence treatment outcome. Patients with a good prednisone response have a significantly lower risk of treatment failure compared to those with a poor prednisone response (PPR), when treated with intensive BFM protocol chemotherapy, whether associated with bone marrow transplantation (BMT) or not. These PPR children have a clinical response and prognosis as poor as that of Ph+ ALL adults [47, 48, 54]. For the treatment of these patients, s elective tyrosine kinase inhibitors have been used in association with chemotherapy and/or BMT. The use of the ABL tyrosine kinase inhibitor imatinib, and derivatives of second generation (e.g., nilotinib, dasatinib) has transformed the treatment and outcome of ALL patients with the *BCR-ABL1* fusion gene [55, 56].

More recently, a group of childhood B-lineage ALLs termed "BCR-ABL1-like" has been described. These ALLs exhibit a similar gene expression profile as that observed in *BCR-ABL1* positive ALL patients. This subtype represents up to 15 % of all B-lineage cases and is frequently associated with deletion or mutation of *IKZF1*. In 50 % of the cases, the *CRLF2* gene is rearranged, which confers a very poor prognosis [6, 36, 37, 57, 58].

The t(8;14)(q24;q32), involving the *MYC* gene (8q24) and the *IGH* locus (14q32), occurs in 85–90 % of cases of surface immunoglobulin positive B-cell ALL. The dysregulation of *MYC* expression appears be responsible for the B-cell proliferation. Two other variants, t(2;8)(p11;q24) and t(8;22)(q24;q11), involving the *MYC* gene and *IGK* and *IGL*, respectively, are less commonly observed [3, 29, 59, 60]. The t(5;14)(q31;q32) is an uncommon translocation, observed in less than 1 % of ALL patients, and results in the fusion of the *IGH* gene with the interleukin-3 (*IL3*) gene. The overexpression of *IL3* appears be involved in the pathogenesis of the leukemia and hypereosinophilia in these patients [3].

Subgenetic alterations involving genes that regulate normal B lymphoid development are identified in 40 % of B-lineage ALL. The most commonly involved gene is *PAX5*, required for B-lineage maturation. Other regulating B-lymphoid development genes frequently involved include the IKAROS family of transcription factors *IKZF1*, *IKZF2*, *IKZF3*, as well as *EBF1*, *TCF3*, *LEF1*, *RAG1*/*2*, *BLNK*, and *VPREB1* [30, 57, 61]. Deletions or sequence alterations of the lymphoid development associated *IKZF1* gene and tumor suppressor gene *CDKN2A*/*B* have been associated with relapse risk, confirming that genetic alterations detected at diagnosis can predict the risk of relapse [6, 36, 37, 61]. Overexpression of *CRLF2*, associated or not with corresponding genomic lesions (*IGH-CRLF2*, *P2RY8-CRLF2* or the p.Phe232Cys mutation) occurs in 5–7 % of childhood B-lineage precursor ALL and in 50 % of individuals with Down syndrome and ALL. These alterations commonly are associated with *JAK1*/*2* mutations and, in patients who do not have Down syndrome, with *IKZF1* mutations and poor prognosis [6, 36, 37].

Genetic Abnormalities in T-Lineage ALL

T-lineage ALL accounts for approximately 15 % of all childhood ALL and in general is considered a high-risk category. This leukemia characteristically presents with chromosomal rearrangements involving T-cell receptor genes, proto-oncogenes, or transcription factor genes, or alterations of key genes or pathways related to T-cell lymphogenesis (Table 41.3).

Developmental genes abnormalities have been found in T-lineage ALL (T-ALL) comprising the basic helix-loop-helix (bHLH) gene family (*MYC*, *TAL1*, *LYL1*), the homeobox gene family (*HOX*) including the HOXA cluster, and the LIM gene family (*LMO1* and *LMO2*). When rearranged near enhancers with the loci 14q11.2, 7q34-q35 or 7p15, that contain the *TRA*/*TRD*, *TRB*, and *TRG* genes, respectively, these regulatory genes become active and lead to dysregulated expression of transcription factor genes. The *TAL1* gene can be involved due to t(1;14)(p32,q11), which occurs in 5 % of childhood T-ALL, or can be affected by a submicroscopic interstitial deletion between the *SIL* and *TAL1*(*SCL*) genes at 1p32. This "*TAL* deletion" occurs in 20–25 % of childhood T-ALL [3, 29–31, 60].

Different T-ALL signatures, based on gene expression profiles, indicate that the leukemic arrest in specific genetic subgroups (*LYL1*, *TLX1*, *TAL1*) occurs at particular stages of thymocyte development (i.e., at the pro-T, early cortical thymocytes, or late cortical thymocyte stage) [62–65] and seems to comprise at least four distinct molecular-cytogenetic subgroups: TAL/MLO, TLX3/HOX11L2, TLX1/HOX11, and HOXA subgroups [66, 64, 65, 67, 68]. A fifth subtype of T-ALL termed "early T precursor" (ETP) comprises approximately 15 % of T-ALL and is associated with a high risk of relapse. Inactivating alterations that disrupt hematopoietic development and cause histone-modification of genes are possible in ETP, as well as somatic activation of regulating cytokine receptors and RAS signaling [67, 69].

The *TAL* deletion leads to expression of a *SIL-TAL* chimeric transcript, resulting from the fusion of the 5′ part of *SIL* to the 5′ region of *TAL1*. In addition, high levels of *TAL1* have been observed in 40–60 % of T-ALL. The aberrant expression of TAL1 may activate a specific set of target genes that are normally quiescent in T-cell progenitors or could exert a negative effect through inhibition of E2A or E2A-HEB heterodimers, leading to a leukemogenic effect.

Table 41.3 Main genetic alterations involving T-cell ALL

	Involved gene(s)	Frequency
Translocation involving T-cell receptor genes		
t(7;10)(q34;q24) and t(10;14)(q24;q11)	*TLX1* (*HOX11*)	7 % children; 31 % adults
t(5;14)(q35;q32)	*TLX3* (*HOX11L2*)	20 % children; 13 % adults
inv(7)(p15q34), t(7;7)	*HOXA* genes	5 %
t(1;14)(p32;q11) and t(1;7)(p32;q34)	*TAL1*	3 %
t(7;9)(q34;q32)	*TAL2*	<1 %
t(7;19)(q34;p13)	*LYL1*	<1 %
t(14;21)(q11.2;q22)	*BHLHB1*	<1 %
t(11;14)(p15;q11)	*LMO1*	2 %
t(11;14)(p13;q11) and t(7;11)(q35;p13)	*LMO2*	3 %
t(1;7)(p34;q34)	*LCK*	<1 %
t (7;9)(q34;q34.3),	*NOTCH1*	<1 %
t(7;12)(q34;p13) and t(12;14)(p13;q11)	*CCND2*	<1 %
Translocation involving oncogenes		
1p32 deletion	*SIL-TAL1*	9–30 %
t(10;11)(p13;q14)	*CALM-AF10*	10 %
11q23	*MLL*	8 %
t(9;9)(q34;q34)	*NUP214-ABL1*	5 %
t(9;14)(q34;q32)	*EML1-ABL1*	<1 %
t(9;22)(q34;q11)	*BCR-ABL1*	<1 %
t(9;12)(p24;p13)	*ETV6-JAK2*	<1 %
Cryptic deletions		
9p21	*P16*	65 % children; 15 % adults
Del(6q)	Unknown	20–30 %
Mutations		
Notch1	*NOTCH1*	50 %
PTEN	*PTEN*	17 %
IL7R	*IL7R*	7–9 %

The *LYL1* gene is involved in the t(7;19)(q34;p13) leading to constitutive overexpression, usually in a more immature T-lineage phenotype. The *MYC* gene can be translocated to a *TCR* locus [t(8;14)(q24;q21)] in some cases of T-ALL [3, 29–31, 62].

In addition to genes encoding bHLH proteins, gene rearrangements of the LIM gene family (encoded by *LMO1* and *LMO2*) and the *TCR* loci have been described in T-ALL. The t(11;14)(p13;q11) (*LMO1*/*TCRD*) occurs in 7–13 % of T-ALL and has been associated with males, high WBC count and extramedullary disease. The t(11;14)(p15;q11) (*LMO2*/*TCRD*) is infrequent and found in <1 % of the cases [3, 29, 70, 71].

Translocations involving the *HOX* genes *TLX1* (*HOX11*) and *TLX3* (*HOX11L2*), complete the list of developmental genes that are inappropriately placed under control of the *TCR* loci. Activation of expression of the *HOX11* gene by chromosomal translocations t(10;14)(q24;q11) and t(7;10)(q34;q24) interferes with normal T-cell development and promotes malignant transformation. HOX11 expression is associated with a favorable prognosis in childhood T-ALL. *HOX11L2* is activated by t(5;14)(q35;q32) and (5;14)(q35;q11). Despite the fact that this finding has been associated with a poor prognosis, this does not seem to apply in children receiving more intensive chemotherapy [3, 29–31, 60].

Recurrent translocations involving the HOXA cluster have been described. This subgroup of T-ALL is characterized by elevated expression of the *HOXA* genes and includes *MLL* rearrangements, inv(7)(p15q34), t(10;11)(p13;q23), and *CALM-AF10* rearrangements as well as the cryptic del(9)(q34.11q34.13) deletion that results in a *SET-NUP214* fusion product. *MLL* fusions are found in 4–8 % of T-ALL. The t(11;19)(q23;p13) that involves *MLL*/*ENL* is the most frequent. Other identified translocations include t(6;11)(q27;q23) (*MLL*/*AF6*), t(10;11)(p13;q23) (*MLL*/*AF10*), t(X;11)(q13;q23) (*MLL*/*AFX1*), and t(4;11)(q12;q23) (*MLL*/*AF4*). T-ALL with an *MLL* fusion is characterized by a specific expression profile with differentiation arrest in early stage thymocyte development [29–31, 60, 61, 72].

Chromosomal translocations involving *NOTCH1*, a gene that regulates the normal embryologic development of

T-cells and other tissues, are rare in T-ALL. In contrast, activating *NOTCH1* mutations are present in more than 50 % of T-cell ALLs. *NOTCH1* regulates oncogenes including the *MYC* and *RAS*, and this is probably the mechanism by which aberrant NOTCH signaling causes T-ALL. This oncogenic mechanism is supported by experimental models, in which mutations of the *NOTCH1* gene can induce T-cell ALL [29–31]. Small molecule inhibitors of the NOTCH pathway thus have the potential to induce remission in T-cell ALL [31].

Cryptic deletions are common in T-ALL and may be concomitant with other changes. The most common cryptic deletion causes loss of the *INK4/ARF* locus at 9p21, important to cell cycle control. Del(6q) also has been observed, but the involved gene is unknown [29, 31]. Inactivating gene mutations in *PTEN* have been described in approximately 17 % of pediatric T-ALL and are associated with poor prognosis [73]. Somatic-gain mutations in *IL7R* have been observed in 7–9 % of pediatric T-ALL [74]. The main genetic alterations in T-ALL are summarized in Table 41.3.

Indications for Testing

Many genetic alterations have important prognostic implications that can guide the selection of therapy. Treatment of the acute leukemias has progressed from uniform strategies devised for large groups of patients to more refined protocols tailored to the risk of relapse in discrete subgroups. Although routinely recorded features such as blast cell immunophenotype and presenting WBC count provide useful criteria for risk assessment, molecular genetic changes are the most sensitive markers of potential leukemia aggressiveness. Hence, overall these are the best suited to guide treatment. *IG* and *TCR* gene rearrangement studies are useful for the diagnosis of childhood ALL, for detection of cerebrospinal involvement [24, 25, 51–53, 75], and for MRD assessment because they occur in the vast majority of ALL patients [16, 45, 46, 76–80].

Molecular detection of chromosomal abnormalities in blast cells of leukemia patients has important prognostic implications that can guide staging and selection of treatment. In addition, detection of specific translocations is used to MRD monitoring [81].

The term "minimal residual disease" has been used to define the lowest level of disease detected by conventional methods of analysis in patients who are in complete continuous remission. At clinical presentation, the number of leukemic cells is approximately 10^{11}–10^{12}; if the patient is not treated, the clone continues to expand, and death occurs with approximately 10^{13} leukemic cells. With cytotoxic treatment, the number of neoplastic cells is diminished and when less than 5 % of leukemic blasts are identified in the bone marrow (BM) by conventional cytology, the patient is considered to be in complete remission. Thus, patients in complete remission have from zero to 10^{10} leukemic cells. The detection of MRD, either after clinical remission was achieved or during treatment, can help direct adjustments to therapeutic strategies and identify patients who are at higher risk of relapse [16, 45, 46, 76–80]. The presence of MRD at the time of transplantation as well as in the post transplant period are also powerful, independent predictors of adverse outcome [82–87].

Available Assays

Detection of Clonality by PCR

Monoclonality in ALL is detected by PCR amplification of the *IG* and/or *TCR* V(D)J region, typically using consensus primers to conserved sequences within the framework regions of the V region and the D and/or J regions (Fig. 41.2). The V(D)J region varies in size and sequence across a population of B or T cells and allows for detection of a monoclonal leukemic cell population by PCR amplification of a unique PCR product specific to the leukemic clone. For a population of nonlymphoid cells, where the *IG* and *TCR* genes are in the germline configuration, amplification will not occur, due to the great distance between the closest V and J regions [8, 9, 11, 15, 17].

RT-PCR for Leukemia-Specific Translocations

PCR analysis of fusion genes is based on the design of oligonucleotide primers within exons at the opposite sides of the breakpoint fusion regions, so that the PCR product contains the tumor-specific fusion sequence. The exact breakpoint at the DNA level may be different from patient to patient and therefore difficult to determine. In the majority of ALL translocations, the breakpoint regions span greater than 2 kb, exceeding the conventional range for PCR. However, because the breakpoints are mostly intronic and spliced out at the messenger RNA (mRNA) level, the preferred target for detection of translocations is the chimeric mRNA [26].

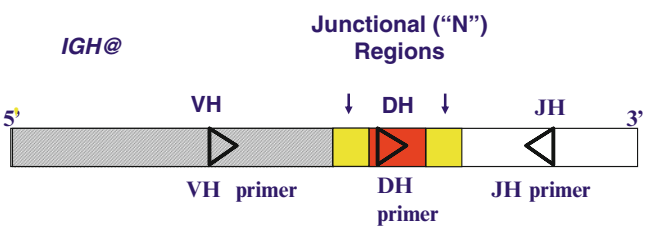

Figure 41.2 Schematic representation of an *IGH* VDJ recombination region and the strategy used to amplify the N regions. Probes for the N regions can be used as patient-specific probes (*boxes* with vertical *arrows* above them indicate N regions)

Reverse transcription-PCR (RT-PCR) requires extraction of total RNA or mRNA from mononuclear cells, reverse transcription of the RNA into complementary DNA (cDNA) and then PCR, followed by a method to detect the RT-PCR product, such as electrophoresis. The sensitivity of the method is specific for each target and can be assessed by amplification of serial dilutions of RNA from diagnostic specimens or cell lines containing the specific translocation into RNA from healthy individuals who do not have the translocation. The presence of a very small number of abnormal cells, in the range of 1 in 10^5 to 1 in 10^6, has been consistently detected using appropriate conditions [88]. This sensitivity is approximately 1000–10,000 times greater than with Southern blot analysis. A PCR test that is sufficiently sensitive to detect one leukemia cell in 10^2–10^3 normal cells is acceptable for diagnostic testing. A higher sensitivity of one leukemia cell in 10^4–10^5 normal cells is required for MRD assessment during follow-up testing [16]. More than one primer set may need to be used to detect all fusion transcripts when the translocation breakpoints can be in different introns of one or both of the fusion genes (Fig. 41.3).

MRD Quantification of *IG* and *TCR* Gene Rearrangements

Real time quantitative PCR (RT-qPCR) of *IG* and *TCR* gene rearrangements can be used to quantify MRD by using allele-specific oligonucleotide (ASO) probes. Sensitivities of one in 10^3–10^5 (Fig. 41.4) are achievable with this strategy [89–94]. Although initial assays used an ASO fluorescent probe to the junctional region, a more useful approach is to use a fluorescent probe complementary to the germline *IGH* and *TCR* gene segments, in combination with an ASO primer complementary to the junctional region [95, 96]. The ASO primer approach theoretically results in more sensitive MRD detection compared with the use of germline primers, because no competition can occur with the amplification of similar rearrangements in normal cells. Although specific amplification can be easily distinguished from incidental nonspecific amplification, conditions with higher stringency of amplification may need to be used to overcome nonspecific amplification while maintaining the efficiency of the method.

Quantification of Leukemia-Specific Translocations for MRD Assessment

Numerous publications have demonstrated the feasibility of the RT-qPCR method to quantify chimeric transcripts resulting from chromosomal translocations that occur in ALL [81, 91]. Although the principles of RT-qPCR are the same whether DNA or RNA is being analyzed, the RT step for RNA represents a major assay variable for accuracy of quantification and sensitivity. In fact, assays must be designed to correct for variations linked to differences in RNA input amount and, more importantly, in efficiency (or inhibition) during RT. For this reason, the number of target gene copies has to be normalized using a ubiquitously and constantly expressed housekeeping gene as a reference (e.g., *ABL1*, *B2M*, and *PBGD*) [97]. The number of chimeric transcripts are expressed in relation to the number of copies of the reference gene transcript.

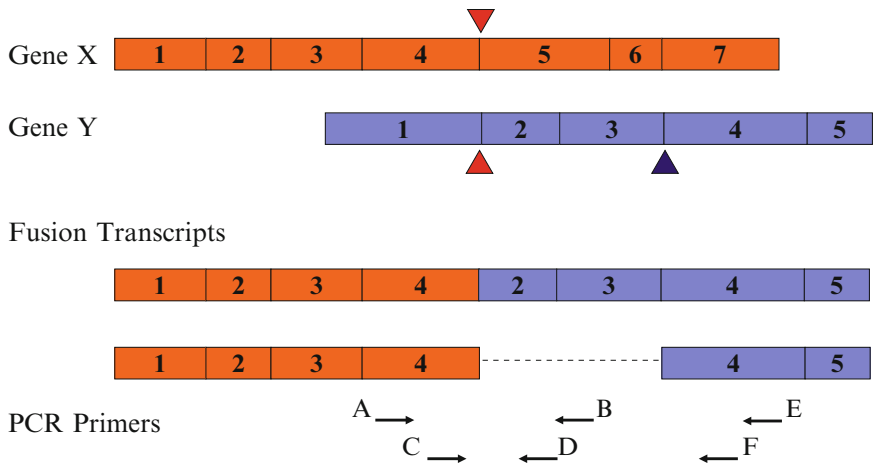

Figure 41.3 RT-PCR detection of different fusion transcripts generated by the same translocation. The possibility of different fusion transcripts requires the use of multiple primer pairs to detect fusion transcripts formed by breakpoints in different introns of the gene(s), depending on the size of the transcript

Interpretation of Test Results

PCR for *IG* and *TCR* Gene Rearrangements

Leukemia-specific *IG* and *TCR* gene rearrangements identified at diagnosis can be used for MRD assessment of BM or peripheral blood samples during and following treatment. However, similar *IG* and *TCR* gene rearrangements from normal lymphocytes in these specimens also are amplified. To discriminate between the leukemia-derived PCR products and PCR products of normal cells with rearrangements resulting in comparable size PCR products, the amplified bands are subjected either to "fingerprint" [98–100] or homo-heteroduplex analysis [18, 101, 102]. What was traditionally called fingerprint analysis consists of PCR amplification with a fluorescent primer and analysis by capillary electrophoresis. Clonal amplification results in a single peak, often in a background of polyclonal, constitutional amplification products. The homo-heteroduplex analysis takes advantage of the different migration properties in a polyacrylamide gel of V-J rearrangements containing a few mismatches (heteroduplex) compared with the fully matched V-J junctions (homoduplex) typical of a clone.

A variety of *IG* and *TCR* gene rearrangements can be present at diagnosis in childhood B-precursor ALL. Oligoclonal *IGH* rearrangements have been observed in 30–40 % of cases and *IGK* rearrangements in 5–10 % and are due to VH replacements, VH-DJH junctions, or de novo *IGH* gene rearrangements [18, 103–106]. Oligoclonality for *TRB* and *TRG* gene rearrangements is thought to be rare in B-lineage ALL [107–109, 111]. One exception was reported by Szczepanski et al., who found *TRG* oligoclonality in 38 % of B-lineage ALLs [17]. Oligoclonality of *TRD* is frequently observed in incomplete rearrangements, such as *VD2DD3* or *DD2DD3* [10, 109, 110]. In T-lineage ALL, oligoclonality is rarely seen at diagnosis [107, 111, 24, 25].

Clonal evolution, that is, different clone characteristics at relapse than the original clone characteristics, has been detected in rearrangements of both the *IG* and *TCR* genes. Rearrangements of the *IG* genes are particularly sensitive to clonal evolution, which occurs in more than 30 % of cases. Clonal evolution of rearranged *TCR* genes is less frequent, but observed in 10–25 % of cases. The likelihood of change in gene rearrangements seems to increase with time, but once they occur, further changes are not commonly observed during additional relapses [17, 112–114]. This clonal evolution may be due to the emergence of a new independent clone, due to secondary leukemia, or due to growth of subclones formed by continuous and secondary rearrangements of these genes [115–118].

RT-PCR for Leukemia-Specific Translocations

Several potential pitfalls must be avoided to prevent false-positive and false-negative results with translocation RT-

PCR assays. First, RNA degradation must be prevented by careful specimen handling, including prompt delivery to the laboratory and cooler temperatures. Second, a control mRNA from the same cDNA preparation used for amplification of the fusion transcript should be amplified to assess the integrity of the RNA, the efficiency of the RT step, and the presence of inhibitors.

A major concern has been raised about the clinical utility of RT-PCR MRD translocation testing in ALL patients because fusion transcripts can be detected in the hematopoietic tissues of healthy individuals. Low levels of *BCR/ABL1* transcripts have been detected in a sizable proportion of healthy individuals [119]. Using a two-round (nested) RT-PCR method, the *MLL/AF4* fusion transcript has been detected in the fetal liver and BM of normal infant samples and in 12 % of pediatric ALL with no cytogenetic or genomic evidence of 11q23 alterations [120]. The significance of these findings is still uncertain.

Molecular Detection of MRD and Clinical Studies

Sequential monitoring of MRD using sensitive and specific techniques with a detection power of one blast cell in 10^3–10^6 normal cells, has importantly refined the assessment of response to treatment [78, 121, 122, 89, 123, 124]. The study of MRD has drawn great interest in clinical oncology because of the potential for tailoring treatment and the possibility of gaining insight into the nature of a cure. Several parameters are critical for the interpretation of MRD studies, including the type of disease (ALL or acute myeloid leukemia [AML]), therapeutic context, timing of sampling, the target gene, sensitivity of the assay, interlaboratory standardization (particularly relevant in multicenter studies), the retrospective or prospective nature of the study, and the number of tests conducted for each patient.

Currently, highly sensitive and specific methods for MRD detection are available. Molecular assays have been applied to the identification of two types of "clone-specific" targets in ALL: breakpoint fusion regions arising from chromosomal translocations, especially fusion transcripts generated by the t(9;22), t(4;11), t(1;19), and t(12;21) translocations, and patient-specific sequences reflecting unique recombinations of *IG* and *TCR* genes [81, 90–93, 139]. Flow cytometry, using fluorescence-activated cell sorting analysis can detect abnormal immunophenotype patterns or combinations of these at diagnosis, which could distinguish leukemic cells from normal cells and be used to detect MRD [125–131].

Early response to treatment, based on the rate of disappearance of leukemic cells in the BM has proven to be an independent prognostic factor in childhood ALL and is being used by several groups as a criterion for the stratification of children in risk-adapted therapy. Morphological analysis, although useful and applicable at any center, has proven to be subjective, of limited sensitivity, and imprecise for the assessment of early response to treatment.

A prerequisite for applying MRD measurements in clinical studies is that the data should be available for all patients. In ALL, PCR-based MRD detection with *IG* and *TCR* gene rearrangements can be applied in more than 90 % of childhood and adult ALL cases. Accordingly, most of the clinical studies of MRD in ALL have used one of the different PCR approaches for the detection of *IG* and/or *TCR* gene rearrangements [16, 90–93]. Clinical application of MRD testing in the stratification and treatment of ALL requires reliable, reproducible, and quality-assured methods, including regular quality assessment to ensure the reproducibility and reliability of the MRD results [91, 92, 94, 132, 139, 93].

MRD has been significantly correlated with clinical prognosis, being particularly useful in the evaluation of an early response and thus permitting a refined stratification of treatment for both children and adults. Stratification into risk groups according to criteria not based on MRD has proven less accurate, especially for low-risk patients [45, 46, 133, 79, 80, 90, 134, 135].

During the initial induction treatment for ALL, the level of MRD is the most important independent prognostic factor regardless of age, risk group, or genetic translocations. The detection of high level MRD (10^{-2}–10^{-3}) on day 15 or day 19 of induction therapy is associated with an unfavorable prognosis, and lower levels with excellent prognosis. The "very good responder" patients could be candidates for less intensive treatment protocols. In contrast, children and adults with higher levels of MRD at the end of induction have very poor prognosis even with more intensive treatment protocols, including BMT [79, 80, 122, 136, 137, 138–141]. Reduction or intensification of treatment based on MRD results was investigated in different clinical trials [94, 139, 142].

Post-remission MDR assessments at different time points have been assessed in several clinical trials. The most important predictive time point for relapse in childhood ALL is the level of MRD measured at day 78 [80, 132]. The value of MRD detection at the end of treatment is questionable, because a negative result does not preclude subsequent relapse, thus reducing the utility of MRD detection as a criterion for elective cessation of treatment [113, 114, 137, 143].

MRD is an independent prognostic factor in relapsed patients and in those pre- and post-BMT [80, 82–87, 138, 144–146]. Reduction of MRD levels to less then 0.1 % prior the BMT is thought to be necessary to achieve a better outcome [82, 83, 87, 144]. Prospective studies are ongoing to better address these issues.

RT-qPCR of fusion transcripts generated by the t(9;22), t(4;11), t(1;19), and t(12;21) has been used to assess MRD [26, 81, 97, 147]. In theory, these fusion transcripts represent ideal targets for MRD assessment because they are very specific and absent in normal cells. However, they are present in only 30–40 % of B-lineage ALL and 10–20 % of T-ALL [94]. In addition, due to large breakpoint regions and a high number of potential fusion partners (e.g., *MLL*), fusion gene targets for MRD assessment are applicable only to a small number of patients [94]. The data reported so far have been controversial, leaving unanswered the question of whether MRD assessment based on tumor-specific translocations would help to identify patients with different outcomes within the same genetically defined subgroup and actually have been limited mainly to the quantitative detection of *BCR-ABL1* transcripts in Ph+ ALL [132]. Fusion transcripts almost invariably persist in chemotherapy-treated patients with ALL bearing the t(9;22), and detection of these transcripts correlates with the high relapse rate of this disease subtype in both adults and children [47, 48]. In studies of a large group of children, Ph^+ ALL appeared to be quite heterogeneous with regard to treatment response [54]. Thus, MRD evaluation may help to identify patients persistently negative for the *BCR*/*ABL1* fusion gene among those with good early responses to treatment, who can be cured with intensive chemotherapy alone. Absence of detectable *BCR*/*ABL1* transcripts could then be used as a surrogate marker to monitor in vivo response to new drugs in childhood Ph^+ ALL [55, 56].

Early conversion to persistently negative RT-qPCR results for the t(4;11) translocation involving the *MLL* and *AF4* oncogenes (particularly after three months) are associated with prolonged complete clinical remission (CCR). In the Interfant-99 protocol, the use of patient specific primers in combination with MLL probes to detect MRD was able to recognize different risk groups in infant ALL [148, 149].

In ALL patients with the t(1;19) translocation, persistently negative RT-qPCR tests are a good indicator of CCR, but positive tests are not necessarily an accurate predictor of relapse, thus reducing the utility of this test for clinical decision making [40, 41]. Continuous monitoring with accurate quantification may represent the most reliable approach.

Residual disease has been investigated in a limited number of patients with ALL carrying the t(12;21) and the results are controversial. Relapse was observed in cases with persistently positive MRD detection at greater than one in 10^3. However, relapse has been reported to occur even in patients with previously negative tests [47, 48, 150, 151]. Larger prospective studies are needed to fully assess the prognostic value of RT-qPCR testing for the t(12;21) translocation, as well as its value as an overall marker for monitoring MRD in childhood ALL [47, 48, 152].

Laboratory Issues

Although numerous methods to monitor MRD in acute leukemias have been developed in the past decade and new technologies are now being used, standardization and quality control still remain pertinent for clinical molecular testing in hematopathology. This is particularly true in efforts to assure reproducible results within multicenter international studies.

Standardization and quality control in the molecular approach for detection of antigen receptor gene rearrangements was addressed within the BIOMED-1 and BIOMED-2 frameworks and more recently in the EuroMRD effort, which developed and validated MRD strategies and provided guidelines to MRD interpretation [16, 91, 92, 94, 139, 153, 11]. One of the major problems resides in the fact that each patient's leukemia has a unique rearrangement, requiring the use of patient-specific primers and/or probes and individual optimization. Use of patient-specific assays represents a major challenge in uptake of this method in clinical molecular laboratories. In an effort to maximize detection of virtually all ALL patients and to prevent false-negative results, research PCR primers have been designed for multiple targets: *TRD*, *TRG*, and *IGK* rearrangements, as well as the *SIL*/*TAL* rearrangement [16]. The method uses a total of 54 primers with ASO probes in single or nested PCR for target identification at diagnosis, sequence analysis of junctional regions, and MRD detection in follow-up samples. A total of 25 PCRs are performed at diagnosis to identify the PCR targets. This standardized approach allows rapid detection of clonal *IG* and *TCR* rearrangements in ALL with high sensitivity and high specificity, and enables discrimination between monoclonal and oligoclonal gene rearrangements. The combination of the four PCR target types allowed PCR monitoring in more than 90 % of B-cell precursor ALL and 95 % of T-ALL cases. In the vast majority of childhood and adult ALL cases, two or more PCR targets were available for MRD monitoring. The sensitivity of detecting PCR targets depended at least partially on the size of the junctional region, with a sensitivity of one in 10^4 for most cases. To increase the percentage of cases successfully stratified by MRD, newly identified molecular targets have been incorporated. The monoclonal *VD2-JA* rearrangements in precursor B-ALL were used as patient-specific targets for MRD detection, because they show high sensitivity and good stability [23]. A sensitive *TRB* RT-qPCR assay was developed [154] with utility for MDR studies in those T-ALLs in which the repertoire of *IG* and *TCR* rearrangements is limited and therefore less sensitive.

Careful standardization and quality control of MRD techniques were also the aims of the European BIOMED-1

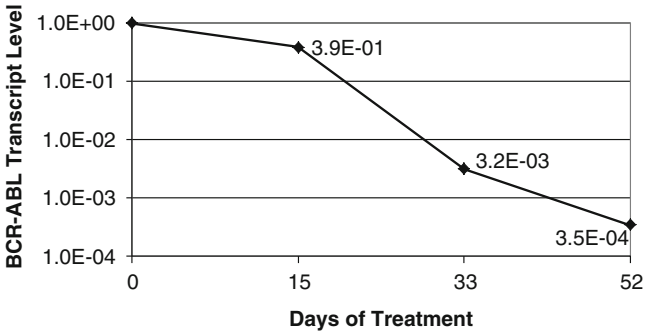

Figure 41.5 Minimal residual disease monitoring by real-time quantitative PCR (RT-qPCR) for a patient with ALL carrying the t(9;22) *BCR-ABL* translocation (p190 Ph+ALL) during the course of treatment

Concerted Action group, with participants from laboratories in several European countries [26]. The five most frequent, well defined ALL chromosomal aberrations with fusion gene transcripts were selected: t(1;19) with *E2A-PBX1*, t(4;11) with *MLL-AF4*, t(9;22) with *BCR-ABL1* (p190 and p210), t(12;21) with *ETV6-RUNX1*, and microdeletion 1p32 with *SIL-TAL1*. PCR primers, positioned to amplify several different transcript versions, were designed according to predefined criteria for single and nested PCR (Fig. 41.3).

The Europe Against Cancer program was established to achieve standardization and quality control for the RT-qPCR technique for detection and quantification of fusion gene transcripts. Twenty-five European laboratories in ten countries collaborated and established consensus standards for RT-qPCR (hydrolysis probe technology) for the main translocations seen in a spectrum of hematologic malignancies, including ALL. A set of 12 primers and nine probes has been selected to cover the most frequent chimeric transcripts, with a threshold of detection of 100 molecules and/or a one in 10^4 dilution [81]. This approach is anticipated to allow accurate quantitative measurement of fusion transcripts with an international consensus protocol for diagnosis and MRD assessment in follow-up samples.

A representative experiment of RT-qPCR detection of the fusion transcript generated by the translocation t(9;22) is shown in Fig. 41.5.

Conclusions and Future Directions

PCR amplification of fusion transcripts resulting from chromosomal translocations and of *IG* and *TCR* gene rearrangements has emerged as a sensitive and reproducible method to monitor MRD in ALL. The measure of the initial response to therapy in patients who have achieved complete remission by morphologic standards can dissect clinical heterogeneity within an apparently genetically homogeneous childhood ALL subgroup. Moreover, MRD monitoring can be applied to the appropriate patient subgroups for early prediction of impending relapses.

However, before any application in clinical decision making, the value of MRD monitoring must be studied in the context of clinical trials. Moreover, high levels of confidence in interpreting MRD results are needed to rule out false-positive and false-negative results, considering the problems and pitfalls of the current technology. In this context, the interpretation of MRD results that are produced by different studies would benefit from international standardization.

MRD analysis should be incorporated in any future clinical trials of ALL investigating a therapeutic question. Moreover, only the combination of simple and reliable MRD methods will allow the potential benefits of MRD monitoring to be extended to all children with leukemia. Finally, genome-based technologies such as microarrays and next generation sequencing will help to identify new genetic lesions in patients who are currently thought to represent the same genetic subtypes of ALL but who differ in MRD clearance and therapeutic response. With such new approaches, new specific markers for MRD monitoring hopefully will be identified.

B-Cell Malignancies

42

Jennifer B. Dunlap, Guang Fan, Nicky Leeborg, and Rita M. Braziel

Abstract

The mature B-cell neoplasms include numerous subtypes of B-cell leukemias and lymphomas (BCL), as well as plasma cell neoplasms. BCL represent 80–90 % of mature lymphoid leukemias and non-Hodgkin lymphomas (NHL) in the Western world. BCL subtypes include numerous distinct diseases, with different biologies, natural histories, morphologic characteristics, immunophenotypes, genetic features, prognoses, and responses to therapy. BCL also include the majority of immunodeficiency-associated lymphomas. Accurate subclassification of BCL has been a challenge for pathologists, resulting in early application of new techniques in molecular analysis to improve diagnostic accuracy. Today, the molecular features of BCL are used to aid in rendering an accurate diagnosis, to predict prognosis, to help determine optimal therapy, and to assess for minimal residual disease (MRD) after therapy. The molecular abnormalities in BCL have commonly been evaluated for clinical purposes, including those occurring in genes coding for antigen receptor (AgR) molecules and those occurring in oncogenes and tumor suppressor genes. This chapter will discuss current molecular testing methods for BCL, as well as some of the newer methods being developed for BCL.

Introduction

The mature B-cell neoplasms include numerous subtypes of B-cell leukemias and lymphomas (BCL), as well as plasma cell neoplasms. BCL represent 80–90 % of mature lymphoid leukemias and non-Hodgkin lymphomas (NHL) in the Western world. BCL subtypes include numerous distinct diseases, with different biologies, natural histories, morphologic characteristics, immunophenotypes, genetic features, prognoses, and responses to therapy. BCL also include the majority of immunodeficiency-associated lymphomas. The currently accepted subtypes of BCL are defined according to the World Health Organization (WHO) Classification of Tumours of Haematopoietic and Lymphoid Tissues [1] and are listed in Table 42.1. Accurate subclassification of BCL has been a challenge for pathologists, resulting in early application of new techniques in molecular analysis to improve diagnostic accuracy. Today, the molecular features of BCL are used to aid in rendering an accurate diagnosis, to predict prognosis, to help determine optimal therapy, and to assess for minimal residual disease (MRD) after therapy. The molecular abnormalities in BCL have commonly been

	Abbreviations used in text
Precursor B-cell lymphoblastic leukemia/lymphoma	Pre-B ALL/LBL
Mature B-cell neoplasms	
Chronic lymphocytic leukemia/small lymphocytic lymphoma	CLL/SLL
B-cell prolymphocytic leukemia	PLL
Hairy cell leukemia	HCL
Lymphoplasmacytic lymphoma	LPL
Plasma cell myeloma/plasmacytoma	PCM
Splenic marginal zone lymphoma	SMZL
Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue	MALToma
Nodal marginal zone lymphoma	NMZL
Follicular lymphoma	FL
Primary cutaneous follicle center lymphoma	PCFL
Mantle cell lymphoma	MCL
Diffuse large B-cell lymphoma	DLBCL
Lymphomatoid granulomatosis	LyG
Primary mediastinal (thymic) large B-cell lymphoma	PMLBCL
Intravascular large B-cell lymphoma	IBCL
ALK positive large B-cell lymphoma	ALK-DLBCL
Plasmablastic lymphoma	PBL
Large B-cell lymphoma arising in HHV-8-associated Castleman disease	HHV-8-DLBCL
Primary effusion lymphoma	PEL
Burkitt lymphoma	BL
B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and BL	HGBCLU
B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma	
Immunodeficiency-associated B-cell lymphoproliferative disorders (LPD)	
LPD associated with primary immune disorders	
Lymphomas associated with HIV infection	
Post-transplant LPD	PTLD
Other iatrogenic immunodeficiency-associated LPD	

evaluated for clinical purposes, including those occurring in genes coding for antigen receptor (AgR) molecules and those occurring in oncogenes and tumor suppressor genes. However, it must be noted that the recent development of techniques such as microarray gene expression profiling, multiplex genetic mutation testing, and array-based comparative genomic hybridization (aCGH) has resulted in a significant expansion of knowledge about the biology of the different BCL and the number of clinically important molecular markers.

Molecular Basis of Disease

B-Cell Antigen Receptor Genes

AgRs are the primary effector molecules of the adaptive immune system and consist of multi-subunit glycoprotein molecules present on all T and B lymphocytes [2]. Each lymphocyte has a unique antigen receptor molecule on its membrane. B-cell AgRs are membrane-bound immunoglobulins (Ig), which include the heavy chain gene (*IGH*) at 14q32, the kappa light chain gene (*IGK*) at 2p11, and the lambda light chain gene (*IGL*) at 22q11. Each AgR gene in germline configuration consists of variable (V), joining (J), constant (C), and in the case of the *IGH* gene, diversity (D) regions. There are approximately 45 V, 23 D, and 6 J regions in the *IGH* gene. During B cell development, one *IGH* allele undergoes rearrangement, with deletion of large intervening DNA segments, followed by DNA repair at the site of recombination. This process is mediated by recombination activating genes (*RAG1/2*) which encode RAG1/2 proteins able to induce breaks in double stranded DNA. DNA damage response proteins then bring the separated AgR gene segments together and form a functional rearranged *IGH* gene [3]. AgR rearrangement occurs in a specific order: first, one *IGH* D segment is fused to one J segment, then this DJ segment is fused with a V segment to form a functional VDJ exon that encodes the variable antigen recognition site of the IGH protein. Following *IGH* rearrangement, the final product is a gene

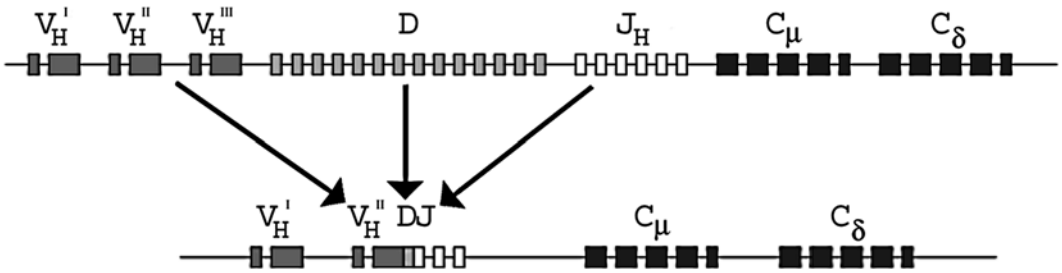

Figure 42.1 Configuration and rearrangement of the *IGH* gene on chromosome 14q32. DJ rearrangement occurs initially, followed by VD rearrangement. The rearrangements occur in a random fashion across B cells, resulting in unique rearrangement in each normal B cell. The rearranged *IGH* gene contains one V_H segment (plus all the upstream V_H segments), one D_H segment, one J_H segment (plus all the downstream J_H segments), and the C_H segments, in that order on the chromosome

containing one V region, one J region, one D region, and multiple C regions, arranged in the following order on the chromosome: V-(D)-J-C (Fig. 42.1). Ig gene rearrangement is an error-prone process and many attempted rearrangements result in nonfunctional AgR genes. If the first *IGH* rearrangement in a cell fails, the second *IGH* allele is rearranged. A single B cell may therefore have two *IGH* rearrangements, one nonfunctional and one functional. The *IGK* alleles rearrange in a similar fashion, but only after the successful rearrangement of one of the *IGH* alleles. The *IGL* alleles rearrange in most cases only if rearrangements of the *IGK* genes fail and both alleles are deleted [4]. Normal B cells that fail to produce a functional *IGH* or light chain rearrangement are usually eliminated through apoptosis.

After successful rearrangement, the Ig genes in mature B cells often undergo additional changes, including somatic hypermutation. In response to antigen exposure, somatic hypermutation occurs in the *IGH* V region (IGVH) of an already rearranged *IGH* gene in germinal center-derived B cells to enhance antigen affinity of the AgR. Somatic hypermutation occurs through point mutations, small insertions, small deletions, or some combination of these. The enzyme activation-induced cytidine deaminase (AID) mediates the process of both class-switching and somatic hypermutation. AID expression is upregulated in germinal centers in response to antigen stimuli [3, 4]. The term "postgerminal center" is used to refer to B cells that have been exposed to antigen in the germinal center and undergone additional somatic mutation of IGVH. Errors in class switch recombination, somatic hypermutation, and AID expression contribute to the pathogenesis of many B cell lymphomas [5].

Structurally and genetically unique AgR rearrangements occur in every B cell and are exploited as markers of cell lineage and clonality. B cells with these unique gene rearrangements may undergo limited clonal expansion as a part of a normal immune response, but uncontrolled clonal expansion occurs in BCL. In this setting, the unique AgR rearrangement can serve as a diagnostic marker of B-cell clonality and a marker for detection of MRD following therapy. Clonal rearrangements of *IGH* and *IGK* can be detected in essentially all malignancies of mature B cells, but many precursor B-cell malignancies will have only *IGH* rearrangements, since malignant transformation occurs before rearrangement of the *IGK* or *IGL* genes.

Recurrent Cytogenetic and Molecular Abnormalities in BCL and Plasma Cell Myeloma

Many, but not all BCL are associated with characteristic cytogenetic or molecular abnormalities that help to establish an accurate primary diagnosis, have specific prognostic significance, and/or serve as targets for MRD assessment. Most of the molecular abnormalities described below have been included under the National Comprehensive Cancer Network Guidelines (Version 3.2012) as "useful testing under certain circumstances for clarification of diagnosis." Table 42.2 provides a summary of most of the recurrent cytogenetic abnormalities identified thus far in subtypes of BCL. This list illustrates the large number of potential targets for molecular testing, but also highlights the increasing challenge for clinical laboratories to provide relevant molecular information to clinicians. There are many additional newly discovered mutations in different BCL, either not yet proven to have clinical relevance and/or not yet part of routine testing algorithms in BCL; some of these are listed in Table 42.3 for the different BCL subtypes. The most clinically relevant BCL subtype-specific cytogenetic and molecular abnormalities, namely those with currently known diagnostic or prognostic significance, are discussed in more detail under the individual BCL categories below. General considerations that are applicable to most or all BCL subtypes are discussed later in the sections on diagnostic and prognostic indications for molecular testing in BCL.

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

Although morphologically and immunophenotypically similar, chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) is quite heterogeneous genetically, with different molecular abnormalities resulting in different natural histories and responses to therapy. New insights into the biology of CLL/SLL have improved the approach to treatment. Many of the relevant chromosomal abnormalities in CLL/SLL are not detected by karyotyping because the low proliferative capacity of most CLL/SLL limits the clinical utility of metaphase cytogenetics. The genetic abnormalities in CLL/SLL therefore usually are detected by interphase fluorescence in situ hybridization (FISH), which has become the clinical standard of care in CLL/SLL. Evaluation for these abnormalities is clinically indicated at diagnosis in most cases of CLL/SLL, because therapeutic decisions are affected by the molecular profile.

Table 42.2 Nonrandom chromosomal abnormalities in B-cell malignancies

Lymphoma subtype	Nonrandom chromosomal alterations	Genes involved
CLL/SLL	Del 13q14 Trisomy 12 Del 11q22-23 Del 17p13 Del 6 3q27	Unknown Unknown *ATM* *TP53*
LPL	Del 6q Trisomy 4

See Table 42.1 for abbreviations.

Adverse molecular prognostic factors in CLL/SLL include lack of IGVH hypermutation and the presence of *TP53* or *ATM* gene mutations. Somatic hypermutation of IGVH is seen in approximately 50 % of CLL/SLL, and long-term progression-free and overall survival is better for patients with hypermutated IGVH. The explanation for this seems to be that unmutated CLL/SLL cells are genomically less stable than mutated CLL/SLL cells, are more likely to have acquired a *TP53* deletion at relapse than those with mutated IGVH, and therefore are more likely to be resistant to salvage chemotherapy. Patients with intact *TP53* gene function appear to have prolonged survival regardless of the extent of IGVH hypermutation [6]. Testing for IGVH hypermutation requires multiple PCR analyses and gene sequencing and is performed at only a few specialty laboratories and academic centers.

The *TP53* gene deletion at 17p13.3 is identified by FISH testing in 7–15 % of CLL/SLL cases at diagnosis (illustrated in Fig. 42.2), but is detected by karyotype at a much lower rate. Other types of *TP53* mutations also occur in many CLL/SLL including missense substitutions, frameshift mutations, and in frame deletions, and are highly correlated with 17p deletion; however, some *TP53* mutations occur in the absence of deletion of 17p [7, 8]. *TP53* maintains genome integrity by orchestrating the repair or elimination of cells with damaged DNA and contributes to the cytotoxicity of many anticancer agents. Both 17p deletion and inactivating mutations of *TP53*

Table 42.3 Common gene mutations and deletions in B-cell lymphomas

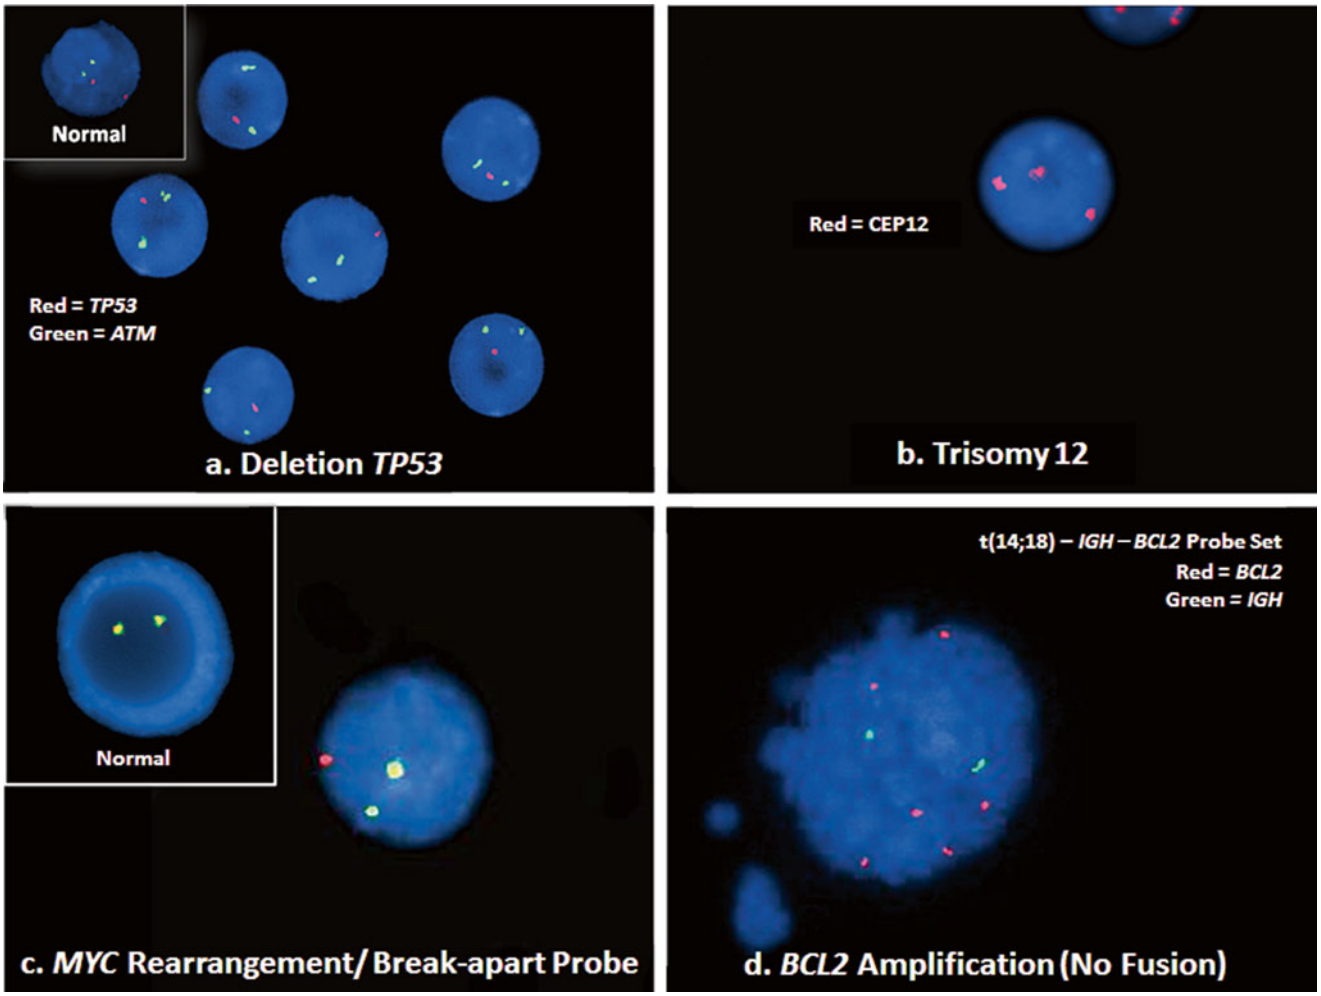

Figure 42.2 Illustrations of typical genetic abnormalities in BCL, detected by interphase FISH. (**a**) CLL/SLL lymphocytes with deletion of *TP53*. This case shows two *green ATM* (11q22.3) signals, but only one *red TP53* (17p13.1) signal (RGG). A normal cell would have two *red* and two *green* signals (RRGG), as seen in the *inset*. (**b**) A centromeric probe (CEP12) for chromosome 12 demonstrates trisomy 12 with 3 *red* signals (RRR) in this cell from the blood of a CLL/SLL patient. A normal cell would have two *red* signals (RR). (**c**) A break-apart probe for the *MYC* gene shows a *MYC* rearrangement with a *yellow* fusion signal for the normal *MYC* and separate *green* and *red* signals for the rearranged *MYC* gene (RGY). The pattern in a normal cell with the break-apart probe would be two *yellow* signals (YY), shown in the *inset*. (**d**) BCL cell with *BCL2* amplification. This FISH result does not show the t(14;18)–*IGH*–*BCL2* fusion signals (RGYY) typical of the translocation. Rather, the pattern of six *red* signals for the *BCL2* gene with only two signals for the *IGH* gene (6R2G) is consistent with *BCL2* amplification. See Table 42.1 for abbreviations

render patients resistant to chemotherapy [9]. *TP53* dysfunction is associated with an adverse clinical outcome in CLL/SLL patients, as well as in other BCL.

Deletions in 11q22-23 are detected by FISH in 14–20 % of CLL/SLL cases and are associated with inactivation of the ataxia telangiectasia (*ATM*) gene. The ATM protein kinase is involved in*TP53* regulation; therefore, *ATM* deletions produce *TP53* dysfunction in CLL/SLL cells. *ATM* deletions most often are detected by FISH and are associated with a poor prognosis, although not as poor as that of patients with *TP53* deletion/mutation. The addition of Rituximab monoclonal antibody therapy which targets CD20 on B cells to chemotherapy regimens appears to overcome the poor prognosis conferred by the 11q deletion [10, 11]. Mutations in *ATM* have been reported in approximately 10 % of CLL/SLL cases and only partially correlate with deletions in 11q. Approximately 18–30 % of cases with 11q deletion show concomitant *ATM* mutations. The significance of an *ATM* mutation in the absence of an 11q deletion is not well established.

As a single abnormality in CLL/SLL, 13q14 deletions convey the most favorable prognosis. CLL/SLL with 13q14 abnormalities usually has IGVH hypermutation. Detected by FISH, 13q14 deletions are seen in 40–55 % of CLL/SLL cases and are thought to affect one or more tumor suppressor genes. Frequent deletions and downregulation of microRNA genes miR15 and miR16 at 13q14 have been described in the

majority of CLL/SLL cases with 13q14 deletions [12]. 13q14 deletions are sometimes seen in other BCL, but the specific gene(s) involved may not be the same.

Trisomy 12 can be detected by FISH or routine karyotyping and occurs in 16–20 % of CLL/SLL cases (FISH illustration in Fig. 42.2). Trisomy 12 usually is associated with unhypermutated IGVH and has been associated with atypical CLL/SLL morphology. Patients with trisomy 12 have an intermediate prognosis, with a median survival exceeded only by patients with single 13q14 abnormalities [10, 11].

Deletions of chromosome 6q are present in approximately 7 % of CLL/SLL cases and can be detected by FISH. The majority are identified at 6q21-23, with a smaller percentage documented at 6q25-27. Although limited, initial studies suggest that this class of cytogenetic abnormality is associated with an intermediate risk profile. Incorporation of FISH probes for 6q in clinical practice may improve our understanding of this molecular abnormality in risk stratification of patients with CLL/SLL.

In addition to the genetic abnormalities described above, exome and genome sequencing studies have identified additional recurrent gene mutations in CLL/SLL (Table 42.3) including those in *SF3B1*, *NOTCH1*, and others [13]. Frameshift mutations in the proline-glutamic acid-serine-threonine (PEST) degradation domain of *NOTCH1* are associated with unhypermutated IGVH, trisomy 12, and a poor prognosis. Missense mutations in *SF3B1*, a gene involved in RNA splicing, are relatively common in CLL/SLL (approximately 10 %) and whereas the data are preliminary, there is evidence that these mutations also confer a worse clinical outcome [13–15].

B-Cell Prolymphocytic Leukemia

B-cell prolymphocytic leukemia (B-PLL) is an aggressive mature B-cell leukemia characterized by splenomegaly with minimal to no lymphadenopathy and prolymphocytes comprising >55 % of circulating lymphoid cells. Complex karyotypes are common, as are *TP53* mutations, 13q14 deletions, and to a lesser extent, trisomy 12. Cases with t(11;14)(q13;q32) are generally excluded from this category and considered leukemic variants of mantle cell lymphoma (MCL). The *MYC* gene can be overexpressed in B-PLL [16] and, although rare, the t(8;14)(q24;q32) translocation that involves *MYC* and is characteristic of Burkitt lymphoma (BL) has been reported in B-PLL [17, 18]. The significance of *MYC* abnormalities in B-PLL is not entirely clear and additional study is needed to elucidate the genetic events underlying the pathophysiology of this disease.

Hairy Cell Leukemia

Hairy cell leukemia (HCL) is an indolent neoplasm of mature B cells characterized by circumferential "hairlike" projections of the B-cell cytoplasmic membrane, splenomegaly, diffuse marrow involvement, and peripheral cytopenias. The *BRAF* V600E point mutation is present in nearly all cases of HCL and has redefined a disease which previously had no known recurrent molecular abnormalities. The *BRAF* V600E mutation is rare in other mature BCL [19]. The apparent specificity of this mutation for HCL makes this a disease-defining mutation with clear diagnostic utility, in addition to possible implications for MRD detection and treatment.

Lymphoplasmacytic Lymphoma

In the 2008 WHO classification, lymphoplasmacytic lymphoma (LPL) is defined as a B-cell neoplasm composed of a mixture of small lymphocytes, plasmacytoid lymphocytes, and plasma cells, that does not fulfill the criteria for any of the other malignancies of small B lymphocytes, i.e., a diagnosis of exclusion [1]. LPL includes Waldenström macroglobulinemia (WM). There are several common cytogenetic abnormalities in LPL, but none are specific for this lymphoma subtype. These abnormalities include 6q deletion, which is seen in approximately 50 % of cases presenting in the bone marrow (BM), less often in cases presenting in lymph nodes, and may be associated with a worse prognosis [20]. Trisomy 4 is present in 20 % of WM [21]. The t(9;14) translocation previously reported in LPL has been reassessed and confirmed not to be associated with LPL [22]. Gene expression profiling studies using flow cytometric sorted cells have shown that WM B cells cluster with CLL/SLL B cells, whereas WM plasma cells segregate with plasma cell myeloma cells [23]. One of the upregulated genes in WM B cells is interleukin-6, a molecule that may be a therapeutic target in LPL. WM is sometimes associated with clonal expansions of cytotoxic T cells in the blood, which can confound diagnosis. These T-cell clones can be eliminated by chemotherapy for LPL [24]. A mutation in *MYD88* is present in almost all patients with WM. This mutation in *MYD88* at 3p22.2 results in an amino acid change (L265P), and triggers NFKB signaling. The *MYD88* L265P mutation is absent or only occasionally expressed in other subtypes of non-IgM LPL, as well as plasma cell myelomas and marginal zone lymphomas [25].

Plasma Cell Myeloma/Plasmacytoma

Plasma cell myeloma (PCM) and related plasma cell neoplasms have two major subgroups by cytogenetic and molecular characteristics with some overlap. The first group is hyperdiploid PCM, which comprises 55–60 % of cases and has trisomy or tetrasomy, predominantly of odd numbered chromosomes. The second group has chromosomal translocations that involve the *IGH* gene on 14q32, with a variety of partner genes. These translocations occur in approximately 50 % of PCM and the different translocations are sometimes associated with specific clinical features and

outcome. Most cannot be identified by karyotyping, but are readily identified by FISH studies utilizing molecular probes for 14q32 and its translocation partners. Translocations involving the *IGH* locus in PCM are believed to occur at the time of isotype class switching, in contrast to other B-cell malignancies.

The t(11;14)(q13;q32) is the most common translocation, occurring in 20–25 % of all PCM. It involves the *CCND1* gene and is associated with a good prognosis and long survival. PCM with the t(11;14)—*CCND1–IGH* translocation often show considerable morphologic and immunophenotypic overlap with LPL. Detection of the translocation and cyclin D1 protein expression by immunohistochemistry (IHC) are important in making the appropriate diagnosis [26].

The t(4;14)(p16.3;q32) portends the worst prognosis in PCM and is seen in approximately 25 % of cases; it involves *IGH* and the fibroblast growth factor receptor-3 (*FGFR3*) and *MMSET* genes at 4p16.3. The t(14;16)(q32;q23) translocation involving the *MAF* gene occurs in approximately 20 % of PCM and conveys an intermediate prognosis, as does the t(6;14)(p25;q32) translocation involving the *MUM1* gene, also known as the *IRF4* gene.

Progressive disease with transformation to high grade variants of PCM with large cell anaplastic or plasmablastic morphology is associated with *MYC* rearrangements [27, 28], *TP53* mutations and deletions, mutations of *KRAS* and *NRAS*, 1p deletions, and amplifications of 1q21 [29, 30].

Cytogenetic abnormalities detected by karyotyping may show significantly different clinical outcomes compared to abnormalities detected by interphase FISH only [31]. For example, monosomy 13 detected by karyotyping is seen in approximately 50 % of PCM and is associated with poor survival, while chromosome 13 abnormalities detected by interphase FISH only are associated with intermediate survival. Multicolor FISH, also known as spectral karyotyping, can detect chromosomal abnormalities in PCM, including deletions, amplifications, and rearrangements that are missed or cryptic by conventional karyotyping, such as Xp11, 8q24, 11q13, 12q13, 13q21, 14q32, and 22q11.2 abnormalities [32]. New classification systems and stratification for treatment of PCM have been proposed due to these novel abnormalities, but further investigation into the clinical significance of this complex and expensive testing is needed before it can move into routine clinical care.

Marginal Zone B-Cell Lymphomas

The marginal zone lymphomas (MZL) are low grade B-cell lymphomas and include splenic marginal zone lymphoma (SMZL), extranodal marginal zone lymphomas of mucosa-associated lymphoid tissue (MALToma), and nodal marginal zone lymphoma (NMZL). Multiple molecular abnormalities occur in MZL, and MZL of different sites have different molecular abnormalities (Table 42.2). Testing for these abnormalities is helpful in confirmation of primary diagnosis and prognosis. Diagnostic and prognostic testing for these molecular abnormalities usually is performed by multicolor FISH.

The most common translocation in gastric, intestinal, and lung MALTomas is t(11;18)(q21;q21), which occurs in 30–50 % of cases [33–35]. The genes involved are the apoptosis inhibitor gene (*API2*) on 11q21, a member of the inhibitor of apoptosis (IAP) protein family with caspase-inhibitory functions, and the *MALT1* gene on 18q21, encoding a human paracaspase protein. The resulting *API2–MALT1* chimeric transcript and fusion protein leads to inhibition of apoptosis and confers a survival advantage on the MZL cells. T(11;18)(q21;q21) is associated with worse prognosis and occurs most frequently in *H. pylori*-positive antibiotic-resistant MZL or advanced gastric MZL, but not in nodal or splenic MZL, nor in extranodal MZL with increased large cells or large-cell transformation. FISH is the most sensitive and specific method for detection of this translocation; however, reverse transcription PCR (RT-PCR) is occasionally used for detection.

An apoptosis regulatory molecule, BCL10, is overexpressed as a result of the t(1;14)(p22;q32) translocation, which involves *BCL10* on 1p22 and the *IGH* gene on 14q32 [36]. Advanced MALTomas sometimes have both *API2–MALT1* and *BCL10–IGH* translocations, and BCL10 appears to interact with the API2–MALT1 fusion protein to synergize activation of NFKB, suggesting that they are part of a common pathway. The *BCL10–IGH* translocation is associated with a worse prognosis in low grade MALTomas and is typically detected by FISH.

The t(14;18)(q32;q21) translocation, also detected by FISH, involves *IGH* on 14q32 and *MALT1* on 18q21. The *IGH–MALT1* translocation occurs in most liver MALTomas, as well as some cutaneous, ocular adnexal, and salivary MALTomas, but is rare in MALTomas of the stomach, intestine, lung, thyroid, and breast, and does not occur in NMZL or SMZL. *IGH–MALT1* does not usually occur with the *API2–MALT1* translocation, but sometimes occurs with trisomy 3 or trisomy 18 or both [37]. The clinical significance of this translocation is not yet established. This translocation should not be confused with the cytogenetically identical, but molecularly distinct t(14;18)(q32;q21) translocation, resulting in an *IGH–BCL2* fusion, which is associated with follicular lymphoma.

Trisomy 3 occurs in more than 50 % of low-grade MZL, and aCGH studies have shown gains at 3q21-23 and 3q25-29, suggesting that *BCL6* is involved in some cases. Trisomy 18 occurs in approximately 30 % of MZL. The genes involved are not well understood and the clinical relevance is unknown.

The t(3;14)(p13;q32) involving *FOXP1* on chromosome 3 and the *IGH* gene on chromosome 14 is present in approxi-

mately 10 % of MALTomas. *IGH–FOXP1* is seen most commonly in MZL arising in the thyroid, ocular adnexa, and skin and is absent in MZL from the lung and stomach. The translocation results in overexpression of FOXP1, is associated with trisomy 3, and may have a more aggressive clinical behavior [38, 39].

A20 (also known as *TNFAIP3*), found at 6q23, is a negative regulator of the NFKB pathway and is inactivated in a subset of MALTomas via mutation, methylation, or deletion [40]. *A20* inactivation is preferentially seen in MALTomas arising from the ocular adnexa, salivary gland, and thyroid. Activating *MYD88* point mutations (L265P), identical to those identified in the activated B-cell-like subtype of diffuse large B-cell lymphoma (DLBCL), and WM have been reported in 9 % of MALTomas, although the clinical significance is not yet clear [41]. Both *A20* and *MYD88* mutations contribute to constitutive activation of the NFKB pathway mediating cell survival and growth.

Follicular Lymphoma

Follicular lymphoma (FL) is the second most common subtype of NHL, accounting for approximately 22 % of cases [42]. FL patients demonstrate a remarkably variable clinical course, with some patients surviving for less than 1 year while others live for more than 20 years [43]. Standard pathologic, immunologic, and genetic analyses of FL have failed to identify a reliable method for prediction of prognosis in newly diagnosed FL patients. Gene expression profiling of a large series of FL suggests that the length of survival of FL patients correlates with the features of nonmalignant cells present in the lymphoma at diagnosis [44]. However, gene expression profiling is not available yet for routine clinical diagnosis and no alternative immunohistochemical algorithm has yet been developed in FL.

The t(14;18)(q32;q21) translocation, detected in approximately 80 % of FL at the time of initial diagnosis, is the cytogenetic hallmark of FL and juxtaposes the *BCL2* oncogene on 18q21 with the *IGH* gene on 14q32. Overexpression of a normal BCL2 protein results from this translocation and protects the cells from apoptosis. Molecular analysis for *IGH–BCL2* translocation using FISH (Fig. 42.2) is often used for confirmation of the initial diagnosis of FL in cases with equivocal histologic and immunologic findings. Molecular testing for *IGH–BCL2* translocation by PCR in FL may be performed to evaluate the course of disease and the impact of therapy [45, 46]. Analysis to aid in evaluation of response to therapy is typically performed by PCR, because FISH is not sensitive enough for detection of a low level of MRD in BM or blood. *BCL2* breakpoints occur most commonly in a 150 base pair (bp) span termed the major breakpoint cluster region (MBR), but may occur in areas of the gene called the minor breakpoint cluster region (MCR) or the intermediate cluster region (3′MBR). The insertion of variable numbers of random extra nucleotides at the breakpoint junction during crossover and the variability of the breakpoints in the *BCL2* fusion gene and the six J_H fragments results in considerable variation in the length of PCR products when testing is performed for this translocation. PCR fragment length usually ranges from 120 to 270 bp for the MBR, but occasional breakpoints as much as 800 bp downstream of the MBR region have been detected with standard MBR primers, resulting in PCR products of more than 1,000 bp. The clustering of breakpoints on chromosome 18 and the high degree of sequence homology among the 3′ portions of the JH segments make the *IGH–BCL2* translocation very amenable to PCR detection and a good PCR target for MRD detection (see section on "Minimal Residual Disease Detection").

Histologic progression occurs in approximately 30 % of FL patients, but the genetic events that are involved in this progression are not completely defined. Studies of paired lymph node biopsy specimens derived from the same FL patient before and after transformation identify at least two mechanisms for transformation. One is associated with high proliferation and one with recurrent oncogenic abnormalities. Mutations in *TP53* occur in 20 % of transformed FL. *MYC* gene expression is markedly increased in 70 % of transformed FL, but appears to be a surrogate marker for the gene expression profiling high proliferation signature [47]. The frequency of *MYC* mutations and translocations in transformed FL is low [48]. Copy number variability in two regions (1p36.22-p36.33 and 6q21-q24.3) are predictors of transformation risk in FL, independent of the International Prognostic Index (IPI) score. These prognostic features may be useful to identify high-risk patients as candidates for risk-adapted therapies [49].

Genes encoding proteins involved with histone modification are frequent targets of somatic hypermutation in both DLBCL and FL and may play an important role in B-cell lymphomagenesis. Both DLBCL and FL may have mutations in these genes, but the frequency of mutation is highest in FL, with *MLL2* mutation in 89 % and *MEF2B* mutation in 13 % of FL [50]. *MLL2* encodes a histone methyltransferase and *MEF2b* cooperates with *CREBBP* and *EP300* to acetylate histones.

Mantle Cell Lymphoma

Molecular testing is performed at initial diagnosis in most patients with MCL as the diagnosis confers a very poor prognosis and mandates aggressive therapy in most cases [51]. Diagnostic testing targets the t(11;14)(q13;q32) translocation, which juxtaposes the *BCL1* or *CCND1* gene on chromosome 11q13 with an *IGH* enhancer, resulting in overexpression of normal cyclin D1 protein and increased cell cycling. This translocation is not completely specific for

MCL, as it also occurs in many plasma cell myelomas. However, no diagnostic problems are caused by this overlap as the *CCND1–IGH* translocation does not occur in the subtypes of BCL with which MCL shows significant morphologic or immunophenotypic overlap. Multiple methods have been used to detect the *CCND1–IGH* translocation, including karyotyping, PCR, RT-PCR for *CCND1* mRNA, and FISH [52]. The optimal diagnostic method has proven to be FISH (Fig. 42.3), which detects >90 % of cases, even in formalin-fixed paraffin-embedded (FFPE) biopsy tissue. PCR detection is less successful because the 11q13 breakpoints are widely distributed; approximately 30–50 % are localized to a 1 kb DNA segment called the major translocation cluster (MTC), but the remaining translocations involve many different sites not easily detectable by PCR analysis. There is little application for the PCR assay when FISH is faster, more specific, and can be performed on FFPE tissue.

The proliferation signature by gene expression profiling can identify MCL patients with the poorest prognosis [53]. The evaluation of Ki-67 by IHC is often used as a surrogate for the gene expression proliferation signature in the routine diagnostic workup of MCL, but is difficult to interpret and is less predictive in the intermediate range. However, a high level of Ki-67 expression is likely associated with poor outcome, independent of the morphologic variant. The mitotic index (counting the number of mitotic figures/mm2) may be superior to Ki-67 expression [54]. Gene expression profiling has identified the transcription factor *SOX11* as a specific marker for MCL and IHC analysis demonstrates strong nuclear staining with SOX11 in >90 % of MCL cases including those that are cyclin D1-negative [55]. While this is potentially a diagnostically useful marker, the prognostic significance remains controversial.

ATM deletions like those in CLL/SLL also are seen in many MCL cases, and progression or aggressive clinical behavior in MCL is associated with *P16* and *TP53* abnormalities [56]. Additionally, recurrent *NOTCH1* mutations occur in MCL; similarly to CLL/SLL, *NOTCH1* mutations are associated with poor prognosis [57]. MCLs rarely have somatic hypermutation of IGVH.

Diffuse Large B-Cell Lymphoma

DLBCL is the most common subtype of lymphoma and this category of the WHO classification represents another clinically and biologically heterogeneous group of BCL. Over the past decade, promising new technologies have been applied to the problem of identification of prognostic subgroups of DLBCL. Microarray gene expression profiling has identified three molecularly and prognostically distinct subtypes of DLBCL: a germinal center B-cell-like DLBCL subgroup (GCB) with a favorable prognosis; an activated B-cell-like DLBCL subgroup (ABC) with a poorer prognosis; and a favorable primary mediastinal large B-cell lymphoma subgroup (PMBL) [58–60].

In addition to distinct gene expression patterns, these DLBCL subgroups have different cytogenetic and molecular abnormalities and utilize different oncogenic pathways. The GCB type of DLBCL derives from the germinal center B cell. *IGH–BCL2* translocations [t(14;18)] identical to those seen in FL are specific to GCB DLBCL and are not seen in the other DLBCL subtypes. GCB DLBCL may also have amplification of the *REL* locus on chromosome 2p,

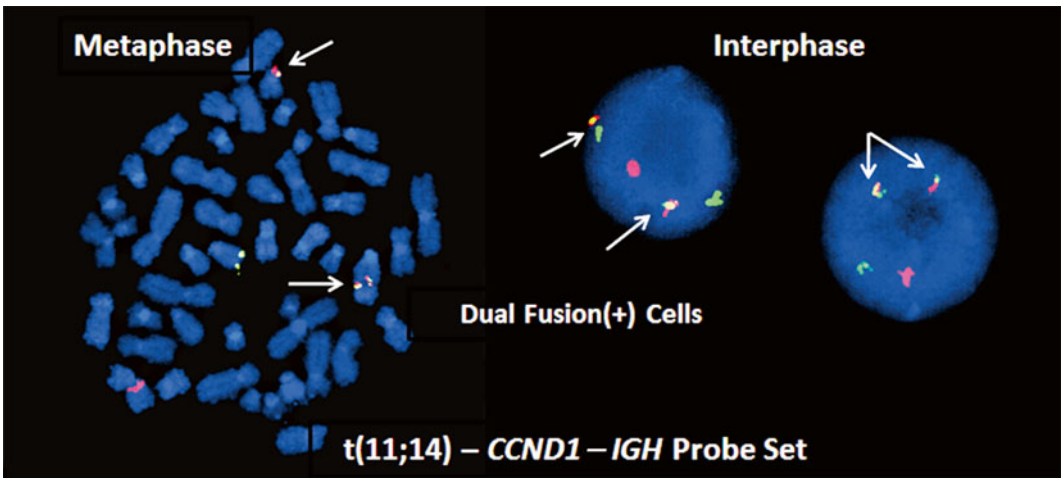

Figure 42.3 FISH analysis for the t(11;14) *CCND1–IGH* translocation in a mantle cell lymphoma (MCL). On the *left* is a single metaphase spread and on the *right* are two interphase cells, all with two *yellow*, one *red* and one *green* signal called a dual fusion signal pattern (RGYY). These probes detect both derivative chromosomes resulting from the translocation. Both derivative chromosomes produce a *yellow* fusion signal, whereas the normal alleles produce separate *red* and *green* signals

deletion of *PTEN* on chromosome 10, and amplification of microRNA cluster mir-17-92 [61], as well as mutations in genes involved in chromatin/histone modification such as *EZH2* and *CREBBP* [50, 62] (Table 42.3).

ABC DLBCL originates from a post germinal center B cell, has a gene expression profile similar to that of activated peripheral blood B cells [58], and is characterized by constitutive activation of the NFKB pathway. Mutations in *A20*, *MYD88* and *CARD11* are thought to contribute to deregulation of the NFKB pathway [63]. Also typical of ABC DLBCL are trisomy 3, increased FOXP1 mRNA expression, deletion of chromosome 6q, deletion of the *INK4a–ARF* tumor suppressor locus on chromosome 9, and gain or amplification of part of chromosome 19 [61] (Table 42.3).

PMBL represents a distinct entity in the 2008 WHO classification, which is more frequent in young adults and typically presents as a mediastinal mass without involvement of lymph nodes or BM. PMBL is thought to be derived from a thymic medullary B cell. The gene expression profile more closely resembles that of classical Hodgkin lymphoma than the other subtypes of DLBCL. aCGH has demonstrated amplification of chromosome 9p24 in up to 75 % of cases and 2p15 in approximately 50 % of cases. Candidate genes include *REL* and *BCL11A* at 2p and *JAK2*, *PDL1*, and *PDL2* at 9p [64]. *SOCS1* mutations and upregulation of NFKB are also genetic hallmarks of PMBL [65].

Mutations or translocations in *BCL6* (3q27) are common abnormalities in DLBCL, occurring in approximately 30 % of cases and not associated with a specific subgroup [66, 67]. Translocations involve both *IGH* and non *IGH* gene partners. The particular translocation partner may dictate the prognostic significance of the *BCL6* translocation, with translocations involving the *IGH* locus having a more favorable prognosis than those with other partner genes. *MYC* translocations are present in approximately 10 % of DLBCL. In contrast to BL, *MYC* rearrangements in DLBCL often are present in the context of a complex karyotype, and in 30–40 % of cases, *MYC* is rearranged with a non-Ig gene. FISH using a *MYC* break-apart probe is useful in the detection of these cases (Fig. 42.2). *MYC* translocations in DLBCL have a worse prognosis with poor response to therapy [68, 69]. Of note, FISH analysis does not detect all cases with significant expression of MYC. IHC for MYC protein identifies a subset of *MYC* FISH-negative DLBCL cases with high levels of MYC protein expression. These IHC-positive, FISH-negative cases have a very poor clinical prognosis, but only if there is also high expression of BCL2 protein [70, 71].

Burkitt Lymphoma

BL is a high grade BCL that is characteristically associated with the t(8;14)(q24;q32) translocation involving the *MYC* gene on 8q24 and the *IGH* gene on 14q32 [72]. Occasional BL demonstrates variant t(2;8)(p11;q24) or t(8;22)(q24;q11) translocations involving *MYC* and the kappa and lambda light chain loci, respectively [73]. These translocations result in increased expression of MYC and markedly increased cell proliferation. The site of translocation of *MYC* is reported to vary between sporadic and endemic BL. In endemic disease, the 8q24 breakpoint occurs up to 300 kb 5′ from the coding region of the *MYC* gene, while sporadic BL characteristically involves a breakpoint in *MYC* exon 1 [74]. The site of translocation in the *IGH* gene also is variable, with endemic cases involving the J region and sporadic cases involving the C regions. The degree of molecular variability in these translocations is the reason they are not amenable to detection by standard PCR assays. Routine karyotyping and FISH analysis using *MYC* probes are successful in detecting almost all *MYC* translocations in BL. BL typically do not have other chromosomal abnormalities. Gene expression profiling of BL and DLBCL has identified typical gene signatures for BL vs DLBCL [75]. The MYC protein and its target genes, as well as some genes expressed in normal germinal center B cells are more highly expressed in BL than GCB DLBCL, while major histocompatibility complex (MHC) class I genes and NFKB target genes are expressed at lower levels in BL than in DLBCL. Some of the recurrently mutated genes in DLBCL (*EZH2*, *SGK1*, *BCL2*, *CD79B*, and *MYD88*) are rarely mutated in BL [76].

B-Cell Lymphoma, Unclassifiable, with Features Intermediate Between DLBCL and BL

A subset of B-cell lymphomas shows morphologic and immunologic overlap with both BL and DLBCL. In some but not all of these cases, the gene expression profile is similar to BL [75]. Historically, these have been called "atypical Burkitt" or "Burkitt-like" lymphomas, but in the 2008 WHO classification, they were put into the category of BCL, unclassifiable, with features intermediate between DLBCL and BL (BCLU) [1]. Unlike classical BL, *MYC* translocations in BCLU frequently involve a non-Ig gene partner and may occur in the background of a complex karyotype. Most of the so-called "double hit lymphomas," defined by the presence of a *MYC* rearrangement and another genetic abnormality, most commonly *BCL2* gene rearrangement, are included in this category. However, some double hit lymphomas may be morphologically and phenotypically indistinguishable from DLBCL or even FL. Identification of double hit lymphomas at diagnosis is clinically important because, regardless of how they are subclassified morphologically, double hit lymphomas have a particularly aggressive clinical course and are often refractory to conventional chemotherapeutic regimens used for DLBCL. In rare cases of "triple hit lymphoma," *MYC*, *BCL2*, and *BCL6* are all rearranged and the clinical outcome is particularly dismal. FISH analysis is typically used at diagnosis for detection of these cytogenetic abnormalities, but will not detect all cases, particularly those with other mechanisms of overexpression of MYC. Because of the possible overlap with typical DLBCL, some institutions now routinely use a diagnostic FISH panel for detection of *MYC*

rearrangements plus *IGH–BCL2* and *BCL6* rearrangements at the time of initial diagnosis for all new DLBCLs and BCLUs.

ALK-Positive Large B-Cell Lymphoma

ALK-positive large B-cell lymphoma (ALK-positive LBCL) is a rare subtype of DLBCL that is typically composed of a monomorphic proliferation of large, immunoblastic-appearing B cells. These malignant B cells may show plasmacytic differentiation and must be distinguished from plasmablastic lymphomas (PBL) and T- and NK-cell anaplastic large cell lymphomas. ALK-positive LBCL is characterized by strong and homogeneous immunostaining with the ALK antibody, usually with a restricted granular cytoplasmic pattern. Despite the fact that they express the ALK protein, the t(2;5)(p23;q35) *NPM–ALK* translocation that is characteristic of T- and NK-cell anaplastic large cell lymphomas, is seen only in rare cases; these cases also show an unusual combined cytoplasmic, nuclear, and nucleolar staining pattern with the ALK antibody. The key genetic abnormality in ALK-positive DLBCL is the genetic alteration of the ALK locus on chromosome 2, with the most frequent abnormality being the t(2;17)(p23;q23)–*ALK–CLTCL1* fusion. FISH analysis with the *ALK* gene break-apart probe is the typical method used to detect *ALK–CLTCL1* translocation in these lymphomas. Approximately 50 cases of ALK-positive DLBCL, which is not associated with immunosuppression or Epstein-Barr Virus (EBV), have been reported [77, 78].

Immunodeficiency-Associated B-Cell Lymphoproliferative Disorders

Immunodeficiency-associated lymphoproliferative disorders (LPD) are heterogeneous and arise in the clinical context of primary (congenital or genetic defect) or acquired immune deficiency. Four types of immunodeficiency-associated LPD are recognized in the current WHO classification: (1) LPD associated with primary immune disorders (PID), (2) lymphomas associated with HIV infection, (3) post-transplant lymphoproliferative disorders (PTLD), and (4) other iatrogenic immunodeficiency-associated LPD [1]. As a group, immunodeficiency-associated LPD are typically of B-cell type, tend to occur at extranodal sites, and range from nonneoplastic proliferations to aggressive malignancies [79]. Morphologically, they range from reactive-appearing lymphoid or plasmacytic hyperplasia to overt lymphoma. LPD are frequently associated with EBV infection. The disease may regress upon restoration of host immune integrity, such as by withdrawal of an immunosuppressive medication, but the presence of lymphoma often requires treatment as a malignancy [80]. The development of B cell monoclonality and the accumulation of molecular alterations causing microsatellite instability, cell cycle dysregulation, or mutations in oncogenes, accompany the progression to lymphoma [81, 82].

EBV and human herpesvirus-8 (HHV-8) are both double-stranded DNA gamma herpesviruses, linked to the pathogenesis of multiple neoplasms arising in immunocompromised hosts. Common to herpesviruses, after a primarily lytic phase (production and release of new virions), latent infection is established with virus persisting in infected cells for the life of the host. Oncogenesis is associated with the latent phase, and in the case of EBV infection, different patterns of latent protein expression are seen in different hematolymphoid neoplasms [83]. Loss of T-cell antiviral immunity increases the risk of uncontrolled proliferation and development of LPD [84]. EBV is commonly implicated in LPD associated with primary immunodefeciency (PID) (subtypes of PID listed in Table 42.4). PID with a particular propensity for the development of EBV-associated lymphomas include X-linked LPD, severe combined immunodeficiency, hyper IgM syndrome (CD40 ligand and CD40 deficiencies), common variable immunodeficiency, and Wiskott-Aldrich syndrome [85]. In patients with an EBV-positive LPD and no apparent cause of acquired immune deficiency, an underlying primary immunodeficiency should be considered, especially in the pediatric population.

BCL in HIV-Positive Patients

Despite the decreasing frequency of lymphoma in HIV patients since the advent of highly active antiretroviral therapy (HAART), there remains a 70-fold increased incidence of NHL in HIV-infected individuals as compared to the general population [86]. Hodgkin lymphomas also are increasing in the HIV-infected population [87]. The frequency of EBV-positivity in AIDS-related lymphomas is approximately 50 % overall, but varies depending on the type of lymphoma. Approximately 30 % of BL, 75 % of

Table 42.4 Primary immunodeficiencies with increased risk of B-cell lymphoma

Immunodeficiency subtype	Genes with mutations
Severe combined immunodeficiency (SCID)	*IL-2RA, RAG1/2, JAK3*
X-linked agammaglobulinemia (XLA)	*BTK*
Common variable immune deficiency (CVID)	*ICOS*
	CD19
	TACI
Hyper IgM syndrome	*CD154 (CD40L)*
	CD40
	IKK-gamma/NEMO
	UNG
	AID
Hyper IgE syndrome	*STAT3*
Familial hemophagocytic lymphohistiocytosis (HLH)	*SH2D1A, XIAP, PRF1, MUNC13-4, STX*
Ataxia telangiectasia (A-T)	*ATM*
Mijmegen breakage syndrome (NBS)	*NMN*
Wiskott-Aldrich syndrome (WAS)	*WASP*
Autoimmune lymphoproliferative syndrome (ALPS)	*FAS/FASL*

PBL, and almost 100 % of Hodgkin and primary central nervous system lymphomas are EBV positive [79]. HHV-8 is seen in nearly all cases of multicentric Castleman disease in HIV-positive patients and dual infection of tumor cells with EBV and HHV-8 is seen in primary effusion lymphoma (PEL). Interestingly, there is also an inverse relationship between EBER-positivity and BCL6 protein expression, with the theory that EBV microRNAs suppress *BCL6* transcription [88, 89]. Chronic antigenic stimulation in HIV patients triggers somatic hypermutation and class switch recombination in B cells, increasing the chance of oncogenic mutations and translocations [5]. Most AIDS-related lymphomas are aggressive BCL (BL and DLBCL), but some additional lymphoma subtypes have a particular association with HIV infection, including PEL, PBL, and DLBCL arising in HHV8-associated Castleman disease [90].

PBL is a rare, highly aggressive neoplasm defined as a diffuse proliferation of large B cells morphologically resembling immunoblasts with an immunophenotype similar to that of plasma cells [91, 92]. PBL classically presents in the oral cavity of HIV-infected patients, though cases in immunocompetent patients and extraoral manifestations are described [91–94]. EBV, most frequently latency type 1 pattern, is present in 75 % of cases overall and increases to nearly 100 % in HIV-associated PBL of the oral cavity. *MYC* rearrangements are the most common recurrent chromosomal abnormality in PBL and 85 % involve rearrangement with an Ig gene partner, usually *IGH*. Those with *MYC* rearrangements are significantly more likely to be EBV-positive (74 % vs 43 %) [95].

PEL is a very rare, but highly aggressive large B-cell lymphoma that typically involves body cavities of HIV patients and is associated with HHV-8 infection. PEL is composed of large immunoblastic or plasmablastic cells, often with an immunophenotype similar to that of PBL. Approximately 70–80 % of cases are associated with EBV; however, EBV is not absolutely required for the diagnosis of PEL and is likely only a cofactor, offering survival advantage in the HHV-8 infected cells [96]. Mutations in the *BCL6* gene are described in PEL, but rearrangements involving the *CCND1*, *BCL2*, and *MYC* genes have not been described [97].

DLBCL arising in HHV-8-associated Castleman disease primarily occurs in HIV-positive patients. These lymphomas are sometimes referred to as plasmablastic because the cells morphologically resemble plasma cells but must not be confused with PBL described above. Unlike PBL, the abnormal B cells in this entity are infected with HHV-8 rather than EBV. The neoplastic B cells show uniform expression of one Ig heavy chain (typically IgM) and are typically Ig lambda positive. PCR analysis for *IGH* gene rearrangements almost always shows a polyclonal pattern.

Mutational analysis of lymphomas arising in the setting of HIV infection shows heterogeneous molecular lesions, with many containing hypermutations in IGVH and mutations in *BCL6* [97]. The most common molecular alteration in AIDS-related lymphomas is mutation of the 5′ noncoding region of *BCL6* [98]. Approximately 50 % of cases have at least one mutation involving the *PAX5*, *RHO–TTF*, *PIM1*, or *MYC* oncogenes, and 23 % of cases show mutations in two or more of these genes [82].

Post-transplant Lymphoproliferative Disorders

PTLD represent a spectrum of lymphoid and plasmacytic proliferations arising in immunocompromised hosts after solid organ, BM, or peripheral blood stem cell transplant. The majority of PTLD arise in the first year after transplant and the risk depends on the type of transplant, degree of immunosuppression, and EBV seropositivity at the time of transplant. PTLDs are characteristically EBV-positive and of B-cell type, although EBV-negative BCL and T-cell lymphomas can occur [1]. The morphology of PTLD varies from polymorphic to a monomorphic population of cells which may be polyclonal or monoclonal. Early lesions resemble infectious mononucleosis but can progress to overt lymphoma, with increasing numbers of large B cells. The neoplastic B cells commonly show a non-germinal center immunophenotype, with the majority having IGVH (as in CLL/SLL) but not somatic hypermutation [81]. Peripheral blood EBV viral DNA levels correlate with PTLD development; although an individual value cannot supplant a tissue biopsy for diagnosis, trends in EBV DNA levels can be used for disease monitoring and guiding therapy [99]. Transition from a reactive morphology to an overt monomorphic, monoclonal malignancy is the natural history of PTLD; however, early recognition may allow alterations in immunosuppressive regimens and regression of disease, avoiding aggressive chemotherapy. Molecular abnormalities associated with progression of PTLD include microsatellite instability, DNA mismatch repair defects, accumulation of mutations in proapoptotic factors *BAX* and caspase genes and DNA repair gene *RAD50,* aberrant somatic hypermutation, and mutations in *MYC*, *BCL6*, and *TP53*. DNA hypermethylation has been described in 60 % of monomorphic PTLD [81].

Indications for Testing

Testing strategies for the molecular abnormalities of BCL are evolving as the number of genes important for diagnosis and prognosis of BCL increases. Thus, the molecular testing performed to confirm a primary diagnosis, predict BCL prognosis, or identify appropriate targeted therapies for subtypes of BCL will not be the same as testing performed for detection of MRD after therapy. At initial diagnosis or relapse of BCL, the laboratory often needs to rapidly evaluate multiple genetic targets, but with only a low level of assay sensitivity. This is in distinct contrast to testing for MRD after therapy, for which a very sensitive assay is needed.

Several major clinical indications for molecular testing in BCL include: (1) to distinguish between a reactive and neoplastic proliferation of B cells, (2) to identify specific chromosomal abnormalities to aid in accurate subclassification of BCL, (3) for prognosis within a BCL subtype when alternative therapies are related to specific molecular abnormalities, and (4) to evaluate response to therapy by molecular analysis for detection of MRD. When there is a need to distinguish between reactive and neoplastic B-cell proliferations, assays for detection of B-cell clonality are most frequently used because they are applicable to virtually all BCL. The *IGH* gene is the most common target evaluated for confirmation of B-cell clonality at diagnosis. The *IGH* gene is also the most common target for detection of persistent BCL following therapy.

Because substantial morphologic and immunologic overlap exists between different BCL subtypes, accurate subclassification by routine histologic and phenotypic evaluation alone is sometimes difficult and may require evaluation for characteristic molecular abnormalities. Assays for specific BCL-associated molecular alterations have more limited clinical utility than clonality testing in that they are applicable to only a subset of BCL patients, but they often provide essential information for accurate subclassification at diagnosis. Assessment of BCL for molecular features related to adverse prognosis is being performed on a more frequent basis than in the past, due to an increased number of significant molecular factors as well as the development of new targeted therapies. Some prognostic factors for poor outcome appear to be relevant only to a particular subtype of BCL, but other factors, such as *TP53* dysfunction and *MYC r*earrangement, seem to be associated with poor prognosis or progressive disease in many BCL subtypes. Patients with BCL manifesting molecular markers of poor prognosis often are treated more aggressively at the time of initial diagnosis. The use of FISH assays for molecular evaluation of BCL at diagnosis and relapse has expanded remarkably over the past several years and will likely continue to expand as new molecular probes are identified. However, it must be stressed that the sensitivity of even the best FISH assay is not sufficient for detection of MRD in treated BCL patients. MRD testing requires the development and implementation of standardized, sensitive, and quantitative testing.

Minimal Residual Disease Detection

In the past, assessment of therapeutic response by molecular testing for MRD was infrequently performed outside of clinical trials. However, recent use of new therapeutic modalities such as monoclonal antibodies and vaccine therapies for treatment of BCL has resulted in improved clinical outcomes, and multiple large prospective studies in Europe have clearly demonstrated the high prognostic value of MRD monitoring in children with acute lymphoblastic leukemia [100]. Molecular remissions associated with prolongation of progression-free and overall survival also have been seen in multiple clinical trials with MRD monitoring in CLL/SLL [101–103]. MRD detection is used in clinical practice for FL. The finding of a persistent positive MRD test is associated with a higher risk of disease relapse [104]. However, the optimal methodology and timing for detection of MRD has yet to be determined for all subtypes of BCL. The consensus for MRD detection of CLL/SLL by multicolor flow cytometry was published in 2007, with comparison to standard flow cytometry and allele-specific PCR [105].

In general, techniques used for MRD detection have a sensitivity to detect one BCL cell in 10^3–10^5 normal cells, depending on the assay method. Flow cytometry analysis can reach a sensitivity of 1 in 10^4 and patient-specific PCR analysis for *IGH* gene arrangements can reach a sensitivity of 1 in 10^5 [106, 107]. An ideal MRD assay would be applicable to all patients with the disease, provide some quantification of the target, be rapid, inexpensive, readily standardized, and disease-specific, as well as demonstrating good intralaboratory and interlaboratory reproducibility. In fact, current MRD assays lack many of these features.

As mentioned above, the most sensitive and specific method of testing for MRD in BCL is patient/clone-specific (allele-specific) PCR analysis for *IGH* gene rearrangements. This method takes advantage of the fingerprint-like sequences of the junctional regions of the rearranged *IGH* gene, which differ in length and composition for each B-cell clone. *IGH* PCR analysis of a BCL is performed and the PCR products (junctional regions of the clonal *IGH* rearrangement) are then sequenced. The *IGH* rearrangement sequence is subsequently used for the design of patient-specific PCR primers, which are used in PCR assays to assess MRD. The usual target for MRD detection is a VH-JH rearrangement. The use of two MRD targets also has been recommended for reliable and sensitive MRD detection [108, 109]. In patient-specific *IGH* PCR, the background signal from polyclonal B cells does not obscure the clonal PCR products, resulting in significantly more sensitivity compared to *IGH* gene rearrangement PCR, which is only approximately one in 10^2 cells, and is not sufficient for MRD detection [110]. The major problem, however, is that patient-specific *IGH* PCR is extremely labor-intensive and currently impractical for routine clinical testing.

Quantitative PCR (qPCR) detection of specific molecular abnormalities is useful in follow-up of patients with BCL. A standard curve is made from a dilution series of either a diagnostic lymphoma sample for patient-specific PCR or a cell-line dilution if patient-specific sequences are not known, and the amount of residual lymphoma cells relative to normal cells in a sample can be calculated by using this standard curve [111]. The qPCR method may be used with fusion gene translocation targets as well as the *IGH* gene, and is amenable to interlaboratory standardization. The determination of the trend in the quantitative copy numbers of residual BCL signals over time may provide important therapeutic information

during and after treatment of BCL patients. PCR analysis using patient-specific primers is extensively used in Europe for molecular monitoring of MRD in patients with precursor B-lymphoblastic leukemia (pre-B-ALL), treated on different clinical trials. In addition, the Europe Against Cancer Program has reported a standardized testing approach for the most common fusion gene transcripts in clinical trials for patients with ALL and BCL [112]. Optimal primer sequences and methods have been reported by the European BIOMED-2 Concerted Action for detection of MRD in patients with pre-B-ALL group. A concise review about why and how to quantify MRD in ALL was published in 2007 [113]. This type of MRD testing is currently performed mainly in specific research laboratories for patients in BCL clinical trials, but as therapeutic options increase, quantitative and sensitive MRD testing is expected to become routine.

Flow cytometric analysis has largely replaced qPCR testing for routine clinical analysis for MRD in CLL/SLL and pre-B-ALL patients, because it provides a faster turn-around-time and is much less labor intensive. The comparability of multicolor flow cytometry and qPCR methods for detection of MRD at the 10^{-4} level has been demonstrated in a CLL/SLL study, in patients treated with fludarabine/cyclophosphamide or fludarabine/cyclophosphamide/rituximab [101].

Other than *IGH* PCR, the only significant molecular target that has been used for MRD detection in BCL is the t(14;18)(q32;q21) in FL. This testing has traditionally been performed on follow-up BM specimens, because the majority of FL patients have detectable disease in the BM at the time of initial diagnosis. With newer therapies that include monoclonal antibodies, a molecular remission in the marrow is desirable and can be achieved in the majority of patients. However, although the durability of clinical remission correlates with the attainment of molecular remission [114, 115], some patients with negative MRD in the BM after therapy have subsequent relapse in peripheral lymph nodes or other tissues. The clinical utility of this testing therefore has been called into question as it is clear that a negative monitoring result in BM does not necessarily predict progression-free survival [116]. Previously involved lymph nodes may serve as a reservoir of neoplastic cells in FL patients [117]. Additional studies are needed to resolve some of these questions.

Another issue with routine clinical testing for MRD in FL is the lack of test standardization across laboratories [118]. In older studies, nested PCR assays were used because they provide the highest level of sensitivity, detecting one FL cell in 10^5–10^6 normal cells. However, nested PCR assays are labor intensive with a high risk of PCR contamination compared with non-nested techniques, so standard PCR or reverse transcription-qPCR (RT-qPCR) assays have been used instead. The analytical sensitivity of PCR and RT-qPCR assays for the *IGH–BCL2* translocation is less than that of nested PCR techniques; at best, sensitivity is one positive cell in 10^4 normal cells [119]. The clinical relevance of the differences in sensitivity between nested PCR and standard PCR analyses for FL is not clear. With a highly sensitive test like nested PCR, the analysis will detect occasional benign *IGH–BCL2* translocation-carrying cells that are known to exist in many unaffected individuals. Therefore, this assay may produce more false-positive MRD results. A slightly less sensitive test using PCR or RT-qPCR may not detect these rare events but also may miss very low level MRD. The best compromise and optimal clinical approach may be the serial measurement of the *IGH–BCL2* translocation by RT-qPCR to trend the quantitative levels of FL cells over time.

Available Assays

Several methods are used by clinical laboratories to detect the known molecular abnormalities in BCL. These include PCR, RT-PCR, RT-qPCR, and FISH. Routine PCR testing in B-cell malignancies today is largely restricted to testing for B-cell clonality, as many of the PCR analyses for other abnormalities have been supplanted by FISH assays, but some testing is still done for specific fusion transcripts [120]. There are multiple other methodologies in development, but not in general clinical usage yet.

Polymerase Chain Reaction Analyses

PCR amplification of genomic DNA is used for detection of AgR rearrangements and can be used for many BCL-associated translocations. However, in genes with numerous translocation partners, such as *IGH* and *MYC*, FISH is more effective than PCR. Translocations involving variable sites over an area of a chromosome too large for the typical PCR may be amenable to RT-PCR due to removal of the intronic regions that results in a smaller amplification region. Typically, RT-PCR cannot reliably be performed on FFPE tissue because RNA is often degraded during tissue processing. PCR using DNA as a substrate can be performed on fresh, frozen, and most FFPE tissue, as well as microdissected and cytology specimens. PCR requires fairly small amounts of DNA and can be performed relatively rapidly, providing a clinically useful result in 1–3 days.

IGH PCR amplifies only rearranged *IGH* alleles because germline alleles have too great a distance between the PCR primer binding sites to allow for amplification. PCR detection of IGVH rearrangements uses V- and J- region primers and relies on the V, D, and J segments being brought into close proximity during rearrangement so that the PCR reaction can amplify across these segments. The closest V and J segments are too far apart in the germline configuration for PCR amplification to occur. *IGH* clonality analysis by PCR uses consensus primers designed to anneal to sequences conserved across the multiple *IGH* V- and J-regions. For *IGH* PCR, one J-region primer will recognize all six J segments because there is a single well-conserved region among the six J regions, but

there is no single V-region primer that will recognize all V segments. V regions have three more highly conserved framework regions (FR I, II, and III) and highly variable intervening sequences called complementarity-determining regions (CDR I and II). Because the FR sequences are more conserved across the different V regions, the V-region primers are designed to bind to FR sequences. The FR III region is closest to the J region in the rearranged state, resulting in a smaller PCR product than for the other FR regions. FR III- and J-region primers amplify the highly variable V-D junction (CDR III) and detect 60–70 % of IGVH rearrangements. The sequence of the FR III V-region primer also affects the detection rate. One interlaboratory comparison showed a difference of 55–70 % based on the specific sequence used for the V-region primer [121]. PCR amplification for all three FR regions with a J-region consensus primer achieves a detection rate of 80–90 % in most BCL.

IGH PCR amplifies any rearranged *IGH* allele, producing a background signal from the polyclonal B cells present in a specimen. The polyclonal background may obscure the signal from a monoclonal B-cell population. Numerous strategies are used for PCR product detection, including gel electrophoresis with colorimetric, fluorescent, or chemiluminescent labeling. Capillary electrophoresis with fluorescently labeled primers is most commonly used and provides slightly enhanced sensitivity and higher throughput, with improved resolution.

Standardized multiplex PCR reagents developed by the European BIOMED-2 collaborative study group are available commercially for AgR PCR clinical testing [112]. These patented reagents simultaneously amplify multiple targets in a single PCR reaction using multiple primer pairs to amplify gene targets within a single DNA sample. Primer length, melting temperature, and specificity are important considerations when developing a multiplex assay to ensure robust amplification of each of the target regions. Additionally, primers must be screened to exclude the possibility of primer dimer formation and nonspecific amplification reactions. The amplified DNA products are designed to be different lengths that can be resolved by conventional gel techniques. The European BIOMED-2 group has published standardized methods for detection of clonal Ig gene and T-cell receptor (*TR*) gene rearrangements (Table 42.5) [112], which has aided comparisons between laboratories.

Table 42.5 BIOMED-2 multiplex PCR for B-cell clonality [122]

Multiplex PCR tube	Expected size range (bp)	Common nonspecific bands (bp)
IGH: V_H-J_H	Tube A: 310–360 Tube B: 250–295 Tube C: 100–170	Tube A: ~85 Tube B: ~228 Tube C: ~211
IGH: D_H-J_H	Tube D: 110–290 (D_H1/2/4/5/6-J_H) 390–420 (D_H3-J_H) Tube E: 100–130	Tube D: ~350 Tube E: ~211
IGK	Tube A: 120–160 (Vκ1f/6/Vκ7-Jκ) 190–210 (Vκ3f-Jκ) 260–300 (Vκ2f/Vκ4/Vκ5-Jκ) Tube B: 210–250 Vκ1f/6/Vκ7-Kde 270–300 (Vκ3f/intron-de) 350–390 (Vκ2f/Vκ4/Vκ5-Kde)	Tube A: ~217 Tube B: ~404
IGL	Tube A: 140–165	

Fluorescence In Situ Hybridization

FISH is a very useful technique for detection of targeted BCL-associated chromosomal abnormalities and can detect both structural and numerical chromosomal abnormalities. Poor growth of BCL cells in culture, which is needed for metaphase cells for routine karyotyping, makes routine cytogenetics difficult for BCL. FISH overcomes the need for metaphase cells, because it can be done with either metaphase or interphase preparations. Genomic probes for the breakpoints of many different BCL translocations and for gene deletions are now readily available and the analyses are routinely performed. FISH assays are particularly useful in detection of chromosomal translocations in which the breakpoints are widely dispersed, because FISH probes are much larger than probes and primers used in PCR analysis. For example, FISH probes can detect almost all of the *MYC* 8q24 breakpoints in the t(8;14)(q24;q32) translocations associated with BL. FISH also can detect some genetic abnormalities that cannot be detected by karyotyping.

Interpretation of Test Results

The relative ease of performing the analytical phase of AgR clonality testing using the BIOMED-2 multiplex PCR reagents and protocols [112, 120], has resulted in many laboratories implementing the procedures. However, interpretation of the BIOMED-1 multiplex clonality test results is considerably more difficult than with previous single primer pair assays. Recognition of this problem in interpretation led to a large study by the EuroClonality Consortium to develop recommendations for interpretation and reporting of the multiplex BIOMED-2 AgR clonality assays [122]. These address not only the complicated types of profiles seen on readout systems, but also propose standardized terminology for the technical descriptions of the assays and for the ultimate molecular conclusions reported.

A synopsis of the proposed EuroClonality uniform system for technical description is provided in Table 42.6. Examples of the different patterns that can be seen in AgR clonality assays are shown in Fig. 42.4. A polyclonal B-cell population produces multiple small peaks with a Gaussian curve pattern

Table 42.6 EuroClonality system for standardized technical description of BIOMED-2 Ig or T-cell receptor multiplex PCR [122]

Type of profile per tube (in duplicate)	Technical descriptions
No peaks but poor DNA quality	No specific product; poor DNA quality
No peaks (without background)	No specific product
Gaussian curve (with or without minor reproducible peaks)	Polyclonal or irregular polyclonal
One or two reproducible clonal peaks	Clonal Weak clonal Clonal + polyclonal background (Gaussian curve or irregular polyclonal)
One or two non-reproducible (clear) peaks	Pseudoclonal
Multiple (>2) non-reproducible peaks	Pseudoclonal
Multiple (>2) reproducible peaks	Multiple products (can be compatible with oligoclonal or may still be compatible with clonal)
Pattern not one of above	Not evaluable

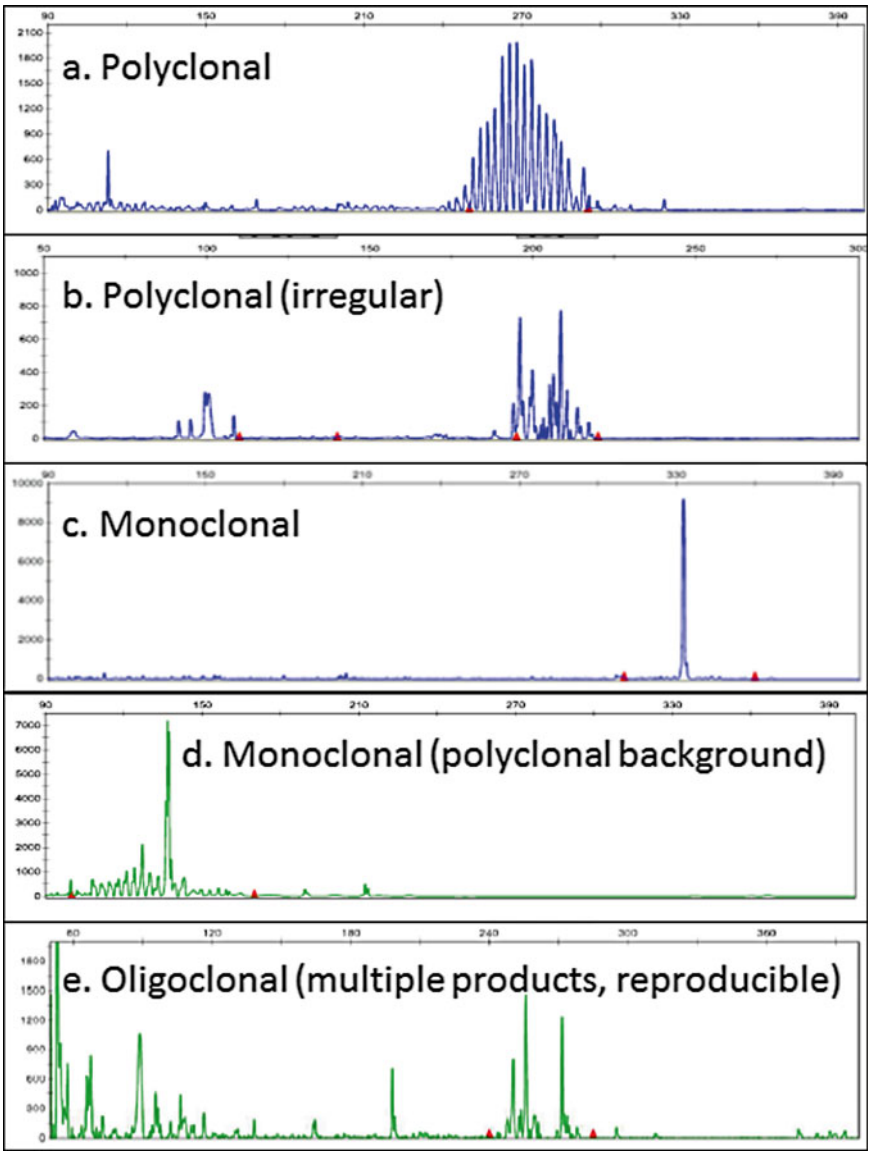

Figure 42.4 Examples of different possible patterns in B cell clonality assays using BIOMED-2 primer sets. (**a**) A polyclonal pattern with a Gaussian distribution of peaks is shown. (**b**) The irregular pattern of multiple peaks is interpreted as a polyclonal B cell population. (**c**) The single peak without a polyclonal background is interpreted as a monoclonal B cell population. (**d**) The single peak with a polyclonal background is interpreted as a monoclonal B cell population. (**e**) An oligoclonal pattern is demonstrated by the multiple distributed peaks of irregular height

(Fig. 42.4a) or an irregular pattern (Fig. 42.4b), while monoclonal B-cell populations typically produce one or two sharp peaks, with or without a polyclonal background (Fig. 42.4d and 42.4c, respectively). To assist with interpretation, various algorithms have been proposed, particularly in the USA. One algorithm used for determining whether a peak is monoclonal compared to the background polyclonal peaks is to require that a monoclonal peak be more than two to three times the height of the adjacent polyclonal peaks [123]; however, these criteria are clearly not useful in all cases. Application of these algorithms can be difficult, so considerable variability in interpretation remains. Adoption of the recommended EuroClonality guidelines for interpretation may improve the consistency of interlaboratory reporting of these assays.

Pitfalls in Interpretation of BCL Testing

Molecular studies of BCL should always be interpreted in conjunction with routine histologic and immunophenotypic information and always with the knowledge of the range of molecular features found in normal and hyperplastic lymphoid populations. Interpretation in this larger clinical and histopathologic context will avoid erroneous interpretations with the potential for adverse clinical consequences. Our knowledge of the molecular events occurring in benign and malignant lymphoid populations is rapidly expanding in this era of genomics and proteomics, such that the interpretation of a particular genetic finding may well change as the field evolves. There are various potential technical and biological pitfalls in the interpretation of molecular analyses for BCL that may result in false-positive or false-negative results.

Reproducible Nonspecific Bands in BIOMED-2 Multiplex PCR Analysis

Accurate interpretation of multiplex PCR AgR clonality results requires knowledge of the location and appearance of certain nonspecific peaks/bands that have been identified and described by the BIOMED-2/EuroClonality consortium (Fig. 42.5c and Table 42.5) [122]. Failure to recognize these nonspecific peaks could result in generation of an erroneous interpretation of clonality, as they are usually reproducible on repeat analyses.

Non-reproducible Clonal Bands in BIOMED-2 Multiplex PCR Analysis

Factitious apparent clonal bands that do not repeat can be seen in AgR clonality testing (Fig. 42.5b). To avoid misinterpretation of these non-reproducible non-clonal peaks/bands, multiplex PCR analyses for AgR clonality should be performed in duplicate [122]. Failure to recognize these non-reproducible non-clonal peaks by duplicate analysis could result in generation of an erroneous interpretation of clonality.

Molecular Abnormalities in Benign Lymphoid Proliferations

The presence of a clonal B-cell population, by itself, does not establish a diagnosis of B-cell malignancy. B-cell clones can be detected by *IGH* PCR in benign lymphoid hyperplasias and aberrant immune responses in the absence of other criteria for malignancy [124–126]. Benign B-cell clonality occurs most frequently in the setting of immune deficiencies, autoimmune diseases, and immunosuppression, and reinforces the critical necessity for interpretation of tests for B-cell clonality in conjunction with clinical, morphologic, and immunophenotypic information. The fact that patients with immune dysfunction have an increased risk of NHL, in particular BCL, further confounds the issue.

Other types of BCL-associated genetic alterations also have been described in benign settings and could result in a false interpretation of malignancy. For example, rare B cells carry a t(14;18)(q32;q21)–*IGH–BCL2* translocation in individuals without FL [127–129]. Nested PCR assays capable of detecting one *IGH–BCL2* translocation-carrying cell in 10^5–10^6 normal cells will be positive in up to half of the tissue biopsies, BM aspirates, and peripheral blood specimens from normal individuals. To date, there is no evidence that these individuals are at higher risk for development of FL. Therefore, diagnostic tests for FL should have a lower sensitivity to avoid detection of the *IGH–BCL2* translocation in unaffected individuals.

Lineage Infidelity or Promiscuity

A potential pitfall in interpretation of molecular tests for AgR rearrangements in BCL is the occurrence of so-called lineage infidelity or promiscuity, which includes the rearrangement of the *TR* genes in BCL. This is particularly common in precursor B-cell malignancies but also may be seen in malignancies of mature B cells. The majority of precursor B-cell malignancies will have rearrangement of the *TRG* gene, and 5–10 % of mature B-cell malignancies also show *TR* gene rearrangements [110, 111, 113]. This finding could lead to erroneous conclusions about cell lineage if not interpreted in conjunction with other clinical and laboratory parameters associated with the case.

Oligoclonality and Clonal Evolution

An oligoclonal pattern is defined as the presence of more bands or peaks than would be expected from a single monoclonal B-cell population, specifically, more than two reproducible bands/peaks per PCR. An oligoclonal pattern can be seen when there is expansion of several B-cell clones in reactive processes or in immunocompromised individuals with a reduced B-cell repertoire, as well as in specimens with very few B-cells. Oligoclonal patterns must be interpreted with care.

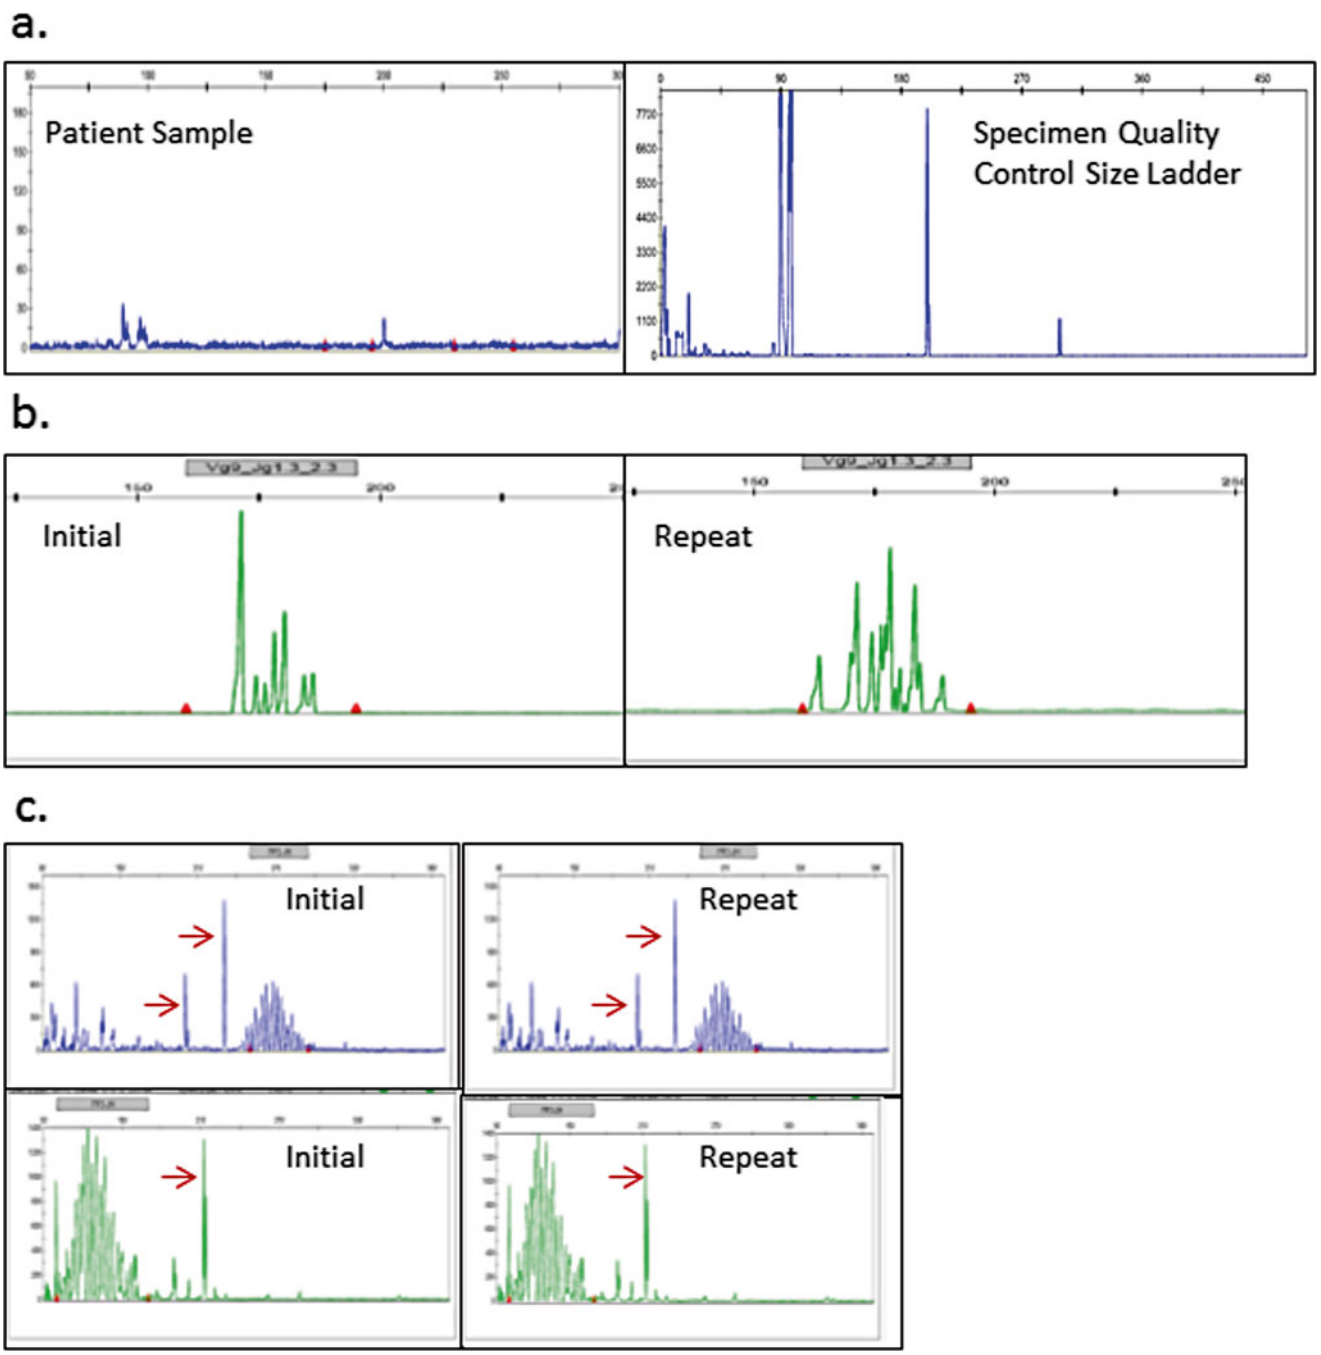

Figure 42.5 Pitfalls in interpretation of PCR assays for Ig clonality assessment using BIOMED-2 primer sets. (**a**) Poor sample quality. The patient sample shows no specific product in the *left panel* but the results are not reliable because the specimen quality control size ladder (*right panel*) illustrates that larger amplicons (> 200 bp) are not amplified well. (**b**) Non-reproducible peaks. Apparent clonal peaks detected initially (*arrows* in *left panel*) were not present on repeat analysis (*right panel*), underscoring the benefit of duplicate analyses. (**c**) Reproducible nonspecific peaks. Well-known, but nonspecific amplicons (*arrows*) are reproducibly detected but do not indicate clonality. Knowledge of the sizes of these nonspecific reproducible peaks is essential to avoid erroneous diagnoses of clonality. (See Table 42.5)

Although it is rare, occasional patients will have two separate monoclonal B-cell populations, resulting in more than two clonal peaks/bands. Specific documentation of two separate B-cell populations by flow cytometry or immunophenotyping is required to support the interpretation of two monoclonal B-cell populations, i.e., a biclonal process.

During the course of disease in some BCL patients, the monoclonal population may develop additional *IGH*

rearrangements that may alter the size of peaks/bands seen by *IGH* PCR (so-called clonal evolution). If *IGH* PCR is used for MRD testing, clonal evolution may change or eliminate the diagnostic PCR band(s) and lead to false-negative results. *IGLK* gene rearrangements involving the kappa-deleting element (Kde) appear to be more stable than *IGH* gene rearrangements, possibly because they usually delete the two enhancers for the *IGLK* gene [106, 129]. However, these *IGLK*-Kde rearrangements are present in only a minority of BCL, limiting their clinical utility.

Inadequate Test Sensitivity

Molecular assays never achieve 100 % analytical sensitivity, so a false-negative result must always be considered. Actual sensitivity will vary between laboratories, but a standard *IGH* PCR of fresh or frozen tissue will usually detect one clonal cell in 10^2–10^3 normal cells. *IGH* PCR using FFPE tissue may have much lower sensitivity, sometimes as low as 40–60 %, and is highly subject to the conditions used for tissue fixation and processing. Every assay for *IGH* clonality must include appropriate sensitivity controls, based on the purpose of the clonality testing for each case. A test sensitivity of one positive cell in 20 normal cells (5 %) is adequate for diagnostic or prognostic testing of almost all BCL, but 5 % assay sensitivity is inadequate for MRD assessment testing. The minimal sensitivity for a test offered for MRD assessment should be one positive cell in 10^4 normal cells, and a sensitivity of one positive cell in 10^5–10^6 normal cells is achievable and desirable for some assays. The *IGH* AgR and *IGH–BCL2* PCR assays usually have different sensitivities, which may lead to discrepant results when both tests are performed for the same specimen.

Poor Specimen Quality

The absence of a polyclonal Gaussian distribution of peaks/bands and/or a clonal signal may be due to poor DNA quality or a paucity of lymphoid cells in the specimen and should result in a check of DNA quality in the control PCR (Fig. 42.5a), as well as evaluation of the T- and B-cell content by IHC or flow cytometry. The quality of extracted DNA or RNA is not usually a problem with fresh or frozen tissue or cells, if viable tissue has been obtained. However, poor DNA quality is a known problem with PCR assays of FFPE tissue which is even less suitable for RNA extraction and testing due to RNA degradation. Different fixatives will affect the success of DNA and RNA extraction. Formalin fixation allows adequate DNA and RNA preservation for PCR in most cases, but adequate DNA or RNA for PCR is difficult to obtain from paraffin-embedded tissue fixed with mercury-based (B5), Zenker, or Bouin fixatives.

Primer Failure

Clearly, the most common cause of false-negative *IGH* PCR results for BCL is the failure of primer binding due to sequence alteration of the primer binding site by somatic hypermutation of IGVH regions in post-germinal center BCL. The false-negative rate with *IGH* PCR ranges from less than 5 % (MCL) to greater than 50 % (MZL, FL, plasma cell dyscrasias). In the BCLs that give false-negative results by *IGH* PCR, clonality may be demonstrated on a PCR analysis for *IGK* rearrangements. The possibility of a false-negative *IGH* clonality result, particularly in post-germinal center BCL (FL and MZL) must always be considered in the interpretation of *IGH* PCR results.

Unusual or Complex *IGH* Rearrangements

Occasional BCL have very complex rearrangements of *IGH* and other associated genes that may confound standard *IGH* PCR testing. This has been seen most frequently in FL, but similar genetic events undoubtedly occur with other *IGH* translocation partners. For example, most FL have a single *IGH–BCL2* rearrangement involving one chromosome 14 *IGH* allele, which is then unable to participate in a functional *IGH* rearrangement. An additional clonal rearrangement of the untranslocated *IGH* allele on the other chromosome 14 usually occurs and can be detected by *IGH* PCR. However, occasional FL will have translocations of both *IGH* alleles to chromosome 18, resulting in the absence of a detectable clonal *IGH* rearrangement by PCR.

Laboratory Issues

Differences across clinical molecular laboratories in PCR testing for *IGH* rearrangements and *IGH–BCL2* translocations has been documented repeatedly by the proficiency testing surveys of the College of American Pathologists [130], as well as by other, independent interlaboratory surveys [131]. The reasons for the lack of reproducibility among laboratories are multiple and not easily overcome. Some strategies for PCR testing and interpretation that improve test performance are discussed below.

Use of Appropriate Controls

Appropriate controls for PCR tests include positive, negative, sensitivity, and no DNA reactions. Laboratories may not know or overestimate the diagnostic sensitivity of their *IGH* and *IGH–BCL2* PCR assays if the sensitivity of the assay was established at the time of test validation, but sensitivity controls are not included in every run because the sensitivity may decline over time or be variable from run to run.

Interlaboratory surveys indicate that some laboratories may not use adequate controls. Apart from the controls mentioned above, an additional important PCR control, particularly with FFPE tissue, is the amplification of a non-rearranging gene to document the presence of adequate DNA in the tested sample and the absence of inhibitors of the DNA polymerase, to avoid a false-negative result.

Amplification of Duplicate Aliquots of DNA

Small samples or samples with few B cells may have insufficient B cells to produce a polyclonal background. In this setting, *IGH* PCR may amplify rare B cells, producing a misleading monoclonal or oligoclonal pattern. Likewise, a sensitive *IGH–BCL2* assay capable of detecting MRD could also amplify a rare benign translocation-carrying cell, as previously discussed. Over-interpretation of a single band or peak on *IGH* and *IGH–BCL2* PCR assays by laboratories not performing the assays in duplicate may cause false-positive results. With amplification of duplicate DNA aliquots for each specimen, only clearly visible bands or peaks of identical size in each duplicate should be interpreted as a positive clonal result. Peaks/bands seen in analyses of specimens containing rare B cells, or rare normal translocation-carrying cells, will not be replicated in both reactions.

Adherence to Strict Criteria for Interpretation and Reporting

The interpretation of assays for *IGH* rearrangements, the *IGH–BCL2* translocation, and other BCL-associated translocations must be performed with caution. The interpretation of even the most commonly performed PCR assays for *IGH* is quite challenging. Therefore, PCR results should be very carefully interpreted and reported, preferentially in conjunction with clinical history, morphology, and immunophenotyping data. Reports should clearly indicate that a false-negative result is a possibility. False-positive PCR results largely can be avoided by performing the assay in duplicate. Parallel analysis of BCL from different sites or pre- and post-treatment in a given patient will allow comparison of PCR product sizes, which can provide very helpful information for interpretation. Testing for MRD assessment is usually done in association with specific clinical trials. Widespread use of the BIOMED-2 multiplex PCR reagents and protocols for AgR clonality testing, together with the adoption of the recommended EuroClonality guidelines for interpretation and reporting, will likely improve interlaboratory consistency over the next few years.

Conclusions and Future Directions

Clinical demand for genetic characterization of BCL at the time of primary diagnosis has intensified as our understanding of NHL biology has increased and therapies targeting specific BCL subgroups have been developed. Today, genetic features of NHL are used to aid in rendering an accurate primary diagnosis, to predict prognosis, to evaluate for MRD during and after therapy, and to help determine optimal therapy. The rapid acquisition of knowledge about BCL biology and translation of this knowledge into targeted therapeutic strategies is occurring at an unprecedented rate. New testing strategies and technologies are essential for clinical laboratories to keep up with the growing information on BCL obtained from research methods such as gene expression profiling, aCGH, proteomics, and exome and genome sequencing.

The role of the hematopathologist is clearly changing and expanding. As gene expression profiling, aCGH, and other genome-wide research identifies novel genes and biologic mechanisms that play important roles in the therapeutic responsiveness and overall survival of lymphoma patients, clinicians are beginning to incorporate this new knowledge into the selection of more targeted therapies. Clinical molecular laboratories today must provide input at the time of initial diagnosis and during and after treatment. Laboratories must ensure the proper performance of molecular tests and the accurate interpretation and clinical use of the results. Testing for initial diagnosis and prognosis for BCL is not the same testing needed for MRD assessment during and after therapy. Furthermore, the lines between classical cytogenetic laboratories and molecular laboratories are blurring due to the marked increase in the use of FISH analysis. Hematopathologists increasingly need to be knowledgeable about both lymphoma biology and different therapies for lymphoma, and to interact closely with clinicians to ensure that appropriate testing is performed and appropriately used for clinical decisions.

Clinical laboratories that perform molecular testing on BCL are faced with two daunting tasks. First and foremost is the necessity of expanding test menus to meet the increasing clinical demand of testing for new molecular markers for NHL. Expanding test menus to meet clinical needs will require implementation of new technologies. These technical advances are essential for rapid testing for a broad panel of relevant genes at a reasonable cost. Several approaches show promise for diagnostic implementation and could alleviate the technological bottleneck that slows down the translation of new molecular knowledge into clinical tests. However, the lack of a reasonable level of reimbursement for molecular testing in general is a major roadblock to successful implementation of new techniques for important new genetic markers in BCL.

The second and equally important task is the urgent need for standardization of molecular testing methods to reduce the differences in test results and their interpretation across clinical molecular laboratories. Lessons learned from the European studies to standardize molecular testing and reporting for BCL are being used to standardize BCL molecular testing in the USA. It is likely that utilization of the BIOMED-2 reagents and protocols, together with the development of optimal proficiency testing materials and consensus interpretation guidelines will make strides towards a comparable level of laboratory standardization of molecular testing in the USA.

T-Cell Lymphomas

43

Jason D. Merker and Daniel A. Arber

Abstract

Mature T-cell and natural killer (NK)-cell neoplasms account for a small proportion of non-Hodgkin lymphomas (NHL). Despite the fact that they are relatively uncommon, T-cell lymphoproliferations often are submitted to the clinical molecular laboratory for testing. The diagnostic need for molecular testing is because T cells do not have a definitive immunophenotypic marker of clonality, like kappa and lambda antigen receptor immunophenotyping in B cells, so molecular methods can be used. A variety of molecular assays are available to evaluate T-cell receptor (*TR*) gene rearrangements, structural and numeric chromosomal abnormalities, and viral sequences associated with mature T- and NK-cell neoplasms. However, many of these molecular tests, especially PCR-based *TR* gene rearrangement testing, have important caveats that must be considered when interpreting the assays. Therefore, molecular results must be considered in the context of available clinical information, histology, immunophenotype, and other laboratory data for proper interpretation and clinical use.

Molecular Basis of Disease

T-cell and natural killer (NK)-cell neoplasms are relatively rare entities, collectively accounting for approximately 12 % of non-Hodgkin lymphomas (NHL) [1]. Subtypes of mature T- and NK-cell neoplasms are defined according to the World Health Organization (WHO) classification system [2], listed in Table 43.1. Despite the fact that they are relatively uncommon, most T-cell lymphoproliferations are assessed in the clinical molecular laboratory. The diagnostic need for molecular testing is because T cells do not have a definitive immunophenotypic marker of clonality, like kappa and lambda antigen receptor immunophenotyping in B cells, so molecular methods can be used. More specifically, two broad categories of molecular changes are used for clinical testing of T-cell lymphomas (TCL): T-cell receptor (*TR*) gene rearrangements and chromosomal alterations such as translocations, insertions, or deletions.

TR Gene Rearrangements

Pluripotent bone marrow (BM) stem cells give rise to progenitor T cells, which migrate to the thymus for primary ontogeny. There, early in T lymphocyte development *TR* genes undergo somatic rearrangement of germline gene sequences, similar to the process that occurs with immunoglobulin

Anaplastic large cell lymphoma, ALK-positive
Anaplastic large cell lymphoma, ALK-negative

heavy chain (*IGH*) and kappa and lambda light chain (*IGK* and *IGL*) genes. The four *TR* genes are: *TR* delta (*TRD*) at chromosome 14q11, *TR* gamma (*TRG*) at 7p14, *TR* beta (*TRB*) at 7q34, and *TR* alpha (*TRA*) at 14q11. In the germline configuration, *TRD* and *TRB* contain multiple variable (V), diversity (D), and joining (J) region segments. The *TRG* and *TRA* loci do not contain D segments. Depending on the locus, the number of segments is 8–67 V segments, 2–3 D segments, and 4–61 J segments [3]. For *TRD* and *TRB*, the somatic rearrangement initially involves the joining of one D to one J segment, followed by the joining of one V segment to the DJ segment (Fig. 43.1). For *TRG* and *TRA*, the V segment is joined to the J segment. The rearrangement process results in the deletion of the intervening coding and noncoding DNA sequences between the linked V, D, and J segments. Thus, the *TRD* and *TRB* gene rearrangements result in V-D-J juxtaposition similar to *IGH*, and *TRG* and *TRA* rearrangements result in V-J rearrangements similar to *IGK* and *IGL*. In all cases, the V-(D)-J segment is joined to the downstream constant (C) region by mRNA splicing. The *TR* genes are ultimately translated into two types of receptors, which exist as heterodimers (αβ or γδ). Of note, the *TR* genes do not undergo somatic hypermutation as occurs with antigen stimulation for the immunoglobulin (Ig) genes.

The *TR* genes generally rearrange in the following order: *TRD*, *TRG*, *TRB*, and finally *TRA* [4]. The *TRD* genes are located within the *TRA* locus, so rearrangement of *TRA* will result in *TRD* deletion on that allele. Also of note for clonal-

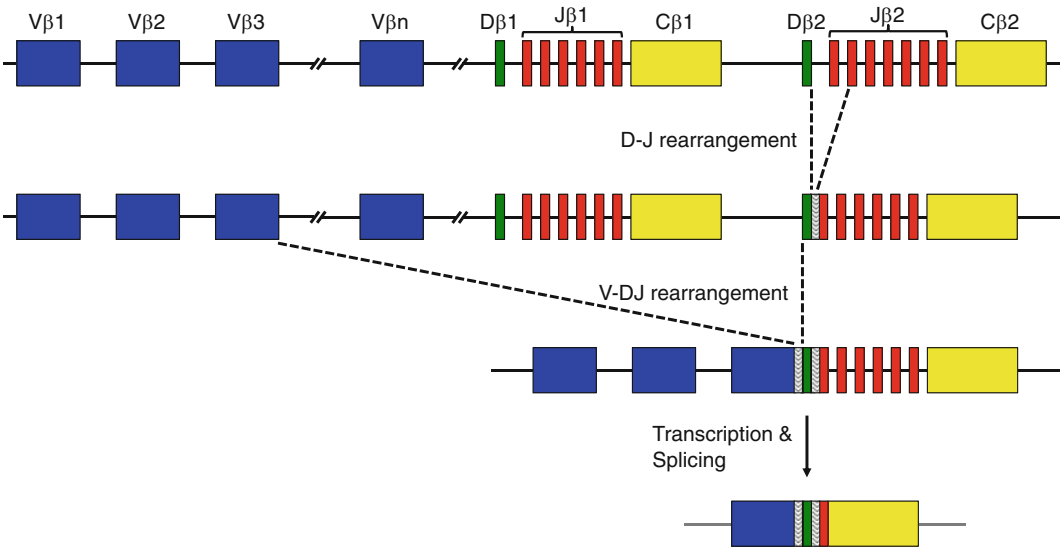

Figure 43.1 The *TRB* locus is used as an example to demonstrate the rearrangement of the variable (V), diversity (D), joining (J), and constant (C) region gene segments. The *hashed white boxes* between the rearranged V-D and D-J gene segments represent variable regions of nucleotide deletion and addition that occur during *TR* gene rearrangement

ity assessment, this hierarchical order of rearrangements results in both αβ- and γδ-T cells containing *TRG* rearrangements. For this and other reasons, *TRG* is commonly used for PCR-based clonality assessment.

The numerous different V, (D), and J segments present within each *TR* locus enable a large number of different V-(D)-J segments to be generated. The *TR* repertoire is further expanded by deletion and addition of nucleotides between the D-J and V-D junctions by terminal deoxynucleotidyl transferase (TdT), and by the combinations of different α–β or γ–δ chains. Collectively, these mechanisms generate extensive diversity of TRs with varying antigen specificity.

More than 95 % of mature, circulating T cells express the αβ receptor. In contrast, γδ T cells are mainly found in the skin, spleen, gastrointestinal tract, and other extranodal sites, which are often sites of origin for γδ T-cell lymphomas. T-cell neoplasms ensue after maturation arrest at one of the stages of T-cell development, such as from immature T cells in T lymphoblastic leukemia/lymphoma, or from more mature T cells in peripheral TCL and mycosis fungoides. Due to a common progenitor as well as some shared functional and immunophenotypic features, NK-cell neoplasms often are classified with mature T-cell neoplasms. Since NK cells do not rearrange the *TR* genes, neoplasms derived from these cells do not demonstrate *TR* gene rearrangements. The mature T- and NK-cell neoplasms of the WHO classification are listed in Table 43.1 [2].

Somatic Chromosomal Abnormalities

A variety of somatic structural and numeric chromosomal abnormalities have been observed in mature TCL, and a subset of these is listed in Table 43.2. ALK-positive anaplastic large cell lymphoma (ALCL), is associated with translocations involving the anaplastic lymphoma receptor tyrosine kinase (*ALK*) gene on chromosome 2. The most common *ALK* translocation is t(2;5)(p23;q35), which occurs in approximately 75 % of ALK-positive ALCL cases and results in the fusion of nucleophosmin (*NPM1*) on chromosome 5 with *ALK* [5, 6]. The t(1;2)(q21;p23) occurs in approximately 15 % of ALK-positive ALCL cases and results in the fusion of the tropomyosin 3 (*TPM3*) gene on chromosome 1 with *ALK* [5, 7]. The numerous other less common *ALK* fusion partners include *ATIC* at 2q35, *TFG* at 3q12, *CLTC* at 17q23, *MSN* at Xq12, *TPM4* at 19p13, *MYH9* at 22q12, and *RNF213* (*ALO17*) at 17q25 [5, 8]. The various translocations result in the activation of ALK, which is not normally expressed in lymphocytes, with subsequent oncogenic actions [5, 6].

Other somatic structural chromosomal abnormalities commonly associated with mature TCL include an inversion of chromosome 14 [inv(14)(q11q32)] associated with T-cell prolymphocytic leukemia [9], and an isochromosome involving the long arm of chromosome 7 [i(7)(q10)] often present with trisomy 8 and associated with hepatosplenic TCL [10]. In addition, amplification of oncogenes and loss of tumor suppressor genes can contribute to the development of mature TCL. As an example, gains involving the long arm of chromosome 9 are observed in more than half of enteropathy-associated TCL [11]. Likewise, loss of function of the *CDKN2B* (*P15*) and *CDKN2A* (*P16*) genes on the short arm of chromosome 9 due to allelic loss and aberrant promoter methylation occurs in mycosis fungoides and Sézary syndrome [12].

Table 43.2 Select somatic chromosomal abnormalities associated with mature T-cell neoplasms

WHO classification	Chromosomal abnormality
T-cell prolymphocytic leukemia	inv(14)(q11q32); *TRA–TCL1*
Enteropathy-associated T-cell lymphoma	Chromosome 9q gains
Hepatosplenic T-cell lymphoma	i(7)(q10)
Primary cutaneous anaplastic large cell lymphoma	*IRF4* (6p25) rearrangements
Anaplastic large cell lymphoma, ALK-positive	t(2;5)(p23;q35); *NPM1–ALK*

Indications for Testing

The diagnosis of a mature T- or NK-cell neoplasm is primarily based on histology, immunophenotype, and clinical information. For a subset of cases, distinguishing between a reactive and neoplastic process is difficult. Furthermore, in contrast to restricted Ig light-chain expression in mature B-cell lymphomas, T cells do not have a definitive immunophenotypic marker of clonality. Therefore, detection of a clonal *TR* gene rearrangement can assist in classifying the suspected lymphoproliferation as reactive or neoplastic. Due to specimen and test availability, clonality assessment most commonly involves PCR-based analysis of the *TRG* locus, or less frequently the *TRB* locus. If sufficient fresh or frozen neoplastic specimen is available, Southern blot analysis of the *TRB* locus may be considered.

Another potential application of *TR* gene rearrangement assays includes determination of clonal relatedness of multiple lesions derived from the same patient. T-cell neoplasms that share the same clonal origin will generally demonstrate identical *TR* gene rearrangement; however, ongoing and secondary rearrangements of the *TR* loci may result in alteration

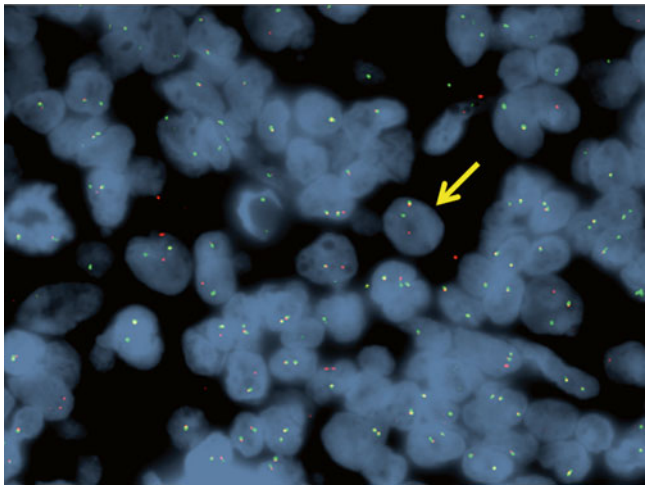

Figure 43.2 Interphase fluorescence in situ hybridization (FISH) image demonstrating rearrangement of the *IRF4* locus with an *IRF4* break-apart probe. The *yellow arrow* points to a cell with an *IRF4* rearrangement with one overlapping green and red fusion signal (indicating a normal unrearranged *IRF4* locus) and separate red and green signals (indicating an abnormal rearranged *IRF4* locus) (Image provided by Andrew Feldman, Mayo Clinic.)

or loss of this initial *TR* rearrangement. Evolution of the *TR* rearrangement has primarily been observed with precursor lymphoid neoplasms [13]. Other reported applications of *TR* gene rearrangement assays include staging, minimal residual disease (MRD) monitoring, and lineage assignment, but most clinical assays do not have sufficient sensitivity for the first two applications and cross-lineage rearrangements are observed at a high enough rate to limit the utility of use for lineage assignment.

Although it is less commonly applied in routine clinical practice, demonstration of somatic chromosomal structural or numeric abnormalities by molecular or cytogenetic methods can assist in classifying the suspected lymphoproliferation as reactive or neoplastic. Only a few T-cell neoplasms are associated with specific chromosomal structural abnormalities, but these may assist with subclassification. As an example, the t(2;5)(p23;q35) involving *NPM1* and *ALK*, as well as other *ALK* rearrangements, are found in ALK-positive ALCL. More recently, data from multiple groups collectively indicate that *IRF4* rearrangements (Fig. 43.2) are found in 25–30 % of primary cutaneous anaplastic large cell lymphomas, but are uncommon in T-cell neoplasms considered in the differential diagnosis, including cutaneous involvement by systemic ALK-negative ALCL, lymphomatoid papulosis, and transformed mycosis fungoides [14–16]. Consequently, testing for *IRF4* rearrangements by fluorescence in situ hybridization (FISH) may assist with the classification of cutaneous CD30-positive T-cell lymphoproliferative disorders in the context of histology, immunophenotype, and clinical information.

Detection of certain viruses can assist with the subclassification of mature T- and NK-cell neoplasms. Epstein-Barr virus (EBV) is strongly associated with aggressive NK-cell leukemia, EBV-positive T-cell lymphoproliferative disorders of childhood, nasal-type extranodal NK/TCL, and angioimmunoblastic TCL [2]. In situ hybridization (ISH) for EBV-encoded RNA (EBER) is the preferred method of testing paraffin-embedded tissue sections. In addition, the retrovirus human T-cell lymphotropic virus type 1 (HTLV-1) is involved in the pathogenesis of adult T-cell leukemia/lymphoma (ATLL) [17], and demonstration of HTLV-1 infection in ATLL cases is performed by HTLV-1 serology and PCR [18].

Available Assays

Clonality assessment is broadly available to assist in the classification of suspected lymphoproliferative disorders. Likewise, other molecular methods are available for the detection of chromosomal abnormalities and viral sequences associated with mature TCL and NK-cell lymphomas.

PCR-Based Clonality Assessment

Clonality assessment is much more frequently performed by PCR methods in clinical practice than by Southern blot analysis. Advantages of PCR-based assays include good sensitivity, short turnaround time, minimal quantity of required DNA, and the ability to utilize partially degraded DNA such as that derived from formalin-fixed, paraffin-embedded (FFPE) tissues. In addition, genomic DNA from fresh or frozen tissues, blood, BM, or body fluids can be used for assessment of T-cell clonality.

PCR-Based Clonality Assessment Using *TRG*

The majority of laboratories that perform PCR-based assessment of T-cell clonality examine the *TRG* locus. The *TRG* contains nine commonly rearranged V segments, which are further grouped into four V gene families based on sequence homology, and 5 J segments [19, 20]. The *TRG* locus is less complex than the *TRB* locus, making primer design to detect all rearrangements simpler. Because the *TRG* locus is rearranged prior to *TRB*, clonal rearrangements involving *TRG* can be detected in both αβ and γδ T cells.

Multiple approaches are used for PCR primer design for the detection of *TRG* rearrangements. Consensus V and J segment primers can amplify the majority of *TRG* rearrangements observed in lymphoid cells [21, 22]. Alternatively, primers directed against the four Vγ families coupled with a group of J-region primers can be multiplexed [3, 23, 24],

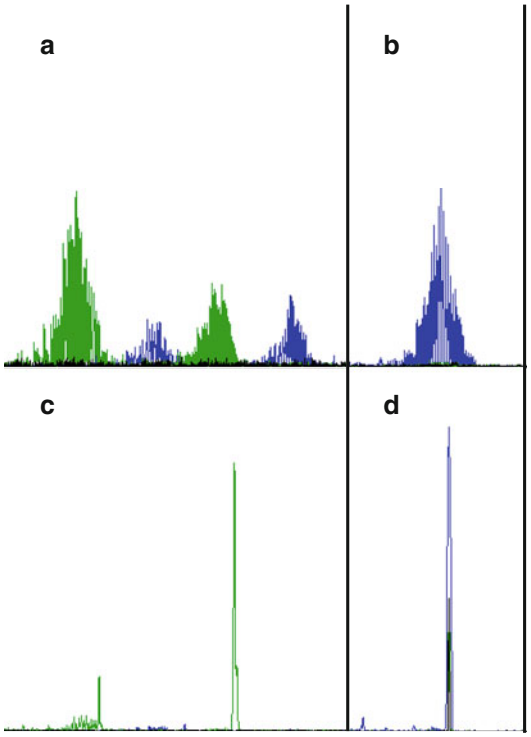

Figure 43.3 Examples of capillary electropherograms for PCR-based analysis of the *TRG* locus with two different primer sets. The assays show polyclonal results for a normal lymph node specimen (**a**, **b**) and clonal results for a T-cell neoplasm (**c**, **d**), using two different methods. The assay depicted in panels (**a**) and (**c**) is based on the BIOMED-2 Concerted Action, and the resulting PCR products are distributed among multiple size ranges. This assay uses two multiplex reactions, and the results from one multiplex reaction are shown. In contrast, the assay depicted in (**b**) and (**d**) uses a single multiplex reaction and results in PCR products distributed within a single size range. The T-cell neoplasm specimen was derived from a patient with mycosis fungoides, and multiple lesions from this patient demonstrated a dominant peak at the size shown. Note that for illustrative purposes, the vertical axes have been rescaled; the dominant clonal peaks in (**c**) and (**d**) are actually tenfold higher than the peak of the corresponding Gaussian distribution in (**a**) and (**b**), respectively

which is currently the most common primer design for PCR-based detection of *TRG* rearrangements. Even with this common approach, significant differences in the assays used by different laboratories affect assay interpretation and performance. After PCR amplification, the products can be visualized by methods including capillary electrophoresis, heteroduplex analysis, or denaturing gradient gel electrophoresis. Examples of two different PCR-based *TRG* assays using capillary electrophoresis are shown in Fig. 43.3.

PCR-Based Clonality Assessment Using *TRB*

Although it is less commonly examined for PCR-based assessment of T-cell clonality than *TRG*, the *TRB* locus may be assessed as an adjunct or alternative to *TRG*. The *TRB* locus is significantly more complex than the *TRG* locus, containing approximately 65 V segments, two D segments, and 13 J segments [25]. The most common primer set used for analysis of *TRB* was developed by the BIOMED-2 study [3] and contains 23 Vβ, two Dβ, and 13 Jβ primers divided among three reaction tubes. The resulting PCR products are examined by capillary electrophoresis or heteroduplex analysis to detect the majority of *TRB* rearrangements.

Southern Blot Analysis Clonality Assessment

Although it is much less frequently performed than the PCR-based assays described above, Southern blot analysis can be a valuable tool for diagnostically challenging lymphoproliferative cases when sufficient fresh or frozen tissue is available. In general, Southern blot analysis of *TR* loci has better inter-observer agreement and fewer issues with false-positive results than PCR-based analysis. However, most biopsies for suspected lymphoproliferative disorders are small and preserved as FFPE blocks, and thus yield neither sufficient quantity nor quality of DNA for Southern blot analysis. In addition, Southern blot analysis is both time consuming and technically demanding.

Southern blot analysis for T-cell clonality most commonly examines the *TRB* locus. Although Southern blot analysis detects a clonal rearrangement in >90 % of T-cell neoplasms, it is generally unable to detect a clonal rearrangement in NK-cell or γδ T-cell neoplasms. Southern blot analysis of the *TRB* locus uses a probe directed against the *TRB* constant regions (Cβ) or probes directed against one or both of the *TRB* J segments (Jβ1 and Jβ2) [26]. An example of a *TRB* Southern blot is shown in Fig. 43.4. Even though numerous rearrangements derived from T lymphocytes are present in a lane, only the clonal rearrangement reaches the detection level.

Guidelines suggest using at least three different restriction enzymes for digestion of the genomic DNA [27]. The presence of up to two non-germline bands in at least two of the three digests is considered definitive evidence of a clonal rearrangement. One or two non-germline bands in only one of the three digests may represent a clonally rearranged allele or a benign germline polymorphism, and performing digestion with an additional restriction endonuclease may assist in distinguishing between these possibilities. Only two of the three digests are required to demonstrate non-germline bands because one of the digests may have a rearrangement that is a similar size to and obscured by the germline band. The allowance for up to two rearranged bands per digest accounts for rearrangement of both *TRB* alleles or for the creation of a new restriction site in the rearranged allele within the probe region. The presence of more than two non-germline bands may indicate oligoclonality or a chromosomal abnormality, but incomplete digestion of

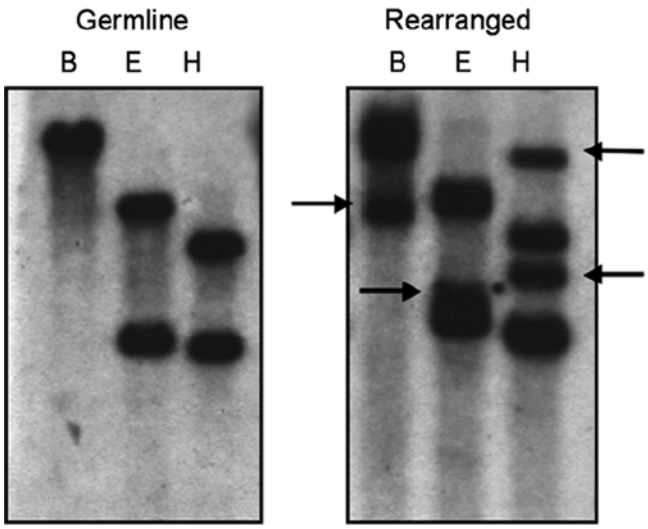

Figure 43.4 Example of a *TRB* Southern blot. Three restriction enzymes (B, *Bam*HI; E, *Eco*RII; H, *Hind*III) were used to digest genomic DNA from germline (*left panel*) and TCL (*right panel*) specimens. The lymphoma specimen demonstrates one or two additional rearrangements (*arrows*) compared to the germline specimen with all three restriction enzymes

genomic DNA or germline polymorphisms also may lead to multiple rearranged bands and must be excluded.

Detection of Chromosomal Abnormalities

Reverse transcription PCR (RT-PCR) and real-time quantitative PCR (RT-qPCR) can be used for the detection or detection and quantitation, respectively, of fusion transcripts such as *NPM1–ALK* found in the majority of cases of ALK-positive ALCL. *NPM1–ALK* and other fusion transcripts involving *ALK* result in the expression of the ALK protein, which is not normally expressed in lymphocytes. ALK expression is a favorable prognostic marker, and patients with ALK-positive ALCL have improved overall survival compared to patients with ALK-negative ALCL [28, 29]. This association appears to be independent of the translocation partner [30]. Furthermore, up to 25 % of ALK-positive ALCL cases involve translocation partners other than *NPM1*, and some *NPM1–ALK* translocations will not be detected by RT-PCR. For these and other reasons, ALK immunohistochemistry is the most widely used test for examining ALK expression in ALCL (Fig. 43.5). RT-PCR and RT-qPCR for *NPM1–ALK* may provide prognostic information or allow MRD monitoring in select patients with ALK-positive ALCL and the *NPM1–ALK* fusion [31]. These sensitive methods should be used with caution in diagnostic situations because low levels of *NPM1–ALK* fusion transcripts have been reported in ALK-negative ALCL, Hodgkin lymphoma, reactive tissue, and even peripheral blood from healthy individuals [32, 33].

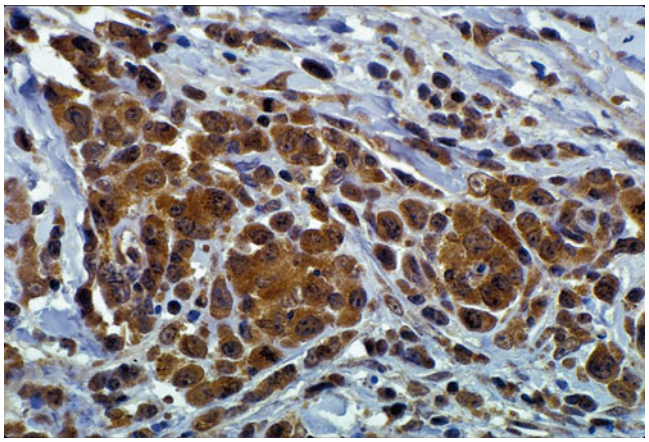

Figure 43.5 Immunohistochemistry demonstrating nuclear and cytoplasmic ALK staining in an ALK-positive anaplastic large cell lymphoma secondarily involving the skin

FISH on fresh or FFPE tissues also can be used to detect *NPM1–ALK* fusions and other *ALK* rearrangements, and FISH for *ALK* rearrangements correlates well with ALK immunohistochemistry [34]. Likewise, FISH can be performed for other structural and numeric chromosomal abnormalities, but FISH testing for mature T- and NK-cell lymphomas is offered in only a few clinical laboratories.

Detection of Viral Sequences Associated with T-Cell Lymphomas

ISH is commonly used for the detection and localization of EBV in tumor cells of the various EBV-positive mature T- and NK-cell neoplasms, especially nasal-type extranodal NK/T-cell lymphoma. ISH can be performed on FFPE tissue sections and identifies EBV RNA within the nuclei of virtually all tumor cells. EBER RNA is most commonly targeted due to the very high copy number in EBV-infected tumor cells. PCR detection of EBV in lymphoid tissue specimens is less useful because the vast majority of adults have been infected with EBV and the assay may detect latently infected background B cells that are not associated with the tumor.

The diagnosis of ATLL involves the demonstration of HTLV-1 infection. This may be performed by HTLV-1 serology or PCR.

Interpretation of PCR-Based T-Cell Clonality Assays

Interpretation of PCR-based T-cell clonality assays is a challenging and commonly debated area of molecular pathology. Interpretation is dependent on assay design and

the method used to evaluate the PCR products. Different interpretive criteria are required depending on assay design [35]. Key features of assay design that influence choice of interpretive criteria include primer selection, multiplexing strategy, use of one or multiple different fluorescently labeled primers, and whether the resulting PCR products result in a single or multiple Gaussian regions. In gel-based assays, interpretation as a clonal rearrangement is based on the finding of a discrete band of an appropriate size in contrast to a smear or ladder of bands derived from polyclonal T cells. With capillary electrophoresis-based assays, a wide variety of interpretive criteria is used, and each laboratory must establish and validate its own criteria for a positive result while considering the many issues described in this section. Commonly applied interpretive criteria for the detection of a clonal T-cell rearrangement include observing a reproducible peak above baseline or establishing a cutoff ratio based on the height of the peak in question relative to that of the polyclonal background [3, 36–38]. Computer-aided algorithms also are used to identify peaks that deviate from the normal distribution curve [39]. Less-stringent criteria can be applied with capillary electrophoresis in follow-up specimens when the size of the expected clonal PCR product is known from prior testing.

Oligoclonal proliferations should be differentiated from monoclonal proliferations. The number of bands on a gel or prominent peaks on a capillary electrophoresis tracing necessary to define an oligoclonal vs monoclonal proliferation depends on the assay design and locus examined. In general, the presence of more than two bands or prominent peaks is considered compatible with an oligoclonal proliferation when examining the *TRG* locus.

Clonality Assay Limit of Detection

The limit of detection for *TR* gene rearrangements by Southern blot analysis has been generally reported to vary from 1–10 % clonal cells [40, 41], with 5 % representing a reasonable estimate in standard clinical practice [26]. The limit of detection for PCR-based *TR* gene rearrangement assays depends on the assay design, extent of polyclonal background, and detection method. As an example, commonly used primer sets developed by the BIOMED-2 study are reported to have limits of detection of 1–10 % when heteroduplex analysis is used and 0.5–5 % when capillary electrophoresis is used [3]. Lower limits of detection can be achieved with patient-specific primers, in the range of 0.01–0.001 %. However, this approach is labor and time intensive, and is not generally utilized for mature TCL outside of the research or clinical trial setting.

Clinical Sensitivity

In principle, virtually all *TR* gene rearrangements can be detected by Southern blot analysis if a sufficiently large clonal T-cell population is present in the specimen. In practice, low tumor burden is a major cause of false-negative *TR* Southern blot analysis of T-cell neoplasms, and consequently PCR-based assays have higher clinical sensitivity [42]. A clonal *TRG* rearrangement is detected in >90 % of mature T-cell neoplasms when family-specific V-region primers are used, and a clonal *TRB* rearrangement is detected in >75 % of mature T-cell neoplasms [43–45]. Rates of detection >95 % in fresh/frozen and FFPE tissues have been reported when both *TRG* and *TRB* loci are examined. False-negative results may occur when the family or consensus primers fail to efficiently anneal to the rearranged V, D, or J segments due to limited homology or alteration of the targeted gene region caused by the rearrangement. False-negative results also may be attributed to primer design. As an example, the BIOMED-2 study did not include a Jγ1.2 (JγP) primer to avoid false-positive *TRG* results from canonical rearrangements [3]. This J segment is used in approximately 3 % of T-cell neoplasms [46]. Consequently, a false-negative *TRG* result may rarely occur if the other *TRG* allele has not rearranged. Finally, specimen sampling issues may result in a false-negative *TR* gene rearrangement if an insufficient number of clonal T cells are present within the tested specimen. An appropriately trained pathologist must review and select the tissue for testing to ensure sufficient abnormal cells are present.

Clinical Specificity

Lack of clinical specificity is a major limitation of PCR-based clonality studies, especially involving the *TR* loci. Clonal rearrangement of *TR* loci has been reported in a variable percentage of myeloid and B-cell neoplasms as well as in a variety of nonneoplastic conditions. In some cases, the detected clonal rearrangement represents a true cross-lineage rearrangement within the neoplastic cell population (e.g., detection of a *TR* rearrangement in B lymphoblastic leukemia/lymphoma [B-ALL]). In many other cases, the detected clonal *TR* gene rearrangement represents either a limited number or a restricted repertoire of T cells in the specimen.

TR gene rearrangements generally should not be used for lineage determination due to lineage infidelity, which is the rearrangement of *TR* genes in non-T cells (or the rearrangement of Ig genes in non-B cells). Clonal rearrangements involving *TRD* or *TRG* occur in approximately 10 % of acute myeloid leukemia cases [47, 48]. Cross-lineage *TR* gene

rearrangements are very common in B-ALL, with over half of cases demonstrating *TRG* rearrangements [49]. In contrast, cross-lineage *TR* gene rearrangements are relatively rare in mature B-cell neoplasms when examined by Southern blot analysis, generally observed in <10 % of cases [50–53]. However, a large study by the BIOMED-2 group using their PCR-based assays examined 369 mature B-cell neoplasms and identified a clonal *TR* gene rearrangement in approximately 25 % of cases [54]. They noted that these cases could be divided into two groups based on the pattern of *TR* gene rearrangements. In approximately 10 % of the cases, the rearrangement involved a single locus and exhibited a strong clonal pattern, probably representing true cross-lineage rearrangements present within the malignant B-cell population. In approximately 15 % of cases, *TR* gene rearrangements were observed at two or more loci and exhibited a weak clonal pattern, probably representing a coexisting restricted or small T-cell population. This underscores that such weak bands or small peaks observed in clonality assays should be interpreted with caution to avoid false-positive results. Subsequent work further illustrates that application of more stringent interpretive criteria to this primer set may improve the clinical specificity of the assay [35].

Detection of Ig gene rearrangements in mature T-cell neoplasms has been observed, but generally at a lower rate than *TR* rearrangements in B-cell neoplasms [51, 52]. In a study of 188 mature T-cell neoplasms by the BIOMED-2 study, 10 % demonstrated clonal Ig gene rearrangements by PCR, but most of these cases exhibited a weak clonal pattern probably representing a coexisting restricted or small B-cell population [44]. Of the different mature T-cell neoplasm classifications examined, the highest level of Ig gene rearrangements was found in angioimmunoblastic T-cell lymphoma (AITL). In this and other studies, up to one-third of AITL cases have clonal Ig gene rearrangements [44, 55]. Likewise, a high percentage of clonal Ig rearrangements have been reported in peripheral TCL, NOS with rates of 10–35 % [44, 55, 56].

TR gene rearrangement studies are typically performed to distinguish monoclonal from polyclonal lymphoproliferations, but the detection of a monoclonal *TR* gene rearrangement is not always indicative of malignancy. *TR* gene rearrangements have been reported in nonneoplastic conditions. Clonal T-cell populations are observed in peripheral blood specimens, especially from older individuals [57–59]. Likewise, oligoclonal and clonal *TR* gene rearrangements occur in individuals with autoimmune disorders, viral infections, reactive lymphoproliferations, and benign cutaneous lesions [60, 61]. As an example, lymphomatoid papulosis (LyP), a benign primary cutaneous CD30-positive T-cell lymphoproliferative disorder, is associated with the development of a malignant lymphoma in approximately 20 % of cases [62]. Over 40 % of LyP cases are associated with clonally rearranged *TR* genes, but this is not indicative of malignancy or predictive of progression to lymphoma [63, 64]. Consequently, in LyP cases, *TR* gene rearrangement studies are of little value.

Pseudoclonality

Pseudoclonality refers to the artifactual detection of an apparently clonal or oligoclonal lymphoid population and is a common problem in PCR-based clonality assessment of certain specimen types. PCR can result in the selective amplification of one or a limited number of *TR* gene rearrangements when there are a limited number of T cells. Small numbers of T cells and consequently pseudoclonal results are commonly encountered in small skin biopsy specimens, needle biopsies, and B-cell malignancies with very high tumor burdens. Duplicate or triplicate testing of these specimen types often will demonstrate different size gene rearrangements, indicating pseudoclonality. If available, testing of other lesions from the patient can assist in distinguishing clonality from pseudoclonality. This approach appears to be particularly useful in distinguishing inflammatory dermatoses from cutaneous TCL [65, 66].

Oligoclonality

Oligoclonal proliferations have a restricted *TR* gene repertoire and occur in processes such as antigen-stimulated expansion of distinct subclones, immune reconstitution, or immunosenescence. The number of predominant peaks or bands required to distinguish monoclonality from oligoclonality depends on the assay and locus examined. For *TRG*, the presence of more than two predominant peaks or bands generally is interpreted as an oligoclonal proliferation. As noted previously, oligoclonal proliferations are commonly observed in individuals with autoimmune disorders, viral infections, reactive lymphoproliferations, and benign cutaneous lesions [60]. Likewise, reduced diversity of the *TR* repertoire and *TR* gene oligoclonality is observed in older adults and during immune reconstitution after chemotherapy or stem cell transplantation [67, 68]. If selective amplification of one of the clones occurs in these oligoclonal proliferations, the result may appear clonal (i.e., pseudoclonality). Replicate testing or testing of multiple neoplastic specimens from the same patient will frequently reveal different sized gene rearrangements, indicating pseudoclonality in these cases.

PCR Products Outside of Size Range

In T-cell clonality assessment by PCR, bands outside the defined size range may represent true *TR* gene rearrangements,

but these must be distinguished from nonspecific PCR products. For size ranges established between the 5th and 95th percentiles, bands or peaks just outside of this size range likely represent true rearrangements. Likewise, significantly oversized or undersized bands or peaks also may represent true rearrangements due to amplification from downstream J segments or partial V segment deletions, respectively [69]. In cases in which the peaks or bands are outside of the size range, sequencing the potential rearrangement product allows definitive characterization.

Weak Clonal Results

Weak bands or small peaks in PCR-based *TR* gene rearrangement assays must be interpreted with caution to avoid false-positive results. Such results should be repeated to ensure that the results are reproducible. In addition, examination of other loci and other involved specimens from the same patient, as well as using an orthogonal detection method, can assist in determining the significance of these weak clonal results. At this time, specific criteria for interpretation of PCR-based clonality testing have not been universally embraced, although (as is discussed above) multiple approaches have been proposed. Each laboratory is required to design, validate, and establish interpretive criteria for their specific assay given the issues and limitations discussed in this section.

Laboratory Issues

Appropriate controls for PCR-based *TR* gene rearrangement assays include positive, negative, sensitivity, and no DNA template reactions. Positive controls can be derived from previously positive patient specimens or characterized cell lines [70, 71]. A polyclonal control is typically derived from tonsillar tissue processed in the same way as clinical specimens. Sensitivity controls can be made by dilution of DNA from a positive cell line in DNA from a specimen with a polyclonal T-cell population, such as tonsil, to determine and then monitor the limit of detection of the assay. The limit of detection for a clonal population in a non-lymphoid background will be lower than in the presence of a polyclonal lymphoid background and may lead to inaccurate assessment of sensitivity. Finally, no DNA template control reactions, which include all PCR primers and reagents but no DNA, should be included to monitor for exogenous DNA or PCR product contamination. For Southern blot analysis, control germline DNA may be obtained from a variety of non-lymphoid cells, such as placenta [26].

In many laboratories, the majority of specimens will be FFPE tissues. Although some DNA degradation is inherent to formalin fixation, the extracted DNA is usually of sufficient quality for PCR-based *TR* gene rearrangement testing. However, some cases, approximately 20 % of cases in one study [45], will not have sufficient DNA quality for successful analysis. Consequently, a non-*TR* or -*IG* control gene must be amplified for each specimen to prevent a false-negative interpretation due to inadequate DNA quality (or the presence of a PCR inhibitor such as heparin). Furthermore, the control gene should be the same size or larger than the largest amplicon in the assay.

Conclusions and Future Directions

A variety of molecular pathology assays are available to evaluate *TR* gene rearrangements, structural and numeric chromosomal abnormalities, and viral sequences associated with mature T- and NK-cell neoplasms. In a subset of TCL, these molecular studies are important for disease classification or determining prognosis. However, many of these molecular studies, especially PCR-based *TR* gene rearrangement studies, have important caveats that must be considered during validation and subsequent clinical use and interpretation of the assays. Therefore, molecular test results must be considered in the context of available clinical information, histology, immunophenotype results, and other laboratory data to ensure proper clinical use of the results.

With the widespread application of genomic and other high-throughput methodologies such as massively parallel sequencing in the research setting, the amount of data regarding the genetics underlying hematolymphoid neoplasms is rapidly increasing. Recurrent somatic mutations as well as structural chromosomal alterations have been identified in lymphoid malignancies. Most of this work has focused on B-cell neoplasms, but projects involving mature T-cell neoplasms are underway. Recently, massively parallel sequencing has led to identification of a recurrent translocation in ALK-negative ALCL [72]. In addition, massively parallel sequencing strategies are being applied to analysis of *TR* loci [73], and clinical assays based on these methods are now in use. These data and new methods have the potential to improve the diagnosis, determination of prognosis, and ability to monitor response to therapy in mature T- and NK-cell neoplasms.

Myeloproliferative Neoplasms and Myelodysplastic Syndromes

44

Albert K. Ho and Daniel M. Jones

Abstract

Myeloproliferative neoplasms (MPNs) and myelodysplastic syndromes (MDS) represent primary clonal hematopoietic disorders that affect the range of immature and maturing blood cell types. This chapter summarizes the distinguishing molecular and cytogenetic features between MDS and MPNs and the most useful clinical molecular tests. An overview is given on the impact of new methods, such as massively parallel sequencing, on our knowledge of pathogenesis. The role of minimal residual disease testing, particularly in MPNs, is discussed in detail.

Keywords

Myeloproliferative neoplasm • Myelodysplastic syndrome • MPN • MDS • JAK2 • BCR-ABL1 • CML • CALR • Calreticulin

Molecular Basis of Disease

Myeloproliferative neoplasms (MPNs) and myelodysplastic syndromes (MDS) represent primary clonal hematopoietic disorders that were among the first neoplasms to be diagnosed and monitored using molecular methods. From the discovery of the Philadelphia chromosome as the causative genomic change in chronic myelogenous leukemia (CML) in 1960 [1], to the recent identification of a common set of mutations producing epigenetic modulation in both MDS and MPN, molecular and cytogenetic testing have been central to the diagnosis of these neoplasms for the last 30 years.

Most cases of MPN now have a diagnostic genetic alteration linked to pathogenesis (Table 44.1), whereas the classification of MDS remains tied to blast count and hematologic features (Table 44.2), with certain genetic changes common to several MDS entities.

Besides affecting the myeloid compartment of the hematopoietic system, MPN and MDS share many overlapping morphologic, genetic, and immunophenotypic features (Table 44.3), with the distinction based on the dominant presenting feature. MPNs have increased numbers of blood components due to abnormal proliferation. In contrast, MDS typically presents with decreased numbers of blood components due to ineffective hematopoiesis. An overlap category of myelodysplastic/myeloproliferative neoplasms is recognized when there are features of both entities. Molecular testing in MPNs has become established as the standard of care for diagnosis, monitoring for residual disease, establishing prognosis, and therapeutic decision making. In MDS, the role of molecular testing is currently more limited with cytogenetic studies representing the primary modality used for subclassification and prognostic stratification. However, mutational and epigenetic studies are poised to become part of the routine workup of MDS in the near future.

Table 44.1 Categories of myeloproliferative neoplasms and their molecular alterations

Type	Cytogenetic change(s)	Genes affected	Pathway type
CML	t(9;22)	*BCR–ABL1*	TK growth
	+8, del17p (CE)		
PV, PMF, ET	XY/XX	*JAK2*	Cytokine receptors
	+9, +1/1q (CE)		
CEL/MPN-U	XY/XX	*FIP1L1–PDGFRA*	RTK
	t(8p11;var)	*FGFR1*-various	
CMML, MPN-U	t(5;12)(q31-q33;p12)	*ETV6–PDGFRB*	
	t(5q33;var)	*PDGFRB*-various	

CE clonal evolution, *CEL* chronic eosinophilic leukemia, *CML* chronic myelogenous leukemia, *CMML* chronic myelomonocytic leukemia, *ET* essential thrombocythemia, *MPN-U* myeloproliferative neoplasm, unclassifiable, *PMF* primary myelofibrosis, *PV* polycythemia vera, *(R)TK* (receptor) tyrosine kinase

Table 44.2 Categories of myelodysplastic syndrome and their molecular alterations

Type	Definition
Refractory cytopenia with unilineage dysplasia, including refractory anemia, neutropenia, and thrombocytopenia	Cytopenia and marrow morphologic dysplasia limited to one of the three primary lineages
	Blasts: <5 % BM, <1 % blood
Refractory Anemia with ringed sideroblasts (RS)	Anemia, ≥15 % BM erythroid precursors meeting definition of RS
	Blasts: <5 % BM, <1 % blood
Myelodysplastic syndrome with isolated del(5q)	Anemia, high platelet count and isolated deletion(s) of chromosome 5q
	Blasts: <5 % BM, <1 % blood
Refractory cytopenias with multilineage dysplasia +/– RS	Cytopenias, morphologic dysplasia identified in two or more lineages
	Blasts: <5 % BM, <1 % blood
Refractory anemia with excess blasts-I	Cytopenias
	Blasts: 5–9 % BM and <5 % blood
Refractory anemia with excess blasts-II	Cytopenias
	Blasts: 10–19 % BM and/or >5 % blood, Auer rods can be present
Myelodysplasia, unclassifiable	Cytopenias
	Blasts: <5 % BM, <1 % blood
	Often used for those cases showing some features of myeloproliferative neoplasms, e.g., increased basophils, eosinophils, and/or fibrosis
Chronic myelomonocytic leukemia	1×10^9/L monocytes in blood, with marrow dysplasia
	Mixed disorder with more of a myeloproliferative pattern in some cases

BM bone marrow

Table 44.3 Shared features between MDS and MPNs

Immunophenotypic similarities	Loss/decreased expression of pan-myeloid antigens
	Aberrant upregulation of adhesion molecules (e.g., CD56)
Cytogenetic similarities	Acquisition of +8 with progression
	Acquisition of TP53 mutations with progression
	LOH/UPD involving myeloid regulatory loci
Molecular similarities	Mutations in the epigenetic regulators including *IDH1*, *IDH2*, *TET2*, and *DNMT3A*
	Mutations in *RAS* genes and myeloid transcriptional regulators such as *ASXL1*

LOH loss of heterozygosity, *UPD* uniparental disomy

Indications for Testing

Myeloproliferative Disorders

Elevated white blood cells (leukocytosis), red blood cells (erythrocytosis), or platelets (thrombocytosis), and/or splenomegaly are the hallmarks of MPNs. However, these changes also can represent reactive phenomena, as a manifestation of the normal bone marrow (BM) stress response to infection, trauma, or other types of injury. Because distinction of reactive and neoplastic expansions can be difficult on clinical and morphologic features, molecular and cytogenetic

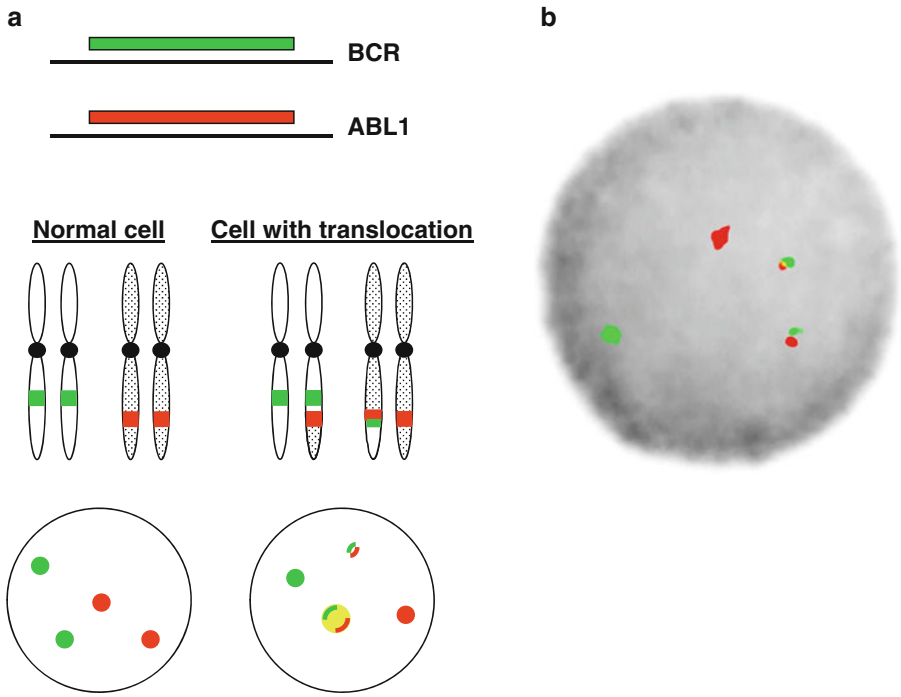

Figure 44.1 *BCR–ABL1* gene rearrangement detected by fluorescence in situ hybridization (FISH). (**a**) Schematic of fusion FISH with orange-labeled probes for *ABL1* gene on chromosome 9 and green-labeled probes on the *BCR* gene on chromosome 22. (**b**) Image from a CML cell showing the t(9;22)

testing can lead to a definitive diagnosis (Table 44.1). The most common MPNs are CML, essential thrombocythemia (ET), polycythemia vera (PV), and primary myelofibrosis (PMF). These entities can have overlapping morphologic and clinical characteristics [2]. A variety of less common MPNs have been recognized in recent years and can be definitively diagnosed by the presence of characteristic cytogenetic or molecular changes.

Chronic Myelogenous Leukemia

Patients with CML typically present with neutrophilia and variable basophilia and eosinophilia. Although some patients are asymptomatic and diagnosed following routine blood work, presentations with fatigue and/or splenomegaly are common. Left untreated, many patients with CML eventually progress to an accelerated phase and then to blast crisis which can be indistinguishable from acute myeloid leukemia (AML).

The medical advances made in the diagnosis and treatment of CML represent some of the greatest achievements in molecular medicine to date. CML was the first malignancy noted to have a defining genetic abnormality when the Philadelphia chromosome (Ph), a translocation between chromosomes 9 and 22, t(9;22) (q34;q11), was identified [1]. Subsequently, the Ph chromosome was identified as the juxtaposition of the breakpoint cluster region (*BCR*) gene on chromosome 22 with the Abelson tyrosine kinase (*ABL1*) gene on chromosome 9 (Fig. 44.1a), resulting in relocalization of an altered ABL1 protein from the nucleus to the cytoplasm, which produces constitutive activation of the ABL growth signaling pathway. The *BCR–ABL1* gene fusion is found in all cases of CML and in about 20–30 % of adult and 2–10 % of childhood B lymphoblastic leukemia (B-ALL) [3].

The differential diagnosis of CML includes benign leukocytosis/leukemoid reaction and the rare chronic neutrophilic leukemia (CNL) and its related atypical chronic myeloid leukemia (aCML). Although CNL and aCML typically lack the basophilia associated with CML other features may be similar. In 2013, cases of CNL/aCML were shown to have a high frequency of activating and truncation mutations in the colony-stimulating factor 3 receptor gene (*CSF3R*) [4].

Essential Thrombocythemia, Primary Myelofibrosis, and Polycythemia Vera

Based on clinical features, ET, PMF, and PV are closely related MPNs, distinguished primarily by their dominant presenting features and clinical course. This close clinical relationship was explained in 2005 when several groups independently identified a point mutation in the *JAK2* tyrosine kinase gene as a recurrent abnormality in these three MPNs, and some cases of chronic myelomonocytic leukemia (CMML). The activating *JAK2* mutation, V617F, is

Table 44.4 Frequency of mutations in different MPNs

Mutation type	PV	ET	PMF	CMML
JAK2 V617F	95 %	50 %	40 %	5 %
JAK2 exon 12/13	5 %	ND	ND	<1 %
MPL codon 505 or 515	ND	5 %	5 %	ND
KRAS–NRAS codons 12/13/61	ND	ND	<1	30–40 %

CMML chronic myelomonocytic leukemia, *ET* essential thrombocythemia, *MPNs* myeloproliferative neoplasms, *ND* not detected, *PMF* primary myelofibrosis, *PV* polycythemia vera

detected in up to 95 % of cases of PV, and approximately 50 % of ET and PMF cases (Table 44.4). A subset of PV, but not PMF or ET, has activating point mutations or in-frame duplications in exon 12 of *JAK2*. Among PMF and ET without V617F, activating mutations in the thrombopoietin receptor gene (*MPL*) are seen in approximately 10 % of cases. Because the JAK2 kinase links multiple cytokine receptors, including the erythropoietin receptor, the thrombopoietin receptor (MPL) and the granulocyte-monocyte cytokine colony stimulating factor receptor (CD116), these mutations define this group of MPNs as having JAK-linked dysregulated cytokine growth factor receptor pathways.

Differences in the features and behavior of *JAK2–MPL*-mutated MPNs are related to the spectrum of other coexisting somatic mutations in any particular case [5], to genetic polymorphisms in the cytokine genes of the affected individual [6], and to the varying gene dosage and level of expression of the mutated *JAK2* or *MPL*. As a result of loss of heterozygosity or mutation of both alleles, *JAK2* V617F can be present in up to several copies per cell, and cases with a higher V617F allele burden often manifest as PV or PMF rather than as ET. In contrast to patients with the V617F mutation, PV patients with *JAK2* exon 12 mutations tend to present at a younger age, and with higher hematocrit, lower platelet count, and lower white blood cell (WBC) count. ET and PMF patients with *MPL* mutations tend to show different patterns of clonal evolution than *JAK2*-mutated cases, with the common karyotypic findings of gains of chromosome 1 in ET with *MPL* mutations and chromosome 9 in PMF with *MPL* mutations [7]. Germline *JAK2* and *MPL* mutations continue to be discovered in families with predisposition to the development of MPNs [8].

Calreticulin gene (*CALR*) mutations occur in 50–71 % of ET cases, and 56–88 % of PMF cases that are negative for *JAK2* and *MPL* mutations [9–12]. These mutations include a variety of insertion and deletions located in exon 9 of *CALR* that shift the translational reading frame and produce a common novel C-terminal peptide sequence. Mutated CALR may differentially influence signaling through the JAK-STAT pathway. *CALR* mutations are largely mutually exclusive with *JAK2* and *MPL* mutations and are not found in PV, CML, AML, or most cases of MDS. *CALR*-mutated PMF is prognostically distinct from *MPL*- and *JAK2*-mutated MPNs and from those cases that lack all three mutations [9–14]. Therefore, testing for *CALR* mutations can assist in the diagnosis of MPN, and provide a genetic marker for monitoring response to therapy.

Myeloproliferative Neoplasms Associated with Eosinophilia

Most causes of significant eosinophilia are reactive or secondary to chronic parasitic infections or due to cytokine-producing malignancies, particularly T-cell lymphoma, Hodgkin lymphoma, and some carcinomas. However, a group of rare MPNs present with eosinophilia and immature/dysplastic myelopoiesis and are characterized by gene fusions involving a variety of growth factor genes (Table 44.1). The majority show fusion of the *FGFR1* gene to a variety of other genes, thereby producing ligand-independent FGFR1 activation. Another type has a chromosome 4 interstitial cryptic *FIP1L1–PDGFRA* fusion that activates the PDFRA kinase, with the neoplasms showing dramatic response to imatinib treatment, similar to CML. A very rare *PDGFRB*-translocation syndrome produces a similar MPN due to fusion with *ETV6* or a variety of other partner genes.

Myelodysplastic/Myeloproliferative Neoplasms

The most common of the mixed myeloid disorders is CMML, which can present with a high WBC count resembling acute monocytic leukemia, or with a low WBC count associated with dyspoietic BM findings. This variability in presentation underlies a heterogeneous molecular pathogenesis. *RAS* gene mutations are identified in the vast majority of cases with hyperproliferative presentations, and a variety of cytogenetic and somatic mutations, including *TET2* and *JAK2* V617F, are seen in other cases [15].

Myelodysplastic Syndromes

Decreased numbers of WBCs (leukopenia), platelets (thrombocytopenia), and erythrocytes (anemia) are among the most common abnormal laboratory findings in patients with MDS. In younger patients, these cytopenias often have a nonneoplastic etiology such as immune-mediated marrow suppression, autoimmune disease, acute bacterial and viral infections, nutritional deficiency (e.g., B12, folate or iron), or toxin exposure. However, with advancing age, cytopenias are increasingly related to genetically mediated BM failure or MDS. The dysplastic changes of MDS can be superimposed upon other causes of marrow suppression, exacerbating the ineffective hematopoiesis. In these cases, abnormal blood cells show impaired maturation and are destroyed by

apoptosis before being released into the bloodstream. These genetically abnormal marrow components often have an atypical morphology (dysplasia) that can be recognized in a BM aspirate smear.

Available Assays and Laboratory Issues

Chronic Myelogenous Leukemia

BCR–ABL1 Detection

In CML, most of the *BCR–ABL1* translocations involve the major breakpoint cluster region (M-bcr) adjacent to exons 12–16 of *BCR* (formerly called exons b1–b5) and result in either the e13a2 or e14a2 *BCR–ABL1* gene fusions (or both transcripts), which encode closely related 210 kD fusion proteins (p210). In contrast, in Ph chromosome-positive (Ph+) B-ALL, 50–65 % of the *BCR* breakpoints arise at the minor breakpoint cluster region (m-bcr), adjacent to exons 1 and 2 of *BCR*, with the *BCR–ABL1* transcript containing the e1a2 junction, which is translated into the p190 BCR-ABL1 fusion protein. Rarely, usually in CML with monocytosis and neutrophilia, the breakpoint occurs in the μ-BCR region (exons 17–20), resulting in a larger p230 fusion BCR-ABL1 protein.

The *BCR–ABL1* fusion gene can be detected by several methods. The Ph chromosome can be visualized by conventional G-banded karyotyping with a false-negative rate of <10 %, which is usually related to more complex fusions that obscure the breakpoints involved. However, karyotyping has a low sensitivity that is not acceptable for minimal residual disease (MRD) monitoring given that only 20 metaphases are usually analyzed (i.e., a maximal sensitivity of 5 %).

Fluorescence in situ hybridization (FISH) on interphase cells is another method to detect the *BCR–ABL1* fusion (Fig. 44.1). Dual-color, dual-fusion probes are typically used and can identify variant breakpoints or three-way translocations that do not result in recognizable Ph+ metaphases. Given an adequate sample, the false-negative rate for FISH is much less than 1 %. The use of FISH for MRD monitoring after completion of therapy is more limited given that the maximal sensitivity is approximately 1 % Ph+ cells, given that only several hundred cells are typically counted [16].

Other molecular methods can be used for detecting *BCR–ABL1* fusions, including PCR from genomic DNA, Southern blotting, or northern blotting. However, the vast majority of clinical molecular laboratories detect the *BCR–ABL1* fusion gene by reverse transcription polymerase chain reaction (RT-PCR). Qualitative RT-PCR has been largely replaced by quantitative/real-time PCR (RT-qPCR) methods using an allele-specific PCR approach with primers directed separately against the M-bcr and m-bcr regions (p210 and p190 isoforms, respectively).

BCR–ABL1 RT-PCR Assay Standardization and the International Scale

Essentially all RT-qPCR *BCR–ABL1* assays normalize the amount of fusion transcript to the level of a control transcript to allow comparison across different levels of input positive cells. This approach also permits assessment of RNA quality, because low levels of the control gene likely indicate a degraded sample. Commonly used genes for normalization include *GAPDH*, *ACTB*, *BCR*, *GUSB*, and *ABL1* [17]. These control genes are expressed at very different levels resulting in highly variable *BCR–ABL1* fusion to control transcript values. This variability between assays using different control transcripts makes comparison of results from different laboratories difficult. Additionally, laboratories use a variety of RNA extraction methods, different reverse transcription protocols, and have different reporting criteria.

Standardization of RT-qPCR assays has become a high priority because molecular milestones of *BCR–ABL1* transcript levels are now the basis of treatment decision-making for CML. The first advance in standardization, led by the Europe Against Cancer (EAC) initiative, was the development of well-validated RT-qPCR primers and probes, as well as standardized PCR conditions for *BCR–ABL1* assays [18]. The second effort, beginning with the European LeukemiaNet collaborative, developed consensus on measurement of therapeutic milestones in CML (Table 44.5) [19]. This effort reached fruition in 2012 and established the International Scale (IS) whereby individual laboratories could adjust their internal *BCR–ABL1*/control transcript ratios to the molecular milestones based on standard calibrators [20, 21].

Table 44.5 Definitions and therapeutic milestones for *BCR–ABL1* disease response

Definitions		
Complete hematologic response (CHR)	WBC count < 10×10^9/L	
	Normal WBC differential	
	≤1% circulating immature cells	
	Platelet count < 450×10^9/L	
	No signs and symptoms of CML	
Major molecular response (MMR)	>3-log reduction in *BCR–ABL1* transcript levels (0.1 % IS)	
Complete molecular response (CMR)	PCR negative	
Complete cytogenetic response (CCyR)	No Ph detected	
Partial/major cytogenetic response (PCyR)	1–35 % Ph+ cells	
Therapeutic milestones	**Suboptimal**	**Failure**
3 months on therapy	Less than CHR	No HR
6 months	Less than PCyR	Less than CHR
12 months	Less than CCyR	Less than PCyR
	Not approaching MMR	
18 months	Less than MMR	Less than CCyR

Ph Philadelphia chromosome, *WBC* white blood cell
Guidelines as reported in [19]

Therapy and Treatment Response Monitoring in CML

With an understanding of the molecular basis of CML, the design and synthesis of small molecules that could inhibit the kinase activity of ABL1 was attempted. This resulted in US Food and Drug Administration (FDA) approval of the kinase inhibitor imatinib mesylate (also called ST1571) in 1999. Before the discovery of imatinib, the widely used therapeutic options for CML were interferon-α with or without cytarabine, hydroxyurea, or allogeneic stem cell transplant (ASCT). With results first published in 2003, the pivotal International Randomized Interferon vs ST1571 (IRIS) study established imatinib as the frontline therapy for newly diagnosed CML, with superior responses and compliance rates compared to interferon/cytarabine [22, 23]. Subsequently, second generation tyrosine kinase inhibitors (TKI) that successfully target BCR-ABL1 were introduced, particularly nilotinib and dasatinib that were both approved as frontline therapy by the FDA in 2010.

Most patients with CML show excellent response to imatinib, with progression-free survival rates at 5 years of >90 %. However, periodic RT-qPCR *BCR–ABL1* testing every 3–6 months during treatment is warranted to monitor for primary or secondary drug resistance. In patients with CML, blood and BM samples show similar levels of *BCR–ABL1* transcript, but testing of blood is preferred due to the ease of collection. While receiving imatinib, most patients quickly show hematologic remission, defined as resolution of leukocytosis, as indicated by a WBC count below 10×10^9/L with a normal differential and ≤1 % circulating immature cells, a platelet count below 450×10^9/L, and disappearance of signs and symptoms of disease, including splenomegaly. On standard dose imatinib, most patients experience hematologic remission within 4–12 weeks. For those patients being monitored by karyotyping, complete cytogenetic response, defined as 0 % Ph+ metaphases when at least 20 cells have been examined, is usually achieved before 12 months. Partial (1–35 % Ph+ metaphases), and especially minor cytogenetic responses (36–95 % Ph+ metaphases) are indicative of suboptimal therapy or drug resistance (Table 44.5).

The primary therapeutic endpoint for CML treatment is a major molecular remission (MMR) defined as a *BCR–ABL1*/control transcript IS ratio below 0.1 %. This IS target was originally established by the IRIS study in which optimal response was defined as at least a three-log decrease in the *BCR–ABL1/ABL1* transcript ratio from the 100 % value that was the median pretreatment level. With the advent of IS calibration, patient-specific responses can now be defined. In many patients on imatinib, complete molecular response can be achieved, such that no *BCR–ABL1* transcripts are detected with an assay that has a diagnostic sensitivity of at least 0.005 % (IS).

Optimally, MMR is achieved within 12–18 months of beginning a TKI. During this initial period, RT-qPCR using peripheral blood is recommended every 3 months, and is usually performed less frequently (every 6–12 months) after MMR is achieved. Cytogenetic testing should be performed at 6 months, 12 months, and possibly 18 months if Ph+ chromosomes are still detected. FISH may serve as a useful surrogate marker of disease level when chromosome analysis does not yield adequate metaphase preparations. Recent studies, including a follow-up on the IRIS trial, have demonstrated that attaining MMR at earlier time points results in improved outcomes in CML [23, 24].

Resistance in CML and Detection of ABL1 Kinase Domain Mutations

When a patient with CML does not meet the milestones for optimal therapeutic response, changes to the treatment regimen must be considered. The first step in the workup of TKI resistance is usually to repeat the RT-qPCR test to confirm the level of residual *BCR–ABL1* transcript, followed by DNA sequencing of the ABL1 kinase domain to assess for the presence of mutations. While ABL1 kinase mutations are the most common cause of resistance, other *BCR–ABL1*-dependent mechanisms of resistance include amplification or additional copies of the Ph chromosome, which can be detected by FISH, and pharmacodynamic factors which inhibit drug effects. Overcoming these factors may be achieved by TKI dose escalation [25]. Imatinib resistance also can be due to *BCR–ABL1* mutation-independent mechanisms (Table 44.6) such as clonal evolution due to *ASXL1*, *IZKF1*, or *RUNX1* mutations [29, 30], *TP53* deletion, or acquisition of AML-type genetic changes [31], which may be detected by a BM karyotyping.

Approximately 50 % of patients displaying secondary TKI resistance in CML, as shown by increasing RT-qPCR

Table 44.6 Testing indicated for drug-resistant CML

Test	Findings	Reference/ guidelines
Bone marrow morphology	Increased blasts, basophils, fibrosis	[19]
Karyotype	Secondary genetic changes, especially del17p/TP53	[26]
ABL kinase domain sequencing	>70 different amino acids in kinase domain, lead to variable upregulation or insensitivity to kinase inhibition	[27, 28]
BCR–ABL1 FISH	Amplification/extra copies of Philadelphia chromosome	[26]
RUNX1, *IZKF1*, or *ASXL1* mutation status	Maturation arrest with blast crisis	[29, 30]

FISH fluorescence in situ hybridization

levels after achieving MMR, will have a mutation in the ABL1 kinase domain [28]. More than 150 different mutations involving over 60 different amino acid residues have been documented in the ABL1 kinase domain. However, 15 *ABL1* mutations account for >85 % of cases [32], with mutations in the T315I gatekeeper and in the P-loop domain most consistently associated with adverse outcomes (Fig. 44.2). The in vivo sensitivity to different kinase inhibitors is largely predicted by response of model cell lines harboring these mutations [33]. Studies of this type have identified the common G250E mutation as being resistant to imatinib, but not to the second generation inhibitors dasatinib and nilotinib, whereas other mutations tend to be resistant to dasatinib but not nilotinib (e.g., T315A, F317L/I/V, and V299L) or to nilotinib but not dasatinib (e.g., Y253H, E255K/V, and F359V/C). The T315I ABL1 kinase domain mutation is resistant to most small molecule inhibitors [34]. Patients with T315I-mutated CML often progress to blast phase and require chemotherapy and ASCT, although some biologic therapies, such as homoharringtonine [35], and third generation kinase inhibitors, such as ponatinib/AP24534 [36], show promise.

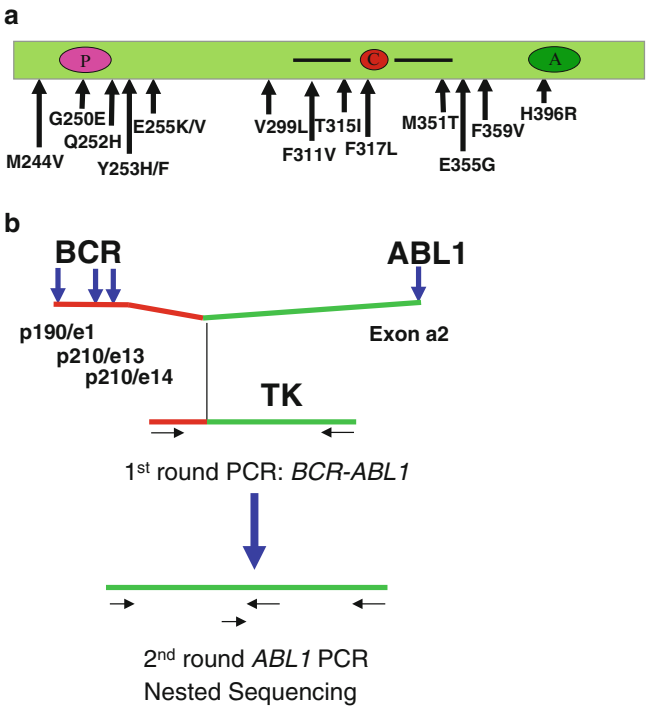

Figure 44.2 *ABL1* mutation in drug-resistant CML. (**a**) Schematic of the ABL1 kinase domain, with P-loop (P), catalytic domain (C), and activation domain (A) indicated. The locations of the 15 most commonly mutated amino acid residues are indicated. (**b**) Schematic of t(9;22) translocation breakpoints with a strategy for two step PCR amplification of the *BCR–ABL1* fusion transcript, followed by amplification of the *ABL1* tyrosine kinase (TK) domain using several primer sets (*black arrows*) prior to sequencing

Several molecular tests detect ABL1 mutations, with the most common being Sanger sequencing to assess the entire kinase domain in one or two cycling reactions [27]. As an initial step, the *BCR–ABL1* fusion gene is specifically amplified (Fig. 44.2b), because residual leukemic cells may only represent a small portion of leukocytes, and Sanger sequencing is not sufficiently sensitive to detect rare mutated transcripts. A more sensitive but more directed approach is to perform mutation-specific real-time PCR reactions to detect the most commonly observed mutations.

Recommendations for when to perform mutation testing of the ABL1 kinase domain vary between different centers. A conservative approach is to trigger testing whenever there is loss of hematologic or complete cytogenetic remission, unexpected cytopenias, or a greater than ten-fold rise in *BCR–ABL1* transcript levels above MMR [27].

Essential Thrombocythemia, Primary Myelofibrosis, and Polycythemia Vera

Both qualitative and quantitative methods are used to detect the common V617F mutation (Fig. 44.3), whereas Sanger sequencing is used to detect the less common *JAK2* exon 12 mutations as well as mutations in *CALR*, *MPL* and *CSF3R*. Testing for *JAK2* V617F is recommended in the initial workup of all suspected MPNs, along with erythropoietin levels for suspected PV, *BCR–ABL1* testing for all cases with

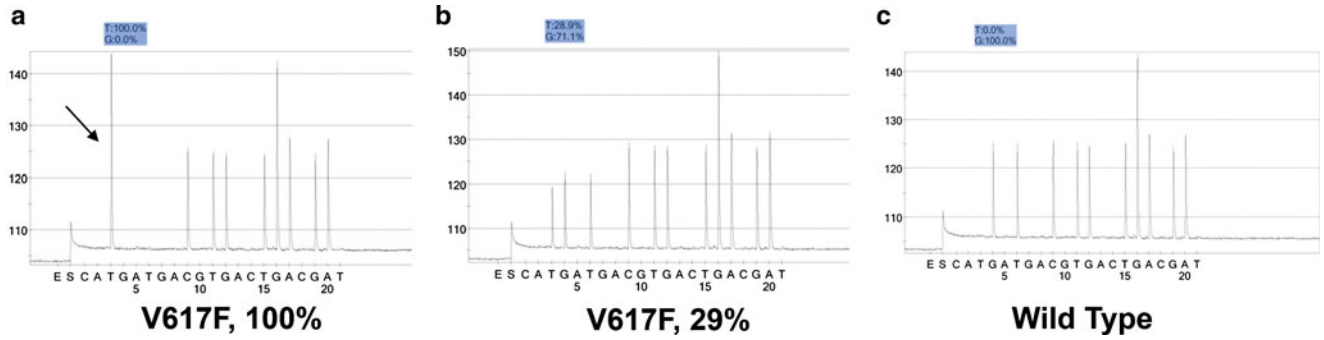

Figure 44.3 *JAK2* mutation detection by pyrosequencing assay. Cases with homozygous V617F mutations (**a**, *arrow* showing T allele), heterozygous mutated and wild type sequences (**b**, both T and G alleles), and wild type results (**c**, only G allele) are illustrated

neutrophilia (especially if accompanied by basophilia or eosinophilia), and BM evaluation for suspected ET or PMF.

Although some therapies for *JAK2*-mutated MPNs, such as lenalidomide and interferon, produce selective decreases in the *JAK2* mutation burden, monitoring *JAK2* mutation levels after therapy is not yet as routine as for CML. Quantitative *JAK2* testing is probably most useful for monitoring for relapse of MPNs after ASCT, and in monitoring of *JAK2* kinase inhibitors [7], most of which are still investigational. Because pathogenic mutations in *JAK2*, *CALR*, *MPL*, and *CSF3R* all affect signaling through the JAK-STAT pathway and may all be candidates for JAK inhibitor therapies, a panel approach for testing has been proposed for newly diagnosed MPNs [37]. Advanced sequencing technologies would thus be an appealing approach for such multigene testing.

Myelodysplastic Syndrome

Cytogenetic Analysis for Diagnosis and Prognosis in MDS

With the exception of one distinctive cytogenetically defined entity (refractory anemia with isolated 5q-), MDS is currently classified in the WHO system based on the number of myeloblasts and whether one or several of the myeloid, monocytic, erythroid, or megakaryocytic lineages are clearly dysplastic (Table 44.2). Because appreciation of morphologic changes in the BM can be difficult, cytogenetic studies are always done to identify the complex genomic changes associated with MDS and to support the diagnosis. Recently, multiprobe FISH panels, which assess the presence or absence of common changes such as del5q/-5, del7q/-7, +8, and del20q, are increasingly being used to supplement karyotyping although their added value remains unclear [38, 39].

Common and less common cytogenetic aberrations in MDS have been used along with hematologic criteria to stratify cases of MDS into low, moderate, and high risk for poor outcome and progression to high-grade MDS/AML (Table 44.7). The most commonly used schema is the International Prognostic Scoring System (IPSS), which was recently revised to add several additional cytogenetic changes (Table 44.8). Although FISH assays are becoming more common for MDS (Fig. 44.4), detection of these aberrations by FISH (especially at low percentages) rather than karyotype may not have the same prognostic significance for the IPSS. Genomic microarrays provide additional gene-based information compared to karyotype and may soon supplement conventional karyotyping in the workup of MDS [41].

Common Somatic Mutations in MDS

At least half of suspected MDS cases have no cytogenetic abnormalities identified by chromosome analysis. In such cases FISH panels typically detect only a few, if any, additional aberrations. Many of these cases will have only mild dysplasia. In these instances, the distinction between a reactive condition and MDS can be difficult, and may only be established after extensive testing and exclusion of all other possible etiologies. Demonstration of clonality within blood or BM cells could more rapidly and definitively offer a diagnosis of MDS.

Several genes that are commonly mutated in MDS have been identified by genomic sequencing. These genes include *TET2*, *IDH1*, *IDH2*, *ASXL1*, *SF3B1*, *DNMT3A*, *EZH2*, and *LNK* (Table 44.9). The mutation types vary and include

Table 44.7 Cytogenetic prognostic subgroups in the revised International Prognostic Scoring System (IPSS-R)

Risk group	Karyotypic findings
Very good	del(11q), -Y
Good	XX/XY, del(20q), del(5q) alone and double, del(12p)
Intermediate	+8, 7q-, i(17q),+19,+21, any other single or double, independent clones
Poor	der(3)q21/q26, -7, double including 7q-, complex changes (3 abnormalities)
Very poor	complex changes (>3 abnormalities)

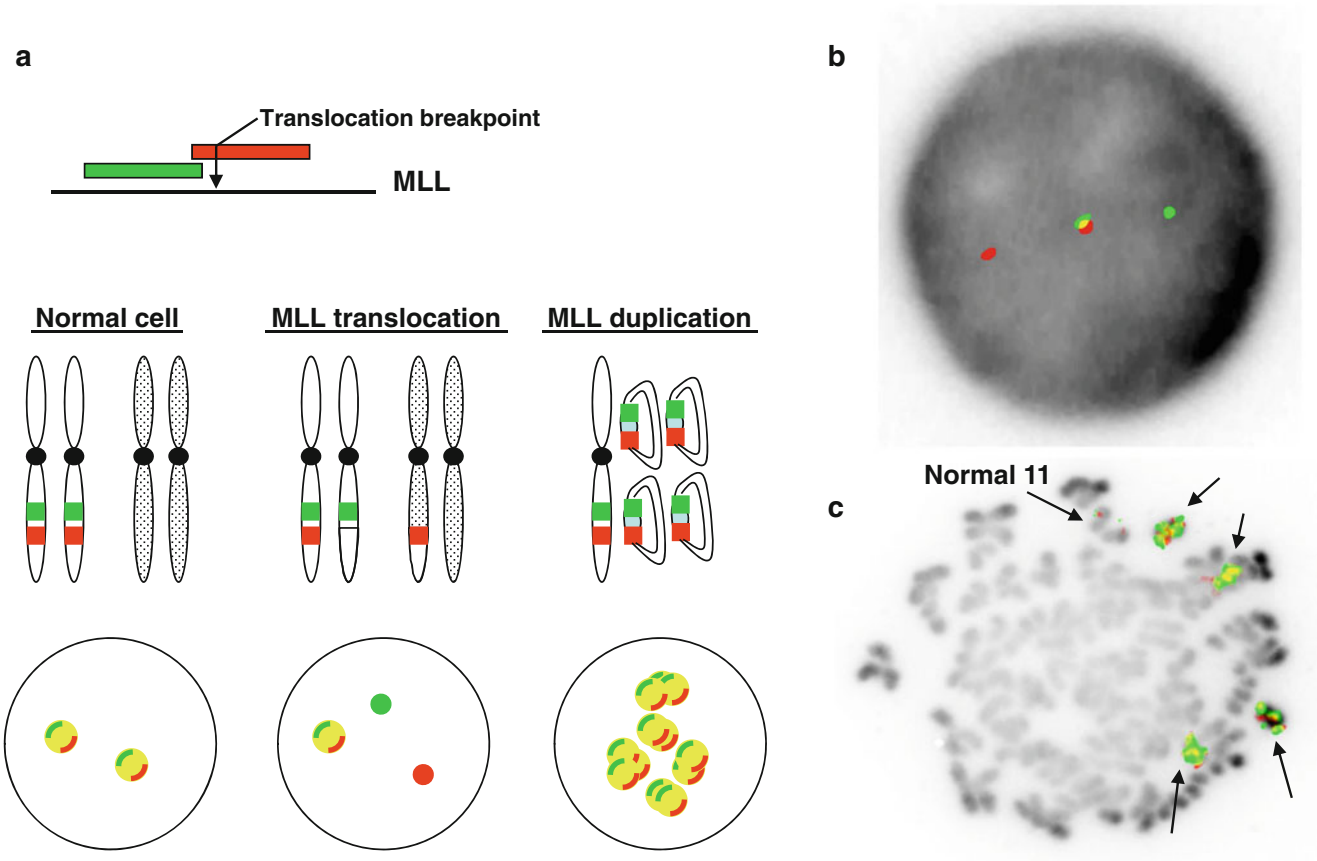

Figure 44.4 *MLL* alterations in MDS and AML. (**a**) Schematic of dual break-apart fluorescence in situ hybridization (FISH) strategy for *MLL* at chromosome 11q23. A green-labeled probe is used for the 5′ exons of *MLL*, with an orange-labeled probe for the 3′ exons with an overlap at exon 6. (**b**) Findings in an interphase cell in an MDS case with a split probe for one copy of the *MLL* gene, indicative of an *MLL* translocation. (**c**) FISH performed on a metaphase spread in a case of AML reveals *MLL* gene amplification associated with ring chromosomes

Table 44.9 Divergent and common molecular pathogenesis of MPNs and MDS

Gene	Mutation % in MPNs (excluding CML)	Mutation % in MDS	Function
Growth regulators			
JAK2	50 %, including ~100 % of PV	2–3 %	Kinase downstream of cytokine receptors
MPL	2–3 %	<1 %	Cytokine receptor
PGFRA	2 %	ns	RTK
PGFRB	<1 %	<1 %	RTK
FGFR1	1–2 %	ns	RTK
CBL	ns	ns	RTK negative regulator
Transcriptional and epigenetic regulators			
TET2	10–30 %; 50 % of CMML, 30 % of SM	25–30 %	Catalyzes conversion of 5-methylcytosine to 5-hydroxymethylcytosine
IDH1–IDH2	1–5 %	5–10 %	Isocitrate dehydrogenase; converts isocitrate to 2-ketoglutarate, TET2 co-regulation
DNMT3A	5–10 %	5–10 %	DNA cytosine methyltransferase
EZH2	3–7 %	5–10 %	Histone methyltransferase complex protein
ASXL1	3–15 %	10–15 %	Transcriptional repression of HOX genes

CML chronic myelogenous leukemia, *CMML* chronic myelomonocytic leukemia, *MDS* myelodysplastic syndrome, *MPN* myeloproliferative neoplasm, *ns* not present or insufficient data, *PV* polycythemia vera, *RTK* receptor tyrosine kinase inhibitor, *SM* systemic mastocytosis

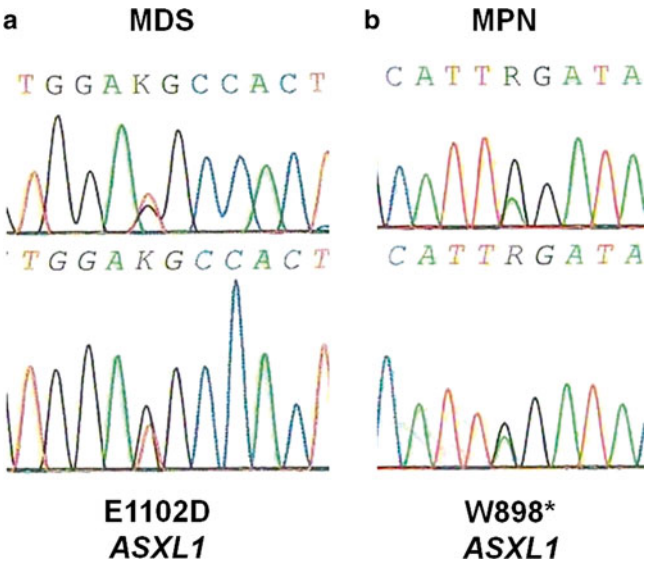

Figure 44.5 Similar mutation profiles in myelodysplastic syndrome and myeloproliferative neoplasms. (**a**) A sequence tracing of the E1102D heterozygous missense mutation in the *ASXL1* gene, in a patient with myelodysplastic syndrome (MDS). (**b**) A nonsense mutation in *ASXL1* (W898*) in a myeloproliferative neoplasm (MPN)

deletions, insertions, missense mutations (Fig. 44.5a), nonsense mutations (Fig. 44.5b), as well as frameshift mutations, and can either be clustered in hotspots or distributed throughout the gene. Detection of any of these mutations can help establish a diagnosis of MDS in patients who otherwise have negative tests. The next generation of risk stratification for MDS has begun to incorporate gene mutations into multivariate outcome prediction models [42–44].

Conclusions and Future Directions

The function of many of the most frequently mutated genes in MDS involves the epigenetic regulation of transcriptional complexes involved in hematopoiesis. For these genes, mutations at several different loci, such as *EZH2*, *TET2*, and *DNMT3A*, can be found in the same tumor. This is in contrast to the essentially mutually exclusive nature of mutations involving cytokine and growth factor genes, such as *BCR–ABL1* or *JAK2*. Another feature of the epigenetic class of genes is that they are commonly mutated in AML as well as in MDS and MPNs (Table 44.9). Taken together; these findings suggest that myeloid neoplasms have a shared pathogenesis involving multifocal dysregulation of the epigenetic program. Given that many new classes of therapeutic agents, including deacetylase inhibitors and hypomethylating agents, target these complexes, it seems likely that detection of these mutations will become critical to individualizing therapy in both MDS and MPNs.

Abstract

HIV-1 quantitative viral load testing and genotypic resistance testing comprise the core aspects of the monitoring of HIV-infected patients on a longitudinal basis. The development of these assays and the clinical interpretation and use of these assays has evolved over decades since 1996 into the current state of practice. Initial uses of viral load testing involved prognostication, followed by the use of viral loads as a marker of response to antiretroviral therapy. Qualitative viral load testing can be used for diagnosis, and proviral DNA assays are used in the diagnosis of HIV in newborns born to HIV-infected mothers. Mutations in the HIV-1 genome were determined to imply resistance or susceptibility to antiretroviral treatment. Genotypic resistance testing correlates these mutations with previously known drug mutations. Phenotypic testing involves the creation of a pseudoviral vector and its performance in the presence of different antiretroviral drugs. Issues surrounding these diagnostic tests, including sample types, assay characteristics, and interpretation of results are delineated in this chapter.

Keywords

HIV-1 • Viral load • Quantitative • Genotypic resistance testing • Resistance testing

Description of the Pathogen

Human immunodeficiency virus types 1 and 2 (HIV-1 and HIV-2), the causative agents of the acquired immunodeficiency syndrome (AIDS), are RNA viruses belonging to the genus *Lentivirus* of the family *Retroviridae* [1]. The replication of all retroviruses involves reverse transcription of the RNA genome into a double-stranded DNA molecule, with subsequent integration into the host genome as proviral DNA. Given this replicative cycle, molecular tests used in the diagnosis and management of HIV-1 infection target either HIV-1 RNA or proviral DNA.

HIV-1 is classified into three distinct genetic groups: M (major), O (outlier), and N (nonmajor and nonoutlier). Viruses in the M group are further divided into eight subtypes (formerly called clades), A–G, H–K, and N–P, and at least 55 circulating recombinant forms (CRFs) as described by the Los Alamos National Laboratory based on the

sequence diversity within the HIV-1 *gag* and *env* genes [1, 2]. The nucleotide sequence of the *env* gene may differ by as much as 25 % among the different subtypes, while viruses within the same subtype generally differ by less than 15 % [1]. Group M virus is found worldwide, with subtype B predominating in Europe and North America, while subtype C predominates in Africa and India. The genetic diversity of HIV-1 plays an important role in the design and interpretation of RNA viral load and genotypic resistance tests.

Clinical Utility

The uses of molecular tests in the clinical management of individuals with HIV-1 infection include the diagnosis of HIV-1 infection, and monitoring response to antiretroviral therapy (ART). The clinical utility of HIV-1 viral load testing, which refers to the quantification of HIV-1 RNA in the blood of infected individuals, has been well studied. Given the availability of commercial test kits, HIV-1 RNA viral load testing has become the standard of care in the clinical management of HIV-infected individuals. HIV-1 RNA viral load is a strong predictor of the rate of progression to AIDS that is independent of CD4 cell count and other factors. Regression models have shown that HIV-1 RNA viral load alone explains half of the variability in prediction of the onset of AIDS and death [3, 4].

Diagnosis of Acute HIV-1 Infection

HIV-1 RNA testing is useful in the diagnosis of acute HIV-1 infection, and a qualitative RNA assay (Aptima, Gen-Probe Incorporated, San Diego) has been approved by the US Food and Drug Administration (FDA) for diagnostic use. Quantitative HIV-1 RNA viral load tests are not approved for the diagnosis of acute HIV-1 infection, and should be specifically validated by the individual laboratory for diagnosis of acute infection, if used for this indication. Acute HIV-1 infection, also referred to as acute retroviral syndrome, has a "window period" after exposure to the virus and prior to seroconversion, when the ELISA and western blot tests are negative or indeterminate [5]. During the window period, patients often are symptomatic with a mononucleosis-type syndrome, which may include fever, fatigue, rash, lymphadenopathy, and oral ulcers [5]. During acute HIV-1 infection, RNA levels are very high in the peripheral blood, usually 10^5–10^7 copies/ml of plasma, making viral load measurement a very useful diagnostic tool; however, if an individual is tested within days to weeks of exposure to HIV-1, the RNA levels may be lower.

The updated algorithm for HIV diagnosis from the Centers for Disease Control and Prevention (CDC) will include initial screening with a third or fourth generation serologic test (HIV1/HIV2 enzyme immunoassay, EIA), followed by an HIV1/HIV2 discriminatory test. In this algorithm, if the initial EIA is positive, but the discriminatory test is negative, the recommended follow up is HIV-1 RNA testing. The fourth generation EIA tests simultaneously detect both p24 antigen and HIV-1 antibody, which narrows the window period and yields a positive test 20 days prior to western blot. The third generation EIA tests detect antibody only and are positive approximately 15 days prior to western blot. The downside of using nucleic acid amplification testing to diagnose acute HIV-1 infection is the potential for false-positive results, which should be suspected if the viral load is <10,000 copies/ml in an individual thought to be acutely infected. To minimize the likelihood of reporting a false-positive result, an HIV1/2 EIA also should be obtained at the time of HIV-1 RNA testing, and repeat RNA and EIA testing should be obtained on all patients within 1–2 weeks. Requiring laboratory approval for using HIV-1 quantitative RNA viral load testing for diagnosis of acute HIV-1 infection is a prudent approach to ensure that the patient has signs and symptoms consistent with acute HIV-1 infection prior to testing.

Diagnosis of HIV-1 Infection in Neonates

Molecular tests are crucial for the diagnosis of HIV-1 infection in neonates, since all infants born to HIV-1 infected mothers remain seropositive into the second year of life due to transfer of maternal immunoglobulin G (IgG) across the placenta. Studies have established the utility of both qualitative proviral DNA and RNA viral load testing for the diagnosis of HIV-1 infection in newborns [6–8]. Current guidelines for the diagnosis of neonatal HIV-1 infection recommend that the molecular testing be performed at ages 14–21 days, 1–2 months, and 4–6 months, with two positive tests obtained separately providing confirmation of HIV-1 infection [9]. Virologic testing also should be performed at birth if the infant is considered at high risk of HIV-1 infection (e.g., mother's HIV-1 viral load not suppressed, or mother is not on ART).

Antiretroviral Therapy Initiation and Monitoring

Clinical guidelines have been established for the initiation of ART [9], and viral load levels are among the parameters used in this decision. After initiation of ART, the goal is to achieve the lowest RNA viral load (usually below the limit of detection of the assay), as this has been shown to correlate with better clinical and virologic outcomes [10, 11].

The classes of antiretroviral drugs that are used in clinical care include: nucleoside reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), entry inhibitors, integrase inhibitors (INSTI), fusion inhibitors, and CCR5 inhibitors (http://www.aidsmeds.com/). The current standard from the Department of Health and Human Services (DHHS) Panel on Antiretroviral Guidelines for treating HIV-1 infected individuals is two NRTIs in combination with either a PI, NNRTI, or integrase inhibitor [9]. In general, a plasma HIV-1 RNA level should be measured at baseline, immediately before beginning therapy, and 2–8 weeks after the start of therapy to determine the initial response [9]. In order to evaluate continued effectiveness of the regimen, testing should be repeated every 3–4 months.

Antiretroviral Therapy Regimen Selection

The replication cycle of HIV-1 is error prone because the reverse transcriptase (RT) does not have proofreading activity [12]. As a result, about one error occurs with each replicative cycle. This error rate coupled with a replication rate that produces about one billion viral particles per day gives rise to a viral "quasispecies." The virus that an individual acquires during transmission may be a strain of HIV-1 with multiple resistance mutations resulting in treatment resistance even prior to initiation of their own treatment with ART [13]. HIV-1 drug resistance also occurs in patients on ART when viral replication is not maximally suppressed to undetectable. These scenarios have led to the recommendations that individuals undergo HIV-1 genotypic resistance testing prior to initiation of therapy and with virologic failure (HIV-1 viral load >1,000 copies/ml) while on ART [9].

The clinical utility of genotypic resistance testing in the management of HIV-1-infected individuals has been studied in several clinical trials [14–16]. These studies demonstrated that genotypic resistance testing is a useful tool in selecting active drugs when changing ART due to virologic failure [9]. The two main types of HIV-1 resistance testing are genotypic resistance testing and phenotypic resistance testing. The regions of the viral genome that are sequenced for HIV-1 genotypic testing include portions of the RT and protease (PR) genes, which correspond to regions with mutations induced in response to therapy with NRTIs, NNRTIs, and PIs. Typically for ART-naive individuals, sequencing of these regions is adequate to detect the important mutations; however, if the patient is on a newer drug, such as an INSTI, then the standard genotypic resistance testing should be supplemented with sequencing of the integrase gene for mutations related to INSTI. HIV-1 phenotypic resistance testing also can be performed on patients with virologic failure on ART to determine which new ART is predicted to be most effective. Phenotypic resistance testing is less preferred given the longer turnaround time and increased expense of this test that involves the creation of a laboratory-modified virus containing portions of the patient's virus that is cultured in the presence of various antiretroviral drug concentrations. Therefore, phenotypic resistance testing is typically reserved for use for individuals with complex mutations where HIV-1 genotypic resistance testing is difficult to interpret for prediction of drug response.

The class of drugs known as CCR5 inhibitors are effective in individuals if their HIV-1 uses CCR5 (and not CXCR4) as a co-receptor to CD4 for entry into target cells [17]. Prior to initiating treatment with a CCR5 inhibitor, the patient's virus must be analyzed to determine whether it is tropic for CCR5, CXCR4, or both. A tropism assay is performed and the results are used to determine whether the patient is a candidate for use of this drug class. If a patient's virus utilizes both, or only CXCR4, the patient would not be a candidate for the CCR5 inhibitor class of ART.

Available Assays

Qualitative HIV-1 RNA and DNA Assays

The APTIMA® HIV-1 RNA Qualitative Assay (Genprobe, San Diego, CA), is the first nucleic acid test US FDA-approved for the diagnosis of HIV-1 infection and can be used to diagnose neonatal HIV-1 infection and acute HIV-1 infection, confirm a repeatedly positive antibody screen, or resolve indeterminate western blots results. The test requires 500 µl of plasma that can be collected in EDTA, acid citrate dextrose, sodium citrate, or in plasma preparation tubes (PPTs). The test is manual, and amplifies and detects the 5′ long terminal repeat (LTR) and pol gene of the HIV-1 genome. This assay detects all HIV-1 group M, N, and O viruses, has a limit of detection (LOD) of 30 copies/ml with a specificity of 99.8 %. An advantage of the APTIMA test is detection of RNA 12 days earlier than EIA detection of antibody and 6 days earlier than testing for p24 antigen (package insert).

Qualitative proviral DNA assays can be used primarily for the diagnosis of neonatal or acute HIV-1 infections. Due to the limited availability of commercial proviral DNA assays, many laboratories have developed their own tests using either standard or real-time amplification methods. The performance characteristics of laboratory developed assays can vary, and performance characteristics to consider include sensitivity, specificity, reproducibility, and the ability to detect non-B subtypes of HIV-1 proviral DNA. A qualitative test is also available that is Research Use Only by Roche, which detects both HIV RNA and DNA, the COBAS® AmpliPrep/COBAS® TaqMan® HIV-1 Qualitative Test, version 2.0. This can detect HIV-1 RNA and proviral DNA in plasma, anticoagulated fresh whole blood, and dried blood spots.

Table 45.1 US FDA-approved HIV-1 viral load tests

Test	Method	Target	Specimen volume[a]	Range
Amplicor HIV-1 Monitor® version 1.5 (Roche Diagnostics Indianapolis, IN)	RT-PCR	HIV-1 *gag* gene		
Standard			200 µl	400–750,000 copies/mL
Ultrasensitive			500 µl	50–100,000 copies/mL
COBAS® Amplicor HIV-1 Monitor version 1.5 (Roche Diagnostics, Indianapolis, IN)	RT-PCR	HIV-1 *gag* gene		
Standard			200 µl	400–750,000 copies/mL
Ultrasensitive			500 µl	50–100,000 copies/mL
COBAS® AmpliPrep/COBAS® Amplicor HIV-1 Monitor version 1.5	RT-PCR	HIV-1 *gag* gene		
Standard			250 µl	500–1,000,000 copies/mL
Ultrasensitive			750 µl	50–100,000 copies/mL
Versant® HIV-1 RNA 3.0 (bDNA) (Siemens Healthcare Diagnostics)	Branched DNA	HIV-1 *pol* gene	1 mL	75–500,000 copies/mL
COBAS® AmpliPrep/COBAS® TaqMan® HIV-1 Test (Roche Diagnostics, Indianapolis, IN)	RT-qPCR			
v 1.0		HIV-1 *gag* gene	1 mL	48–10,000,000 copies/mL
v 2.0		HIV-1 *gag* gene and LTR	1 mL	20–10,000,000 copies/mL
RealTime Taqman® HIV-1 (Abbott Molecular)	RT-qPCR	HIV-1 integrase gene	1 mL	40–10,000,000 copies/mL

RT-PCR reverse transcription-polymerase chain reaction, *RT-qPCR* reverse transcription-quantitative polymerase chain reaction
[a]For tests that use an automated extraction instrument (AmpliPrep and RealTime), the specimen volume listed refers to the volume of sample that is loaded on the instrument, which is greater than the actual volume of specimen taken through the extraction

Viral Load Assays

Currently, six US FDA-approved tests are available for the quantification of HIV-1 RNA from plasma specimens. These assays differ in their limit of detection, linear range, gene target, and input plasma volume (Table 45.1). The earliest available viral load tests (Amplicor Monitor and Versant bDNA) have essentially been replaced by the real-time quantitative reverse-transcriptase PCR (RT-qPCR) tests. The RT-qPCR assays that are approved by the US FDA offer several advantages over the earliest available viral load assays, including more extensive automation, broader linear range, and decreased risk of carryover amplicon contamination due to their automation and closed tube system. The lower limit of quantification is an important characteristic of all viral load assays and is defined as the lowest amount of nucleic acid that can be quantified with "acceptable precision." RT-qPCR tests can have a LOD as low as 20–40 copies/mL; this is achieved due to a larger sample input plasma volume, usually approximately 1 mL. The two US FDA-approved RT-qPCR tests have good correlation and agreement between viral load values, with mean/median differences in viral load values ranging from 0.22 to 0.56 $\log_{10}$ copies/ml depending on the subtype of the samples [18–20]. On average, there is very good agreement between the different viral load tests, but caution should be used when switching viral load tests for management of an individual patient since the differences in viral load values may be significant and could lead to different management decisions [21]. For example, a patient whose viral load becomes detectable upon switching tests when they were previously suppressed would be considered to have failed therapy, when in fact the change in viral load was due to a difference in the test sensitivity. Although agreement in viral load values with the different tests is improving, the same viral load test should be used when monitoring patients over time, and, if the viral load test is changed, then a new baseline viral load should be obtained.

Increasing genetic diversity of HIV-1 isolates from individuals in the USA has been reported, primarily from those who have immigrated from Africa and Asia [22, 23], so detection of non-B subtypes is taking on increased importance. The RT-qPCR tests were intentionally designed to detect not only non-B subtypes but also many CRFs. The COBAS Taqman version 1 test measures all subtypes of group M and N viruses and many CRFs [24], while the recently approved version 2 test has improved quantification of CRFs and of Group O virus. The Abbott RealTime test quantifies all group M, N, and O viruses, and CRFs [25, 26].

Ongoing international surveillance of HIV-1 isolates ensures that these assays maintain their ability to detect evolving viral genetic diversity, which occurs because of the high recombination activity within the HIV-1 subtypes and CRFs [27].

Proper collection and processing of blood samples are essential to ensure accurate assessment of viral load levels; the key is to minimize RNA degradation. For conventional and RT-qPCR assays, EDTA is the preferred anticoagulant for blood collection, and the plasma must be separated from blood cells within 4–6 h of collection, as delays in processing may lead to a falsely decreased viral load value. Plasma specimens can be stored at 4 °C for several days without significant degradation of RNA, and HIV-1 RNA has been shown to remain stable after three cycles of freezing (−70 °C) and thawing [28]. For long term storage, plasma samples should be frozen at or below −70 °C [29]. Vacutainer PPTs may be acceptable for the collection of blood specimens for viral load testing, but this specimen type must be validated by the individual laboratory. The PPTs contain a gel barrier which, after centrifugation, physically separates plasma from the cellular components [30]. Whole blood collected in PPTs can be held at room temperature for as long as 6 h after collection and shipped as plasma (in the original tube) at ambient temperature or on wet or dry ice without affecting the HIV-1 viral load [31]. Freezing PPTs (after separating the plasma) prior to testing can give higher viral load values compared to those obtained when the plasma is separated and stored at 4 °C which is thought to be due to the lysis of cells releasing proviral DNA as well as virions adherent to platelets [32–36]. For this reason freezing specimens in PPTs in situ is not recommended, although Fernandes et al. showed that it could be done when using the Abbott platform, and this is likely due to the additional centrifugation prior to testing [37]. The PPTs provide a closed sample collection system, which is a safe, convenient, and practical approach to shipping specimens collected at sites remote from the laboratory.

Although measuring viral load in plasma is the standard of care in clinical practice, these tests have been adapted for use with other specimens, most notably serum, dried blood spots, cerebrospinal fluid (CSF), seminal fluid or semen, and cervical secretions. When serum specimens are used, the viral load is decreased approximately 50 % compared to plasma [38]. Both whole blood and plasma dried spots can be used for viral load testing; in fact, viral load levels from dried plasma spots are equivalent to those obtained from fresh frozen plasma specimens [39]. Similarly, HIV-1 RNA from dried whole blood spots, corrected for hematocrit (number of spot RNA copies per milliliter of blood)/([100-hematocrit]/100), yields viral load results comparable to those obtained from plasma [40]. HIV-1 RNA in dried plasma spots remains stable for up to 16 days when stored at 4 °C or ambient temperature [41]. RNA from dried blood spots has been shown to be stable up to 1 year at room temperature or cooler [42]. Viral load levels in CSF have been used in the evaluation of patients with AIDS dementia, and if virus is quantified, ART that penetrates into the CSF compartment is chosen for treatment [43].

Drug Resistance Assays

Antiretroviral resistance can be detected using either genotypic or phenotypic assays. HIV-1 genotypic assays identify mutations or changes in the nucleotide sequence known to confer decreased susceptibility to antiretroviral drugs. Phenotypic resistance testing, on the other hand, refers to a viral trait or behavior resulting from the expression of a specific genotype. HIV-1 phenotypic assays measure viral replication in the presence of antiretroviral drugs. Results of phenotypic assays are typically reported as the inhibitory concentration of a drug that reduces in vitro HIV-1 replication by 50 % (IC_{50}). The IC_{50} is usually reported as the fold change in IC_{50} relative to a wild-type strain. A "virtual phenotype" is a test where the results of the genotypic assay are entered into a database containing matching genotypic and phenotypic results from thousands of clinical specimens, and the closest matching phenotypic results are averaged and reported as the virtual phenotype. Studies have demonstrated that the virtual phenotype is equivalent to conventional phenotyping for clinical decision making regarding changes in drug therapy. The virtual phenotype, while useful clinically, is not longer available [44, 45].

Two US FDA-cleared genotypic tests are available that include reagents for sequencing and software programs to assist with sequence alignment and interpretation (Trugene HIV-1 Genotyping Kit and OpenGene DNA Sequencing System, Siemens Healthcare Diagnostics, Tarrytown, NY; ViroSeq HIV-1 Genotyping System, Abbott Molecular, Des Plaines, IL) (Table 45.2). Though the Trugene HIV-1 assay has been widely used and much of our understanding of the clinical utility of HIV genotypic testing has come from studies with this test, effective December 2014 Trugene HIV-1 test is no longer available. HIV-1 RNA is extracted followed by reverse transcription and PCR amplification of the entire PR gene and most of the RT gene, which are sequenced using automated dideoxynucleotide terminator cycle sequencing. The PR and RT gene sequences are analyzed by comparison to a reference sequence (wild type HIV-1 strain) to identify mutations. For patients who have been exposed to INSTI, the HIV-1 integrase genotype (HIV-1 Integrase Inhibitor Resistance by Sequencing; GeneSeq® for Integrase Inhibitors Assay) can be performed by reference laboratories, since the typical genotypic tests only detect mutations in the PR and RT genes not the integrase gene where the INSTI resistance mutations reside.

Table 45.2 Available assays for resistance testing

Assay	Method	Comments
Trugene® HIV-1 Genotyping Kit and Open Gene DNA Sequencing System (Siemens Healthcare Diagnostics)*	Genotypic	US FDA-cleared; Detects protease and reverse transcriptase mutations
Viroseq® HIV-1 Genotyping System (Abbott Molecular)	Genotypic	US FDA-cleared; Detects protease and reverse transcriptase mutations
GeneSeq® for Reverse Transcriptase and Protease Inhibitors Assay (Monogram Biosciences)	Genotypic	Detects protease and reverse transcriptase mutations
GenoSure® MG (Monogram Biosciences)	Genotypic	Detects protease and reverse transcriptase mutations
HIV-1 Genotype, RT and Protease Genes (Quest Diagnostics Nichols Institute)	Genotypic	Detects protease and reverse transcriptase mutations
GeneSeq® for Integrase Inhibitors Assay (Monogram Biosciences)	Genotypic	Detects integrase mutations
HIV-1 Integrase Inhibitor Resistance by Sequencing (ARUP, Salt Lake City, UT)	Genotypic	Detects integrase mutations
PhenoSense®GT (Monogram Biosciences)	Combined genotypic and Phenotypic	Detects protease and reverse transcriptase mutations
PhenoSense™ HIV (for Reverse Transcriptase and Protease Inhibitors) (Monogram Biosciences)	Phenotypic	Detects protease and reverse transcriptase mutations
PhenoSense™ for Entry Inhibitor Susceptibility (Monogram Biosciences)	Phenotypic	Measures susceptibility to entry inhibitors (Fuzeon®)
PhenoSense™ Integrase (Monogram Biosciences)	Phenotypic	Measures susceptibility to integrase inhibitors
Trofile™ Co-receptor Tropism (Monogram Biosciences)	Tropism	Used prior to initiating therapy with maraviroc

*This test is no longer commercially available

Phenotypic assays measure the ability of HIV-1 to replicate in the presence of various concentrations of an antiretroviral drug using high-throughput automated assays based on recombinant DNA technology. The single commercially available assay, PhenoSense (Monogram Biosciences, South San Francisco, CA) (Table 45.2) amplifies the PR and RT genes using RT-PCR and the amplified product is inserted into a modified HIV-1 vector which lacks RT and PR genes and has a luciferase reporter gene inserted into the viral envelope gene. Viral replication, in the presence of various drugs, is measured by quantification of luciferase expression [46] and results are reported as fold-change in IC_{50} compared to a wild-type control. Increases in IC_{50} of greater than 2.5-fold can be reliably detected by this assay.

Prior to initiating therapy with a CCR5 inhibitor (maraviroc), the patient's virus must be assessed for use of the CCR5 as a co-receptor, as viruses that use CXCR4 as a co-receptor will not be susceptible to this drug. The commercially available Trofile assay (Monogram Biosciences, South San Francisco, CA) generates pseudoviruses using full-length *env* genes amplified from the patient's virus. Co-receptor tropism is then determined by measuring the ability of the pseudoviral population to infect CD4+ U87 cells that express either CXCR4 or CCR5. Depending on which cells are infected, the patient's virus is then designated X4-tropic, R5-tropic, or dual-tropic [47]. Patients are candidates for a CCR5 inhibitor if their virus is solely CCR5-tropic. Patients with CCR5-tropic virus that are treated with maraviroc may develop resistance to the drug due to either (1) mutations that allow the virus to adapt and use CXCR4 co-receptors or (2) structural changes in the envelope of a R5-tropic virus that prevent the drug from being effective [48, 49].

The currently available range of resistance testing (genotype and phenotype) provides clinicians with tools to better assess how to tailor the ART regimen, as well as determine whether drugs that are considered "resistant" by genotype may be usable in a salvage regimen after analysis by phenotypic testing.

Little data directly address specimen collection and processing for HIV-1 resistance testing which are very sensitive to RNA degradation because the methods require the amplification of a large portion of the 9 kilobase viral genome (1,200–1,600 base pairs). Current recommendations for resistance testing are to follow guidelines established for HIV-1 RNA viral load testing regarding collection, processing, and storage of specimens. Considering the cost of these assays and the variability of viral load measurements near the limit of quantification, resistance testing is not recommended until the viral load in the plasma is >1,000 copies/ml. Both the Trugene and ViroSeq assays successfully genotype non-B subtypes of HIV-1 [50].

Interpretation

Qualitative HIV-1 RNA Assays

CDC guidelines recommend use of HIV-1 RNA testing for the diagnosis of HIV infection when the screening result (by EIA) is not confirmed by the HIV-1/2 discriminatory test. This raises important issues regarding the implementation of the algorithm, as laboratory directors will need to determine whether to use plasma or serum samples, and assess if the same sample used for screening/discriminatory testing should be used for RNA testing. Testing for RNA after the serologic tests raises concerns of cross contamination between samples, as serologic testing is not routinely performed with the same precautions to prevent carryover of RNA between samples, as is needed for molecular testing. An assessment of the specimen integrity, including contamination prevention and storage conditions, following serologic testing is needed to assess the specimen adequacy for RNA testing. Removing an aliquot of plasma/serum prior to serologic testing for RNA testing, would reduce the risk of cross contamination and assure proper specimen storage, but this would be very labor intensive, particularly for laboratories with a low positivity rate, and risk misidentification. Asking for a second specimen to be collected for RNA testing requires an additional visit for the patient and may decrease the likelihood that testing is done, plus increases the turnaround time for final results. Consideration of these issues and discussions with healthcare providers prior to implementation of the testing algorithm for HIV-1 diagnosis should increase the likelihood of a successful adoption of the algorithm.

Viral Load Assays

HIV-1 RNA viral load assays have become the standard of care for monitoring response to ART. In order to effectively use HIV-1 viral load assays in clinical practice, the changes in viral load that represent a clinically important change in viral replication must be defined. This requires knowledge of both viral biology and assay performance. The available HIV-1 viral load assays have an intra-assay variability of 0.12–0.2 $\log_{10}$ on repeated testing of individual samples [38, 51]. Biologically, HIV-1 RNA levels are fairly stable in individuals who are not receiving ART; the biological variation is approximately 0.3 $\log_{10}$ [52]. Therefore, changes in HIV-1 RNA levels must exceed 0.5 $\log_{10}$ (three-fold) to represent biologically relevant changes in viral replication. For all the viral load assays, the intra-assay variability is even greater near the lower limit of quantification, so for HIV-1 RNA values less than 3 $\log_{10}$ (1,000 copies/ml), small changes in viral load should not be overinterpreted. Reporting viral load levels as $\log_{10}$-transformed data may assist in preventing clinicians from over-interpreting small changes in viral load.

Several clinical illnesses, including herpes simplex virus infections, acute infections, and opportunistic infections, as well as vaccinations for influenza, tetanus, or pneumonococcal infection, can lead to transient increases in HIV-1 RNA levels [53–55]. For some individuals these increases in viral load may be quite dramatic, even greater than 1 $\log_{10}$ change; however, HIV-1 RNA levels usually return to baseline within a month of the acute event. For this reason viral load measurements should be avoided during acute illness or within a month of vaccination.

False-positive results can occur with HIV-1 viral load assays and are attributed to carryover contamination with amplicons, limitations in assay chemistry, or cross-contamination of specimens during specimen processing. Carryover contamination has been essentially eliminated with the automated RT-qPCR tests (TaqMan and RealTime) since the test reaction is not open to the air after the amplification step. An advantage of the Versant bDNA assay is that carryover contamination does not occur with this signal amplification method. However, the Versant bDNA assay chemistry involves complex hybridization of nucleic acid probes which can result in nonspecific hybridization leading to false-positive results. The assay has a specificity of approximately 98 % when testing specimens from HIV-1-negative individuals [56]. Most of the false-positive samples have viral load values of less than 2,000 copies/ml. Contamination with HIV-1 RNA during specimen processing can lead to false-positive results with any of the assays, although this risk is reduced with the automated extraction systems used in the RT-qPCR tests.

Drug Resistance Assays

Interpretation of genotypic resistance testing is very complex and requires a detailed understanding of the genetics of resistance. For many drugs, the mutations associated with resistance have been well characterized when used as monotherapy. However, when drugs are used in combination, as is the standard of care for HIV-1-infected individuals, interactions may occur, which may increase or decrease individual drug efficacy. These interactions, although they are complex, must be understood to accurately interpret genotypic results. A current and comprehensive discussion of the specific mutations associated with each antiretroviral drug and the interactions of mutations is available from a variety of sources, including Los Alamos National Laboratory HIV Databases (http://hiv-web.lanl.gov), International AIDS Society-USA (http://www.iasusa.org), and Stanford University HIV Drug Resistance Database (http://hivdb.stanford.edu).

The proper interpretation of genotypic drug resistance assays involves (1) identification of resistance mutations and (2) interpretation of how these mutations alter viral susceptibility to specific antiretroviral drugs. While establishing appropriate quality control guidelines for the technical aspect of an assay is common practice, the complex interpretation of HIV-1 genotyping assays represents a challenge for molecular pathologists. Since interpretation of genotypic assays is so complex and critical to patient care, FDA-cleared assays provide software programs that assist in base calling, sequence alignment, and identification of the resistance mutations by comparing the sequence to a wild-type HIV-1 sequence.

After identifying the resistance mutations, a "rules-based" software program is used to interpret the implications of the various mutations for response to different drugs. For example, with the OpenGene system (Siemens Healthcare Diagnostics Inc, Tarrytown, NY), the manufacturer provides regular interpretation software updates which are cleared by the US FDA prior to release. In addition to listing the mutations identified in the RT and PR genes, an interpretive report is provided that lists each drug and provides a designation of either "no evidence of resistance," "possible resistance," "resistance," or "insufficient evidence." A similar approach is used in the ViroSeq assay (Abbott Molecular), though the interpretation of all mutations may not be identical for both systems. These rules-based interpretation systems are essential for providing clinicians with results in a user friendly format that is easily understood and clinically useful without the need for an extensive knowledge of the genetics of HIV-1 resistance. Clinically, resistance results must be interpreted in the context of the treatment history of each patient, which usually means avoiding drugs previously used to treat the patient when possible.

Mutations in HIV-1 are reported with a specific nomenclature in which amino acids are reported using single letter abbreviations. The wild-type amino acid encoded by the nucleotide triplet is followed by the location of the mutation (codon number) and then the mutant amino acid. For example, K103N indicates that the lysine (wild type) at codon 103 is replaced by an asparagine (mutant). Genotyping reports include a list of the mutations identified as well as the effect of the mutations on antiretroviral drug susceptibility (Table 45.3).

An important issue for the interpretation of HIV-1 phenotypic assays is defining the cutoff change in IC_{50} that is associated with resistance. Initially, this cutoff was established based on the technical performance of the assays, which is the increase in IC_{50} that could be reliably detected when compared to wild-type virus. Clinically important increases in IC_{50} have been defined for most drugs, and these cutoffs can vary with different drugs. For example, with abacavir, stavudine, and lopinavir, the fold change in IC_{50} that is clinically important is 4.5, 1.7, and 10, respectively [57]. However, with NNRTIs, four- to ten-fold increases in IC_{50} values in therapy-naive subjects were not associated with a poor virologic outcome [58]. Reports of phenotypic assay results include not only the change in IC_{50} value but also an interpretation of whether there is an increase or decrease in susceptibility compared to wild-type HIV-1.

Table 45.3 Example of a genotypic resistance report

Resistance associated RT mutations: A62V, K65R, A98G, L100I, V179D, M184V	
Nucleoside and nucleotide RT inhibitors	***Resistance interpretation***
Abacavir (ABC)	**Resistance**
Didanosine (ddI)	Possible resistance
Zidovudine (AZT)	No evidence of resistance
Lamivudine (3TC)/emtricitabine (FTC)	**Resistance**
Stavudine (d4T)	Possible resistance
Tenofovir (TDF)	**Resistance**
Nonnucleoside RT inhibitors	***Resistance interpretation***
Efavirenz (EFV)	Possible resistance
Etravirine (ETR)	Possible resistance
Nevirapine (NVP)	Possible resistance
Resistance associated PR mutations: L10V, I13V, L63P	
Protease inhibitors	***Resistance interpretation***
Amprenavir (APV)/fosamprenavir (FPV)	No evidence of resistance
Atazanavir (ATV)	No evidence of resistance
Darunavir + ritonavir (DRV/r)	No evidence of resistance
Indinavir (IDV)	No evidence of resistance
Lopinavir + ritonavir (LPV/r)	No evidence of resistance
Nelfinavir (NFV)	No evidence of resistance
Saquinavir + ritonavir (SQV/r)	No evidence of resistance
Tipranavir + ritonavir (TPV/r)	No evidence of resistance

RT reverse transcriptase

The DHHS guidelines recommend genotypic resistance testing for individuals who are not ART-experienced [9], and phenotypic testing is typically reserved for those individuals who have resistance in all of the classes of drugs by genotyping tests. Phenotypic testing can take 1–2 weeks and is significantly more expensive than genotypic testing. If both tests are used, it is key to remember that the results of the assays may not agree, as the presence of a resistance mutation does not obviate its expression in a phenotypic assay. Interpretation of these assays depend on the patient's drug regimen history, and so the genotypic and phenotypic testing may actually provide complementary information which explains the reasons for virologic failure [57].

The currently available genotypic and phenotypic methods can detect a mutant virus only if it comprises at least 20 % of the total viral population. Therefore, resistance testing is best used to predict failure of a regimen rather than ensure success, because a mutant may be present at a

concentration below the detection limit of the assay. Detection of these minor mutants is important because, in the presence of drug selection pressure, these minority populations will quickly predominate. Likewise, drug selection pressure is required for mutations to persist, and in the absence of drug selection pressure the viral population can revert back to wild type. One study showed that this reversion back to wild type can occur within weeks to months of withdrawing the antiretroviral drug [59]. Although the virus may appear susceptible to the specific drug, reintroducing the drug will select for resistant virus again. For this reason, it is recommended that specimens for resistance testing be obtained while the patient is on ART.

Laboratory Issues

With the proven clinical utility and the availability of commercial assays, HIV-1 RNA viral load testing is performed routinely in many clinical laboratories. The appropriate choice of a viral load assay will vary depending on the laboratory. Issues to consider include available space, volume of testing, turnaround time requirements, expertise of technologists, and cost of reportable result. Each of the viral load assays has its strengths and weaknesses. The Amplicor Monitor assay has largely been replaced by the RT-qPCR tests due to the automation which reduces technologist time and the closed system which prevents carryover and contamination.

Since the initial step in some genotypic and all phenotypic assays involves amplification of viral RNA, genetic fingerprinting programs within the resistance testing platforms are a very important tool to assist the laboratory in detecting contamination or sample mix-up. Each sequence that is generated is compared to a laboratory specific database that contains the sequences of other specimens and controls. Due to the variation in the HIV-1 sequence (due to its frequent mutation rate), an exact or a highly similar match should not be present in the database unless it is an earlier specimen from the same patient. Identification of different patients with highly similar sequences can be a clue to problems with contamination in the laboratory. Rarely, highly similar sequences may be evidence that transmission has occurred between two patients within a healthcare system and has been used for contact tracing in some contexts [60]. This genetic fingerprinting function is included in the Trugene System, allowing all sequenced specimens to be checked against the fingerprinting database. The ViroSeq system uses UTP and uracil *N*-glycosylase (UNG), which is a very effective method to control for contamination of amplified products. As with viral load testing, extreme care must be taken to avoid cross contamination of specimens during processing for resistance testing.

The College of American Pathologists (CAP) Surveys Program offers proficiency testing for HIV-1 viral load measurements and HIV-1 genotypic testing (for the PR and RT genes only), with challenges provided three times per year. A similar program is offered through the Quality Control for Molecular Diagnostics (QCMD, http://www.qcmd.org/), which provides challenges for qualitative HIV-1 DNA testing, qualitative and quantitative HIV-1 viral load testing, and HIV-1 genotypic resistance testing.

Phenotypic resistance testing, which requires culture of HIV-1, is not performed in clinical laboratories but is available from one commercial laboratory through Monogram Biosciences.

There are specific CPT codes available for HIV-1 RNA viral load testing as well as resistance testing. Reimbursement rates vary greatly from state to state and in some states may be below the cost of performing the tests. Adequate reimbursement is essential to assure access to resistance testing for all HIV-1 infected individuals.

The Future

The use of ART in combination with HIV-1 RNA viral load and drug resistance testing has revolutionized the clinical care for HIV-1-infected persons. Future advancements for these tests will likely focus on improved test performance and automation. The COBAS® AmpliPrep/COBAS® TaqMan® HIV-1 Test is the most sensitive of the RT-qPCR tests with an lower limit of quantification (LLOQ) of 20 copies/ml. Continued modification of these tests may further reduce the LOD, although it is unclear how much more sensitivity can be obtained with current technologies, without increasing the input sample volume to levels that are not practical. Newer technologies such as digital PCR may allow a further lowering of the LOD. If more sensitive tests become available, clinical trials will be needed to determine if patients with viral load values suppressed to these low levels (<20 copies/ml) have an improved outcome compared to those suppressed to 40–50 copies/ml. Current resistance testing technology will not allow assessment of mutations in patients with viral load values below 500–1,000 copies/ml, making best alternative therapy selection difficult in this group.

Digital PCR is a new technology that is currently under development for the quantification of infectious pathogens. The technology involves partitioning the reaction mixture by the generation of thousands of droplets, each of which is amplified by PCR and determined to be positive or negative. By counting the number of positive droplets, the absolute concentration of virus (target nucleic acid) in the initial reaction is determined. Digital PCR is still in the development phase, and has yet to demonstrate adequate sensitivity for

viral load testing. One possible role of digital PCR is to serve as a method to better correlate the concentrations of different lots of the World Health Organization (WHO) HIV-1 international standards, since digital PCR is an independent method to determine viral load values.

The advent of next-generation sequencing has allowed researchers to evaluate the HIV-1 quasispecies much more closely, evaluating variants that exist in 1–5 % of the HIV-1 population, which is much improved over the 20 % that can be detected with traditional sequencing. Several research groups have assessed individuals failing ART and found that some patients had low-level resistance mutations that explained why the patient's viral load was less likely to become undetectable on therapy [61]. This is promising technology, although more clinical data on outcomes in these individuals are needed [62], as well as determining the clinical relevance of mutations found in very low concentration (<1 % of the quasispecies) [63]. These issues will need to be resolved for next-generation sequencing to be used routinely in the clinical laboratory.

One clear unmet need for the future is the development of viral load and resistance testing that is appropriate for use in resource-constrained areas. For molecular testing to be performed routinely in resource-constrained laboratories, the test must be simple, reliable, and inexpensive. The test should be able to be performed without electricity or refrigeration. In these settings, the absolute viral load is less important, and viral loads in $\log_{10}$ increments are acceptable. Besides withstanding a potentially uncontrolled storage environment, the test should be easy to maintain and troubleshoot, with appropriate quality assurance features. Development of microfluidic devices that can be used in such settings [64, 65] are promising advances, but the clinical implementation of these has lagged behind the technical development.

Hepatitis B and C Viruses

46

Frederick S. Nolte

Abstract

Hepatitis due to infections with hepatitis B virus (HBV) and hepatitis C virus (HCV) are major global public health problems. Molecular diagnostic methods are now standard of care for the diagnosis, management and monitoring therapy of patients with chronic hepatitis B and C. After a brief description of the viruses and clinical manifestations of infection, the clinical utility of viral load testing and genotyping for HBV and HCV are reviewed. The relative advantages and limitations of the commercially available methods for performing these tests will be compared and key laboratory issues affecting the results are highlighted. The chapter also provides guidance for interpretation of these test results and insight into future directions for molecular diagnostic testing in patients with hepatitis B and C.

Keywords

Hepatitis B • Hepatitis C • Hepatitis B virus • Hepatitis C virus • Viral load • Genotyping • Molecular diagnostics

Introduction

Viral hepatitis is believed to have existed in antiquity, with references traced back to the fifth century BC. Over time, research led to the understanding that the disease was caused by more than one virus. Understanding of the pathogenesis began with the landmark discovery of the Australia antigen, subsequently renamed hepatitis B surface antigen (HbsAg) by Blumberg and coworkers in 1965 [1]. What followed was a rapid growth in information about the hepatitis B virus (HBV), development of serologic and molecular tests for HBV, understanding of the natural history and pathogenesis of infection, development and approval of antiviral therapies, and, most importantly, the development of effective vaccines for prevention of HBV infection.

Although non-A, non-B hepatitis has been thought to have a viral etiology since 1974, the virus eluded investigators for more than a decade. In 1989, a brute force application of molecular cloning techniques through the joint efforts of the Centers for Disease Control and Prevention (CDC) and Chiron Corporation led to the identification of the hepatitis C virus (HCV) [2]. This discovery led rapidly to the development of serologic screening assays for HCV infection prior to blood donation, which dramatically reduced the incidence of post-transfusion chronic hepatitis. Sequencing of the HCV genome also provided impetus for the development of molecular assays for detection, quantification, and characterization of HCV. Although there has been explosive growth in information about this medically important virus since its discovery, much remains to be learned about its pathogenesis, treatment, and prevention.

The key characteristics of HBV and HCV are summarized in Table 46.1. Both viruses represent major global public health problems, with an estimated 350 million and

Table 46.1 Characteristics of hepatitis B virus and hepatitis C virus

Characteristic	Hepatitis B virus	Hepatitis C virus
Type of virus	Hepadnavirus	Hepacivirus
Viral genome	3.2 kb, relaxed circular, partially double-stranded DNA	9.5 kb, positive-sense, single-stranded RNA
Routes of transmission	Parenteral Sexual Injection drug use Perinatal	Parenteral Injection drug use Blood products before 1990 Perinatal (infrequent) Sexual (infrequent)
Frequency of acute icteric disease	Common in adults Uncommon in children	Uncommon
Frequency of evolution to chronic disease	Infrequent (<10 %) in adults Common in children	Frequent (>80 %)
Estimated number of acute infections/year in the USA	185,000	38,000
Estimated number of chronically infected persons in the USA	1,250,000	2,700,000
Estimated number of chronically infected persons in the world	350,000,000	170,000,000
Treatment	Interferon pegylated interferon-α Nucleoside/nucleotide analogs	Pegylated interferon-α with: Ribavirin and Protease inhibitors or RNA polymerase inhibitors or NS5A inhibitors RNA polymerase inhibitor and Ribavirin alone
Prophylaxis	Recombinant Hepatitis B vaccine Immune globulin	None

Source: Adapted from Lauer GM, Walker BD. Hepatitis C virus infection. *N Engl J Med*. 2001;345:41–52

170 million persons chronically infected with HBV and HCV, respectively. Although clinical characteristics and risk factors for infection may give some indication of the specific etiology of viral hepatitis, the diagnosis is laboratory based. Laboratory diagnosis is based on serologic and molecular tests because cell culture techniques for isolation of HBV and HCV are not effective. This chapter reviews the molecular tests that are available to detect, quantify, and characterize HBV and HCV and how these tests can be used for effective diagnosis and clinical management of patients.

Hepatitis B Virus

Description of the Pathogen

The HBV genome is a 3.2 kilobase relaxed circular, partially double-stranded DNA molecule. It has four partially overlapping open reading frames encoding the viral envelope (pre-S and S), nucleocapsid (precore and core), polymerase, and X proteins. After binding to hepatocytes, the virion is taken up into the cell by endocytosis and uncoated. The partially double-stranded DNA genome is converted to a covalently closed circular DNA (cccDNA) in the cell nucleus. The cccDNA is used as a template for transcription of the pregenomic RNA (pgRNA) and messenger RNA in the cell nucleus. The pgRNA moves into the host cell cytoplasm and serves as the template for translation of the HBV reverse transcriptase (RT) as well as the core protein by the cellular translational proteins. Concurrently, the HBV RT reverse transcribes the pgRNA to a new circular DNA molecule. Early in the replication cycle, some of the newly synthesized genomes will circulate back to the nucleus to maintain and increase the pool of cccDNA [3].

Although HBV is a DNA virus, it replicates by a RT that lacks proofreading activity and, as a result, is prone to errors. The overlapping open reading frames of the genome limit the types of mutations that can be tolerated. However, variations in HBV sequences have been detected in almost all regions of the genome. Consequently, HBV exists as quasispecies, and different patients may be infected with different strains and genotypes.

Seven phylogenetic genotypes (A through H) of HBV have been identified, most of which have distinct geographic distribution. Genotypes are defined by intergroup divergence of greater than 8 % in the complete genome nucleotide sequence. All known genotypes have been found in the USA with the prevalence of A, B, C, D, and E–G being 35 %, 22 %, 31 %, 10 %, and 2 %, respectively [4]. Recent data suggest that HBV genotype plays an important role in the progression

of HBV-related liver disease as well as response to interferon alpha (IFN-α) and pegylated IFN-α; however, HBV genotyping is not necessary in routine clinical practice [5].

Clinical Utility

Serologic assays with high levels of sensitivity, specificity, and reproducibility have been developed to detect HBV antigens and their respective antibodies. This complicated system of serologic markers is used for diagnosis of HBV infection and to define the phase of infection, degree of infectivity, prognosis, and the patient's immune status. The presence of HBV DNA in the serum is a marker of viral replication in the liver and has replaced hepatitis B e antigen (HBeAg) as the most sensitive marker of viral replication. HBeAg is the extracellular form of the hepatitis B core protein. Molecular assays to quantify blood levels HBV DNA are useful for the initial evaluation of HBV infections, monitoring of patients with chronic infections, and assessing the efficacy of antiviral treatment [3, 5]. In addition, US blood donors are routinely screened for HBV DNA by qualitative tests to detect donors in the early stage of infection [6]. Antiviral resistance mutations are detected by molecular methods that identify known mutations associated with drug resistance.

The initial evaluation of patients found to have HBsAg in serum should include routine liver tests and a variety of virologic tests including HBV DNA tests [5]. Chronic HBV infection is a disease of variable course, and establishing baseline laboratory values at the time of diagnosis is important clinically for the tracking of disease progression over time and to evaluate candidates for liver biopsy. Monitoring disease activity in chronically HBV-infected patients is best done by measuring aminotransferase (ALT) levels at regular intervals in HBeAg-positive patients. However, serial HBV DNA testing is recommended in HBeAg-negative patients. The determination of serum HBV DNA levels (viral load) is important in the pretreatment evaluation and monitoring of therapeutic response in patients with chronic infection [5]. Currently, therapy for chronic HBV infection does not eradicate the virus and has limited long-term efficacy. The decision to treat should be based on ALT elevations, the presence of HBeAg or HBV DNA viral load of >2,000 IU/ml or both, the presence of moderate disease activity and fibrosis on liver biopsy, and virologic testing to exclude concurrent infections with hepatitis D virus (HDV), HCV, and human immunodeficiency virus (HIV). The goals of treatment of chronic hepatitis B are to achieve sustained suppression of HBV replication and to prevent further progression of liver disease. Parameters used to indicate treatment response include normalization of serum ALT, decrease in serum HBV DNA level, and loss of HBeAg with or without detection of anti-HBeAg. Currently, eight US Federal Drug Administration (FDA)-approved therapies are available for treatment of chronic HBV infection: IFN-α, pegylated IFN-α2a, four nucleoside analogs (NS; lamivudine, telbivudine, entecavir, and emtricitabine) and two nucleotide analogs (NT; adefovir and tenofovir). Several factors predict a favorable response to IFN treatment with the most important being high ALT and low serum HBV DNA viral load, which are indirect markers of immune clearance.

Therapy usually does not eradicate the virus because of the difficulty of eliminating the covalently closed circular form of the HBV genome from the liver and the existence of extrahepatic reservoirs of HBV. Endpoints of treatment have traditionally been clearance of HBeAg, development of anti-HBe antibodies, and undetectable serum HBV DNA using insensitive hybridization assays with detection limits of approximately 10^6 genome copies/ml. Achieving these endpoints usually is accompanied by resolution of liver disease as evidenced by normalization of the ALT level and decreased histologic activity on liver biopsy. The response usually is sustained at long-term follow-up. Nevertheless, most responders continue to have detectable HBV DNA when sensitive nucleic acid amplification tests are used. Responses to antiviral therapy are categorized as biochemical, virologic, or histologic and as on-therapy, or sustained off-therapy (Table 46.2) [5].

Table 46.2 Definitions of response and time of assessments for antiviral therapy for chronic hepatitis B virus (HBV) infection

Response definitions	
Biochemical response	Decrease in serum ALT to within normal range
Virologic response	Decrease in serum HBV DNA to undetectable levels by nucleic acid amplification assay, and loss of HBeAg in patients who were initially HBeAg positive
Primary non-response (NS and NT analogs only)	Decrease in serum HBV DNA by <2 $\log_{10}$ IU/ml after at least 24 weeks of therapy
Virologic relapse	Increase in serum HBV DNA of ≥1 $\log_{10}$ IU/ml after discontinuation of treatment by at least two tests performed >4 weeks apart
Histologic response	Decrease in histology activity index by at least 2 points and no worsening of fibrosis score compared to pretreatment biopsy
Complete response	Fulfill criteria of biochemical and virologic response and loss of HBsAg
Time of assessment definitions	
On-therapy	During therapy
Maintained	Persists throughout the course of treatment
Off-therapy	At the end of a defined course of therapy
Sustained-6	6 months after discontinuation of therapy
Sustained-12	12 months after discontinuation of therapy

ALT aminotransferase, *NS* nucleoside, *NT* nucleotide

Several variations in the nucleotide sequence of HBV have important clinical consequences. An important mutation in the S gene is a glycine-to-arginine substitution at codon 145 (G145R) in the conserved "a" determinant, which causes decreased affinity of the HBsAg for anti-HBs antibodies [7]. HBV with this mutation has been found in children of HBsAg-positive mothers who develop HBV infection despite vaccination and an adequate anti-HBs antibody response after vaccination, as well as in liver transplant recipients who have recurrent infection despite administration of HBV immune globulin [8, 9]. These immune escape mutants have raised concern about vaccine efficacy and serologically silent infections. The G145R mutation has been reported in many countries and is responsible for 2–40 % of vaccine failures. Although there is diminished binding to anti-HBs antibodies, the vast majority of S mutants can be readily detected with the current generation of HBsAg tests. Thus, an initial concern that widespread use of HBV immune globulin and vaccination would result in HBV mutants that would escape detection in the HBsAg test was unfounded.

Mutations in the basal core promoter and the precore genes affect the synthesis of HBeAg and commonly arise under immune pressure [10]. The most common basal core promoter mutation has a dual change of A to T at nucleotide (nt) 1,762 (T1762) and G to A at nt 1,764 (A1764) that diminishes the amount of mRNA and hence HBeAg secretion [11]. The predominant precore mutation is a G to A change at nt 1,896 (A1896), which leads to premature termination of the precore protein at codon 28, thus preventing the production of HBeAg [12]. The A1896 mutation is infrequent in North America and Western Europe but is geographically widespread. This geographic variability in frequency is related to the predominant genotypes in a geographic region because the mutation is found only in genotypes B, C, D, and E.

The A1896 mutation was first reported in patients with chronic active hepatitis or fulminant hepatitis. However, the A1896 mutation also can be present in asymptomatic carriers and viruses with this mutation replicate no more efficiently than wild-type HBV. Thus, the pathophysiologic significance of this mutation is unclear [13]. However, the clinical picture of persistent HBV replication and active liver disease in HBeAg-negative patients appears to be increasingly prevalent, and in some regions the A1896-mutant virus may be more prevalent than wild-type virus.

Therapy for chronic hepatitis B requires long courses of treatment with NS or NT analogs. A major concern with long-term therapy is the development of antiviral resistance. The rate at which resistant mutants are selected is related to pretreatment serum HBV DNA viral load, rapidity of viral suppression, duration of treatment, and prior antiviral exposure. The incidence of genotypic resistance also varies with the sensitivity of the methods used to detect resistance mutations and the patient population tested. The definitions of terms used to describe resistance to NS and NT analogs are summarized in Table 46.3 [5].

Table 46.3 Definitions of terms used to describe antiviral resistance of HBV

Term	Definition
Virologic breakthrough	Increase in serum HBV DNA >1 $\log_{10}$ above nadir after achieving a virologic response during continued treatment
Viral rebound	Increase in serum HBV DNA >20,000 IU/ml or above pretreatment level after achieving a virologic response during continued treatment
Biochemical breakthrough	Increase in ALT above upper limit of normal after achieving normalization during continued treatment
Genotypic resistance	Detection of mutations that have been shown in vitro to confer resistance to drug being administered
Phenotypic resistance	In vitro confirmation that a mutation decreases the susceptibility to the drug as demonstrated by an increase in the inhibitory concentration

ALT aminotransferase

Table 46.4 Antiviral agents and the HBV mutations associated with resistance

Antiviral agent	Description of agent	Mutations associated with resistance
Lamivudine	Nucleoside analog (cytidine)	(L180M + M204V/I/S), A181V/T, S202G/I
Telbivudine	Nucleoside analog (dTTP)	M204I, A181T/V
Entecavir	Nucleoside analog (2-deoxyguanosine)	T184S/C/G/A/I/L/F/M, S202G/C/I, M250V/I/L
Emtricitabine	Nucleoside analog (cytidine)	M204V/I
Adefovir	Nucleotide analog (dATP)	A181V/T, N236T
Tenofovir	Nucleotide analog (dATP)	A194T, N236T, A181V/T

Typically, when a patient experiences a virologic breakthrough, HBV resistance genotyping should be performed. The standardized nomenclature of HBV antiviral resistance mutations is shown Table 46.4 [3, 14, 15]. No HBV mutations are associated with resistance to IFN-α or pegylated IFN-α2a.

Available Assays

HBV DNA Detection and Quantification

The commercially available tests for quantification of HBV DNA in serum and plasma are listed in Table 46.5. These tests employ either branched DNA or real-time PCR for

Table 46.5 Commercial assays for quantification of HBV DNA

Assay (manufacturer)	Method	Dynamic range
COBAS Taqman HBV test (Roche Diagnostics, Indianapolis, IN)[a]	Real-time PCR	1.7×10^{2}–8.5×10^{8} copies/ml[b]
Real-time HBV (Abbott Laboratories, Abbott Park, IL)[a]	Real-time PCR	1.0×10^{1}–1×10^{9} IU/ml
Versant HBV DNA (Siemens Corp., Washington, DC)	Branched DNA	3.3×10^{3}–1×10^{8} copies/ml
Artus HBV PCR (Qiagen, Valencia, CA)	Real-time PCR	2×10^{2}–1×10^{8} IU/ml
Affigene HBV Trender (Cepheid, Sunnyvale, CA)	Real-time PCR	1.7×10^{2}–1.7×10^{8} IU/ml

[a]US FDA-cleared
[b]COBAS Ampliprep/COBAS Taqman test v2.0 dynamic range is 54–1.1×10^{8} copies/ml

amplification and differ in their limits of detection and dynamic ranges. The COBAS Taqman (Roche Diagnostics, Indianapolis, IN) and the real-time (Abbott Laboratories, Abbott Park, IL) HBV tests are approved for in vitro diagnostic use by the US FDA. The others are available as research use only (RUO) kits or analyte specific reagents (ASRs). All of the quantitative HBV DNA test formats have been used in monitoring the status of HBV infection before and after treatment.

Qualitative assays for detection of HBV DNA in blood donations are produced by Gen-Probe Inc. (San Mateo, CA) (using transcription-mediated amplification) and Roche Diagnostics (using PCR) with limits of detection of 11 IU/ml and 15 IU/ml, respectively. However, the value of nucleic acid testing compared to serology for HBV screening of blood donors remains controversial and has not been universally adopted [6].

HBV Genotyping

Two commercial HBV genotyping systems are available as RUO kits. Innogenetics Inc. (Alpharetta, CA) offers three different line probe assays for HBV phylogenetic genotyping, detection of precore mutations, and detection of all relevant lamivudine, emtricitabine, telbivudine, adefovir, and entecavir resistance mutations as well as known compensatory mutations [16, 17]. All assays use PCR to amplify portions of the relevant genes to produce a biotinylated product. The PCR products are denatured and hybridized to a series of informative probes immobilized on a nitrocellulose strip. The hybrids are visualized on the strip after addition of streptavidin–alkaline phosphatase and colorimetric substrate. The mutations are identified by the colored patterns of PCR product hybridization to the probes. The line probe assays typically have better sensitivity for detection of sequence variants than direct Sanger sequencing.

Interpretation of Test Results

A major dilemma in the interpretation of serum HBV viral load results is what values should be used to define treatment indications and response. Because HBV DNA may persist in individuals who have serological recovery from acute infection, low levels may not be associated with progressive liver disease and viral clearance is an unrealistic treatment endpoint. An arbitrary value of 20,000 IU/ml (>10^{5} copies/ml) was chosen as a diagnostic criterion for chronic hepatitis B at the 2000 NIH conference [18]. However, progressive liver disease can be found in individuals with lower levels. In addition, wide fluctuations in HBV viral load from undetectable to >2 million IU/ml are observed in some patients with chronic hepatitis B [19, 20]. Consequently, serial monitoring is more important than reliance on a single cutoff value in determining prognosis and the need for treatment.

The first manifestation of antiviral resistance is an increase in HBV viral load >1 $\log_{10}$ from nadir during treatment in a patient who had an initial virologic response. Virologic breakthroughs often are related to therapy noncompliance, so compliance should be assessed before testing for genotypic resistance. HBV viral load levels tend to be low initially because antiviral-resistant mutants have decreased replication fitness. However, compensatory mutations that can restore replication fitness often emerge during continued therapy leading to progressive increases in HBV viral load followed by biochemical breakthrough. Antiviral resistant mutations can be detected months to years prior to biochemical breakthrough. Thus early detection of these mutations can prevent hepatitis flares and liver decompensation. Cross-resistance mutations do occur that limit future treatment options and multidrug-resistant mutants in patients who have received sequential monotherapies have been described [21].

Laboratory Issues

A World Health Organization (WHO) international HBV standard was created in 2001 in response to the recognized need to standardize HBV DNA quantification assays [22]. The WHO HBV standard is a high-titer, genotype A virus preparation (code 97/746) which was assigned a potency of 10^{6} IU/ml. A second standard (code 97/750) was established in 2006 and is quantitatively equivalent to the first standard. The standard established that 1 IU was equivalent to 5.4 genome equivalents by testing the pooled material with a range of commercially available and laboratory-developed tests. However, despite the availability of HBV DNA standards, the various quantitative assays usually have different conversion factors for copies to IU/ml, which may reflect their different amplification and detection chemistries. Laboratories should report HBV viral load test results in IU/ml as both $\log_{10}$ transformed and arithmetic values.

As with any viral load test, some of the variability in quantification may be attributable to sample processing. Either serum or plasma can be used for most tests. Whole blood should be centrifuged within 6 h of collection and the serum or plasma removed from the cells. Short-term storage of serum or plasma is safe at refrigerator temperatures (4 °C). Freezing at temperatures ≤20 °C is recommended for long-term storage of samples.

The standardized nomenclature for reporting of HBV antiviral resistance mutations shown Table 46.4 should be used when resistance genotyping is performed. The inability of genotyping assays to detect minor populations of circulating HBV is a significant technical issue. In general, direct sequencing is limited to resolution of populations which are ≥20 % of the viral population. HBV is included in the hepatitis viral load proficiency testing surveys available from the College of American Pathologists.

Future Directions

Molecular assays for quantification and genotyping of HBV will become more fully integrated in the testing strategies for the diagnosis and management of patients with chronic hepatitis B. Clinical practice guidelines now reflect the importance of HBV viral load and genotyping tests in improving patient outcomes and this is likely to create more demand for these tests. The current generation of real-time PCR viral load assays meets the clinical needs and development and adoption of the WHO international standard has improved the agreement between results of different assays. Improved HBV treatment will depend on development of better laboratory tools for assessing genotypic resistance. Genotyping beyond individual mutation detection to a more comprehensive genomic analysis to predict fitness and other polymutational phenotypes, and detection of minor resistant populations will be possible with next-generation sequencing methods [22, 24].

Hepatitis C Virus

Description of the Pathogen

HCV is an RNA virus with a positive-sense, single-stranded genome of approximately 9,500 nt encoding a single polyprotein of about 3,000 amino acids. The long open reading frame is flanked at each end by short untranslated regions (UTR). The genome structure is most similar to viruses of the family *Flaviviridae*, which includes many of the arthropod-borne viruses. As in other flaviviruses, the three N-terminal proteins of HCV (core, envelope 1 [E1], and envelope 2 [E2]) are probably structural and the four C-terminal proteins (nonstructural 2, 3, 4, and 5) are thought to function in viral replication. HCV is classified within the family *Flaviviridae* in its own genus, *Hepacivirus*.

The 5′ UTR is a highly conserved region of 341 nt and has a complex secondary structure. It contains an internal ribosome entry site and is important in the translation of the long open reading frame. The 3′ UTR contains a short region that varies in sequence and length, followed by a polypyrimidine stretch of variable length, and finally a highly conserved sequence of 98 nt, which constitutes the terminus of the genome. The function of the 3′ UTR is not known but is thought to be essential for viral replication.

The E1 and E2 regions of HCV are the most variable regions within the genome at both the nucleotide and amino acid levels. Two regions in E2, called hypervariable regions 1 and 2 (HVR1 and HRV2, respectively), show extreme sequence variability, which is thought to result from selective pressure by antiviral antibodies. E2 also contains the binding site for CD81, one of the putative cell receptors or coreceptors for HCV.

The nonstructural regions 2 (NS2) and 3 (NS3) contain a zinc-dependent autoprotease that cleaves the polyprotein at the NS2-NS3 junction. The aminoterminal portion of the NS3 protein also is a serine protease that cleaves the polyprotein at several sites. The carboxyterminal portion of the NS3 protein has helicase activity, which is important for HCV replication. The NS4A protein is a cofactor for NS3 serine protease. The NS5B region encodes the RNA-dependent RNA polymerase, which replicates the viral genome. A region in NS5A has been linked to IFN-α response and therefore is called the IFN-α-sensitivity determining region (ISDR).

HCV Genotypes

The first complete HCV genome sequence was reported by Choo et al. in 1991 [25]. As additional genome sequences from isolates from different parts of the world were determined and compared, it was evident that HCV exists as distinct genotypes with as much as 35 % sequence diversity over the whole viral genome [26]. Much of the early literature on genotyping is confusing because investigators developed and used their own classification schemes. However, a consensus nomenclature system was developed in 1994. In this system, the genotypes are numbered using Arabic numerals in order of their discovery, and the more closely related strains within some types are designated as subtypes with lowercase letters. The complex of genetic variants found within an individual isolate is termed the "quasispecies." The quasispecies results from the accumulation of mutations that occur during viral replication in the host.

The genotype and subtype assignments and nomenclature rules for HCV have recently been updated [27]. Seven major genotypes and 67 subtype of HCV are now recognized with another 20 provisional subtypes. HCV strains belonging to

different genotypes differ at 30–35 % of nucleotides and those that belong to the same subtype differ at <15 % of nucleotides at the genome level.

HCV genotypes 1, 2, and 3 are found throughout the world, but there are clear differences in their distribution [28]. HCV subtypes 1a, 1b, 2a, 2b, 2c, and 3a are responsible for more than 90 % of infections in North and South America, Europe, and Japan. In the USA, type 1 accounts for approximately 70 % of the infections with equal distribution between subtypes 1a and 1b. In Japan, subtype 1b causes more than 70 % of HCV infections. Although subtypes 2a and 2b have wide distributions in North America, Europe, and Japan, subtype 2c is widespread in a region of northern Italy. HCV subtype 3a is common among intravenous drug users in the USA and Europe. The other subtypes of genotype 3 are common in Nepal, Bangladesh, India, and Pakistan. Genotype 4 is prevalent in North Africa and the Middle East, and genotypes 5 and 6 are limited to South Africa and Hong Kong, respectively [29]. Subtype 4a constitutes the majority of infections in Egypt, and this and other subtypes of genotype 4 are found in Zaire and Gabon. Subtype 5a is predominant in South Africa, where some reports indicate that it is responsible for more than 50 % of infections. Subtype 6a infections are common in Hong Kong. To date, only 2 genotype 7 infections has been reported in patients from Central Africa [30].

The retrospective nature of most of the genotype studies has not allowed determination of the role of genotype as a risk factor for disease progression nor separation of genotype from other known risk factors for severe disease, such as older age at infection, male gender, alcohol consumption, and concurrent viral infection. However, in two prospective studies, viral genotype did not correlate with disease progression [31, 32].

Clinical Utility

HCV RNA Detection and Quantification

Detection of HCV RNA in serum or plasma by nucleic acid amplification methods is important for confirming the diagnosis of HCV, distinguishing active from resolved infection, assessing the virologic response to therapy, and screening the blood supply. These tests are incorporated into diagnostic algorithms for hepatitis C proposed by the CDC [33], American Association for the Study of Liver Diseases [34], and National Academy of Clinical Biochemistry [35].

The detection of HCV RNA in the plasma or serum is the earliest marker of infection, appearing 1–2 weeks after infection and weeks before elevation of liver enzyme levels or the appearance of anti-HCV antibodies. Approximately 80 % of individuals infected with HCV will be chronically infected with the virus. In antibody-positive individuals, HCV RNA tests can distinguish active from resolved infections. In patients with a high pretest probability of infection, a positive serologic screening test is usually confirmed with a test for HCV RNA rather than the recombinant immunoblot assay (RIBA). This strategy is cost-effective and more informative than using the RIBA to confirm positive antibody screening tests in a diagnostic setting [36]. However, with the discontinuation of the HCV RIBA by the manufacturer in 2012, all reactive HCV antibody screening tests should be followed by US FDA-approved HCV RNA testing [37].

HCV RNA testing also is helpful for the diagnosis of infection in infants born to HCV-infected mothers due to persistence of maternal antibody, and in immunocompromised or debilitated patients who may have blunted serologic responses. An HCV RNA test also should be used for patients suspected of having an acute infection and in patients with hepatitis of no identifiable cause.

HCV RNA tests are the most reliable means of identifying patients with active HCV infection. A negative HCV RNA test in a serologically positive individual may indicate that the infection has resolved or that the viremia is intermittent. Up to 15 % of chronically infected individuals have intermittent viremia and, as a result, a single negative HCV RNA determination may not be sufficient to exclude active infection when the index of clinical suspicion is high [38]. In these individuals a second specimen should be collected and tested.

The use of anti-HCV antibody tests to screen the blood supply has dramatically reduced the risk of transfusion-associated HCV infection in developed countries. The risk in the USA from blood that is negative for anti-HCV antibodies is less than 1 in 103,000 transfused units [39]. To drive the risk of infection from transfusion even lower, blood donor pools currently are tested for the presence of HCV RNA [40]. The serologic screening tests for HCV have a 70-day window period of seronegativity, and antigen detection tests are not yet available for blood product screening. HCV RNA testing is estimated to reduce the detection window by 25 days and reduce the number of transfused infectious units from 116 to 32 per year [41].

Assays for the detection and quantification of HCV core antigen in serum have recently been commercially developed but are not yet US FDA-cleared for diagnostic use (Ortho Clinical Diagnostics, Rochester, NY; Bio-Rad, Hercules, CA; and Abbott Laboratories, Abbott Park, IL) [42–46]. These tests significantly shorten the serologically silent window period using seroconversion panels, and their performance correlates closely with RNA detection tests in blood donors. However, the analytical sensitivity is less than most RNA tests, at approximately 10,000 IU/ml. The analytical sensitivity of the core antigen test is too high to be used in the monitoring of late events during and after treatment. Antigen detection may represent a cost-effective

alternative to HCV RNA testing to distinguish active from resolved infections in resource-poor settings.

HCV viral load testing is useful in pretreatment evaluations of patients being considered for therapy, since a viral load of less 600,000 IU/ml is one of several predictors of achieving a sustained virologic response [47, 48]. Other factors associated with achieving a sustained response to therapy include the absence of cirrhosis, age <40 years, female gender, white race, viral genotype 2 or 3, and presence of C or T at position rs12979860 near the gene for lambda IFN 3 (*IL28B*) [49, 50].

HCV viral load does not predict disease progression and is not associated with severity of liver disease [51]. This is in sharp contrast to HIV-1, in which the viral load is the principal factor determining the rate of disease progression. Monitoring HCV viral load in untreated patients is not warranted and should be discouraged. Until recently, the standard therapy for patients with chronic HCV infection was pegylated IFN-α in combination with ribavirin administered for either 48 weeks for HCV genotype 1, 4, 5, and 6 infections, or for 24 weeks for HCV genotype 2 and 3 infections. Sustained virologic response (SVR) rates were attained in 40–50 % of patients with genotype 1 and in 80 % or more of those with genotype 2 and 3 infections. SVR is defined as the absence of detectable HCV RNA in plasma or serum as determined with a test that has a limit of detection of ≤50 IU/ml and is considered a virologic cure.

The first direct acting antivirals (DAA) for treatment of hepatitis C were approved by the US FDA in 2011. Both are NS3/4A serine protease inhibitors, boceprevir (BOC) (Merck, Kenilworth, NJ) and telaprevir (TVR) (Vertex, Boston, MA). These DAA agents are used in combination with pegylated IFN-α and ribavirin. Triple therapy for genotype 1 infections has led to approximately a 30 % increase in SVR over the previous standard of care therapy in all patient subgroups. Limited phase 2 testing has shown that TVR also has activity against genotype 2 infections but not against genotype 3 infections. BOC appears to have activity against both genotypes 2 and 3 infections. However, neither drug should be used to treat patients with genotype 2 and 3 infections [52].

The algorithms for monitoring HCV viral load in patients receiving triple therapy and the stopping rules are shown in Fig. 46.1 [52]. The important time points for response-guided therapy are at 8, 12, and 24 weeks for BOC and 4, 12, and 24 weeks for TVR. Treatment with all three drugs should be stopped if HCV RNA level is >100 IU/ml at week 12 or detectable at week 24 for BOC triple therapy and if HCV RNA level is >1,000 IU/ml at weeks 4 or 12 and/or detectable at week 24 with TVR.

The goal of treatment is a SVR, defined as no detectable HCV RNA in serum or plasma by a highly sensitive assay (limit of detection ≤10–15 IU/ml) 6 months after the end of treatment. Patients who achieve a SVR have little or no chance of virologic relapse of their disease.

In 2013, two more potent DAAs were approved by the US FDA: sofosbuvir (Gilead Sciences, Inc., Foster City, CA), a NS5B polymerase inhibitor [53], and simeprevir (Johnson &

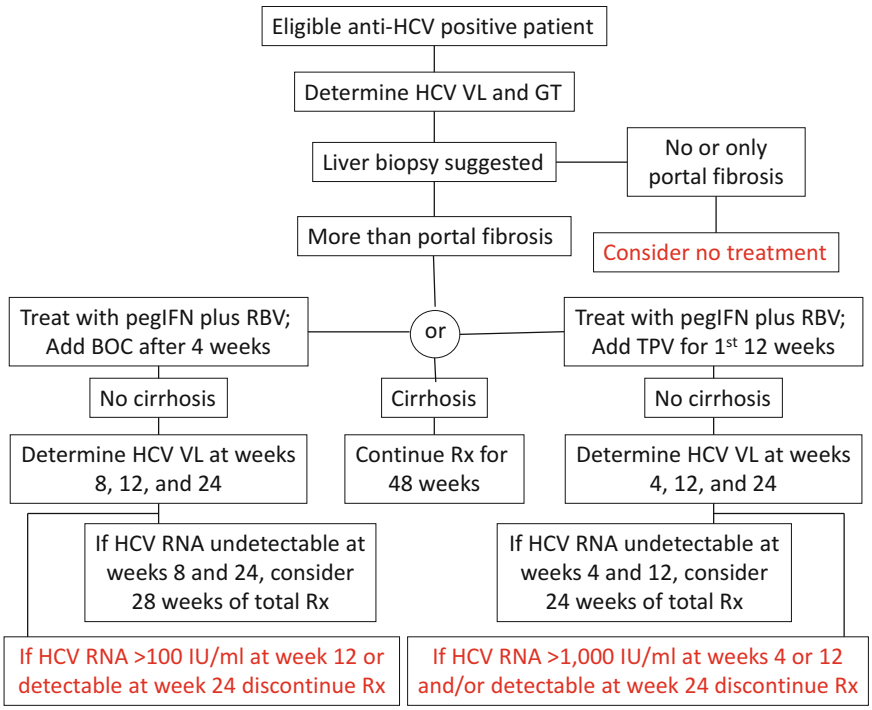

Figure 46.1 Triple therapy algorithms for treatment-naive patients with chronic HCV genotype 1 infections. Stopping rules in *red* (Adapted from Ref. 53). *BOC* boceprevir, *GT* genotype, *IU* international units, *pegIFN* pegylated interferon-α, *RBV* ribavirin, *Rx* treatment, *TVP* telaprevir, *VL* viral load

Johnson, New Brunswick, NJ), a second generation protease inhibitor [54]. Sofosbuvir was approved in combination with pegylated IFN-α and ribavirin for treatment of genotypes 1 and 4 and in combination with ribavirin alone for genotypes 2 and 3. Simeprevir was approved by the US FDA for treatment of genotype 1 infections in combination with pegylated IFN-α and ribavirin, but only for patients with genotype 1 who have not failed therapy with first generation protease inhibitors.

Monitoring of on-treatment viral load levels does not affect management decisions with a sosobuvir-based regimen since treatment failure is almost exclusively due to relapse [53]. However, given the expense of the drugs and the potential risk of viral resistance with inappropriate use, viral load testing at week 4 and end of treatment at either week 12 or 24 depending on the regimen seems prudent.

Viral load levels should be determined at weeks 4, 12, and 24 to assess treatment response and for stopping rules in patients treated with simeprevir, pegylated IFN-α, and ribavirin. Discontinuation is warranted for patients who are unlikely to achieve a SVR based on the on-treatment virologic response. If HCV RNA level is >25 IU/ml at week 4, the entire regimen should be discontinued. If the HCV RNA level is >25 IU/ml at week 12 or 24 after the simeprevir has been completed, the pegylated IFN-α and ribavirin should be discontinued [54].

Numerous other DAAs have been developed and are currently in clinical trials. These include NS3/4A protease inhibitors, NS5B polymerase inhibitors, and inhibitors of host cell proteins required for HCV replication. The most current recommendations for all aspects of HCV treatment can be found at http://www.hcvguidelines.org/.

HCV Genotyping

Sequence analysis of variable regions of the HCV genome has been used to investigate outbreaks of infection and to study modes of transmission. Two large outbreaks of infection associated with contaminated lots of anti-rhesus D immunoglobulin (anti-D) in Ireland and Germany were investigated using molecular typing [55, 56]. In both studies, sequence analysis showed that the HCV infecting the women was the same as that found in the implicated batches of anti-D. In another report, sequencing part of the NS3 region provided evidence of patient-to-patient transmission during colonoscopy [57]. Sequence analysis also has been used as part of investigations of HCV infections associated with blood transfusions. In addition, molecular genotyping has been used to study vertical and sexual transmission of HCV [58–61].

Although a number of baseline factors are predictive of response to treatment of chronic hepatitis C infection, HCV genotype is a strong and consistent predictor for achieving a SVR to pegylated IFN-α and ribavirin. In the large clinical trials of combination therapy with pegylated IFN-α and ribavirin, only 30 % of patients infected with genotype 1 had a SVR compared to 65 % of patients infected with genotypes 2 or 3 [47, 48].

Several studies focused on the identification of isolates within a genotype with different responses to IFN, and led to the definition of the ISDR. For example, Enomoto et al. found that genotype 1b isolates in Japan identical to the HCV-J prototype strain within the carboxyterminal part of the NS5A protein were resistant to IFN [62]. In contrast, patients infected with genotype 1b strains with mutations within this region had a better response to IFN. This region of amino acids 2,209–2,248 in the NS5A protein is the ISDR. The same group recently confirmed and extended their observations. They found that sustained response rates correlated with the number of mutations in the ISDR with a larger group of patients and identified the mutation sites within the ISDR that were significantly associated with sustained response [63]. Although these results have been confirmed for Japanese isolates, in studies of patients from other countries the majority of IFN-sensitive isolates showed no or only a few mutations in the ISDR [64, 65]. The reasons for the different findings are not clear but may involve racial, virologic, or other factors.

The determination of HCV subtypes has no clinical relevance in patients treated with IFN and ribavirin, while different treatment durations based on viral load kinetics are recommended for patients with different HCV genotypes. However, the emergence of resistant variants and virologic breakthrough were more common in patients infected with HCV subtype 1a than 1b when treated with TVR triple therapy [66]. HCV subtyping may play a role in helping to select treatment regimens and predict the development of resistance to DAA drugs. In addition, triple therapy with a protease inhibitor is not recommended for patients infected with genotypes 2 and 3.

Antiviral-resistance mutations that cluster around the catalytic site of the NS3/4A serine protease emerge during protease inhibitor therapy and are associated with failure and relapse [52]. Similar resistant variants are detected in both BOC- and TVR-treated patients, suggesting that cross-resistance occurs with these protease inhibitors. Also antiviral-resistant variants are found in about 5 % of patients prior to treatment, but do not appear to impact response to either protease inhibitor. Currently there is no role for antiviral resistance genotyping at baseline or during treatment with the protease inhibitors [67].

Several mutations in the NS3/4A protease are associated with reduced susceptibility to simeprevir. One of the most common and clinically relevant mutations is the substitution Q80K. This mutation may be present at baseline in approximately 30 % of patients with genotype 1a and is associated with lower SVR rates. For patients with genotype 1a, Q80K mutation testing is recommended and patients with this variant should be offered other treatment options [68].

IL28B Genotyping

Human genome wide association studies identified multiple single nucleotide polymorphisms (SNPs) in a region 3 kilobases upstream of the human INF-λ-3 or *interleukin-28B* (*IL28B*) gene on chromosome 19 that are associated with spontaneous clearance of HCV infection and treatment response to pegylated IFN-α and ribavirin. A SNP at position rs129779860 T/C is associated with an approximately two-fold change in response to treatment in both patients of European and African ancestry. Because the favorable C/C genotype is in substantially greater frequency than the unfavorable T/T genotype in European than in African populations, this genetic polymorphism also explains approximately half the difference in response rates between the two populations [69]. The C/C genotype also strongly enhances spontaneous HCV clearance in a natural history setting among individuals of both European and African ancestry [70].

A second SNP in the same region of *IL28*, rs80999117 T/G, has been implicated in both treatment-induced viral clearance rates and spontaneous clearance of HCV infection in Japanese, Australian, and Swiss populations [71, 72]. The rs129779860 and rs80999117 polymorphisms are approximately 4,000 base pairs apart and show high levels of linkage disequilibrium, resulting in distinct haplotypes in the studied populations. INF-λ-3 is a type III IFN that shares many characteristics with IFN-α, a type I IFN. However, INF-λ-3 has less antiviral activity against HCV than IFN-α, but the unique INF-λ-3 receptor is more liver cell-specific than the IFN-α receptor.

The predictive value of rs129779860*IL28B* genotyping for a SVR to treatment with pegylated IFN-α and ribavirin is superior to baseline viral load, HCV, fibrosis stage, age, and gender, and is higher for HCV genotype 1 than for genotypes 2 or 3. The IL28B C/C genotype is also a robust pretreatment predictor of a SVR to protease inhibitor triple therapy. However, as new more potent direct acting antiviral agents are developed, *IL28B* genotype will discriminate responders and non-responders less well. Currently there are no US FDA-cleared tests for *IL28B* genotyping.

Available Assays

Many test kits for detection or quantification of HCV RNA are commercially available. These tests are based on traditional reverse transcription-polymerase chain reaction (RT-PCR), transcription-mediated amplification (TMA), branched-DNA (bDNA) assay, or, most recently, real-time RT-PCR methods.

Qualitative Detection HCV Assays

Two US FDA-approved qualitative HCV RNA test kits are available for diagnostic use: the Amplicor HCV test v2.0 (Roche Diagnostics) and the Versant HCV RNA qualitative test (Siemens Corp.). The Amplicor HCV test v2.0 is based on RT-PCR amplification of a portion of the 5′ UTR and has an analytical sensitivity of 50 IU/ml [73]. The test incorporates an internal control to detect PCR inhibitors and deoxyuridine triphosphate (dUTP) and uracil-N-glycosylase in the reaction mixture to prevent false positives due to amplicon carryover. The test is available in two formats, a manual microwell plate assay and a semiautomated assay designed for the COBAS instrument. The performance characteristics of the Amplicor HCV tests are well established [74].

The Versant HCV RNA qualitative test also targets the 5′ UTR but uses TMA to amplify the targeted region. The analytical sensitivity of the Versant HCV RNA assay is 5 IU/ml. The increase in analytical sensitivity over the Amplicor tests is due in part to the larger sample volume (500 µl vs 200 µl) and the use of a specific target capture step to isolate HCV RNA rather than total RNA precipitation. This test also uses an internal control RNA to detect the presence of amplification inhibitors.

The Versant HCV RNA assay can detect residual serum HCV RNA in some patients with no detectable HCV RNA determined by the Amplicor v2.0 assay at the end of treatment with IFN and who subsequently have a virologic relapse [75, 76]. However, this difference was not observed with end-of-treatment samples from patients treated with pegylated IFN-α [77]. The two qualitative HCV RNA assays demonstrate excellent concordance with specimens submitted for HCV diagnosis [78]. The difference in analytical sensitivity between the two tests does not result in any meaningful difference in clinical sensitivity when the tests are used diagnostically, because typically patients with chronic hepatitis C infection to present for initial evaluation with very high viral loads.

The Procleix HIV-1/HCV test (Gen-Probe Inc.) also uses TMA technology and is approved by the US FDA for the screening of blood products [79]. The Ampliscreen HCV RNA test v2.0 is an RT-PCR assay (Roche Diagnostics) designed for blood screening that is based on the Amplicor HCV test. Both assays have analytical sensitivities of less than 50 IU/ml.

Quantitative HCV Assays

Several assays are commercially available for quantification of HCV RNA levels in patients. These assays use conventional RT-PCR, bDNA, or real-time RT-PCR to amplify the HCV RNA. Most clinical laboratories use one of the US FDA-approved real-time RT-PCR (RT-qPCR) assays for determining HCV viral loads. The Amplicor HCV Monitor test v2.0 (Roche Diagnostics) is a quantitative RT-PCR assay that amplifies the same target region as the qualitative Amplicor HCV test. The assay uses an internal quantification standard to calculate the amount of HCV RNA in a sample. The assay has a sensitivity of 600 IU/ml and a 2.9 $\log_{10}$ dynamic range. Specimens with values greater than the

upper limit of quantification (500,000 IU/ml) can be diluted 100-fold and retested as recommended by the manufacturer. The Amplicor HCV Monitor test is available in both manual microwell plate and semiautomated COBAS instrument (Roche Diagnostics) formats.

The Versant HCV RNA Assay v3.0 (Gen-Probe, Inc.) uses bDNA technology. The sensitivity of the Versant HCV RNA Assay v3.0 is 615 IU/ml, with a 4.1 $\log_{10}$ dynamic range. A number of changes to the design of the v3.0 test improved both the sensitivity and specificity over the v2.0 test. These include an increased number of capture probes, improved probe design, the use of non-natural synthetic nucleotides in detection probes, and redesigned label extenders. The System 340 bDNA analyzer (Gen-Probe, Inc.) automates all incubations, wash steps, readings, and data analysis. The instrument can process two 96-microwell plates per run.

Overall, the results of the Versant HCV RNA Assay v3.0 and the Amplicor HCV Monitor Test v2.0 have been found to be in substantial agreement [80, 81]. The results of the Amplicor Monitor test are reported as IU/ml and those of the Versant assay are reported as either copies/ml or IU/ml. Both tests have minimal HCV genotype bias and have similar analytical sensitivities. The Versant results tend to be more precise than the Amplicor Monitor results, but the Amplicor Monitor test is better able to discriminate low-positive from negative specimens. The Versant assay has a much greater dynamic range than the Amplicor Monitor test; however, a pretest sample dilution permits quantification of high viral load specimens by the Amplicor Monitor test. The throughput and level of automation are much greater with the Versant assay than with the Amplicor Monitor test.

The two US FDA-approved RT-qPCR assays for HCV viral load both amplify 5′UTR sequences but employ different amplicon detection probes. The probe in the Abbott RealTime HCV assay (Abbott Laboratories) is labeled with a 5′ fluorophore and a 3′ quencher. In the unhybridized state the probe assumes a random coil configuration that keeps the quencher in close proximity to the fluorophores and inhibits fluorescence. Upon hybridization to the target sequence the fluorophore and quencher are separated and fluorescent signal is produced. Reduced genotype bias is achieved by annealing the probe to the target at a relatively low temperature that permits probe binding despite mismatches between the probe and the target. Quantification is performed using an internal calibrator. The assay has a very low limit of detection (12 IU/ml) and quantification (12 IU/ml), and a 7 $\log_{10}$ dynamic range [82].

The Roche RT-qPCR assays (Roche Diagnostics) employ 5′ exonuclease probes from which the fluorophore and quencher are released as the probe is hydrolyzed by the action of the *Taq*Man DNA polymerase as it extends the primer during amplification. The assays are calibrated externally by the manufacturer and lot specific calibration coefficients are used by the system software to calculate the HCV RNA concentrations. An internal quantification standard is added prior to nucleic acid extraction to correct for the presence of any amplification inhibitors that may be present in the samples. The earlier versions of these assays had significant genotype bias, particularly with regard to genotype 4 [83–85]. The second versions of these assays were modified to improve genotype inclusivity by using a smaller sample input volume and redesigning the primer set [86]. The manual and fully automated versions of the assay differ in their limits of quantification and dynamic ranges (Table 46.6).

RT-qPCR assays have broader dynamic ranges than conventional RT-PCR and bDNA assays and limits of detection that are comparable to the available qualitative assays. Diagnostic testing and therapeutic monitoring therefore can be performed with a single test, greatly simplifying nucleic

Table 46.6 Commercial HCV RNA tests

Test (company)	Method	Lower limit of detection (IU/ml)	Dynamic range
Qualitative			
Amplicor HCV Test v2.0 (Roche Diagnostics, Indianapolis, IN)[a]	RT-PCR	50	NA
Versant HCV RNA Assay (Siemens Corp., Washington, DC)[a]	TMA	5	NA
Ampliscreen HCV Test v2.0 (Roche Diagnostics)[a]	RT-PCR	<50	NA
Procleix HIV-1/HCV Assay (Gen-Probe, Inc., San Mateo, CA)[a]	TMA	<50	NA
Quantitative			
Amplicor HCV Monitor Test v2.0 (Roche Diagnostics)	RT-PCR	600	$600–5\times10^5$

acid testing. If conventional RT-PCR or bDNA assays are used, then an additional more sensitive qualitative test is needed to adequately assess treatment response. The package inserts for the protease inhibitors BOC and TVR include statements that an HCV assay with a lower limit of quantification ≤25 IU/ml should be used to monitor response to therapy.

HCV Genotyping Assays

A variety of laboratory-developed and commercial assays are used for HCV genotyping. The methods include nucleic acid sequencing, reverse hybridization, subtype-specific PCR, DNA fragment length polymorphism, heteroduplex mobility analysis, melting curve analysis, and serologic genotyping. Currently there is only one US FDA-approved HCV genotyping assay, the Abbott RealTime HCV Genotype II assay (Abbott Laboratories).

A commercially available reverse hybridization line probe assay is the most commonly used method for genotyping HCV among clinical laboratories participating in the HCV proficiency-testing surveys of the College of American Pathologists. This reverse hybridization assay was developed by Innogenetics and is now marketed as the Versant HCV Genotype 2.0 Assay (Siemens Corp.). In this line probe assay (LiPA), biotinylated PCR products from the 5′ UTR and core regions of the HCV genome are hybridized under stringent conditions with oligonucleotide probes attached to a nitrocellulose strip: 19 type- and subtype-specific probes interrogate the 5′UTR and an additional three probes interrogate the core region. The core region probes were added to provide better discrimination of subtypes 1a and 1b and genotype 6 [87]. Hybridized PCR products are detected with a streptavidin-alkaline phosphatase conjugate. The pattern of reactive lines defines the genotype and in some cases the subtype. The second-generation assay discriminates among genotypes 1a, 1b, 2a/c, 2b, 3a, 3b, 3c, 3k, 4a/c/d, 4b, 4e, 4h, 5a, and 6a/b. The results from the Versant HCV Genotype 2.0 Assay correlate well with results obtained by direct sequencing assays of the 5′ UTR and other genes at the genotype level and at distinguishing subtypes 1a and 1b, but may not be able to adequately identify the other subtypes [88]. Mixed genotype infections can be recognized as unusual patterns of hybridization signals. However, the LiPA requires a considerable amount of amplicon for typing, and the assay may regularly fail when the viral load is less than 10^4 copies/ml.

A DNA enzyme immunoassay (Sorin Biomedica, Irvine, CA) for HCV genotyping is based on hybridization of denatured amplicon from the core region to genotype-specific probes that are bound to the wells of a microtiter plate. Mouse monoclonal antibodies to double-stranded DNA are used to detect the hybrids. The results of the DNA enzyme immunoassay were highly concordant with the results of other genotyping methods in two evaluations [89, 90].

Sequence analysis of amplified subgenomic sequences is the most definitive way to genotype HCV strains. Genotyping schemes based on sequencing variable genes such as E1, C, and NS5B provide enough resolution to determine types and subtypes [29, 91]. The 5′ UTR is too highly conserved to discriminate all subtypes reliably. Genotyping methods targeting highly variable regions have higher failure rates due to primer mismatches and failed amplification reactions. Sequencing reactions can be performed directly on PCR products or on cloned amplicons. Mixed infections with multiple genotypes may be missed by sequence analysis. Definitive detection of mixed infections requires analysis of a large number of clones. Cloning may, however, emphasize artifactual nucleotide substitutions introduced by the DNA polymerase during amplification or by selection during the cloning procedure, and is generally not practical for the clinical laboratory.

The practice of using sequence analysis of a single subgenomic region for HCV genotyping has been challenged by the description of naturally occurring intergenotypic recombinants of two HCV genotypes [92–95]. The recombinant forms have been detected in patients in Russia (genotypes 2k and 1b), Vietnam (genotypes 2 and 6), and France (genotypes 2 and 5), as well as in experimentally infected chimpanzees (genotypes 1a and 1b).

A novel HCV genotyping method using a solid phase electrochemical array was developed by GenMark Diagnostics (Carlsbad, CA). The method uses sequence specific capture of a PCR amplicon from the HCV 5′UTR by surface-bound oligonucleotide capture probes formed within a preassembled monolayer with electrochemical detection using ferrocene-labeled oligonucleotide signal probes. High concordance between the GenMark and LiPA HCV genotyping (Siemens Corp.) tests were observed at the HCV genotype level; however, there were minor discrepancies in genotype 1 subtype identifications by the two tests due to differences in the regions of the HCV genome interrogated [96].

Laboratory-developed methods also are used to genotype HCV, including subtype-specific PCR [26], primer-specific and mispair extension analysis [97], nested restriction site-specific PCR [98], restriction fragment length polymorphism [99], heteroduplex mobility analysis [100], and melting-curve analysis with fluorescence resonance energy transfer probes [101, 102].

Interpretation of Test Results

The presence of HCV RNA in serum or plasma defines active infection, and HCV RNA is usually detectable within the first week after exposure. However, a single negative HCV RNA test result does not exclude the possibility of active infection because viremia may be intermittent in some

chronically infected patients [103]. An HCV RNA test may be the only evidence of infection in individuals with false-negative antibody tests. False-negative HCV antibody tests can occur in HIV-1 infected individuals, patients undergoing hemodialysis, and patients with HCV-associated essential mixed cryoglobulinemia [104–106].

A negative HCV RNA test at the completion of therapy defines an end-of-treatment response (ETR), and a negative test 6 months after the completion of therapy defines a SVR. The test used to assess these treatment endpoints must have an analytical sensitivity or lower limit of detection of ≤10–15 IU/ml because the use of less sensitive tests can lead to misidentification of responders [107, 108].

HCV RNA quantitation is useful in planning duration of therapy and in predicting the likelihood of response to treatment. Patients with high HCV RNA levels tend to respond less well to IFN and ribavirin, but lengthening the course of therapy from 24 to 48 weeks more than doubles the response rate. Patients with viral loads greater than 600,000 IU/ml are considered to have high HCV RNA levels. HCV viral load does not predict disease progression, is not correlated with disease severity, and, consequently, should not be routinely monitored in untreated patients. Viral load testing can be used in an early assessment of viral kinetics in patients undergoing treatment with IFN and ribavirin. Patients who fail to achieve at least a 2 $\log_{10}$ decline in viral load after 12 weeks of treatment have little chance of an SVR and therapy should be discontinued. Viral genotyping helps inform the choice of therapy, predict the outcome of therapy and determine its duration as described above (Fig. 46.1). No association between genotype and disease progression or severity has been proven, so genotyping should be reserved for those patients being considered for treatment.

Laboratory Issues

The use of internal controls increases the confidence in negative HCV RNA test results and eliminates concerns that the test is falsely negative because of the presence of amplification inhibitors in the sample or poor recovery of the viral RNA. False-negative HCV RNA results also may occur if the specimen was not processed or stored appropriately due to the lability of the viral RNA. Serum or plasma should be separated from the cellular components of blood within 6 h of collection to avoid significant loss of HCV RNA. Once separated, the sample is stable for 3 days at 4 °C. Storage for longer periods should be at −70 °C.

False-positive HCV RNA tests can result from contamination of the sample with HCV target RNA or amplicon. However, widespread use of real-time PCR methods which combine target amplification and detection in a single tube has eliminated amplicon contamination as potential source of false-positive test results.

HCV RNA tests should be used for follow-up of low-positive HCV antibody screening tests if the RIBA is not available. Only the qualitative HCV RNA tests are US FDA approved for diagnosis but are not widely available in clinical laboratories. Although the quantitative tests are not intended for diagnostic use, the newer real-time PCR-based assays have similar sensitivity as the qualitative tests and should work well to diagnose both acute and chronic HCV infections.

Much has been written about the lack of agreement and the genotype bias of early commercially available versions of the HCV quantitative assays. The development the WHO First International HCV RNA standard and its acceptance by the manufacturers of these assays as a calibrator was a significant advance in HCV RNA quantification [109]. However, despite the implementation of an international standard, HCV RNA measurements are not equivalent between the different assays [85, 110]. Therefore, patients should be tested with the same assay during the course of their treatment to minimize the potential for patient management errors [111]. The major sources of this variability are differences in genotype bias between the assays and the fact that the WHO standard is an imperfect standard. Its value was derived from a consensus concentration obtained by diverse viral load assays in numerous laboratories rather than by an independent chemical method.

The widespread use of tests not cleared by the US FDA for HCV genotyping has placed an increased burden on clinical laboratories to verify the performance characteristics of these tests prior to clinical use. When validating HCV genotyping tests, laboratories should take advantage of the published evaluations and commercially available genotype panels to streamline the verification process.

The College of American Pathologists has a well-established proficiency testing program for laboratories performing tests for detection, quantification, and characterization of HCV RNA. These surveys have shown a steady improvement in the performance of laboratories over time that probably reflects progress in both the available technologies and laboratory practices.

Future Directions

Although the incidence of new HCV infections in the USA is declining, the number of individuals infected for more than 20 years who are at risk for serious complications is expected to increase until about the year 2015. In the 23 years since the discovery of HCV, the major route of transmission through blood transfusion has all but been eliminated, improvements in therapy have resulted in better response rates, and molecular tests have proven invaluable in the diagnosis and management of patients with HCV.

The CDC has expanded its previous recommendations for prevention and control of HCV infection to include antibody screening all persons born between 1945 and 1965.

Consequently, more infected individuals will be identified and many will be candidates for therapy. Several new classes of direct acting antiviral agents for HCV infection will be available soon, further increasing the number of candidates for therapy [112]. As new testing guidelines and therapies evolve, the number of molecular tests performed will increase and the test menu may change to include not only HCV viral load testing and taxonomic genotyping but analysis of mutations leading to antiviral resistance and predicting patients' responses to therapy. Refer to the website http://www.hcvguidelines.org/ for the latest recommendations. On the technology front, next-generation sequencing will become increasingly important in the analysis virus populations with applications in epidemiology, viral evolution, and antiviral resistance testing.

Viral Infections in Transplant Recipients

47

Raymund R. Razonable and Randall T. Hayden

Abstract

Viruses are major opportunistic pathogens that cause significant morbidity and mortality after transplantation. They do not only cause direct clinical illness, but have indirect effects that increase the risk of graft failure and mortality. The clinical presentation of viral infections is very nonspecific, and hence, the role of the clinical laboratory is essential in confirming diagnosis. There have been remarkable improvements in the laboratory diagnosis and monitoring of viral infections, with the evolution from conventional culture methods to more sensitive molecular assays. A number of nucleic acid-based detection assays are currently used in clinical practice for the diagnosis, surveillance, and monitoring of viral infections in transplant patients. Some have the ability to quantify viral load, which is useful for differentiating latent from active infection, for differentiating mild from potentially severe disease, and for monitoring therapeutic response.

The majority of molecular tests for viral diagnosis in transplantation lack standardization, and their clinical uses across different testing sites have been difficult. Variability in specimen type, nucleic acid extraction methods, target sequence, limit of detection, and quantitative and calibration standard are some of the reasons for varying viral load reports from different assays. This lack of standardization not only complicates management of individual patients, but also hampers the development of consensus interpretive and treatment guidelines. This book chapter discusses the clinical application of molecular tests for the diagnosis of adenovirus, BK virus, parvovirus B19, cytomegalovirus, Epstein Barr virus, and the other members of the herpes virus family.

Keywords

Viral infections • Transplantation • Herpes viruses • Polyomaviruses • Parvovirus • Adenovirus • Cytomegalovirus

Introduction

Transplantation is a standard treatment modality for many end-stage clinical illnesses that would otherwise be fatal. The use of immunosuppressive drugs, which are essential to prevent and treat graft rejection after solid organ transplantation (SOT) and graft-vs-host disease (GVHD) after allogeneic hematopoietic stem cell transplantation (HSCT), increases the risk of opportunistic infections.

Viruses are major opportunistic pathogens that cause significant morbidity and mortality after SOT and HSCT [1]. Viruses not only cause clinical syndromes directly, but also have indirect effects that increase the risk of graft failure and mortality [1]. The clinical presentation of viral diseases in transplant recipients can be classic or atypical with non-specific manifestations. Hence, the role of the clinical laboratory is essential in confirming clinical suspicions of viral infection [2]. In this regard, the last decade has seen remarkable improvements in the laboratory diagnosis and monitoring of viral infections. Test methods have evolved (and continue to evolve) from conventional culture methods to more sensitive molecular assays. Conventional methods have slow turnaround time and poor sensitivity, while molecular tests, which rely on the detection of viral nucleic acids, provide rapid turnaround time and improved sensitivity.

A number of nucleic acid-based detection assays (also known as nucleic acid tests [NATs]) are currently used in clinical practice for the diagnosis, surveillance, and monitoring of viral infections in transplant patients, but the most widely used are based on the polymerase chain reaction (PCR) (Table 47.1) [2]. Other molecular methods used in the clinical laboratory are based on RNA amplification (nucleic acid sequence based amplification and transcription-mediated amplification) and on signal amplification. Some NATs quantify the amount of virus in a sample (defined as the viral load), which is useful for differentiating latent from active infection, for differentiating mild from potentially severe disease, and for monitoring therapeutic response.

The increased sensitivity of molecular tests for viral detection has posed an important challenge in differentiating active from latent infection. A number of viruses that cause clinical disease in transplant recipients exist in a latent state, and there is concern that highly sensitive molecular assays may detect nucleic acid from such latent, non-replicating viruses in the absence of active disease. If not interpreted in the proper clinical context, this may lead to unnecessary treatment.

Table 47.1 Clinical utility of molecular diagnostic tests for viruses in transplantation

Clinical use	General assay characteristics	Specific clinical applications
Diagnosis	Rapid turnaround time thereby facilitating targeted antiviral therapy Highly specific for the pathogen of interest More sensitive than conventional methods such as culture High sensitivity may detect latent virus: viral quantification or detection of viral RNA may aid in the differentiation of replicating from latent virus	Nucleic acid tests for adenovirus, BK virus, parvovirus B19, herpes simplex virus, varicella zoster virus, cytomegalovirus, Epstein Barr virus, and other herpesviruses are sensitive and rapid methods for confirming clinical suspicion of specific viral diseases
Surveillance	Guide initiation of preemptive therapy strategy Identifies patients at high risk of clinical disease (risk stratification) Identifies patients at high risk of treatment failure and relapse (prognosis)	Surveillance for cytomegalovirus infection by nucleic acid testing guides the initiation of antiviral treatment prior to the onset of clinical disease Surveillance for BK virus in kidney transplant recipients identifies infection prior to the onset of nephropathy, thereby allowing preemptive reduction in immunosuppression as treatment Surveillance for Epstein Barr virus infection identifies patients at high risk of post-transplant lymphoproliferative disease High cytomegalovirus and Epstein Barr virus viral loads indicate high risk of clinical disease, although widely applicable viral thresholds have been difficult to define due to lack of assay standardization
Monitor treatment responses	Guide the duration of antiviral therapy Early indicator of risk of treatment failure Early indicator of disease relapse Early indicator of the emergence of resistant viruses	Treatment of cytomegalovirus disease is generally continued until the virus is undetectable by a sensitive PCR test Viral load testing for cytomegalovirus, Epstein Barr virus, and BK virus generally decline following initiation of a successful treatment strategy Rise in cytomegalovirus, Epstein Barr virus, and BK virus viral load during treatment indicates relapse, an over-immunosuppressed state, or the possible emergence of drug resistance

The majority of molecular tests for viral diagnosis in transplantation lack standardization, and their clinical use across different testing sites has been difficult, if not impossible [3, 4]. Most viral laboratory-developed tests (LDTs) do not use international standards, and hence, the performance characteristics vary widely and the results are not directly comparable. Variability in specimen type (plasma, whole blood, or peripheral blood leukocytes), nucleic acid extraction methods, target sequence, limit of detection, and quantitative standard are just some of the reasons why values obtained from different LDTs are not directly comparable (Table 47.2). This lack of standardization not only complicates management of individual patients, but also hampers the development of consensus interpretive and treatment guidelines.

This chapter discusses the clinical application of molecular tests for the diagnosis of viral infections in transplant recipients. Although many viruses can infect transplant recipients, this chapter will focus on more commonly encountered pathogens, including adenovirus, BK virus (BKV), parvovirus B19, cytomegalovirus (CMV), Epstein Barr virus (EBV), and the other members of the herpes virus family.

Adenovirus

Description of Pathogen and Clinical Utility of Testing

Adenoviruses are a family of 57 immunologically distinct, non-enveloped, double-stranded DNA viruses that cause a variety of clinical syndromes in humans [5, 6]. Each adenovirus serotype, termed groups A through G, is associated with a distinct clinical illness, which in immunocompetent hosts can manifest as self-limited respiratory, gastrointestinal, or conjunctival disease [5]. Infection with adenovirus occurs throughout the year, although a predominance of cases is observed during fall and winter months [7]. Adenovirus infections occur most commonly in children, those living in close quarters, and immunocompromised patients including transplant recipients [5].

The incidence of adenovirus infection after transplantation is estimated at 5–15 % of patients [8, 9]. In a large prospective study of 263 adult SOT recipients, adenovirus DNA was detected in the blood of 7.2 % of patients during the first year after transplantation [8]. However, this study may have underestimated the true incidence of adenoviral disease since it did not capture localized and non-viremic infections. Children have a higher incidence of adenoviral infection compared to adult patients. Adenovirus was detected in 10 % of 484 pediatric liver recipients [10], compared to only 5.8 % of 191 adult liver recipients [11]. In a cohort of pediatric allogeneic HSCT recipients, the probability of developing adenovirus infection was 12.3 % [12], while the incidence was 2.5 % in adult allogeneic HSCT recipients [13].

Adenovirus infection after transplantation may or may not be associated with clinical symptoms [5]. The clinical manifestations, rate, and severity of infection may vary based on immunosuppression level, the type of SOT or HSCT, and the time to onset since transplantation [5]. Since immunosuppression is most intense during the early period after transplantation, clinical disease is most often seen during the first 3 months after transplantation [5]. In a prospective study, 60 % of SOT patients with adenovirus DNA detectable in blood after transplantation had no clinical symptoms [8]. For the remaining 40 % of SOT patients, symptoms were related to gastrointestinal and respiratory tract infections [8]. Nonspecific symptom of fever also was observed in SOT recipients. In liver transplant recipients, infection with adenovirus serotype 5 was associated with hepatitis while serotypes 1 and 2 were associated with pneumonia [10, 11]. Adenovirus may involve the allograft, which can manifest as allograft dysfunction and may be mistaken for rejection. Adenoviral pneumonia may contribute to bronchiolitis obliterans, graft loss, or even death in lung transplant patients [14]. Adenovirus infection can cause hemorrhagic cystitis and graft dysfunction after kidney transplantation [15]. In highly immunosuppressed patients, such as allogeneic stem cell transplant recipients, adenovirus infection may manifest as disseminated disease with involvement of the liver, gastrointestinal tract, and lungs [12]. Adenovirus infection is reported as one of the most significant risk factors for death in allogeneic HSCT recipients [12].

Available Assays and Interpretation of Results

The gold standard for the diagnosis of invasive adenoviral disease is histological evaluation of a tissue specimen [5], which demonstrates typical cytopathic inclusions known as "smudge cells." The presence of adenovirus within the tissue

sample may be confirmed through the use of immunohistochemistry or in situ hybridization. Less invasive approaches to diagnosis are (1) antigen detection, (2) culture, and (3) molecular assays using blood and other fluids from affected organs. A single diagnostic test may not be able to detect all adenovirus serotypes. Enzyme immunoassays (EIAs) are typically the basis of rapid antigen detection kits. Rapid antigen detection kits are commercially available but their performance characteristics in the transplant population have not been rigorously studied. Moreover, while most EIAs can detect serotypes associated with ocular or gastrointestinal disease, they are not able to detect all adenovirus types and some have been associated with a low sensitivity of detection [5]. Rapid detection of adenovirus also can be done by immunofluorescence, using either polyclonal or monoclonal antibodies [5]. Culture techniques suffer from prolonged turnaround time. Although time to detection has improved with the introduction of the shell vial assay [5], sensitivity remains an issue.

PCR Tests for the Detection of Adenovirus

Nucleic acid detection using PCR has emerged as the preferred diagnostic tool for identification of adenoviral infections in transplant recipients [16]. Adenovirus PCR testing is generally more sensitive than culture-based methods [17]. In a study of HSCT recipients, adenovirus NAT had a higher sensitivity compared to viral culture and antigen detection [18, 19]. Numerous molecular assays are available, including commercial reagents and LDTs, with widely variable performance characteristics. The assay performance differences are (at least in part) dependent on the specimen type, primers used, and extraction method, among other factors. Whole blood, plasma, stool, urine, respiratory secretions (e.g., bronchoalveolar lavage), and other body fluids have been used. Comparability of tests is complicated by the fact that very few are cleared by the US Federal Drug Administration (FDA) for clinical in vitro diagnostic use. Some qualitative assays are US FDA cleared, but only for use with respiratory samples. Compounding the problem is the lack of internationally standardized quantitative calibrators. Many NATs will not detect all adenovirus serotypes, although a few have been developed to detect all known adenovirus serotypes [17, 20]. Some multiplex PCR systems include adenovirus in a test for simultaneous detection of many respiratory viruses [21]. However, multiplexed PCR can reduce the sensitivity of viral detection. Some of the broadly multiplexed viral tests have diminished sensitivity for adenovirus compared to adenovirus-specific tests. The large number of adenovirus serotypes and their genetic heterogeneity can complicate adequate validation of these assays. Hence, verification of NAT assay performance should include a wide variety of adenovirus serotypes, with assessment of both sensitivity and quantitative accuracy.

Quantitative Adenovirus Tests

Quantitative NAT for adenovirus can be used for risk stratification and prognostication [16, 18, 19]. Serial surveillance of the blood for adenovirus DNA in transplant recipients may identify the infection prior to the onset of clinical illness. Detection of adenoviral DNA in asymptomatic patients can allow for preemptive therapy for patients with a high risk of progression to clinical disease, such as those with high viral load, severe lymphopenia, and receiving intense immunosuppression for GVHD or allograft rejection [16]. Recent guidelines have recommended serial adenovirus surveillance of blood of high-risk allogeneic HSCT recipients to identify and predict the onset of invasive adenoviral disease [9, 17]; however, the clinical utility of this approach remains uncertain [22]. In one prospective study of 97 allogeneic HSCT recipients, surveillance of the blood identified adenovirus in five patients (5 % incidence, including one with a very high viral load), although this did not have an impact on the clinical outcome of these patients [23].

Some groups have even demonstrated the clinical utility of quantitative adenovirus PCR surveillance of stool samples to predict subsequent adenovirus viremia [16, 20]. In these studies, the detection of high levels of adenoviral DNA in the stool preceded the onset of viremia by at least 11 days [16, 18, 20]. The incidence of viremia was 73 % for those with $>1 \times 10^6$ copies of adenovirus DNA per gram of stool, while patients with lower values did not develop adenoviral viremia [20]. Serial stool surveillance predicted invasive adenoviral disease with 100 % sensitivity and 83 % specificity [20].

Adenovirus may be shed asymptomatically for prolonged periods of time, and thus, recovery of adenovirus from urine, upper respiratory secretions, or stool sites by culture does not necessarily confirm adenovirus as the cause of a specific disease [24, 25]. Indeed, the detection of adenovirus in one site, such as the urine alone, has poor predictive value and, therefore is not recommended for routine surveillance. However, the detection of adenovirus at two or more sites is highly predictive of invasive disease [24, 25]. Quantitation of viral load may help differentiate true infection from subclinical shedding, although the viral load threshold for discriminating a clinically relevant infection is not defined due to a lack of studies using standardized assays.

Quantitative adenovirus NAT can be used for monitoring treatment response. Treatment of established adenovirus disease consists of cautious reduction of immunosuppression and supportive care. There is no US FDA-approved antiviral drug for the treatment of established adenoviral disease, although cidofovir (CDV) has been used most frequently [5]. Treatment responses may be monitored by quantitative adenovirus PCR. Failure of the viral load to decline by 1 log within 2 weeks of treatment, or a persistent rise in viral load has been associated with mortality [26]. Generally, a higher adenoviral DNA level in the blood is associated with poor

prognosis and a higher rate of treatment failure [6]. In a study of 27 adult allogeneic HSCT recipients, the peak adenovirus DNA load was significantly higher among seven patients who died of adenovirus disease compared to those without adenovirus-related death (1×10^8 vs 3×10^5; $p < 0.001$) [6].

BK Virus

Description of Pathogen and Clinical Utility of Testing

BKV is a non-enveloped, double-stranded DNA virus that belongs to the family *Polyomaviridae*, together with JC virus (JCV) [27]. Both BKV and JCV are named by the initials of the patients from which the viruses were originally identified. Primary BKV infection is common during childhood and is typically asymptomatic. More than 90 % of adults have serologic evidence of past BKV infection. BKV is transmitted through oral or respiratory routes. After primary infection, BKV remains latent in urothelial cells and leukocytes [27]. Reactivation of latent virus resulting in asymptomatic urinary shedding may occur in up to 10 % of healthy individuals [27].

In transplant recipients, BKV reactivation is more common and may lead to cytopathic changes in the urothelium. BKV viruria has been detected in up to 40 % of kidney transplant recipients and up to 75 % of allogeneic HSCT recipients [27]. The vast majority of BKV viruria in transplant recipients is subclinical, but kidney transplant and HSCT patients with viruria at very high levels may have clinical manifestations [28–31]. High levels of urinary tract BKV replication may result in sloughing of altered epithelial cells with nuclear inclusions (known as "decoy cells"), which are excreted in the urine and may be detected by urine cytologic examination [32, 33]. Inflammation elicited by necrosis and denudation of the tubular basement membrane is followed by infiltration of lymphocytes, tubular atrophy, and fibrosis. In the absence of therapeutic intervention, approximately 30–50 % of kidney transplant patients with high-level BKV viruria progress to viremia and end organ disease.

The two major clinical syndromes associated with BKV after transplantation are BKV-associated nephropathy (BKAN; in kidney transplant recipients) [29, 34, 35] and hemorrhagic cystitis (primarily in allogeneic HSCT recipients) [28, 36]. BKAN occurs in 1–10 % of kidney transplant recipients, while recipients of other solid organ allografts rarely develop BKAN. BKAN is most commonly manifested by a rise in serum creatinine with corresponding renal histopathologic findings of varying severity, including inflammation, tubular atrophy, and fibrosis, together with viral inclusions that can be identified by electron microscopy, immunohistochemistry, or in situ hybridization. Hemorrhagic cystitis, often of late onset, affects 5–15 % of allogeneic HSCT patients [37]. Occurring in the post-engraftment period, hemorrhagic cystitis may be characterized by abdominal pain, dysuria, frequent micturition, and microscopic or gross hematuria [28, 37]. Severe hematuria leading to clot formation, ureteral obstruction, and renal failure has been reported. The other diseases associated with BKV infection are ureteric stenosis, pneumonitis, and hemophagocytic syndrome [27].

Antiviral drug treatment is not established for BKAN or for hemorrhagic cystitis [27]. Cidofovir has been used anecdotally for the treatment of BKV infection in transplant patients [27], although data to convincingly support this antiviral therapy in transplant patients is not available. A randomized controlled clinical trial comparing CDV to placebo for the treatment of BKAN has been halted due to poor enrollment of study subjects. In the absence of the proven effectiveness of antiviral therapy, reduction in immunosuppressive therapy is regarded as the first line of treatment [27], since the pathogenesis of BKAN involves an imbalance between BKV replication and BKV-specific immune control.

Available Assays and Interpretation of Results

Histopathology for BKV

Histopathology is the gold standard for diagnosis of BKAN [38]. Early and accurate diagnosis of BKAN is essential to prevent graft failure. However, often no clear clinical symptoms of BKV infection are present, and the only clinical sign may be a gradual rise in serum creatinine. Histopathology of allograft biopsy specimens with BKAN shows extensive viral cytopathic effect, necrosis of the cells of the tubules and collecting ducts, and varying degrees of interstitial inflammation [38]. The pathology is focal and patchy, and, thus, this invasive procedure may yield false-negative results due to sampling error [32]. Likewise, in HSCT patients with late onset hemorrhagic cystitis, a biopsy of the bladder epithelium is needed to demonstrate the potential role of BKV infection [37].

A noninvasive alternative for diagnosis of BKV infection is to examine the urine for the presence of decoy cells, which contain characteristic intracellular viral inclusion bodies [39]. Identification of decoy cells confirms active BKV replication, but this finding is not highly specific for BKAN or hemorrhagic cystitis. Several studies have demonstrated that the sensitivity of urinary decoy cell detection in kidney transplant recipients with BKAN is modest (and comparatively less than molecular methods). In one study, urine decoy cell detection had 25 % sensitivity and 84 % specificity in identifying four patients with BKAN among a cohort of 114 kidney transplant patients [39]; the corresponding positive

predictive value for concurrent BKAN was only 5 % and the negative predictive value was 97 % [39]. Decoy cell detection has been used to support the diagnosis of late-onset hemorrhagic cystitis due to BKV in HSCT recipients, but this is nonspecific, since decoy cells can be detected in other viral infections, such as adenovirus, and may be confused with malignancy [37].

Molecular Tests for BKV

Molecular tests are the most common method for diagnosis of BKV infection in kidney transplant recipients. Diagnosis of active BKV infection is most commonly achieved using quantitative PCR (qPCR) for BKV DNA, which has been demonstrated to have better predictive value than urinary decoy cell detection for the diagnosis of BKAN. BKV qPCR can be performed using urine or blood samples of transplant recipients, with urine samples providing higher sensitivity and blood samples providing higher specificity for probable BKAN. A positive relationship between BKV DNA levels in blood and impairment of renal allograft function has been shown, suggesting that viremic patients are at high risk for BKAN [27].

BKV viral load in the blood and urine has been demonstrated to be significantly higher in patients with biopsy-proven BKAN compared to those without BKAN [34]. In a study of 78 kidney transplant recipients, including ten patients who developed BKV viremia at a median of 23 weeks after transplantation, the mean BKV viral load in plasma was significantly higher in the five patients with BKAN than patients without histologic evidence of nephropathy (2×10^4 copies/ml vs 2×10^3 copies/ml, respectively; $p<0.001$) [40]. Furthermore, the plasma BKV level increased over time to as high as 1×10^7 copies/ml in all patients who developed BKAN. BKV plasma viral load had 100 % sensitivity, 88 % specificity, 50 % positive predictive value, and 100 % negative predictive value for histologically proven BKAN [39, 40]. In another study, a BKV viremia threshold of $>1.6\times10^4$ copies/ml had 100 % sensitivity, 96 % specificity, 50 % positive predictive value, and 100 % negative predictive value of diagnosing BKAN [39]. In this same study, a BKV viruria threshold of $>2.5\times10^7$ copies/ml had 100 % sensitivity, 92 % specificity, 31 % positive predictive value, and 100 % negative predictive value for diagnosis of BKAN [39].

Molecular assays are the most common method for diagnosis of BKV infection in allogeneic HSCT recipients with hemorrhagic cystitis. BKV often is considered in the differential diagnosis of late onset hemorrhagic cystitis in HSCT recipients. The optimal test for detecting BKV in the urine is PCR for viral DNA. However, demonstrating BKV DNA by PCR alone has low specificity since even healthy individuals and HSCT recipients without hemorrhagic cystitis may shed and excrete BKV DNA in the urine. To improve the specificity, other features of reactivated BKV should be demonstrated including high peak BKV DNA (usually in the range higher than 10^9–10^{10} copies/ml or greater, a three log rise in BKV viral load from baseline that coincides with the onset of late onset hemorrhagic cystitis, or the presence of significant BKV viremia (usually higher than 10^4 copies/ml) [37]. If BKV DNA is not demonstrated by PCR in patients with hemorrhagic cystitis with decoy cells, other viral etiologies should be considered, such as adenovirus and CMV.

Molecular tests are the most common method for screening kidney transplant patients for BKV infection. The results of prospective studies indicate that BKV replication, as measured by BKV DNA qPCR tests of the urine, precedes BKV viremia by a median of 4 weeks [29, 30], and histologically proven BKAN by a median of 12 weeks [29]. Current guidelines recommend screening kidney transplant recipients for BKV infection by urine and/or plasma BKV qPCR at least once every 3 months during the first 2 years after transplantation [27, 41], and then annually until the fifth year after transplantation [27, 41]. In high-risk individuals, such as those who received intense immunosuppression for the treatment of acute rejection, other experts recommend monthly screening during the first 6 months after kidney transplantation [27, 41]. Using this strategy, at least 80–90 % of patients who develop BKAN can be identified before significant histopathology and functional renal impairment occurs [27, 41]. All patients with high-level urinary BKV viral load ($>10^7$ copies/mL) should have follow-up plasma BKV viral load testing [27, 41]. In patients with sustained plasma BKV viral load of $>10^4$ log 10 copies/ml for more than 3 weeks, a presumptive diagnosis of BKAN is made [27, 30]. The positive predictive value for BKAN in patients with high-level urinary BKV viral loads ($>10^7$ copies/ml or decoy cells) persisting for more than 2 months [30, 31, 35], or plasma BKV viral loads of $>10^4$ copies/ml is more than 50 % [27, 41]. Moreover, in patients with allograft dysfunction, the positive predictive value of plasma BKV viral load may exceed 90 % [42]. If definitive diagnosis of BKAN is sought in patients with suggestive urine and blood BKV viral loads, allograft biopsy and histopathology may be performed.

Molecular tests can be used to monitor response to treatment. BKV viral load testing is used for monitoring the response to antiviral therapy or reduction of immunosuppressive therapy in patients with BKV infection and disease [27, 41, 42]. An effective treatment response following reduction in immunosuppression, treatment with CDV or leflunomide, or allograft nephrectomy in kidney transplant recipients with BKAN is indicated by a decline in BKV viral load in the blood and urine, although the rate of decline over time is not uniform or defined [27, 41, 42]. A similar decline in BKV viral load should be seen following CDV or leflunomide therapy in HSCT recipients with late onset hemorrhagic cystitis [37].

The caveat in the clinical utility of molecular tests for the diagnosis and monitoring of BKV-associated disease is the lack of standardization (Table 47.2). The performance of these LDTs can vary widely due to differences in the specimen type used (for blood samples: whole blood or plasma; for urine samples: cell pellets, supernatants, or resuspended urine samples), the methodology, and the limits of detection, among others. Methodologies vary widely in terms of nucleic acid extraction, molecular amplification target gene (large T gene or VP-1 gene), quantitative calibrators, and detection reagents [43]. As a result, values obtained by different LDTs may not be comparable, which makes development of interpretive clinical guidelines difficult. The planned establishment of a WHO international quantitative standard for BKV should dramatically improve test standardization and may have a substantial impact on our ability to monitor and treat patients in a more uniform manner.

The Herpes Viruses

Cytomegalovirus

Description of Pathogen and Clinical Utility of Testing

Cytomegalovirus (CMV), a large, enveloped, double-stranded DNA virus belonging to the *Betaherpesvirinae* subfamily, is the most common herpes infection in SOT and HSCT recipients [44, 45]. A ubiquitous infection in humans, about 60–80 % of adults have serologic evidence of previous CMV infection [46–49]. Primary CMV infection may occur during infancy, preschool age, or sexually active years. Primary CMV infection in immunocompetent individuals often has a subclinical presentation, although it also may manifest with an infectious mononucleosis-like illness characterized by fever and lymphadenopathy. After the resolution of the primary infection, CMV becomes latent in various cells, with episodic subclinical reactivation throughout life that is controlled by a functioning immune system [46–49]. In transplant recipients, however, CMV reactivation and infection may result in a potentially severe clinical illness.

Transplant recipients may acquire CMV as a primary infection, reactivation, or reinfection (or superinfection) with a new strain [46–48]. Primary CMV infection occurs when a CMV-seronegative transplant candidate receives an allograft, hematopoietic stem cells, or blood products from a CMV-seropositive donor (CMV D+/R− transplant) [46–48]. Primary CMV infection is often characterized by severe illness due to the inability of immunosuppressed transplant patients to mount an effective immune response. Reactivation CMV infection occurs in a CMV-seropositive transplant recipient (CMV R+) when endogenous latent virus reactivates from latency. Reactivation of CMV often is associated with milder clinical illness among SOT recipients. However, reactivation of CMV may lead to severe and recurrent disease for allogeneic HSCT CMV R+ patients, especially if they receive hematopoietic stem cells from a CMV-seronegative donor (CMV D−). Reinfection or superinfection occurs when a CMV R+ patient receives an allograft from a CMV D+, and the infection is due to donor-transmitted virus. Genetic analysis demonstrates that the majority of CMV infection in CMV D+/R+ patients originates from donor-transmitted virus [50].

The clinical manifestations of CMV disease after transplantation can be classified either as CMV syndrome or tissue invasive disease. CMV syndrome, which occurs in approximately 70 % of CMV disease cases, is characterized by fever, arthralgias, and myelosuppression [47–49]. In 30 % of cases, CMV disease presents with end-organ involvement, such as interstitial pneumonia, hepatitis, esophagitis, gastritis, colitis, and rarely chorioretinitis [47–49]. In addition, CMV is associated with numerous indirect effects such as increased risk of allograft rejection, graft failure, and concomitant opportunistic infections due to bacteria, viruses, or fungi [47–49].

The incidence and severity of CMV disease in transplant recipients is influenced by the type of organ transplant, CMV status of the donor and recipient, and the overall level of immunosuppression [47–49]. The highest risk groups are lung and intestinal transplant recipients and allogeneic HSCT recipients, especially those who receive a haploidentical transplant and cells from unrelated donors. Individuals with no preexisting CMV-specific immunity, such as CMV D+/R− SOT patients, are at highest risk of CMV disease. CMV R+ patients who received allogeneic HSCT from a CMV D− are at high risk of CMV disease due to the lack of CMV-specific immunity in the transplanted hematopoietic stem cells. Symptomatic disease may occur in any transplant patient if there is severe suppression of the immune system, such as following treatment of rejection or GVHD.

Due to the negative impact of CMV disease on transplant outcome, prevention is a key component in the management of all SOT and HSCT recipients [45, 51]. The two approaches used to prevent CMV disease in transplant patients are antiviral prophylaxis and preemptive therapy. Antiviral prophylaxis is accomplished by the administration of antiviral drugs, most commonly oral valganciclovir, for a defined period of time to all patients at risk for CMV disease [45, 51]. The major disadvantage of this approach is delayed-onset CMV disease, which occurs in high risk CMV D+/R− SOT patients after they complete antiviral prophylaxis [52]. In preemptive therapy, transplant recipients are monitored using CMV PCR or antigenemia tests to detect early CMV replication; and antiviral treatment, usually valganciclovir or intravenous ganciclovir (GCV), is administered as soon as viremia or antigenemia is detected but prior to the

onset of clinical symptoms [53]. The strategy of preemptive therapy is dependent on the availability of CMV NAT or antigenemia assays to guide treatment decisions (see discussion below) [2].

Available Assays and Interpretation of Results

Histopathology and Serology

Laboratory tests are essential to confirm the clinical suspicion of CMV disease in transplant patients. Histopathology with or without immunohistochemistry or in situ hybridization may be required to confirm tissue-invasive CMV disease. Because of the impaired and delayed ability of transplant patients to mount an effective immune response, CMV serologic testing to demonstrate IgM and IgG antibodies against CMV is rarely useful for the diagnosis of CMV disease after transplantation. Instead, serologic testing is used mainly prior to transplantation for CMV disease risk stratification. Depending on the donor and recipient CMV immune status, patients may be classified as high risk (e.g., CMV D+/R− SOT recipients) or low risk (CMV D−/R− patients) [45].

Viral Culture

Viral culture is a highly specific method that confirms the clinical suspicion of CMV disease. Viral culture can be done of blood and other body fluids such as respiratory secretions and cerebrospinal fluid (CSF). Viral culture of urine specimens is of low sensitivity and specificity for active CMV disease, since it often indicates urinary shedding, and therefore is not recommended for routine use in adult transplant recipients [2, 45, 51]. While viral culture of blood is highly specific and predictive of CMV disease and its severity, its major drawbacks are poor sensitivity and slow turnaround time [2]. The turnaround time for conventional culture results is between 2 and 3 weeks, thereby rarely affecting clinical care. The rapid centrifugation shell vial method has reduced the time for virus detection, with results obtained in 24–48 h, but this method still lacks sensitivity (compared to antigenemia or molecular techniques) [2]. Because of this, viral blood culture is no longer commonly used in clinical practice, although it remains helpful for end-organ viral detection in respiratory secretions and tissue samples.

CMV Antigenemia Tests

Antigenemia assays are based on detection of CMV proteins such as pp65 in peripheral leukocytes [2]. CMV antigenemia was used by many transplant centers for CMV surveillance and diagnosis because it is much more sensitive than viral culture [45]. Numerous studies have demonstrated the clinical utility of CMV antigenemia assays for rapid diagnosis of CMV disease, for surveillance of patients at high risk of infection (and to guide preemptive therapy), and for monitoring treatment response [54, 55]. However, the antigenemia assay is a labor-intensive test and lacks standardization. Since it relies on the presence of peripheral leukocytes, the assay must be performed within a relatively short period after sample collection and prior to leukocyte degradation in clinical samples [2]. The reliance on leukocytes may limit the applicability of the CMV antigenemia test in certain patient populations such as those with leukopenia, including HSCT recipients.

Molecular Tests for CMV Detection and Quantitation

Molecular testing methods have revolutionized the laboratory diagnosis of CMV disease in transplant recipients [2]. Laboratories have increasingly relied on NAT for CMV detection and quantitation, with the vast majority of CMV NAT being LDTs [56]. Commercial primers and probes are available as analyte specific reagents (ASRs). Most qualitative NATs that detect CMV DNA are difficult to interpret due to the potential detection of latent virus. Hence, the vast majority of CMV NATs rely on quantitative viral DNA detection [2, 56]. Assays that target RNA are more specific for active viral infection, although they suffer from modest sensitivity [57].

As with other quantitative assays described in this chapter, the major drawback to quantitative CMV NAT was the lack of standardization until recently [2, 3]. A wide range of factors may affect the performance characteristics of CMV NATs, including result accuracy and precision (Table 47.2). Difference in specimen type (i.e., whole blood, plasma, serum, leukocytes) is a common contributor to assay performance variability between laboratories. For example, NATs using whole blood are more sensitive than use of plasma samples, especially at lower viral load values, but less specific [58]. Nucleic acid extraction methods (e.g., manual vs automated, or liquid phase, magnetic bead or silica membrane/column), molecular amplification target gene (DNA polymerase gene, glycoprotein B gene, immediate early gene, major immediate early gene, or other CMV genes), and primer sequences and detection reagents (commercial vs noncommercial), quantitative calibrators (Roche, Acrometrix, Advanced Biotechnologies, and Qiagen), number of PCR cycles, and the range and limits of detection are some of the other factors that cause variability in the results of CMV NATs [43]. For example, the mean CMV viral load reported by laboratories that used Roche calibrators (4.32 log 10) was significantly lower than those that utilized Acrometrix (4.87 log 10, $p=0.0003$), ABI (5.06 log 10, $p<0.0001$), and Qiagen (5.03 log 10, $p<0.0001$) calibrators [43]. Result variability using Roche calibrators were lower compared to Acrometrix and ABI calibrators [43]. Accordingly, the results of CMV NATs vary widely and are not directly comparable. The lack of standardization among the various CMV NATs was highlighted by a paper comparing the results of samples sent to 33 different laboratories across North America and Europe [3]. In this study, wide inter-assay variability in viral

load was reported by the participating laboratories [3]. For example, one sample had a four-log difference in viral load reported from two laboratories [3].

In 2011, the World Health Organization developed an international quantitative CMV standard, with the goals of adoption by commercial manufacturers and individual laboratories for CMV NATs. The COBAS Ampliprep/COBAS Taqman CMV test (Roche) has been calibrated according to this international standard, and was approved by the US FDA for viral load monitoring of SOT patients with CMV disease [59]. This specific CMV test has a limit of detection of 137 IU/ml up to 9.1×10^6 IU/ml [56, 59]. Reporting of all quantitative CMV results in international units (IU) should allow portability of results (comparable results achieved irrespective of laboratory or method), assisting in care of individual patients and in the effort to develop uniform guidelines for treatment [56].

CMV NATs are the most commonly used method to establish the diagnosis of CMV disease in transplant recipients [45, 56]. Numerous studies established the clinical utility of LDTs and commercially available quantitative PCR assays for the diagnosis of CMV disease in transplant patients [45, 47, 48, 51, 60, 61]. Generally, transplant patients with CMV disease have higher viral load values than those with asymptomatic infection [53]. For example, a single-center study demonstrated that compared to those without detectable viremia, the risk of CMV disease is increased 50-fold in liver transplant recipients with viral loads greater than 2,860 copies/10^6 peripheral blood leukocytes [53]. However, the specific quantitative thresholds to signify clinically relevant disease from asymptomatic infection have been difficult to define, largely due to the lack of assay standardization noted above. Numerous authors have suggested that quantitative viral threshold values associated with active disease vary depending on the sample type (plasma vs whole blood vs leukocytes), type of transplant (lung vs kidney, and SOT vs HSCT), the overall net state of immunosuppression (T-cell depleted vs non T-cell depleted), whether CMV infection is primary vs reactivation, and the assay used for detection, among other factors. Moreover, there may be cases of compartmentalized (or localized) tissue-invasive CMV disease that have no detectable level of viremia. In these cases, demonstration of CMV in tissue by histopathology may be required [47, 48, 53].

CMV NATs are useful in predicting the risk of CMV disease in transplant recipients [45, 56]. Using CMV PCR assays, transplant patients are monitored for evidence of CMV replication so that antiviral therapy can be administered prior to the development of clinical symptoms [53, 62]. This is the principle behind the "preemptive therapy" approach to CMV disease prevention, which is the most common strategy for the prevention of CMV disease in allogeneic HSCT recipients. Preemptive therapy also can be used in SOT recipients at moderate risk of CMV disease, such as CMV R+ kidney and liver transplant recipients. Using this approach, blood samples for CMV detection are collected at least once weekly during the first 12 weeks (or 100 days) after transplantation; some centers may monitor highest risk allogeneic HSCT recipients more frequently (e.g., twice weekly). Early studies evaluating the clinical utility of qualitative CMV PCR using cell-based samples demonstrated high sensitivity, poor specificity, and poor positive predictive value [2].

Several more contemporary approaches have been developed to improve the clinical specificity of CMV NAT, including the use of quantitative PCR assays, detection of CMV DNA in plasma (instead of leukocytes), and detection of CMV messenger RNA (mRNA) rather than DNA. Detection of CMV DNA in plasma rather than in leukocytes provides better correlation with clinical disease [2]. Quantitative CMV NAT methods have the potential to define a viral threshold that distinguishes asymptomatic infection from active CMV disease. For example, in a single center study that evaluated 97 liver transplant recipients by quantitative CMV PCR testing, a viral load threshold between 2,000 and 5,000 copies/ml of plasma was defined as the optimal cut off for predicting CMV disease with a sensitivity of 86 %, specificity of 87 %, positive predictive value of 64 % and a negative predictive value of 96 % [62]. However, for reasons discussed above, the lack of assay standardization has limited the generation of a viral load threshold that is widely applicable across populations and laboratories.

CMV viral load testing is useful in assessing therapeutic response in patients with CMV disease [45, 56]. Three antiviral drugs are US FDA-approved for the treatment of CMV disease: GCV, CDV, and foscarnet (phosphonoformic acid [FOS]); of these three, GCV is the most widely used in clinical practice. Current guidelines recommend that the duration of treatment of CMV disease should be guided by the clinical resolution of symptoms and clearance of the virus from the blood [44, 45]. Accordingly, CMV viral load testing is performed weekly to document virologic response and clearance during antiviral treatment. Several studies have reported >90 % or about one log reduction in viral load during the first 1–2 weeks after initiation of antiviral therapy in the vast majority of patients [63, 64]. In a minority of patients, the viral load decline may be delayed for up to 2 weeks. Moreover, the rate of viral load decline varies by individual patient, as influenced by the underlying immunosuppression, preexisting virus-specific immunity, and potentially viral strain variation [65, 66]. Patients with low pretreatment viral loads will generally achieve an undetectable viral load sooner than those with high pretreatment viral loads [59, 64]; hence, more prolonged antiviral therapy generally is given for patients with higher initial viral loads. Thus, molecular tests

allow an individualized approach to management. In general, antiviral therapy is continued until the CMV viral load is below the limit of detection [51, 59]. Discontinuation of antiviral treatment in patients with detectable viremia is a risk factor for CMV disease relapse [67]. However, an overly sensitive CMV viral load test may lead to over-treatment if the assay can detect "non-clinically relevant" virus [61].

CMV viral load testing is a useful marker of CMV disease relapse. The optimal duration of antiviral treatment for CMV infection and disease, as discussed above, should be individualized based on clinical and virologic resolution of infection. Hence, sequential monitoring of CMV viral load after initiation of therapy allows the identification of patients at risk of recurrent infection. Up to 30 % of transplant patients treated for CMV infection and disease will develop relapse of viremia or clinical symptoms after discontinuation of antiviral therapy. In clinical practice, CMV relapse is heralded by the reappearance of CMV DNA in the blood following initial successful viral load suppression. Patients generally are monitored by CMV viral load testing weekly for up to 4 weeks following an antiviral treatment course to monitor for relapse. Retreatment with intravenous GCV or oral valganciclovir is generally effective for treatment of relapse.

CMV relapse is most common in patients with severe immunosuppression and without CMV-specific immunity. Early laboratory predictors of CMV relapse are a high peak CMV viral load and a slow rate of decline in CMV viral load (also known as viral decay) [62, 68, 69]. In a study of 52 SOT recipients with CMV disease who were monitored with the Amplicor CMV Monitor test (Roche) [68, 69], the time to clearance of CMV DNA from plasma was 33.8 days in the 12 patients with relapsing CMV disease compared to 17.2 days in the group without recurrent disease ($p=0.002$). The viral load half-life with treatment was 8.8 days compared to 3.2 days ($p=0.001$) in the group with and without recurrent disease, respectively [62]. Moreover, those with very high pretreatment viral load values had higher risk of CMV relapse [67]. In a prospective study of 24 SOT patients with CMV infection or disease who received a 14-day course of IV GCV, the CMV viral load prior to the initiation of antiviral therapy was statistically higher in eight patients who had CMV relapse compared to the 14 who did not relapse (80,150 copies/10^6 leukocytes vs 5,500 copies/10^6 leukocytes, respectively, $p=0.007$) [67]. As discussed above, transplant patients who discontinue antiviral therapy with ongoing viremia have a higher risk of clinical relapse, compared to those who have attained viral load suppression, even if they have resolution of clinical symptoms [67]. In this study, those who had CMV infection relapse had a detectable viral load at the end of treatment (mean 18,800 copies/10^6 leukocytes), while viral load was undetectable in the non-relapsing group [67].

CMV Drug Resistance Testing

Failure of viral load to decline to an undetectable level, or a rise in viral load after an initial decline, following initiation of antiviral therapy suggests potential drug resistance [45, 51, 70]. Risk factors for CMV drug resistance are (1) prolonged exposure to antiviral drugs, (2) severe immunosuppression, (3) lack of CMV-specific immunity (i.e., CMV D+/R−), and (4) suboptimal antiviral drug concentrations [45, 51, 70]. Fortunately, resistance to GCV and other drugs is uncommon, with rates estimated at less than 5 % of all CMV disease cases [45, 51, 70].

CMV drug resistance can be confirmed by either phenotypic or molecular (genotypic) testing [71]. Phenotypic assays rely on analysis of growth characteristics of viral isolates in the presence of different concentrations of antiviral drugs and therefore require viable virus. Phenotypic assays are biologically more relevant for detection of drug resistance. However, phenotypic assays are labor intensive with subjective test result interpretation, and require at least 1 month to obtain results, which is generally not timely for clinical care.

Molecular assays can detect the presence of nucleotide sequence changes associated with drug resistance [71]. Genotypic results generally correlate with clinical drug resistance and provide rapid results that can guide clinical therapeutic selection. Drug resistance is indicated by mutations in the UL97 gene (which encodes viral kinase) and/or the UL54 gene (which encodes the CMV DNA polymerase) [71]. UL97 mutations are more common and confer resistance to GCV, while UL54 mutations are less common but confer resistance to any or all of the three anti-CMV drugs (GCV, FOS, and CDV). GCV resistance mutations are most frequently mapped to the UL97 gene within codons 460 and 520 and either point mutations or deletions within the codon range 590–607 [71]. One caveat for genotypic assays is the presence of some normal baseline sequence variability in the UL97 and UL54 genes in drug-sensitive CMV strains [71].

Epstein Barr Virus

Description of Pathogen and Clinical Utility of Testing

EBV is an oncogenic gamma-herpesvirus that causes B-cell proliferation in humans [72]. A common infection in humans, EBV frequently is acquired by exposure to infected body fluids, such as saliva. In healthy individuals, primary EBV infection can be asymptomatic or can cause infectious mononucleosis, which is characterized by fever, sore throat, and lymphadenopathy. Following primary infection, EBV establishes lifelong latency in various organs which serve as reservoirs and vehicles for transmission to susceptible EBV-seronegative transplant recipients.

EBV infection after transplantation can occur either as a primary infection (in an EBV-seronegative transplant recipient who received an organ from an EBV-positive donor) or as a reactivation infection (in EBV-seropositive transplant recipients). EBV infection can manifest as an asymptomatic infection or as post-transplant lymphoproliferative disorder (PTLD) [72]. The term PTLD encompasses a heterogeneous spectrum of lymphoproliferative disorders, typically of B cell origin, from benign reactive hyperplasia to mononucleosis-like illness and fulminant non-Hodgkin lymphoma. The EBV genome is found in >90 % of B-cell origin PTLD, especially during the first 2 years after transplantation [72]. In contrast, a large number of late-onset PTLD (those occurring 2 or more years after transplantation) may be EBV-negative and may not involve B cells. The median time to the development of PTLD in SOT patients is 6 months, whereas in HSCT patients, signs and symptoms could appear within 70–90 days after transplantation. The clinical features of PTLD are similar in both SOT and HSCT patients.

The incidence of EBV-induced PTLD varies widely from 0.8 %–20 % depending on the EBV donor and recipient pre-transplant immune status, type of SOT or HSCT, patient age, and the type of immunosuppression [72]. The highest risk factor for PTLD after transplantation is primary EBV infection [72, 73]. Hence, an EBV-naive and seronegative transplant recipient who receives an organ allograft from an EBV-seropositive donor (referred to as EBV D+/R−) is at highest risk of PTLD [72, 73]. Children are at high risk of PTLD likely due to a lack of prior EBV immunity [74]. Primary EBV infection in an EBV D+/R− transplant patient generally leads to massive B cell proliferation [73]. Mutant cells that are produced during massive B cell proliferation may not be eliminated optimally in patients with severe immunosuppression and ineffective T cell function, resulting in progression to PTLD [72]. This risk is augmented in the presence of CMV disease and the use of lymphocyte-depleting immunosuppressive drugs for treatment of rejection after SOT [75]. Because of the role of T cells in EBV control, allogeneic HSCT recipients who received T cell-depleted grafts, and those receiving intense immunosuppression for GVHD are at highest risk of developing PTLD [76].

Available Assays and Interpretation of Results

Histopathology for EBV

The definitive diagnosis of PTLD is established by histopathology [72]. A variety of special studies are used to complement the histopathologic diagnosis of PTLD, including immunophenotyping by flow cytometry, immunohistochemical stains, and molecular tests [72]. Documenting the presence of EBV-specific nucleic acids in the affected tissues establishes the diagnosis of EBV-associated PTLD, and suggests the role of EBV infection in the pathogenesis of PTLD. In this regard, in situ hybridization that targets the EBV-encoded small nuclear RNA is the preferred approach and is more sensitive for detecting EBV-infected cells than in situ hybridization directly targeting EBV DNA [72].

Serology for EBV

The challenge for clinicians and the clinical laboratory is to predict patients that are at highest risk of developing PTLD. Serology may be performed to demonstrate IgM and IgG antibodies to viral capsid antigen (VCA) or antibody to the Epstein Barr nuclear antigen (EBNA) [72]. The most important role of EBV serology in transplantation is the pre-transplant assessment of donor and recipient EBV immune status by serologic testing for PTLD risk stratification [72]. The presence of anti-VCA IgM antibody and the absence of EBNA antibody suggest acute or recent infection, and this may indicate increased risk of developing PTLD in a transplant recipient. Serology, however, is generally unreliable as a diagnostic tool for either PTLD or primary EBV infection in immunocompromised patients due to delayed or absent humoral immune responses. Moreover, transplant patients often receive blood products, and the passive transfer of antibodies may render EBV IgG antibody assays difficult to interpret [72].

Molecular Tests for Detection of EBV

EBV PCR testing is the most common test to diagnose EBV infection after transplantation. A multitude of EBV PCR LDTs and commercial tests have been developed over the past decade, and have been used clinically to quantitatively detect active EBV infection in the post-transplant setting [77, 78]. Generally, EBV PCR can be used (1) to demonstrate the presence of EBV infection in patients with PTLD [72, 77, 78], (2) for surveillance of EBV replication in high-risk EBV D+/R− transplant patients [72, 77, 78], and (3) for surveillance of treatment efficacy in EBV-associated PTLD [72, 77].

The optimal approach for utilization of quantitative EBV PCR assays remains uncertain [77]. As with other quantitative molecular tests, the lack of assay standardization is one of the major impediments to optimal use of EBV viral load in the clinical care of transplant patients [77]. While there has been remarkable progress in the development of various EBV PCR assays, their clinical utility and comparability has been hampered by the lack of an international reference standard [77]. Moreover, differences in nucleic acid extraction methods (liquid phase, magnetic beads, or silica membrane/column), quantitative calibrators (Qiagen, Roche, Abbott, Acrometrix, or Advanced Biotechnologies), detection reagents (commercial or noncommercial reagents), and molecular amplification target gene (EBNA gene, DNA polymerase gene, or LMP-1 gene) are among some of the factors that contribute to the widely variable EBV viral load results obtained with different assays [43]. Because of these

variables, commercial and LDT EBV PCR assays are not standardized and cannot be directly compared.

In turn, no interpretative guidelines exist, nor are there clinically relevant EBV viral load thresholds to guide management of EBV infection and PTLD across centers. One large study that compared 28 laboratories in Europe and North America showed wide interlaboratory variation in detection and reporting of EBV viral load values from the same specimen [4]. Significant and extreme interlaboratory variability exists in both qualitative and quantitative EBV PCR results, raising questions regarding the validity of interinstitutional result comparison in the absence of formal cross-referencing of assays between institutions [4, 43]. In contrast, within most laboratories, intralaboratory result reproducibility and result linearity are reasonable. Hence, trends in the EBV viral load of patients over time using the same assay are a more useful test compared to single values or compared to serial testing performed at multiple institutions [4, 77]. There are now efforts to harmonize commercial and LDTs with the recent introduction of an international calibration standard for EBV PCR tests.

The optimal sample for EBV PCR testing is not defined, and this further contributes to the variability of results between assays performed in different laboratories (Table 47.2). Some laboratories prefer whole blood while others use plasma, serum, or lymphocytes [4, 77]. Detecting EBV in other body fluids may be useful in specific situations, such as the demonstration of EBV DNA in the CSF of a patient with PTLD involving the central nervous system [79, 80], or in bronchoalveolar lavage fluid of a patient with PTLD involving the lungs [77]. Cell-containing samples such as whole blood and lymphocytes are generally more sensitive compared to plasma and serum, but may more often contain latent EBV. EBV viral load testing using plasma improves specificity for the diagnosis of EBV-positive PTLD, while not significantly lowering sensitivity relative to assessments in cell-containing blood compartments [4, 77]. In the absence of widely accepted treatment thresholds (due to lack of assay standardization), serial detection using quantitative methods may afford the greatest clinical predictive value.

PTLD may be heralded several weeks before clinical symptoms by the presence of EBV infection in peripheral blood [72]. Based on this natural history, EBV qPCR testing has been used in the clinical setting to detect EBV infection in high-risk transplant patients, including EBV D+/R− and pediatric transplant recipients [72]. The frequency for monitoring patients is not standardized. Weekly monitoring may be used during the early post-transplant period. Monthly monitoring for EBV infection may be used during the first year since most EBV disease will occur during this period [72]. Demonstration of EBV DNA in the blood should trigger a reduction in immunosuppression (as first-line treatment of EBV infection and possible PTLD) and evaluation for PTLD [72]. In one study of a cohort of 1,131 SOT and HSCT patients, 66 (5.6 %) patients developed PTLD [78]. PTLD developed in 53 of 376 patients (14 %) who had at least one positive EBV PCR in a whole blood sample, compared to 13 of 755 patients (2 %) who had repeatedly negative samples [78]. The risk of PTLD was directly correlated with the degree of viremia, with PTLD occurring in 11 % of patients with EBV PCR viral loads between 10^3 and 10^5 copies/ml, compared to 37 % of patients with EBV viral loads higher than 10^5 copies/ml of whole blood [78].

As a result of wide variability in assay methods, no consensus threshold for prediction of EBV-positive PTLD has been defined. In general, however, a low EBV viral load that may be observed even in healthy EBV-seropositive transplant recipients can be clinically relevant in EBV D+/R− transplant recipients. In contrast, a high or increasing EBV viral load should trigger evaluation for possible PTLD in all transplant recipients. Screening for EBV by qPCR should permit early diagnosis of PTLD that will then allow institution of a therapeutic strategy, which typically consists of reductions in immunosuppression and the administration of anti-CD20 monoclonal antibodies (Rituximab). Cytotoxic chemotherapy is reserved for established PTLD that does not respond to initial reduction in immunosuppression and anti-CD20 monoclonal antibody therapy.

Herpes Simplex Virus Types 1 and 2

Description of Pathogen and Clinical Utility of Testing

The alpha-herpesviruses, herpes simplex virus types 1 and 2 (HSV-1, HSV-2), are important causes of mucocutaneous illness, aseptic lymphocytic meningitis, encephalitis, fulminant hepatitis, and disseminated disease in humans [81]. Classically associated with oro-labial ulcerative diseases, HSV-1 infection is acquired early in life. The prevalence of HSV-1 infection increases with age, reaching 80 % by 60 years of age [82]. HSV-2 infection, which is associated with genital herpes, occurs less frequently. The prevalence of HSV-2 infection increases with sexual activity and age, and reaches 26.3 % by 49 years of age [83].

Following primary infection, HSV-1 and HSV-2 establish latency in dorsal nerve root ganglia. Periodic HSV-1 and HSV-2 reactivation from latency occurs throughout life with clinical and subclinical manifestations. The majority of HSV infections in transplant recipients result from reactivation of latent virus, especially during the early post-transplant period and during periods of severe immunosuppression [81]. In some cases, primary HSV infection may be acquired from the transplanted organ (donor-transmitted HSV) [84] or acquired naturally as a result of intimate contacts during the post-transplant period.

The most common clinical manifestations of HSV disease after transplantation, whether primary infection or reactivation, are oro-labial, genital, or perianal disease [81, 85]. Classically, HSV lesions are vesicular or ulcerative and localized. In severe cases, particularly among highly immunocompromised transplant patients, HSV infection can disseminate to develop organ-invasive manifestations such as hepatitis [81]. Fever, leukopenia, and hepatitis are the most common presenting signs and symptoms of disseminated disease [81]. CNS involvement may occur in the form of encephalitis or meningitis. HSV reactivation occurs most commonly during the first month after transplantation [81]. Hence, standard clinical practice is prophylactic treatment of transplant recipients with antiviral therapy (usually with acyclovir, valacyclovir, or valganciclovir) during the first 4–6 weeks after transplantation [81]. Thereafter, risk of HSV disease decreases dramatically, though it remains higher than that in immunocompetent hosts.

The clinical presentation of mucocutaneous HSV disease in transplant recipients is often typical, with vesicles and ulcers, such that the diagnosis may be made on clinical criteria. Occasionally, clinical manifestations may be atypical, and other pathogens may be suspected. In these cases, clinical laboratory confirmation of HSV infection is helpful. The clinical laboratory is also helpful in the diagnosis of invasive HSV disease, such as those with suspected CNS involvement and those with herpes hepatitis.

Available Assays and Interpretation of Results

The laboratory methods available for the diagnosis of HSV infection are (1) direct fluorescent antibody (DFA) testing of mucocutaneous lesions, bronchoalveolar lavage, and other samples, (2) histopathology of biopsy specimens, (3) serologic testing, (4) viral culture, and (5) HSV PCR testing.

Direct Fluorescent Antibody Testing for HSV

Serologic detection of HSV antibodies is rarely useful for diagnosing acute HSV infection in transplant recipients since HSV seropositivity is very common, and generation of antibodies during primary HSV infection may be delayed due to the effects of immunosuppression. HSV antigens can be detected on scrapings of ulcerative mucocutaneous lesions by immunofluorescent microscopy. The Tzanck smear, which demonstrates viral cytopathic effects, can be done on scrapings obtained from herpetic ulcers. However, the Tzanck smear is not very specific for HSV since similar findings can be demonstrated in other herpes virus infections.

Viral Culture for HSV Identification

Viral culture of the vesicular fluid is very sensitive for the diagnosis of HSV disease since vesicles typically contain very high concentrations of HSV during the first 48 h of clinical disease. Indeed, viral culture is a reference standard for HSV detection in body fluids, although it has now been largely supplanted by HSV PCR as the diagnostic test of choice for CSF specimens [86]. HSV PCR is increasingly used, but has not supplanted viral culture for the detection of HSV in body fluids other than CSF [87].

Molecular Tests for HSV

HSV PCR assays provide high sensitivity and specificity, and a more rapid turnaround time compared to culture [87–89]. In one study that compared HSV PCR to viral culture in 200 dermal, ocular, and genital samples, HSV PCR detected the virus in 88 samples whereas the shell vial culture was positive only in 69 samples [87]; there were 19 samples that were detected by HSV PCR alone while no sample was positive by viral culture alone [87]. Molecular assays can be optimized to distinguish HSV-1 from HSV-2, which is important epidemiologically and for patient counseling regarding disease acquisition [89]. HSV PCR can be multiplexed for the detection of other viruses that may present similarly with vesicular lesions such as VZV. In one study, HSV and VZV were co-detected in 1.3 % of dermal, ocular, and genital specimens over 8 years [90].

HSV PCR is especially useful for identifying HSV in blood or other sterile fluids, as viral cultures have poor sensitivity in detecting HSV in these samples. If disseminated disease is suspected in transplant patients, detection of HSV by PCR in any blood compartment will confirm the clinical suspicion, and signifies a poor prognosis [91]. Histopathology with immunocytochemistry for HSV may be needed to document tissue-invasive disease in patients suspected to have fulminant herpes hepatitis, although in these cases, the HSV PCR of a blood specimen will almost certainly be diagnostic [92].

Quantification of HSV in a clinical sample, such as the CSF, genital secretions, or blood, has been suggested as a prognostic indicator of severity of infection and as a guide for duration of treatment. In one study, the quantity of HSV DNA in cervicovaginal secretions was directly correlated with the signs and symptoms of HSV disease [93]. Likewise, there was a strong correlation between HSV viral load and the presence of histopathologically proven HSV esophagitis [94]; in this study, an HSV viral load in the blood greater than 2.5×10^4 copies had 83 % sensitivity and 100 % specificity for a diagnosis of HSV esophagitis. A significant association between initial HSV viral load and the duration of treatment course was demonstrated in a study of patients with HSV encephalitis [95]; hence, quantitative HSV PCR may assist in the monitoring of response to antiviral therapy in these patients [96]. However, HSV PCR tests in clinical use are predominantly qualitative assays (i.e., reported as positive or negative); and the potential value and optimal use of viral load testing in guiding clinical decisions, while promising, remains uncertain.

Varicella Zoster Virus

Description of Pathogen and Clinical Utility of Testing

Varicella zoster virus (VZV) is a highly infectious alphaherpesvirus that causes "chickenpox" during primary infection. VZV primary infection is characterized by fever, other constitutional symptoms, and a vesicular, pruritic, widely disseminated rash that starts on the face and spreads down the trunk. The distinctive feature of VZV infection is the evolution of the rash so that papules, vesicles, and crusted lesions may all be seen at the same time. Moreover, the rash typically spares the palms and the soles. Primary infection is typically a self-limited illness in the immunocompetent patient. However, primary VZV infection may infrequently lead to hepatitis, pneumonitis, encephalitis, retinal necrosis, and purpura fulminans [97].

Following primary infection, VZV establishes latency in cranial nerve and dorsal root ganglia. Latent VZV can reactivate later in life as herpes zoster (known as shingles), which is characterized by a vesicular exanthem with a dermatomal distribution [98]. Some patients, especially those who are immunocompromised, such as transplant patients, may develop severe, disseminated zoster. These cases may include visceral involvement [98], such as fulminant hepatitis [99]. Cutaneous lesions may become secondarily infected with bacteria, and patients with herpes zoster may have long-term sequelae, including painful and debilitating postherpetic neuralgia [98].

VZV infection in transplant recipients is mainly due to reactivation, since the vast majority of older adults are seropositive for VZV due to childhood infection. Children also are typically vaccinated against VZV using live-attenuated virus vaccine, and possess vaccine-induced immunity. Accordingly, over 90 % of transplant recipients are seropositive and have immunity against VZV. VZV reactivation, which manifests as mono- or multi-dermatomal herpes zoster, occurs in approximately 8–11 % of transplant patients [98]. The peak incidence of herpes zoster occurs during the first year after SOT or allogeneic HSCT [98]. While the majority of herpes zoster remains localized to one or a few adjacent dermatomes, severely immunocompromised transplant patients may have disseminated disease with visceral involvement [98], including fulminant VZV hepatitis [100].

Since the vast majority of patients are immune to VZV prior to transplantation, primary VZV infection is rarely seen after transplantation. Chickenpox, however, may be seen in unvaccinated pediatric transplant recipients and in the minority of adults who are VZV-seronegative. The clinical manifestations of VZV infection in these patients are typical but can be especially severe, sometimes with visceral involvement [98].

The diagnosis of primary VZV infection and herpes zoster is usually clinical due to their classic clinical presentation. However, transplant patients may have atypical presentations or may have disseminated zoster that can mimic other disease states. Therefore, in transplant patients who may develop rash from a multitude of other infectious and noninfectious causes, laboratory testing for VZV can be an important tool to establish a definitive diagnosis.

Available Assays and Interpretation of Results

For the definitive diagnosis of VZV infection and herpes zoster, rapid DFA or PCR diagnostic assays are preferred [101]. PCR is currently the most sensitive test for the detection of VZV and may be used for detecting VZV in vesicle fluid, blood (in case of suspected disseminated or tissue-invasive disease), other body fluids such as CSF, or tissues [102]. Most of the assays are LDTs and provide qualitative results, although some clinical laboratories offer VZV quantification tests [101, 102]. The potential clinical applications of quantitative VZV PCR assays include prognosis of disease severity (higher viral load is associated with more severe disease) and in guiding treatment strategies (higher viral load may require a more intensified and longer duration of treatment). However, these potential applications have not been widely utilized in clinical practice. Some VZV PCR assays have been incorporated into multiplexed PCR tests for viral illnesses [103]. Viral culture is much less sensitive than PCR and has a slower turnaround time [98]. Serologic testing is rarely helpful in the diagnosis of VZV infection and herpes zoster in transplant recipients [98].

Human Herpesviruses 6 and 7

Description of Pathogens and Clinical Utility of Testing

Human herpesvirus 6 (HHV-6) and 7 (HHV-7) are lymphotropic β-herpesviruses that infect the majority of humans during the first few years of life [104, 105]. Primary HHV-6 and HHV-7 infections may be asymptomatic or manifest clinically as a febrile illness associated with rash, diarrhea, respiratory symptoms, or seizures [106]. HHV-6 is comprised of two different variants, HHV-6A and HHV-6B [107]. HHV-6B is responsible for the majority of documented primary infections in children [106]. Primary HHV-6 and HHV-7 infections result in lifelong latency in mononuclear cells [107]. In less than 1 % of infected individuals, HHV-6 persistence occurs as a result of the integration of the virus into the host chromosome [108].

HHV-6 and HHV-7 infections occur either as primary infections or reactivations in transplant recipients [104–106]. The reported rates of HHV-6 infection after transplan-

tation have varied widely from 20–55 %, while HHV-7 infection has been reported in up to 46 % of transplant patients [104, 106]. Because the virus exists in latent form in >95 % of adults, the vast majority of post-transplant infections are due to reactivation of latent virus. Reactivation of both viruses occurs relatively early, generally within the first 2–4 weeks after transplantation [104, 106]. Primary HHV-6 and HHV-7 infections occur rarely, and are seen mainly among HHV-6 and HHV-7 seronegative children who may have acquired the infection from seropositive donors or as a result of natural transmission in the community [104, 106].

While HHV-6 and HHV-7 reactivations are common, clinical disease associated with these viruses is uncommon, and hence, routine surveillance in transplant recipients is not recommended [105]. There have only been a few sporadic cases of symptomatic HHV-7 infection reported, including patients presenting with fever, myelitis, and myelosuppression [106]. Clinical disease due to HHV-6 occurs in only 1 % of transplant patients, and most reported cases have been due to HHV-6B [104, 106]. In a study of 200 liver transplant recipients, HHV-6 infection was demonstrated by PCR in 51 % of patients at a median of 27 days after transplantation [68, 69]. However, HHV-6 associated disease was documented only in two patients (incidence, 1 %) [68, 69]. HHV-6 may manifest as a febrile syndrome accompanied by some degree of bone marrow suppression, an illness similar to CMV infection [104, 106]. HHV-6 also has been reported as a cause of febrile dermatosis, hepatitis, gastroduodenitis, colitis, pneumonitis, and encephalitis after transplantation [104, 106]. HHV-6 infection in liver or renal transplant patients is an independent risk factor for CMV disease [109]. CMV viral load was significantly higher in HHV-6 positive patients compared to those without HHV-6 infection (median viral load 1,560 copies/ml vs undetectable, respectively; $p<0.001$). An increase in HHV-6 viral load was significantly associated with the development of opportunistic infections, including invasive fungal disease [109].

Available Assays and Interpretation of Results

Clinical laboratory tests available for the detection of HHV-6 and HHV-7 infection are serology, culture, antigen detection, histopathology with immunohistochemistry, and PCR tests [104–106]. Among them, PCR testing with the use of LDTs has emerged as the diagnostic method of choice in transplant recipients [104–106]. In contrast, HHV-6 and HHV-7 IgM and IgG may identify acute or previous infections, but serologic testing is not routinely performed in clinical practice due to poor sensitivity and specificity in identifying acute infection in transplant patients with impaired ability to mount an effective immune response. Moreover, high seroprevalence rates limit the potential utility of serology in the diagnosis of acute HHV-6 or HHV-7 disease after transplantation. Viral culture for these agents is not typically performed in clinical laboratories.

Molecular methods using LDTs are preferred for detection of HHV-6 or HHV-7 in active disease (Table 47.1) [104–106]. HHV-6 and HHV-7 PCR can be performed using whole blood, plasma, peripheral blood leukocytes, or other body fluids such as CSF and bronchoalveolar lavage fluid [104, 106]. PCR of peripheral blood mononuclear cells is the most sensitive technique for detecting these viruses, but the use of this specimen type may not distinguish latent from active infection. To increase specificity for active infection, quantitative PCR is preferred over qualitative assays. In addition, methods that utilize noncellular samples (such as plasma) or those that detect mRNA may increase specificity for active HHV-6 or HHV-7 infection [104, 106]. A clinically relevant viral load threshold has been difficult to define due to lack of standardized assays, but a level of more than 1,000 copies/ml has been demonstrated in one study to be associated with mortality after allogeneic HSCT [110].

Surveillance for HHV-6 and HHV-7 by PCR is not routinely performed nor recommended after transplantation because of the low rate of clinical disease and the high rate of subclinical viral reactivations [104, 106]. The role of HHV-6 and HHV-7 PCR is in the diagnosis of active infection and in guiding antiviral treatment responses [104, 106]. A decline in HHV-6 and HHV-7 viral load should be anticipated during effective therapies with GCV, CDV, or foscarnet.

The interpretation of HHV-6 PCR results should consider the potential detection of chromosomally integrated HHV-6 [111, 112]. In approximately 1 % of individuals, HHV-6 latency exists in the form of chromosomal integration, and hence, every nucleated cell in the body will have detectable HHV-6 DNA. In a cohort of 548 liver transplant patients, chromosomally integrated HHV-6 was detected in seven patients (1.3 %) [111]. When HHV-6 is chromosomally integrated in germ cells (eggs or sperm), the viral genome is inherited in a Mendelian pattern [112]. Accordingly, clinical samples containing nucleated cells will always have detectable HHV-6 DNA, but without discernible clinical effect. Patients with chromosomally integrated HHV-6 are characterized by extremely high levels of HHV-6 DNA in whole blood [112]. In a consensus report, chromosomally integrated HHV-6 should be suspected when the viral load exceeds 5.5 logs in whole blood [112]. Such high levels have been mistaken as active infection and have led to unnecessary antiviral treatment. Chromosomally integrated HHV-6 can be confirmed by demonstrating persistently elevated levels on subsequent serial testing, the presence of one viral DNA per nucleated cell, and testing of hair follicle samples for HHV-6 [112].

Human Herpesvirus 8

Description of Pathogen and Clinical Utility of Testing

Human herpesvirus 8 (HHV-8) is a gamma-herpesvirus that primarily infects CD19+ B cells and endothelial-derived spindle cells [109, 113]. Primary HHV-8 infection in immunocompetent individuals is associated with mild nonspecific symptoms of diarrhea, fatigue, rash, and lymphadenopathy [109]. In immunocompromised individuals, however, HHV-8 is associated with neoplastic diseases. Unlike most of the human herpes viruses, HHV-8 infection is geographically restricted [114]. Hence, seroprevalence rates vary widely by geographic region with estimates of 0–5 % in North America, northern Europe, and Asia, 5–20 % in the Mediterranean and Middle East, and >50 % in parts of Africa [114].

HHV-8 is the etiologic agent of Kaposi's sarcoma (KS), a multicentric neoplasm of lymphatic endothelium-derived cells, which manifests clinically in individuals with compromised immunity as multifocal progressive mucocutaneous lesions with dissemination to the visceral organs, including transplanted allografts [114]. Other less common malignant diseases associated with HHV-8 are primary effusion lymphoma (PEL) and Castleman's disease (CD) [114]. HHV-8 has been reported as a potential cause of bone marrow suppression and monoclonal gammopathy after transplantation [114].

HHV-8 disease may occur in the transplant setting either as a primary infection in HHV-8 seronegative recipients of allografts from HHV-8 seropositive donors [115–117] or as a secondary reactivation of endogenous latent HHV-8 [118]. The incidences of these clinical diseases mirror the geographic distribution of the virus. Hence, the incidence of KS after transplantation is as low as 0.5 % among transplant recipients from North America, Asia, and northern Europe to as high as 28 % among HHV-8 seropositive transplant recipients from the Middle East [114]. The median time to the onset of KS is 30 months after transplantation [114].

Risk factors for HHV-8-associated disease, specifically KS, include older age, male gender, and residence or exposure in an HHV-8 endemic area. For example, in Saudi Arabia, KS was the most common tumor in kidney transplant recipients [119]. Both pre-transplant HHV-8 seronegativity and seropositivity have been associated with the development of KS, suggesting that both primary HHV-8 infection and reactivation can result in clinical disease [114]. Because control of HHV-8 infection is mediated by T cells, the intensity of pharmacologic immunosuppression and the use of anti-lymphocyte agents may play a role in HHV-8 pathogenesis after transplantation [120]. HHV-8 T-cell responses were notably absent in transplant patients at the onset of KS, and these responses were restored following reduction in immunosuppression, which coincided clinically with remission of KS [120]. Sirolimus may have a protective role against KS, potentially due to antiproliferative effects. There have been reports of KS regression following a change in the immunosuppressive regimen from cyclosporine to the mTOR inhibitor sirolimus [114].

Available Assays and Interpretation of Results

HHV-8 infection can be diagnosed serologically or by molecular testing [114, 121]. Demonstration of HHV-8 seroconversion or an IgM response can indicate acute HHV-8 infection, but the clinical utility of this in the transplant setting is limited [114]. Serological assays are non-standardized and methodologies are directed against different antigens [121]. Accordingly, the sensitivity of serology is highly variable and ranges from <80 %–>90 % [121, 122]. As noted previously in this chapter, the utility of serologic testing is also severely limited in the post-transplant setting. In some centers located in endemic regions, HHV-8 serological screening of the donors and recipients may be done to stratify the risk of HHV-8 infection and clinical disease after transplantation.

HHV-8 PCR testing offers high sensitivity and specificity for detecting active HHV-8 infection [114]. Quantification of HHV-8 viral load in clinical samples has the potential utility of predicting subsequent occurrence of KS [114, 123, 124]. In a case study of a liver transplant patient who developed KS, retrospective analysis of clinical specimens indicated that HHV-8 was detected in the serum more than 3 months prior to KS onset [124]. HHV-8 viral load testing can be used to monitor patients with KS and assess their response to therapy [114, 125–127]. For example, HHV-8 viral load peaked at the time of diagnosis and declined to undetectable levels during treatment of KS [128]. HHV-8 viremia was associated with the stage and progression of KS, and hence, quantification of HHV-8 DNA load could be a useful tool for monitoring transplant patients with KS [114, 121, 125, 126]. In a cross-sectional study of 43 patients who developed KS after transplantation, progression of the disease was associated with higher viral load, defined as >1,000 copies/μg of DNA [126].

The diagnosis of KS requires histopathology to demonstrate the pathognomonic findings of spindle-shaped cells with vascular channels lined by abnormal endothelial cells [105]. Immunohistochemistry using monoclonal antibodies against HHV-8 antigens or in situ hybridization can be a useful adjunct to demonstrate the presence of HHV-8 in KS and other angiogenic proliferative diseases [105, 114, 129].

Parvovirus B19

Description of Pathogen and Clinical Utility of Testing

Parvovirus B19 is a small, single-stranded, linear, non-enveloped, DNA virus that commonly infects humans. Most people are infected between the ages of 5 and 15 years [130].

Up to 80 % of older adults have antibodies against parvovirus B19 [131]. The virus is primarily spread person-to-person by infected respiratory droplets. However, vertical transmission and transmission via blood products and organ transplantation has been reported [131]. During active infection, the virus replicates most efficiently and preferentially in human erythrocyte precursors. Infection appears to confer lifelong immunity among immunocompetent individuals, although reinfection is possible. Parvovirus B19 can persist in the bone marrow and other tissues, supporting reactivation as a mechanism for disease after transplantation [132].

Parvovirus B19 infection can be either symptomatic or asymptomatic depending on the patient's age and immunologic status [130]. Nonspecific flu-like symptoms may occur during primary infection, but distinctive clinical entities attributed to parvovirus B19 infection have been well-described in immunocompetent and immunocompromised hosts, including erythema infectiosum, hydrops fetalis, polyarthralgia syndrome, and aplastic anemia [130]. Parvovirus B19 occurs in <1–2 % of transplant recipients [131]. However, some studies have reported that up to 30 % of organ transplant recipients develop parvovirus B19 viremia, with or without clinical manifestations [133]. In transplant recipients, the most common presentation of parvovirus B19 infection is recurrent and progressive aplastic anemia, which is reported in 99 % of all cases in the literature [134]. Fever, arthralgia, and rash were observed in 25 %, 7 %, and 6 % of patients, respectively [134].

Available Assays and Interpretation of Results

Parvovirus B19 infection should be specifically suspected in transplant recipients with otherwise unexplained anemia. Diagnostic testing can be performed by serology or direct viral detection in clinical specimens, such as blood, bone marrow, and organ biopsies or resections (i.e., liver, lung, or kidney). In immunocompromised patients, parvovirus B19 serology may not be reliable due to inadequate or delayed antibody-mediated immune response [134]. In one study, parvovirus B19 IgM antibody was present in only 75 % of transplant recipients at the time of disease onset [134].

Molecular testing offers higher sensitivity and specificity for the detection of parvovirus B19 infection compared to serologic testing, although all tests are LDTs [134]. The positive predictive value of a positive parvovirus B19 PCR test for the diagnosis of parvovirus B19 disease in an immunocompromised host with red cell aplasia is high. Hence, the detection of parvovirus B19 by PCR is highly suggestive of the diagnosis in a patient with unexplained anemia after transplantation [134]. In contrast, the detection of parvovirus B19 DNA in an asymptomatic patient with no anemia is of questionable significance, and likely represents subclinical reactivation. Most molecular assays are qualitative tests and detect low-level parvovirus B19 that characteristically persists long after the clinical resolution of the illness. Parvovirus B19 DNA can be detected by PCR in the serum of some patients for a prolonged period after acute infection [134]. Thus, a positive parvovirus B19 PCR test must be carefully interpreted in the context of the clinical setting and other laboratory test results.

Confirmation of parvovirus B19 disease may require bone marrow examination [131]. The classic bone marrow findings include overall hypercellularity, the presence of giant pronormoblasts with finely granulated cytoplasm and glassy intranuclear inclusions with a clear central halo (lantern cells), and the absence of late normoblasts. Histopathologic findings can be complemented by in situ hybridization or immunohistochemical staining to demonstrate the presence of parvovirus B19 in the bone marrow [131]. While these histopathologic findings are characteristic of parvovirus B19 disease, PCR testing may be performed to demonstrate the presence of the virus in the bone marrow [134].

Laboratory Issues and Future Directions

Clinical laboratories face many challenges with viral testing in transplant and other severely immunocompromised patients. These challenges encompass virtually every aspect of testing and stem not only from the wide number of viruses and their classic and atypical clinical presentations, but also from a lack of consensus regarding optimal testing practices and result interpretation, a near absence of US FDA-cleared, standardized assays, and a scarcity of material for test validation and proficiency testing.

Important considerations for viral testing in the transplant setting include optimal specimen type, collection (technique and frequency), preservation, and storage depending on the potential viral infection, the clinical question being asked (surveillance, diagnosis, or treatment response), and the site of potential involvement. Assay selection, required performance characteristics, and test interpretation are interrelated to these issues. However, the literature for many or most relevant viral pathogens remains clouded by a lack of standardization. In the absence of commercially available, automated test kits, test results can vary tremendously, particularly between different laboratories. Even with the recent availability of quantitative standards for some viruses, unanswered questions remain related to the clinical use of standardized results, and unified quantitative treatment thresholds have not yet been developed. Most laboratories with transplant programs must develop both the appropriate viral LDTs as well as the interpretive guidelines for their patient populations. Further complicating clinical viral testing is that most of these viruses have a high rate of latency in the general population. Detection may not correspond to disease or risk of progression. Risk stratification using viral

load results may be based on factors such as underlying disease, transplant type, graft relatedness, presence of GVHD, and the degree of immune suppression. However, an absence of clear, uniform interpretive guidelines may lead to questions of appropriate test utilization, both from clinical utility and cost perspectives.

Despite substantial challenges, progress in understanding the clinical usefulness of viral testing in the transplant setting has been impressive. A growing body of literature supports the use of aggressive, quantitative surveillance to reduce morbidity and mortality due to CMV and other viruses. The number of published viral genome, primer, and probe sequences has mushroomed, as has the number of available platforms and amplification chemistries. The recent introduction of international quantitative standards for CMV and EBV promises to allow some degree of normalization between assays and laboratories. Such standardization should spill over to other viruses such as BKV, adenovirus, and others. In their absence, those involved in such testing must navigate an increasingly complex landscape to select and properly interpret the methods best suited to improving care of their transplant patient populations and patient care settings.

Viral Infections of the Central Nervous System

48

Duane W. Newton and Christine C. Ginocchio

Abstract

Although relatively rare and typically benign, viral infections of the central nervous system (CNS) can have a significant impact on affected patients. This chapter provides a description of the epidemiology and diagnosis of a variety of important pathogens associated with CNS infections, including enteroviruses, herpesviruses, and arboviruses, as well as viral agents which cause CNS infections in immunocompromised patients.

Keywords

Infection • Central nervous system • Enterovirus • HSV • VZV • HHV-6 • Arbovirus • Immunocompromised • Cytomegalovirus • JC virus • HIV

Introduction

Viral infections of the central nervous system (CNS) are relatively infrequent and usually result in a benign, self-limiting disease [1–4]. However, in a small percentage of cases, these infections can have extremely serious consequences that result in a spectrum of permanent neurologic sequelae or death. Viral agents gain access to the CNS by either neuronal or hematogenous spread, and infections can occur at many sites throughout the CNS including the spinal cord, leptomeninges, dorsal nerve roots, nerves, and brain parenchyma. Viral CNS infections are classified clinically as either meningitis or encephalitis, although a close interrelationship exists between the two disease states [1–4]. Host factors (age, sex, immune status, genetic differences) and viral factors (serotype, receptor preference, cell tropism, viral load) in concert with geographic and seasonal factors contribute to the potential for the development of CNS disease [1–4].

Epidemiology of Viral CNS Disease

Viral meningitis, meningoencephalitis, and encephalitis frequently occur in epidemics and as seasonal outbreaks (late spring through autumn) in temperate climates, and account for the majority of viral CNS infections [1–4]. The most common viral agents responsible for CNS disease are listed in Table 48.1. In the USA and in countries that immunize against mumps, enteroviruses account for approximately 80–92 % of all cases of meningitis in which a causative agent is identified [3–6]. In addition, the recently characterized human parechoviruses are the agents of a portion of viral meningitides whose etiology was previously unrecognized [5, 6]. In countries that do not immunize against mumps, mumps virus accounts for up to 30 % of viral meningitis cases [7]. Arthropod-borne viruses (arboviruses) (Table 48.2) account for the majority of the remaining cases of meningitis in the USA [8–10].

Reoviridae	*Coltivirus*	Colorado tick fever	Western mountain USA

[a]La Crosse, Cache Valley, Jamestown Canyon, and Snowshoe hare

Encephalitis occurs at a lower frequency than meningitis, with arboviruses being the leading cause both worldwide and in the USA [8–10]. Flaviviruses and alphaviruses are the most frequent arboviruses causing encephalitis and are responsible for the majority of mosquito and tick-borne encephalitis that cause epidemic and endemic disease in Asia, Europe, and the Americas [8–10]. Case fatality rates vary greatly, ranging from 5–70 %. Human immunodeficiency virus (HIV) and rabies virus (genus *Lyssavirus*) are other important causes of encephalitis worldwide [1, 2]. Herpes simplex virus (HSV) CNS infections affect all ages, occur at all times of the year, and have the highest encephalitis mortality rate in the USA [1–4]. In a small number of cases, childhood viral diseases including rubella, measles, varicella-zoster virus (VZV), mumps, and human herpes virus 6 (HHV-6) can progress to neurologic disease during primary infection or with viral reactivation (VZV and HHV-6). Cytomegalovirus (CMV) [11–13] and JC polyomavirus (JCV) [14] are responsible for encephalitides in immunocompromised patients.

Overview of Diagnostic Testing for Viral CNS Disease

Traditionally, the diagnosis of viral CNS infection has been based on laboratory findings in conjunction with patient history, clinical manifestations, and geographic and epidemiologic factors [1–4, 8, 9]. The diagnosis of viral encephalitis requires supplemental tests, including lumbar puncture, radiographic imaging such as computed tomography (CT) scans and magnetic resonance imaging (MRI) studies, and in some cases brain biopsy.

In general, patients with viral meningitis typically have a cerebrospinal fluid (CSF) pleocytosis with 10–500 leukocytes/mm^3, a slightly elevated protein (<100 mg/dL), and a glucose level greater than 40 % of a simultaneously drawn serum sample [1, 2]. However, there can be a tremendous range of values that often overlap with those indicative of bacterial meningitis. Patients with viral meningitis or encephalitis may or may not have a CSF pleocytosis [15]. Therefore, normal CSF cell counts should not be used as a sole exclusion criterion for both diagnosis and determining which samples should be tested by molecular methods for viral pathogens. CSF glucose levels can be normal or low, as seen with bacterial meningitis. Encephalitis can lead to hemorrhagic necrosis with elevated protein levels and the presence of red blood cells.

Negative cultures for bacterial, fungal, and mycobacterial pathogens can aid in the diagnosis of viral CNS infections but can take several weeks for definitive results. However, bacterial cultures may be falsely negative if patients have been treated with antibiotics prior to sample collection. Traditionally, the identification of the specific virus relied on

viral culture, serologic detection of virus-specific IgM and IgG antibodies (either systemic or intrathecal), or both [3, 4, 16–18]. However, the ability to isolate the virus is highly dependent on the viral species, time of sample collection, sample handling and processing, and prior treatment of the patient with antiviral agents. In only approximately 10–16 % of viral meningitis cases is the causative agent identified using viral culture [3, 4, 7, 16–19]. Serologic diagnosis can be made from serum in certain cases as early as 5 days after infection with the development of specific IgM antibodies, but often takes weeks to demonstrate a diagnostic rise in IgG antibody titers between acute and convalescent serum samples [3, 4, 14, 16–18, 20, 22]. Some patients with West Nile viral infections have detectable IgM antibodies in the serum for up to 500 days after infection, making the distinction between recent and past infection difficult [22]. In addition, immune status of the patient can affect the development of virus-specific antibodies. Since CNS infection may compromise the integrity of the blood–brain barrier, interpretation of CSF serology can be problematic.

Currently, molecular amplification methods that detect viral pathogens in CSF play a critical role in the rapid and accurate diagnosis of viral CNS infections [16, 18, 19]. This approach has largely abrogated the need for brain biopsy for the diagnosis of encephalitis and, in cases where biopsy is needed, can be used to detect viral pathogens in tissue specimens. In most cases, CSF is easily obtained, especially compared to brain biopsy. CSF should be stored frozen, preferably at ≤70 °C, to maintain the stability of viral nucleic acids. Isolation of the nucleic acids is achieved using a variety of extraction methods (described in Chap. 2) that also remove amplification inhibitors and neutralize any DNases or RNases present in the sample. The volume of CSF required can vary significantly and is dependent on the viral target, relative levels of virus present in the CSF, and the sensitivity of the testing method.

Results from molecular tests can be available within 24 h and possibly as soon as 2 h for applications utilizing real-time PCR technologies that incorporate amplification and detection in one step. This is in contrast to viral culture and serology, which can require up to 28 days for a final result. In the case of enteroviral infections, rapid detection of this pathogen has been shown to direct the selection of appropriate therapy, decrease the number of patients unnecessarily placed on empiric antibiotic therapy, shorten length of hospitalization, and save medical costs [23–26]. Overall, molecular amplification assays are highly sensitive and, depending on the virus and amplification target, can detect as low as one viral particle per reaction. High assay specificity is obtained by gene-specific targeting and often is significantly more sensitive and specific than serologic testing, which can demonstrate cross-reactivity among related viruses. Multiplex assays offer the versatility of screening for several pathogens in one test. Quantitative assays are useful for differentiating active from latent infection for herpesviruses and for monitoring response to antiviral therapy.

The last decade has seen a significant increase in the availability of commercially developed systems, assays, and reagents for molecular detection of viral infections. Table 48.3 lists the currently available US Food and Drug Administration (FDA)-cleared systems/assays and a representative selection of commercially available analyte-specific reagents (ASRs) that can be used in laboratory-developed tests (LDTs). This is not intended to be an exhaustive list, but represents several that are available in the US market. In addition, many types of reagents and kits are available from other manufacturers, including many that are Conformité Européenné (CE)-marked and not available in the USA.

This chapter reviews the advances in the molecular testing for the most common causes of viral meningitis and encephalitis, including the enteroviruses, herpesviruses, and arboviruses. In addition, viruses affecting persons with immune suppression, including human immunodeficiency virus type 1 (HIV-1), JCV, and CMV are briefly discussed.

Enteroviruses and Parechoviruses

Epidemiology and Disease

Human enteroviruses are small, nonenveloped, single-stranded RNA viruses that are distributed into seven species (human enteroviruses A, B, C, and D and human rhinoviruses A, B, and C) of the Picornaviridae family (www.picornaviridae.com; accessed June 2014). The non-polio enteroviruses, including the coxsackieviruses, echoviruses, and numbered enteroviruses, are responsible for approximately 50 million infections per year in the USA and possibly more than a billion worldwide [4, 27, 28]. Enteroviruses cause an array of illnesses in both adults and children, including respiratory, ocular, cardiac, gastrointestinal, and neurologic diseases, as well as skin and oral eruptions [27, 28]. In the neonate, enteroviruses can cause a sepsis-like picture or meningoencephalitis, which can be severe. Outside the neonatal period, children under 5 years of age appear to be the most susceptible to infection, partly due to a lack of acquired immunity and poor hygienic habits. Encephalitis is uncommon and meningitis is rarely associated with complicated disease and poor clinical outcome; enteroviral meningitis may be more severe in adults than in children. Although enteroviral infections can occur year-round, the majority of the infections in temperate climates occur during the summer through autumn months.

Human parechoviruses are related but molecularly distinct members of the *Picornaviridae* that were originally classified as additional serotypes of enteroviruses (echovirus 22 and 23) because of similarities in clinical and laboratory

Table 48.3 Commercial molecular assays and reagents available in the USA for detection of relevant viral agents

Target	Manufacturer	Test name	Method
US FDA-cleared[a] for CSF			
Enterovirus (EN)	bioMérieux, Inc.	NucliSENS EasyQ Enterovirus	Real-time NASBA

[b]Not US FDA-cleared for diagnosis of CNS infections

characteristics [6]. However, parechovirus has now been established as its own genus based on extensive molecular studies. Increased surveillance and molecular phylogenetic studies have identified 16 distinct types [6]. The epidemiology and clinical presentation of parechovirus infection overlap with enteroviruses. While neonates and young children are primarily affected by both viruses, parechovirus infections in persons over age 10 have rarely been reported [6].

Laboratory Diagnosis

Many enteroviruses can be cultured in human and primate cell lines [27]. No single cell line is optimal for all enteroviral types, and therefore several different cell lines susceptible to enteroviral infection typically are used for clinical testing. Viral CSF culture has a sensitivity of approximately 65–75 %, in part because of the lability of the virus and possible low levels in the CSF. Furthermore, not all enteroviral serotypes are able to be recovered in tissue culture, including several coxsackievirus A strains that require mouse inoculation for detection. Isolation of enteroviruses in culture can take 3–8 days and therefore is generally not rapid enough to affect either treatment options or length of hospitalization, resulting in unnecessary antibiotic therapy until bacterial CSF cultures are negative at 48–72 h. Several serologic assays can be used to diagnose enteroviral infections, but are not clinically useful because they can be cross-reactive, nonspecific, and difficult to interpret due to the extended incubation and prodromal periods found with many enteroviral illnesses. In addition, culture of parechoviruses is also difficult, so the detection of both enteroviruses and parechoviruses is primarily performed using molecular methods.

Molecular Tests

To increase the sensitivity of enterovirus detection and to reduce the diagnostic turnaround time, molecular tests have been developed [19, 24, 29–36]. The molecular testing methods utilize either reverse transcription-polymerase chain reaction (RT-PCR) amplification combined with enzyme-linked immunosorbent assay (ELISA) [24, 29, 31–34, 36], real-time RT-PCR [35], or nucleic acid sequence-based

amplification (NASBA) combined with molecular beacon technology [30]. The assays utilize primer sequences selected from the conserved 5′ untranslated region (5′ UTR) of the enteroviral genome. Sequence variations are present in this region, and the scope of detection of the various enteroviral serotypes is dependent on primer sequence selection [24, 29–36]. Since different serotypes circulate in distinct areas of the world, assays should be validated using local clinical isolates and reference strains known to be endemic in the region. Overall, enterovirus molecular tests are highly sensitive, some detecting the majority of enteroviral isolates at as low as 0.1 tissue culture infectious dose 50 ($TCID_{50}$) [24, 29–36]. The molecular enterovirus tests are generally very specific, but have been shown to cross-react with rhinovirus [29, 35]. The significance of this cross-reactivity is discussed later in this chapter.

The availability of commercial reagents for molecular detection of enteroviruses has increased substantially in recent years. Two systems for the detection of enteroviruses from CSF samples are US FDA-cleared: Xpert EV (Cepheid, Sunnyvale, CA; 2007) and NucliSENS EasyQ Enterovirus (bioMérieux, Durham, NC; 2008) (Table 48.3). Cepheid's Xpert platform is a closed, integrated extraction and real-time amplification and detection system using TaqMan hydrolysis probe chemistry. This platform is capable of single unit testing, with a total testing time of approximately 1.5 h. bioMérieux's NucliSENS EasyQ system is based on NASBA isothermal RNA amplification with real-time target detection using molecular beacons, with a total testing time of 5 h. Both assays target 5′ UTR of the enterovirus genome.

A representative list of ASRs available commercially is presented in Table 48.3. These ASRs can be used on different amplification and detection platforms, providing flexibility for the design of LDTs. Analytical assessments of the Xpert assay have demonstrated very good performance characteristics. In a multicenter study comparing Xpert to a combined standard of clinical and laboratory data to define true infection, Xpert demonstrated 94.7 % sensitivity and 100 % specificity, with an overall accuracy of 98.6 % [37]. When used in a point of care test setting to maximize clinical impact of the results, Xpert also performed well (100 % sensitivity, 98.9 % specificity) for samples for which a result was obtained [38]. However, the authors reported a 16 % invalid rate for Xpert EV on initial testing, and these samples were not included in the calculations of performance. This invalid rate was similar to an 8 % rate from a previous study that assessed the performance of Xpert during routine use [39]. These authors reported that the invalid rate could be reduced by sample dilution or a single freeze–thaw without impacting the assay performance characteristics.

Although US FDA-cleared in 2008, comparatively fewer studies have been published evaluating the performance of the EasyQ system (bioMérieux). One study conducted by Landry et al. prior to US FDA clearance of this system compared an early version of the real-time NASBA assay to the original NASBA assay combined with electrochemiluminescence (ECL) detection of enterovirus in CSF and stool samples [30]. The real-time NASBA assay was 91 % sensitive and 100 % specific compared to NASBA-ECL upon initial testing of 160 samples, with an indeterminate rate of 2.5 %. A more recent report assessing the CE-marked version of the real-time NASBA EasyQ assay demonstrated a 90 % sensitivity and 100 % specificity compared to an LDT using a conventional RT-PCR method [40]. Marlowe et al. evaluated the Xpert assay compared to both the EasyQ assay and a TaqMan-based LDT, with 25/25 positive samples detected by Xpert, 24/25 detected by the LDT, and 21/25 detected by EasyQ [41]. These authors also showed an initial 7.2 % (10/138) invalid rate for Xpert EV, which was attributed to a single lot of reagents, with eight of ten resolved upon repeat testing with a new reagent lot.

CE-marked assays for the detection of enteroviruses in CSF are available from bioMérieux/Argene Biosoft (Varilhes, France). Enterovirus Consensus Assay utilizes RT-PCR and stair primer technology that was designed to overcome the problems associated with sequence divergence in the primer-binding regions, thus ensuring the detection of all enteroviral serotypes [29]. The assay was shown to be more sensitive than assays using the original Rotbart [32, 33] and Zoll [36] primers, and only exhibited cross-reactivity with rhinovirus type 3. Studies have determined that the sensitivity of the assay is <0.4 $TCID_{50}$ and can detect approximately six RNA copies per input reaction.

Implementation of molecular testing for enteroviruses into routine use can positively impact the management of patients with suspected meningitis. Multiple studies have shown shorter duration of hospitalization, decreased use of inappropriate antibiotics, reduced ordering of ancillary laboratory tests, and overall decreases in health-care costs when enterovirus results are rapidly available [23–26]. These benefits have the potential to be maximized with systems such as Xpert, and should continue to improve with the increased development of more on-demand, near-patient platforms.

Molecular detection of parechoviruses has been limited to the use of RT-PCR LDTs in a limited number of clinical laboratories. Similar to assays for detection of enteroviruses, most assays for the detection of parechoviruses target the 5′ UTR, with recently described assays capable of detecting all known parechovirus types [42]. Several studies which have retrospectively analyzed stored CSF specimens have demonstrated an overall prevalence for parechoviruses of 2–3 % in CNS infections, but prevalence in individual years can vary widely from 0–10 % [6, 43–46].

Herpesviruses

The herpesviruses, including herpes simplex virus types 1 and 2 (HSV-1, HSV-2), VZV, CMV, and HHV-6, are large (150–200 nm), enveloped viruses with a linear, double-stranded DNA genome packaged in an icosahedral capsid. These viruses cause a broad spectrum of viral CNS disease including meningitis, encephalitis, meningoencephalitis, myelitis, and polyradiculitis [1, 2]. Epstein-Barr virus (EBV) DNA has been detected in virtually all AIDS-related cases of primary CNS lymphomas [47]. CMV is discussed briefly under diseases associated with immunosuppression and in detail in Chap. 47. The role of HHV-7 in CNS disease remains unclear.

Herpes Simplex Virus

Epidemiology and Disease

HSV-2 is the usual cause of HSV meningitis and accounts for approximately 1–5 % of all cases of viral meningitis and 4–6 % of cases of viral encephalitis overall (adult and pediatric) [1–4, 48, 49]. The clinical course of the disease usually is self-limiting and generally not associated with permanent neurological damage. HSV-2 also causes Mollaret's meningitis, a benign recurrent meningitis [50].

HSV-1 is responsible for the majority of HSV-associated encephalitis and for 10–20 % (approximately 1,250 cases per year in the USA) of all viral encephalitis cases (adult and pediatric). Approximately 30 % are primary HSV-1 infections, and the remaining cases are due to HSV reactivation. In contrast to HSV meningitis, HSV encephalitis can be a devastating disease, resulting in persistent focal neurologic disease due to damage to one or both temporal lobes [1–4, 48, 49]. Encephalitis occurs in approximately 60–75 % of babies with disseminated HSV disease, and the mortality rate for cases of HSV-2 encephalitis can be as high as 80 % without appropriate antiviral therapy [51].

Diagnosis

CSF viral cultures are positive only in approximately 15 % of HSV meningitis cases due to primary infection and, with the exception of neonatal infection, are rarely positive in cases of HSV encephalitis [1–3, 32, 33, 48, 49, 51]. Traditionally, the diagnosis of HSV encephalitis was dependent on obtaining tissue by brain biopsy for viral culture, electron microscopy, immunohistochemical staining, and the demonstration of intrathecal production of HSV-specific antibodies [1–3, 16–18, 49, 51].

Over the last decade, studies comparing HSV CSF PCR with brain biopsy and/or intrathecal HSV-specific antibody production for the diagnosis of HSV CNS infections have demonstrated sensitivities and specificities ranging from 96–98 % and 96–99 %, respectively [16, 51–53]. HSV PCR can identify infected persons who fail to either seroconvert with primary infection or demonstrate significant rises in antibody titers after reactivation. Finally, HSV PCR can aid in differentiating HSV antibody increases due to active HSV CNS infection from reactivation in persons with concomitant CNS disease not related to HSV. Another advantage of PCR assays for diagnosis of HSV encephalitis is that the assay sensitivity remains high (95 %) up to approximately 1 week after initiating therapy [52]. However, CSF samples collected early after symptom onset may be negative in some patients with HSV CNS disease, so repeating the lumbar puncture and HSV PCR testing is recommended in such cases when HSV infection is strongly suspected [54]. Caution should be exercised if using CSF PCR for test of cure since DNA can be slow to clear from the CSF (as many as 21 % of CSF specimens can remain PCR positive for more than 15 days after successful completion of therapy) [52]. Although HSV viral loads are not correlated with prognosis [55, 56], persistent detection of HSV in the CSF of neonates with encephalitis has been shown to be a poor prognostic indicator [56, 57].

Varicella-Zoster Virus

Epidemiology and Disease

The most common manifestation of VZV resulting from primary infection is chickenpox and generally occurs in early childhood [58]. VZV-associated neurologic syndromes include acute cerebellar ataxia, diffuse or focal encephalitis, meningitis, transverse myelitis, and Reye syndrome [1, 2, 58]. Herpes zoster (also known as shingles), resulting from the reactivation of latent VZV infection, occurs in approximately 20 % of immunocompetent persons (generally 45 years or older) and the incidence is approximately 15 % higher in persons with immunosuppression [58, 59]. In a small percentage of all zoster cases, severe complications can occur, including meningitis, encephalitis, myelitis, Ramsay Hunt syndrome, Guillain-Barre syndrome, and contralateral hemiplegia [58–60]. Ocular manifestations are more common in reactivation disease, such as herpes zoster opthalmicus and acute retinal necrosis, especially in immunocompromised individuals and those not treated with antiviral therapy [61, 62]. Interestingly, concomitant herpes zoster rash may only be present in less than half of patients with VZV CNS disease [63].

Diagnosis

Studies have demonstrated that the recovery of VZV in culture is poor (20 % positive), as is serologic diagnosis (48 % positive) [64]. Antigen detection by immunofluorescent staining improves detection from vesicular lesions (82 % positive), whereas PCR was the most sensitive, with a

detection rate of approximately 95 % [64]. Based on improved detection with PCR assays, VZV accounts for 6–30 % of all herpesviruses detected from CSF [20, 21, 64–71]. However, results need to be interpreted cautiously since VZV DNA has been detected in CSF without overt disease, particularly in immunosuppressed individuals.

Human Herpes Virus 6

Epidemiology and Disease

HHV-6 is generally acquired early in life and is manifested as exanthem subitum (more commonly known as roseola), or as a non-exanthemous febrile illness, sometimes accompanied by severe neurologic manifestations, including febrile seizures, meningitis, meningoencephalitis, and encephalitis [72]. Detection of HHV-6 in children with febrile seizures is important for identifying children with a potential for the recurrence of seizure episodes due to ongoing HHV-6 infection. Immunocompromised patients can manifest severe HHV-6 reactivation infections, including encephalitis [72].

Diagnosis

Culture confirmation of HHV-6 infection is not routinely performed in clinical virology laboratories due to the complexity of the testing, which requires purification and culture of patient lymphocytes or co-cultivation of activated patient lymphocytes and activated human umbilical cord blood lymphocytes [72]. Serologic confirmation of the disease depends on the detection of IgM in primary infection or conversion from either a negative to a positive IgG antibody response or a four-fold or greater rise in IgG antibody titer [72]. However, antibody titers can be difficult to interpret for several reasons: IgM antibodies may not develop in some children, can be positive with HHV-6 reactivation, and can remain positive for extended periods of time; and significant rises in HHV-6-specific IgG antibody titers can be found during infections with other herpesviruses. The detection of HHV-6 DNA in the CNS by PCR can support the diagnosis; however, in a percentage of cases, HHV-6 DNA can be found in normal brain tissue and in the CSF of children without evidence of CNS disease [72]. Although rare, chromosomal integration of HHV-6 can complicate the interpretation of positive molecular tests from body fluids, and may result in the misdiagnosis of acute CNS infection [73]. Quantitative methods may be more accurate for correlating the presence of HHV-6 with active disease [74, 75].

Molecular Tests for Herpesviruses

Comparisons of the sensitivity of HSV PCR to viral culture, antibody detection, and direct immunofluorescence assays have clearly established the utility of PCR as a first-line diagnostic test in the clinical laboratory [7, 16, 18, 19]. Most PCR assays are applicable to the majority of conventional or real-time PCR instruments. The assays for herpesviruses use different primer sets targeting a number of genes including: DNA polymerase gene (HSV-1, HSV-2, CMV, EBV, VZV, HHV-6); UL42, glycoprotein B (gB), glycoprotein D (gD), or thymidine kinase (TK) genes (HSV); genes 28 and 29 (VZV); and major capsid protein, U89/U90 (HHV-6). Identification of the specific herpesvirus is achieved using either traditional methods, including the use of species-specific primers, hybridization with species specific probes, agarose gel electrophoresis, restriction enzyme analysis, ELISA-based colorimetric detection methods [20, 21, 64, 66–68, 70], or fluorescent probe technologies that permit real-time detection [65, 69, 71]. One commercial assay has been US FDA-cleared for the detection of herpesviruses in CSF (Table 48.3, Simplexa™ HSV 1 and 2 Direct Kit, Focus Diagnostics, Cypress, CA). Two assays are US FDA-cleared for the detection of HSV from oral and anogenital lesions: the Multicode—RTx HSV 1 and 2 kit (EraGen Biosciences, Madison, WI) and the IsoAmp HSV assay (Biohelix, Beverly, MA). A third assay is US FDA-cleared for the detection of HSV from anogenital lesions: the BD ProbeTec™ Herpes Simplex Viruses (HSV 1 and 2) Q*x* Assay (Becton Dickinson, Sparks, MD). None of these US FDA-cleared HSV tests for lesions should be used for the diagnosis of HSV CNS infections.

Several commercial test kits or ASRs are available for the detection of herpesviruses in CSF (Table 48.3). Roche Diagnostics (Indianapolis, IN) has developed ASRs for CMV, HSV-1, HSV-2, VZV, and EBV identification using the LightCycler instrument [65, 69, 71]. A single-tube amplification and detection step allows the identification of both HSV-1 and HSV-2 and the differentiation of subtype by melting-curve analysis [65]. The manufacturer's claim of sensitivity is approximately 12.5 copies or 2.5–6.3 genome equivalents per reaction.

ASRs for several herpesviruses are available from Cepheid (Sunnyvale, CA), Epoch Biosciences/Nanogen (Bothell, WA), EraGen Biosciences (Madison, WI), and Focus Diagnostics (Cypress, CA). Although not available for sale in the USA, Artus Biotech (Artus GmbH, Hamburg, Germany) has CE-marked systems and assays for the detection of herpesviruses. Easy*artus* HSV 1 and 2, EBV, VZV, and CMV PCR kits are approved for use with BioRobot EZ1 DSP for specimen extraction, and LightCycler (Roche), ABI PRISM 700 and 7900HT SDS (Applied Biosystems Foster City, CA), and the Rotor-Gene 3000 (Corbett Research, San Francisco, CA) for amplification and detection. Real-time PCR for the same viruses can be accomplished using the *artus* Herpes Virus LC-PCR kits. Assays with these reagents have been optimized for use on the LightCycler (Roche) with manufacturer-claimed limits of detection (copies/PCR) of

5.0 for HSV-1 and -2, 28.9 for EBV, 4.0 for VZV, and 4.9 for CMV. Assessments of clinical and analytical performance of the commercially available reagents has been limited; however, a recent study evaluating the performance of ASRs from Cepheid, EraGen, and Roche for the detection of HSV-1 and -2 from pediatric CSF samples demonstrated comparable clinical and analytical sensitivities among the assays [76].

Multiplex assays that can simultaneously screen for the six major herpesviruses (HSV-1, HSV-2, CMV, VZV, EBV, and HHV-6) offer some distinct advantages including the identification of a herpesvirus that may not have been considered in the original diagnosis and the detection of co-infections in the CNS [77]. However, caution must be used in determining the significance of detecting more than one herpesvirus because low level reactivation may occur in the presence of immune suppression due to the primary infection.

Several LDTs targeting herpesviruses have been validated for CSF specimens and/or brain tissue using either traditional or real-time PCR methods [16, 21, 65–71]. Herpes Generic Consensus kit (bioMérieux/Argene Biosoft, Varilhes, France) uses the same stair primer technology as in their enterovirus assay to compensate for sequence divergence in the primer binding regions of the six herpesviruses [66]. After PCR amplification and generic colorimetric detection of the herpesvirus, the Herpes Identification Hybridoma well kit (bioMérieux/Argene Biosoft, Varilhes, France) is used to identify the specific herpesvirus present. All primers, probes, an internal control, external controls, and all PCR reagents, with the exception of amplification enzyme, are provided in the test kit. Assay sensitivity varies between 5–50 copies per PCR reaction, with EBV being the least sensitive. This assay is available as a research use only (RUO) kit in the USA and is CE-marked kit outside of the USA.

Microarray-based technology offers the opportunity to expand the detection capabilities of multiplex real-time PCR assays, and has been applied to the development of LDTs [78] and commercially available assays [79] for detection of viral CNS infections. Clart Entherpex kit (Genomica, Coslada, Spain) is a CE-marked multiplex real-time PCR DNA microarray allowing the simultaneous detection of HSV-1 and -2, VZV, CMV, EBV, HHV-6, HHV-7, HHV-8, and human enteroviruses in CSF, and has demonstrated similar clinical and analytical sensitivity compared to single-endpoint PCR for detection of these viral targets [79].

Arboviruses

Epidemiology and Disease

Alphaviruses, flaviviruses, and bunyaviruses are responsible for the majority of the arboviral encephalopathies (Table 48.2) and are found throughout the world [1, 2, 10]. Arboviruses have an RNA genome, with the exception of African Swine Fever Virus which has a DNA genome. The arboviral encephalitides are zoonotic, and transmission of the viruses occurs between susceptible amplifier vertebrate hosts (such as birds, squirrels, and chipmunks) via blood feeding arthropods (including mosquitoes, psychodids, ticks, and ceratopogonids). Peak incidence occurs in summer and continues through the fall months when arthropods are most active, but cases can continue to occur in the winter months in warmer regions. Humans, horses, and domestic animals can develop a clinical illness, with the majority of human arboviral infections being either asymptomatic or manifesting as a flu-like self-limiting illness. Arboviruses can occasionally enter the brain by mechanisms not clearly understood, with productive infection of brain cells occurring, resulting in encephalitis, often with a fatal outcome or permanent neurologic damage in the affected individual [1, 2, 10].

The mosquito-borne viruses were first discovered in the 1930s [10]. Until 1999 and the emergence of West Nile virus (WNV) in Queens, New York [80], the most important cause of epidemic and endemic encephalitis in the USA was St Louis encephalitis virus (SLE), which is found throughout the lower 48 states. From 1964 to 2009, confirmed cases of SLE averaged approximately 100 cases per year, and over 4,500 cases of neuroinvasive disease have been reported to the Centers for Disease Control and Prevention (CDC; Atlanta, GA) since 1964 [8]. Less than 1 % of the SLE cases are clinically apparent, with a case fatality rate of 5–25 % for symptomatic persons [8].

Since the initial outbreak in 1999, WNV has migrated across the USA, and through 2011 all but two states (Alaska and Hawaii) have reported bird, mosquito, vertebrate, or human cases [8, 9]. WNV is responsible for neuroinvasive disease (encephalitis and meningitis) and what is termed West Nile fever, which is typically less severe and does not show signs of neuroinvasion [80]. Through 2014, over 18,000 cases of neuroinvasive WNV infections with over 1,200 deaths have been reported to the CDC [8, 9]. Approximately one in 150 WNV cases progress to meningitis or encephalitis, which is the most common neurological manifestation. Case fatality rates remain constant at approximately 10 %, with advanced age being the most important risk factor for death [8–10]. In addition, WNV has been transmitted to persons receiving either transfusions or transplanted organs from asymptomatic donors infected with WNV [9, 80, 81]. Phylogenetic analysis has shown that WNV can be separated into two lineages [82], with lineage 2 being associated with recent outbreaks in Europe.

La Crosse virus is found in several midwestern and mid-Atlantic states, and an average of 80–100 cases are reported per year, usually in children under the age of 16 years. Since 1964, eastern equine encephalitis virus and western equine encephalitis virus have been responsible for 270 and 639 cases, respectively [8]. In the northern USA, Powassan virus is a minor cause of encephalitis and is transmitted by ticks

[8]. Japanese encephalitis virus, found mainly in Asia and the Pacific, is the leading cause of encephalitis worldwide, with more than 45,000 cases reported annually [1, 2, 10]. Venezuelan encephalitis virus remains the third most common cause of equine encephalitides and the most common cause of epidemic encephalitis in Central and South America [1, 2, 10].

Diagnosis

By the time persons present with encephalitic symptoms, the viremic phase of the disease often has ceased and infected persons have developed serum and intrathecal IgM or IgG antibodies or both [10, 80]. Since IgM antibodies do not cross the blood–brain barrier, the identification of virus-specific IgM antibodies in the CSF is strongly suggestive of CNS infection. A variety of assays, including hemagglutination inhibition, complement fixation, plaque reduction neutralization test (PRNT), IgM antibody capture ELISA (MAC-ELISA), IgG antibody ELISA, indirect immunofluorescence (IFA), and antigen capture ELISA, have been useful in the identification of arboviral infections [10, 20, 80, 83]. The identification of virus-specific IgM antibodies or the demonstration of a four-fold or greater rise in neutralizing IgG antibodies in either CSF or serum is achieved by PRNT using multiple arboviruses. Commercially available MAC-ELISAs are more reliable, rapid, and reproducible compared to LDTs [20, 80, 83]. In persons with immunosuppressive disorders or who are very early in the course of the infection, antibody titers can be negative and the diagnosis is dependent on isolation of the virus. However, due to the transient nature of the viremic stage and probably low levels of virus in the CSF and serum, virus isolation using cell culture generally has been unsuccessful and not practical for most clinical laboratories.

Although serological confirmation of disease remains the gold standard, molecular tests are important for identifying early infection prior to seroconversion, infection in transplant tissues and blood [80, 81], infection in immunocompromised patients, and confirmation of a clinical diagnosis [80, 84–87]. A positive result with a nucleic acid amplification assay is diagnostic of an arboviral infection; however, a negative result does not exclude the possibility of an arboviral infection. For example, up to 55 % of CSF samples and only approximately 10 % of serum samples are positive using a molecular test in patients with serologically confirmed cases of WNV disease [80]. Nevertheless, the molecular detection of arboviral nucleic acids is standard for vector-borne disease surveillance studies and control programs [80, 84–86, 88] and for monitoring both the blood supply and transplantation tissues [80, 81].

Molecular Tests

Several assays using traditional RT-PCR, nested RT-PCR, real-time RT-PCR, and NASBA combined with either ECL or molecular beacon detection have been developed for the identification of arboviral infections [80, 84–88]. Assay methods are highly sensitive, specific, and rapid, with results available in as little as 2 h for real-time RT-PCR and NASBA molecular beacon assays. Primers usually target the NS1, NS3, NS5, and 3′ NC regions of the genomes of the flaviviruses. Primer-probe sets may be virus specific [84–86], or universal primers can be used for the detection of all flaviviruses [87]. Although commercially available reagents are limited for the molecular detection of WNV in Europe, there are none available in the USA. Furthermore, proficiency testing (PT) performed with early versions of commercial tests and LDTs showed good performance in the ability to detect WNV lineage 1, but an inability of more than 40 % of participating laboratories to detect lineage 2 [89]. Although the performance in detecting lineage 2 improved slightly in a recent assessment [90], one-third of testing laboratories were unable to detect both lineages. Accommodations for sequence variation must be incorporated into assay design to ensure the optimal detection of both WNV lineages 1 and 2.

Viral Agents Associated with Immunosuppression

Cytomegalovirus

Epidemiology and Disease

CMV is an enveloped, double-stranded DNA virus with particles ranging in diameter from 120–200 nm. CMV disease may be due to primary infection but generally is related to CMV reactivation in association with progressive immune deficiency [11–13]. Neurological syndromes associated with CMV include peripheral neuropathy, ventriculoencephalitis, myelitis/polyradiculopathy, and diffuse micronodular encephalitis with dementia [11–13].

Diagnosis

The presumptive diagnosis of CMV CNS disease has been based primarily on clinical presentation, serologic testing, neuroradiologic studies including CT scan and MRI, CSF chemistries, and the magnitude and types of CSF pleocytosis [11–13]. CSF viral culture is positive in only approximately 50 % of patients with CMV CNS disease, and culture is relatively slow, requiring 1–4 weeks for a final result [11–13].

Molecular Tests

Molecular methods are used to more accurately and rapidly detect CMV in patients with active CMV CNS disease [91]. The detection of CMV DNA by PCR in CSF of acquired immunodeficiency syndrome (AIDS) patients was highly sensitive (100 % negative predictive value for CNS disease) but did not always correlate with active CMV CNS disease

(68.4 % positive predictive value for CNS disease) [91]. Sensitive qualitative PCR may detect non-replicating virus, which could clearly limit the use of these tests in the differentiation of asymptomatic infection from active CNS disease. Quantitative PCR assays with established cut-off values for differentiating infection from active disease may provide a superior alternative to qualitative PCR. For example, CSF from AIDS patients with autopsy-proven CMV encephalitis had a median value of 3,333 CMV genomes/10^5 cells compared to a median value of 125 CMV genomes/10^5 cells for AIDS patients with neurologic symptoms not related to CMV, and a median value of 19 CMV genomes/10^5 cells for HIV-1 seronegative controls [91]. High levels of cellular CMV correlated with marked histopathologic changes in AIDS patients. Additional studies are necessary to determine the level of CMV DNA that would be considered indicative of active CNS disease.

Several manufacturers produce commercially available ASRs for real-time PCR-based detection and quantification of CMV DNA from a variety of clinical specimen types (Table 48.3). A different approach, used in both transplant recipients and HIV-1-infected persons for diagnosing active disease vs asymptomatic CMV infection, is based on detection of CMV mRNA transcripts (immediate-early and early, UL83, pp150, and pp67 gene transcripts) [91, 92]. Although commercial assays are not available, CMV transcript detection can be a useful target for the differentiation of active infection from latent infection. The detection of pp67 mRNA in CSF is most accurate for the diagnosis of active CMV CNS disease (100 % positive predictive value [PPV], 97 % negative predictive value [NPV]), when compared to viral culture (100 % PPV, 82.7 % NPV) and qualitative DNA PCR (68.4 % PPV, 100 % NPV) [92]. In addition to diagnostic utility, quantitative PCR and pp67 mRNA assays have been effective for monitoring response to therapy for CMV infections [91].

Human JC Polyomavirus

Epidemiology and Disease

Human JCV is a small (40 nm) nonenveloped DNA virus with an icosahedral capsid. Primary infection with human JCV generally occurs early in life, is usually asymptomatic, and results in a latent infection of both renal tissues and B lymphocytes [14]. Reactivation occurs during cell-mediated immune deficiency and can lead to progressive multifocal leukoencephalopathy (PML), a rapidly evolving severe demyelinating disease of the CNS that is usually fatal. This disease is primarily but not exclusively seen in patients with AIDS and, prior to the era of highly active antiretroviral therapy (HAART), was a serious cause of infection in 2–10 % of AIDS patients. A review of cases over a 10-year period also showed that approximately 20 % of non-AIDS patients with PML had hematologic malignancies or were bone marrow transplant recipients [93].

Diagnosis

The diagnosis of PML can be difficult, is generally presumptive, and typically based on recognition of characteristic multifocal white matter lesions using imaging techniques (CT or MRI) in patients manifesting subacute neurologic deficits. Although laboratory tools such as serology, virus isolation, and electron microscopy have been used to aid in diagnosis [14], these tests have had limited utility due to poor specificity (serology), labor intensiveness (cell culture), or impracticality (EM). Histopathologic analysis of brain biopsies often has been required to confirm the diagnosis and remains the gold standard for diagnosis [94].

Molecular Tests

Several PCR-based strategies have been used for detection of JCV in CSF for the diagnosis of PML and to monitor patients with AIDS who achieved a PML remission as a result of HAART [14, 95–97]. Testing has been performed using unique or sequential CSF samples, with assays using single or nested PCR combined with conventional or real-time detection technologies. Primers target different noncoding and coding (VP1, VP2, small T-antigen, large T-antigen) regions, often with variable results, presumably due to the large amount of sequence variation within the various subtypes of JCV [14]. PCR detection of all JCV genotypes can be improved if primers that target the more conserved regions of the genome or degenerate primers are used; however, care must be taken in assay design to prevent cross-reaction with other polyomaviruses. PCR assays have a rate of detection of JCV in CSF from patients with PML ranged from 30–89.5 % [95–97]. Specificity of PCR for identifying viral isolates of JCV was 100 %, while specificity for the diagnosis of confirmed PML was generally about 95 % [95–97]. However, in patients with PML on HAART, the sensitivity of PCR for detection of JCV in CSF is considerably lower than in patients with PML not on HAART [98]. In summary, CSF examination for JCV DNA was shown to be useful for confirming the diagnosis of PML. However, a negative test does not exclude the possibility of PML and brain biopsy is necessary to confirm such cases.

Human Immunodeficiency Virus

Human immunodeficiency viruses are enveloped, plus-stranded RNA retroviruses. Early in the course of infection, HIV-1 enters the CNS [99, 100]. A complex interaction between the virus and host immune responses leads to neurological damage that is manifested by several

syndromes including meningitis, encephalitis, peripheral neuropathies, and AIDS dementia complex (ADC) [99, 100].

Molecular Tests

High HIV-1 RNA levels in CSF correlate with an increased incidence of ADC and with the presence of cerebral atrophy [99]. Most persons with high CSF viral load have concomitant high plasma viral load. However, there are patients on HAART with either low-level or undetectable plasma viral load (<50 copies/ml) who have signs of neurologic disease and high CSF viral load (>50,000 copies/ml). Suppression of plasma viral load does not always correspond with HIV-1 suppression in other body compartments, and the monitoring of such compartments may be indicated in certain clinical situations. Therefore, when neurological symptoms are evident, measurement of HIV-1 RNA levels in the CSF becomes important. Detectable viral load in the CSF can affect the selection of HAART, since not all drugs penetrate the CSF to the same degree. In addition, due to the large overlap of neurological symptoms associated with the AIDS-related neurological disorders, such as CMV encephalopathies and PML, CSF viral load can aid in the differential diagnosis of ADC [92]. The measurement of CSF viral load, using commercially available methods described in Chap. 45, can be performed once the laboratory has validated this off-label sample type.

Interpretation of Results

The enhanced performance of molecular assays compared to conventional methods has significantly improved diagnosis of viral CNS infections, and detection of specific viral nucleic acid targets in the CSF most often represents true positive results. Potential scenarios for false-positive results could include analytical cross-reactivity of primers/probes due to homology between related viruses. Assays for the detection of enteroviruses can cross-react with some rhinovirus types, which provides challenges in the interpretation of results from respiratory specimens, but should not impact interpretation of CSF results because rhinoviruses are not CNS pathogens. Clinical false-positive results may also occur in the detection of CMV nucleic acid in the CSF which may represent latent rather than reactivated infection. As mentioned above, quantitative or viral mRNA-targeted assays may be more useful than DNA-targeted qualitative assays in identifying reactivation. False-negative molecular results are possible and can be due to analytical factors related to specimen quality and integrity (collection, transport, storage). In addition, assay limitations due to mutation or sequence variation should be recognized, and processes for assessing and monitoring these components of assay performance over time should be included in the laboratory's quality assurance program. Furthermore, timing of specimen collection (within the first week of an arboviral infection), and prior therapy (impact of HAART in detection of JCV) must be considered in interpreting negative results.

Laboratory Issues

A major limitation in the use of molecular assays for the diagnosis of viral CNS infections is the relative lack of US FDA-cleared options available for US laboratories. Although several assays/systems have recently reached the market, these have been limited to the detection of enteroviral infections. Due to the extreme difficulty in performing clinical trials of an appropriate scope to obtain US FDA clearance, it is unlikely that US FDA-cleared products for other targets in the CSF (notably HSV) will be available in the near future. This will compel laboratories either to verify alternative specimen types on currently available US FDA-cleared assays or utilize ASRs or LDTs, both of which may limit widespread utilization of the technology. In addition, the number and diversity of commercially available PT panels has not kept pace with the growth in utilization of molecular assays for the diagnosis of CNS infections. Regulatory compliance through the use of in-house PT panels or specimen exchange programs causes additional challenges to the laboratory. Finally, operational attention in the design of the laboratory, including when, where, and on which platforms certain assays are being performed, also needs to be taken into consideration. For example, separation by time, location, and potentially even platforms for extraction, amplification and detection steps, as well as CSF samples and lesion samples submitted for detection of HSV. Lesion samples are a high volume specimen type, generally contain a high viral titer, and demonstrate high positivity rates for most laboratories. These factors can present an unwanted, but controllable opportunity for environmental cross-contamination of CSF samples.

Conclusions and Future Directions

Currently, the application of molecular testing for the detection of clinically relevant viral CNS infections is considered an essential component in standard of care clinical testing for many viral infections. For certain viral pathogens, such as HSV and enteroviruses, molecular tests are considered the new gold standard. For other viruses, correlation of molecular results with other laboratory findings, such as serologic status, clinical presentation, and patient management is still an active area of study. Nevertheless, molecular tests are rapid, accurate and significantly impact patient management and outcome. The selection of the best method or target must

be carefully considered, as variations in both can affect the overall performance of the assays. In certain cases, where latent viruses may be detected, quantitative assays or assays that target mRNA rather than DNA may provide more useful clinical correlation for CNS disease. Laboratories must thoroughly evaluate and validate the tests, continue to monitor technical performance, and maintain strict environmental precautions to prevent cross-contamination of samples. Standardization of test methods, cooperative participation in PT programs, and support by the laboratory community for the development of commutable molecular standards will improve performance and correlation of intralaboratory and interlaboratory results.

Bacterial Infections

49

Kevin Alby and Melissa B. Miller

Abstract

Molecular techniques have revolutionized the detection and identification of microorganisms. Real-time PCR has allowed for the rapid and accurate detection of MRSA, VRE, and group B *Streptococcus*. The identification of difficult and slow-growing organisms has been expedited by sequence-based methods such as 16S rRNA gene sequencing. Rapid identification of organisms and detection of resistance markers directly from positive blood culture bottles has become a reality. Finally, a transformation is taking place with the introduction of MALDI-TOF into clinical laboratories that promises to improve the accuracy and speed of bacterial and fungal identifications by days. The advantages of these methodologies and their associated clinical applications, along with their inherent pitfalls and problems, are elucidated in this chapter.

Keywords

MRSA • *Staphylococcus aureus* • VRE • *Enterococcus* • Group B *Streptococcus* • Antimicrobial resistance • Mass spectrometry • MALDI-TOF • 16S rRNA • Tuberculosis • Sepsis • Molecular epidemiology

Introduction

As the general population ages, the incidence of chronic conditions rises, the prevalence of antimicrobial resistance increases, and emerging pathogens arise, the laboratory diagnosis of infectious diseases has evolved and become more complex. As the complexity of diagnostic microbiology has increased, so have the methods employed to detect infectious agents. The implementation of molecular technology in the clinical microbiology laboratory in some cases has augmented traditional methods, such as culture and serology, while in other circumstances it has completely replaced traditional methods. For routine bacteriology (i.e., blood cultures, urine cultures, and respiratory cultures), culture has remained the gold standard primarily based on a lower cost and the potential complex nature of infections. However, in situations where low quantities of the pathogen may be present, the patient may have received antibiotics prior to specimen collection, the etiologic agent may require unusual culture conditions, or a more rapid turnaround time is needed, molecular testing approaches are particularly beneficial.

Currently, the optimal use of molecular techniques in microbiology resides with specimens in which a limited number of pathogenic organisms are sought (i.e., detection of methicillin-resistant *Staphylococcus aureus* from nares or vancomycin-resistant *Enterococcus* from rectal swabs) and in cases where the enhanced sensitivity, decreased turnaround time, and/or patient impact of molecular methods outweighs the increased cost to the laboratory

(i.e., molecular identification of organisms directly from positive blood cultures). A particularly exciting transition in clinical microbiology is the use of mass spectrometry (MS) for the identification of a wide spectrum of bacterial and fungal organisms as well as the detection of antimicrobial resistance. This chapter discusses the most common molecular methods and their applications in clinical bacteriology laboratories, including the associated advantages and disadvantages.

Bacterial Identification

Probe Hybridization

The molecular methods used for the identification of bacterial organisms cultured from patient specimens include direct probe hybridization and sequencing. Direct probe hybridization can be used for culture confirmation as well as direct detection of organisms from clinical material. Both nucleic acid probes and peptide nucleic acid (PNA) probes are commercially available.

Probes are single-stranded oligonucleotides that vary in size from 20 base pairs (bp) to a few kilobases, but are generally less than 50 bp. Probe specificity is defined by the nucleic acid sequence of the probe. Bacterial identification using probes to 16S rRNA or 23S rRNA are commonly used due to the relatively high copy number of rRNAs in bacteria which increases the sensitivity of direct detection. Further, rRNA sequences contain conserved regions in addition to hypervariable regions allowing for the level of identification to be varied depending on the probe sequence. Commercially available probes for culture confirmation include Group B *Streptococcus*, *Listeria monocytogenes*, *Neisseria gonorrhoeae*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, and several mycobacteria including *M. tuberculosis* (Hologic, San Diego, CA). In addition, probes for direct detection of group A *Streptococcus* from throat swabs are available (Hologic). Although more expensive than conventional culture and identification methods, probe-based detection and identification methods have moderately increased sensitivity and specificity and decreased turnaround time [1]. However, both false-negative and false-positive results may occur. Bacterial strains may possess polymorphisms that prevent probe hybridization [2, 3] or different strains may contain similar sequences that result in cross-reactivity [4, 5]. Additional disadvantages of probe hybridization methods are the limited number of commercial probes and the inability to probe clinical specimens directly.

In situ hybridization (ISH) allows for the detection of nucleic acid sequences in cells or tissues fixed to glass slides. Probes, which can be DNA, RNA, or PNA, are typically short (15–30 bps) allowing for easier penetration and access to the target sequence. Both colorimetric and fluorescent ISH (FISH) probes are used in histopathology and clinical microbiology. Advantages of ISH in histopathology are the ability to evaluate the host tissue response and identification of the specific cells containing the infectious agent(s). In addition, "non-culturable" or difficult to culture organisms can be detected by ISH, i.e., *Tropheryma whipplei* for Whipple's disease. Disadvantages include autofluorescence by some microorganisms (including *Pseudomonas*, *Legionella*, many yeasts, and molds), specificity and reliability of certain probe sequences, insufficient probe penetration of sample material, secondary structure of target sequence, low target content, and photobleaching [6].

In clinical microbiology, the direct identification of microbial organisms in patient samples or cultures often is determined using commercial PNA-FISH probes (AdvanDx, Woburn, MA). PNA probes have a neutral peptide-like backbone, as opposed to the negatively charged sugar–phosphate backbone of DNA probes [7]. However, like DNA probes, PNA probes hybridize to DNA and RNA in a sequence-specific manner and can be fluorescently labeled for ease of detection. Reported advantages of PNA probes include stronger and faster hybridization, discrimination of one bp difference, resistance to nucleases and proteases, survival under stringent conditions (e.g., high temperature) that allow for access to regions with secondary structure, and increased hydrophobicity that allows for penetration of cell membranes during ISH [7]. Commercial PNA probes include many multi-labeled probe kits for the discrimination of morphologically similar organisms including *Staphylococcus aureus*/coagulase-negative *Staphylococcus*, *Enterococcus faecalis*/other enterococci, *Escherichia coli*/*Pseudomonas aeruginosa*, gram-negative rods (*E. coli*, *P. aeruginosa*, *Klebsiella pneumoniae*), yeast (*C. albicans*/*parapsilosis*, *C. tropicalis*, and *C. glabrata*/*krusei*), and Group B *Streptococcus* (AdvanDx, Inc., Woburn, MA). PNA-FISH probes are used by clinical laboratories for the identification of organisms from positive blood culture bottles in less than 2.5 h, which has a significant positive impact on patient care and institutional cost savings [8–11].

Sequencing

In many larger laboratories, sequencing is used to rapidly and accurately identify organisms. Sequencing is more rapid than conventional methods, but initial growth of an isolate is still required prior to sequencing. Ideal applications of sequencing for organism identification include *Mycobacterium* spp., aerobic actinomycetes including *Nocardia* spp., select anaerobes and gram-positive bacteria, which are organisms that are typically slow-growing or dif-

ficult to identify by routine methods. Sequencing can also be used to identify organisms that cannot be cultured because they are inherently difficult to grow or as a result of antibiotic therapy. In this situation, sequencing would need to be performed directly from the clinical specimen, but this practice must be used with caution and only for specimens from sterile sites. A substantial body of evidence exists for direct sequencing from explanted heart valves for the identification of organisms causing endocarditis [12, 13].

Many bacterial genome regions are used for sequence-based identification in clinical laboratories, but the 16S rRNA gene is the most common target. The 16S rRNA gene encodes for the highly conserved rRNA associated with the small subunit of the ribosome and is often used for taxonomic purposes and species identification. While 16S rRNA is highly conserved among bacteria, nucleotide variations unique to each species are concentrated in specific regions. The entire gene is 1,550 bp including the conserved and variable regions, but discriminatory sequence can generally be obtained using 500 bp [14]. Universal primers complementary to the conserved regions on either side of the variable region permit amplification from all bacterial species and the resulting amplicon contains unique sequence for identification. Commercial research use only kits are available for sequencing of 16S rRNA (MicroSeq; Applied Biosystems) (Thermo Fisher Scientific, Waltham, MA), but many clinical laboratories use laboratory-developed protocols. Notably, some organisms are identical by 16S rDNA sequencing (e.g., *M. chelonae* and *M. abscessus*, *S. pneumoniae* and *S. mitis*). However, some of the identical organisms by 16S rDNA sequencing can be differentiated by sequencing other genes, such as those of the internal transcribed space (ITS) region, *rpoB*, *secA*, or *hsp65* [15–17].

Sequence results are more robust than conventional culture methods because they are less subjective if a comprehensive and accurate database is used for sequence comparison. Analysis of the sequence data involves evaluating the quality of the sequence obtained and subsequent comparison of the sequence with known sequences through public and/or commercial databases, such as NCBI GenBank, MicroSeq, Integrated Database Network System (SmartGene, Raleigh, NC), or RipSeq (Isentio, Palo Alto, CA). Once an isolate is growing in culture, the entire procedure can be done in about 1.5 work days. Beyond the relatively long time to result compared to mass spectrometry, other limitations are the quality of public databases or the expense of access to curated databases, and the similarity of 16S rRNA sequences of some organisms.

Mass Spectrometry

A major advancement in bacterial identification is the routine use of mass spectrometry (MS) in clinical microbiology laboratories [18]. Traditionally, bacterial identification is achieved by performing a number of biochemical reactions to identify the unique combination of phenotypic properties that are specific to a particular microorganism. Originally performed individually, these phenotypic tests have been streamlined and are now performed on automated instruments. Although automated systems have reduced the time to identification relative to traditional methods, there is still room for improvement.

The use of MS to identify organisms was first described in the mid-1970s [19], but not until the advent of using matrix assisted MS was the reliability and reproducibility sufficient for clinical applications [20]. The type of MS most commonly used in clinical microbiology is *M*atrix *A*ssisted *L*aser *D*esorption/*I*onization *T*ime *O*f *F*light (MALDI-TOF) MS. As illustrated in Fig. 49.1, the core of MALDI-TOF MS for bacterial identification is that differences in DNA lead to

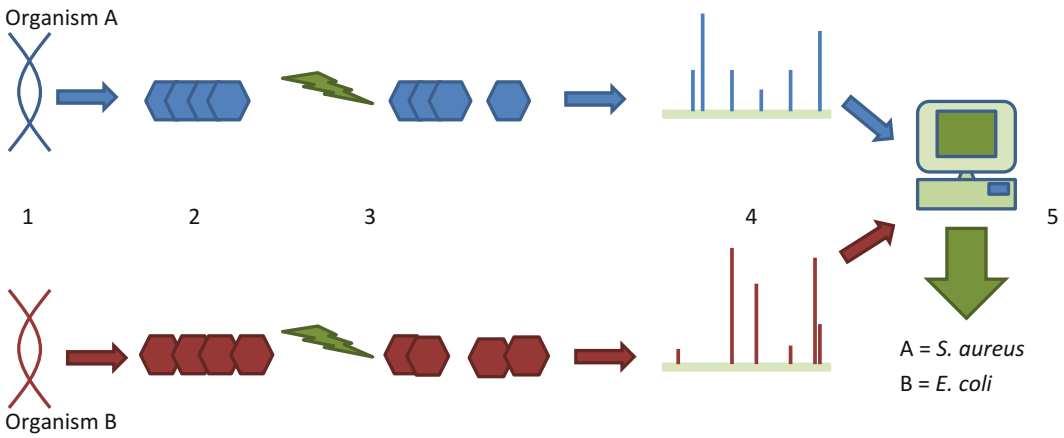

Figure 49.1 Schematic of MALDI-TOF mass spectrometry for differentiation of two organisms (A and B). Differences in DNA (*1*) encode for different protein products (*2*) which are differentially fragmented under laser excitation (*3*). These fragmented proteins produce organism-specific spectra (*4*), which are compared against a reference database of spectra (*5*) for organism identification

differences in the protein composition of an organism, and the differences in protein composition can be resolved by MALDI-TOF MS. The technology works by using the laser to create a cloud of ions to which a current is applied and released into a flight chamber. The ions are generated from the bacterial isolate that has been smeared onto a target slide and overlaid with a matrix solution (typically α-cyano-4-hydroxycinnamic acid). The matrix solution is critical for even distribution of the laser energy, generation of primarily singly charged ions, and reproducible results. The process of using smeared bacterial isolates is often referred to as whole cell or intact cell MS (WCMS or ICMS) [21, 22]. As the ions travel through the flight chamber they are separated according to their size and charge, with the smallest and most highly charged particles moving fastest through the chamber. The ions strike a detector at the end of the chamber, and a spectrum is generated that provides the relative quantity of ions of a particular mass–charge ratio. These spectra are algorithmically compared to a reference database with identity and confidence values assigned.

Much like 16S rRNA gene sequencing, the strength of this application relies on a robust reference database for comparison [18]. Several studies have shown that identification rates significantly increase after database augmentation [23–25]. Also, much as quality sequence reads are necessary for identification, high quality spectra are a must for good reference matching and identification. Ideal spectra for identification typically consist of proteins in the 2–20 kDa range, which is rich in ribosomal and other cytoplasmic proteins. Obtaining quality spectra using WCMS can be difficult with organisms such as mycobacteria, filamentous fungi, and yeasts, due to their rigid cell walls [18, 26]. Therefore, these organisms must undergo an additional extraction step to make the internal cellular proteins more accessible for ionization. The most basic extraction step is to apply a formic acid solution to the smeared spot and allow it to dry before adding the matrix solution. Higher order bacteria, such as mycobacteria and *Nocardia* spp., and filamentous fungi require a more rigorous extraction, typically involving bead beating, formic acid, and acetonitrile treatments [27]. In general, MALDI-TOF MS performs well, typically identifying >90 % of routine organisms to the correct species [18, 28, 29]. Two MALDI-TOF MS platforms currently are used in clinical microbiology laboratories: the MALDI Biotyper (Bruker Daltronics, Billerica, MA) and VITEK MS (bioMerieux, Durham, NC) each offering FDA-cleared databases. Additional developments in MALDI-TOF MS for the clinical microbiology laboratory include detection of antimicrobial resistance and direct pathogen detection from blood cultures (see below).

Another emerging technology for the identification of microorganisms is the use of PCR electrospray-ionization mass spectrometry (ESI/MS). This methodology uses conserved primers to generate PCR amplicons directly from a specimen source as well as MS to generate an approximation of the base content of the amplicons. This information is unique enough to develop spectral signatures for different organisms. These spectra are then compared to a database which provides likely identifications based on the primer sets used as well as the relative abundance of the organism(s) identified [30]. PCR ESI/MS has several advantages: (1) direct detection of a wide variety of potential pathogens (viruses, bacteria, and fungi) from specimens; (2) more rapid and cost-effective testing compared to sequencing technologies such as next-generation sequencing; and (3) to provide information outside the constraints of array-based technologies such as only being able to query a limited number of predefined organisms [30]. In fact, this technology can be used in pathogen discovery as new pathogens will not be identified but will group with similar known organisms. This was done successfully during the Sudden Acute Respiratory Syndrome (SARS) pandemic [31]. Still, as with all new technologies, work remains to be done to optimize the process for routine clinical use including further optimization of extraction methods as well as the development of additional primer sets.

Antimicrobial Resistance Detection

The increased emphasis on faster turnaround times for results combined with availability of more targeted therapeutics has created a niche for rapid molecular detection of resistance determinants in clinical microbiology laboratories. Antimicrobial resistance can be detected by probe hybridization, nucleic acid amplification (NAA) technologies such as PCR, and sequencing. However, the use of molecular methods to detect microbial resistance is not without its limitations. Multifactorial resistance mechanisms, polyclonal or polymicrobial infections, phenotypic synergism, and unknown genotype–phenotype relationships can prevent accurate determination of resistance using molecular methods.

Amplification Methods

Methicillin-Resistant *Staphylococcus aureus*

The most established application of molecular bacterial resistance testing is the detection of methicillin-resistant *Staphylococcus aureus* (MRSA). Resistance to methicillin in staphylococci is almost exclusively caused by a single mechanism, the alteration of the penicillin binding protein PBP2 to the conformer PBP2a. This change is mediated by a well-defined genetic component, the *mecA* gene. The altered PBP2a has a lower affinity for methicillin and other penicillinase-stable β-lactams such that resistance is conferred.

Traditional detection methods include chromogenic agars, oxacillin screening agars, and traditional disk diffusion for cefoxitin and minimum inhibitory concentration testing for oxacillin. These methods require 12–24 h of incubation. Decreasing the time to differentiate methicillin-susceptible staphylococcus aureus (MSSA) and MRSA by use of either protein-based methods (PBP2a latex; Oxoid, Cambridge, UK) or molecular methods for the detection of the *mecA* gene (see below) is associated with improved patient outcomes and institutional cost savings [9, 32].

Vancomycin-Resistant *Enterococcus*

First detected nearly 30 years after the introduction of vancomycin, vancomycin-resistant enterococci (VRE) developed in part due to increasing use of vancomycin for *Clostridium difficile* colitis and MRSA infections [33, 34]. Vancomycin acts by blocking the transglycosylation and transpeptidation steps of cell wall biosynthesis. The resistance phenotype is based on lowering the affinity of vancomycin for its target peptidoglycan precursors and is encoded by the *van* genes. High-level resistance (MIC, ≥64 μg/ml) is encoded *vanA* and *vanB* which are typically found on transposons, or the chromosomally associated *vanD*, and is generally found in *Enterococcus faecium* and *Enterococcus faecalis* [35–37]. Also chromosomally encoded are the *vanC* genes of *Enterococcus gallinarum*, *Enterococcus casseliflavus*, and *Enterococcus flavescens*, which are associated with low-level resistance (MIC, 2–32 μg/ml). Because *vanA* and *vanB* tend to reside on mobile elements and confer high-level resistance, detection of enterococci containing these resistance determinants is critical for effective infection control measures.

Although numerous laboratory-developed NAA assays and commercial analyte specific reagents (ASRs) are available, only a few assays for the molecular detection of VRE from rectal sites are cleared by the US Food and Drug Administration (FDA) (Xpert *vanA* test, Cepheid, Sunnyvale, CA; BD GeneOhm VanR, Becton Dickinson, Sparks, MD; and IMDX VanR, Intelligent Medical Devices, Beverly, MA). Although VRE in the USA and Europe most commonly contains *vanA*, *vanB* should also be considered due to its lower but significant prevalence. The main advantages to the molecular detection of VRE are increased sensitivity, increased specificity (exclusion of *vanC* mediated resistance), and decreased time-to-result [38–40].

Mycobacterium tuberculosis

Although resistance to antituberculosis drugs is not a new phenomenon, new methods have been developed to identify resistant strains. Due to the slow growth of *M. tuberculosis* (TB), molecular techniques are well suited to not only detect TB directly from patient specimens but also screen for resistance (see Chap. 53). Several test kits have been CE-marked for clinical use in Europe. These include the Genotype MTBDR system (Hain Lifescience, Germany), the Innogenetics INNO-LiPA Rif.TB (Gent, Belgium), and the Xpert MTB/RIF cartridge for the Cepheid GeneXpert platform, with the latter also receiving FDA clearance. All the systems detect rifampin resistance as it is the most common resistance found among the first-line TB drugs. In addition, rifampin resistance can be a marker for multidrug-resistant (MDR) TB in geographic regions with endemic MDR-TB [41]. Rifampin resistance is determined by analyzing the *rpoB* gene for specific mutations in the 81 bp rifampin resistance determining region using hybridization probes [42]. The Genotype MTBDR system also determines isoniazid resistance by screening the *katG* and *inhA* genes [43, 44]. An expanded Genotype MTBDRsl panel adds detection of resistance to fluoroquinolones, aminoglycosides, and ethambutol. Additional information on mycobacterial detection and resistance can be found in Chap. 53.

Mass Spectrometry

Much like the revolutionary impact on bacterial identifications, MS will likely impact resistance testing. Preliminary studies have demonstrated the rapid identification of MRSA, extended spectrum beta lactamase (ESBL) organisms, and carbapenemase-producing organisms by MALDI-TOF MS. Resistant organisms can be identified in two ways using MS. Similar to genetic approaches, resistant organisms can be identified by the presence or absence of characteristic mass peaks. This approach has been most widely used in the identification of MRSA by MS, though there are conflicting reports as to its effectiveness [45–47]. The other approach to identifying resistant organisms using MS is to apply a phenotypic approach such as measurement of substrate modification. For example, to determine the presence of a microbial carbapenemase, a carbapenem and test organism can be co-incubated followed by MS detection of native carbapenem drug peaks and/or peaks of its hydrolyzed products in the supernatant [48, 49]. Although this approach only detects resistance mechanisms that modify the substrate, it has the distinct advantage of looking for a phenotype instead of a particular resistance determinant. This can be especially useful in the cases of ESBLs and carbapenemases which have many genetic determinants that cause the same phenotype [50].

Specific Applications

Staphylococcus aureus/MRSA

Screening patients for MRSA nasal colonization is a central strategy for preventing the spread of this organism in health care settings. The reference method used to accurately detect

resistance due to altered PBP2 in *S. aureus* is NAA and detection of the *mecA* gene. Conventional and real-time PCR have been used to detect *mecA* both on bacterial isolates and directly on patient specimens. However, direct specimen testing has limitations, often including a lower positive predictive value than conventional methods based on the possible co-detection of MSSA and methicillin-resistant coagulase-negative staphylococci [51, 52]. Manufacturers have circumvented this problem through the detection of the SCC*mec-orf* junction in the *S. aureus* genome. However, strains that contain the SCC*mec* cassette but have a non-functional or deleted *mecA* (so-called "*mecA*-dropouts") will be falsely positive. In addition, MRSA strains that carry *mecC*, a *mecA* homologue, will be falsely negative in these assays, though the prevalence of these strains is still low [53]. Several FDA-cleared molecular assays are available for the detection of MRSA with or without MSSA detection from nasal swabs and clinical specimens, such as positive blood cultures and swabs obtained from skin and soft tissue infections (Table 49.1). NAA detection of MRSA is at least equal in sensitivity to culture-based methods, but has the advantage of offering a faster turnaround time, which, when combined with appropriate infection control interventions, may significantly decrease hospital costs by decreasing the number of health-care-associated MRSA infections [54].

Group B *Streptococcus* (*S. agalactiae*)

Although the incidence of Group B *Streptococcus* (GBS) neonatal disease has been declining since the 1990s due to enhanced prevention efforts, it is still the leading infectious cause of morbidity and mortality in neonates in the USA. In 2002, the Centers for Disease Control and Prevention (CDC), with the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics, first published guidelines to perform vaginal–rectal screening of all pregnant women at 35–37 weeks gestation. Women who are colonized should be given intrapartum prophylactic treatment. Thus, accurate GBS results are critical to ensure appropriate antibiotic administration. Additionally, if a woman's GBS colonization status is not known due to lack of prenatal care or premature delivery, she should receive prophylactic antibiotics based on risk assessment, specifically for gestation less than 37 weeks, membrane rupture more than 18 h prior to delivery, or a fever of greater than 38 °C [55]. Since antibiotic administration is not without risks to the mother and newborn, intrapartum rapid molecular tests for GBS colonization are beneficial.

The first molecular technique used for routine GBS screening was direct probe hybridization either to colonies or swab-inoculated Lim broth. Although this provided the advantage of decreased turnaround time and reduced technologist time [56], it is not cost-effective for routine antepartum screening. Further development of molecular technologies in GBS detection has resulted in seven FDA-cleared molecular tests (Table 49.2) and numerous laboratory-developed tests (LDTs). Notably, the BD GeneOhm StrepB test (BD GeneOhm Sciences, San Diego, CA) and the Cepheid Smart GBS and Xpert GBS offer detection of GBS directly from rectovaginal swabs for antepartum or intrapartum detection of GBS colonization. FDA-cleared in 2006, Xpert GBS performed on the GeneXpert (Cepheid) is a moderate-complexity test that is self-contained from extraction to result. This technology makes random access testing for intrapartum screening feasible. Given that approximately 10 % of women with negative cultures at 35–37 weeks' gestation are GBS positive at the time of delivery [57],

[a]Sensitivities and specificities were calculated using culture as the gold standard and vary depending on whether used for antepartum or intrapartum screening in the cited reference. Package insert data are indicated by an asterisk (*)

intrapartum testing is the most accurate test for colonization at the time of delivery. As an intrapartum screening test at one institution, the Xpert GBS had a sensitivity of 95.8 % and specificity of 64.5 %, whereas the antenatal culture was 83.3 % sensitive and 80.6 % specific, when intrapartum culture was used as the gold standard [58]. In a multicenter study of the IDI-StrepB assay (BD GeneOhm), when intrapartum culture was the gold standard, molecular detection at the time of labor was 94 % sensitive and 95.9 % specific [59]. Relative to either the sensitivity of antenatal cultures (54 %) or risk factor analysis (42 %), the sensitivity of the IDI-StrepB assay was superior [59]. The advantage in all these applications is the decreased turnaround time relative to culture in the intrapartum setting. Additional data regarding the sensitivity and specificity of molecular tests for GBS detection is shown in Table 49.2.

Sepsis

The use of molecular methods for the diagnosis of sepsis has been a challenging endeavor. Only one FDA-approved test is available for the identification of potential pathogens directly from blood obtained from septic patients, and this test is limited to candidemia. The gold standard remains automated blood cultures, and this reference method may be difficult to match owing to the large amount of blood that is cultured (typically 40 ml). Nonetheless, research use only products are available for direct testing of blood. Roche Molecular Systems SeptiFast (Branchburg, NJ) uses multiplex real-time PCR and melt curve analysis, while the Molzym SepsiTest (Bremen, Germany) uses multiplex PCR followed by sequencing, and the SIRS-Lab Vyoo (Jena, Germany) uses multiplex PCR followed by gel electrophoresis. These products vary in both the organisms and the resistance determinants detected, as well as analytical performance characteristics [60–64]. In general, these products suffer from both a lack of sensitivity and specificity, as well as requiring additional optimization before routine clinical use is possible.

Other shortcomings of NAA-based diagnosis of sepsis include the inconclusive clinical significance of the detection of pathogen DNA in the blood stream and the inability to obtain full antimicrobial susceptibility results [62]. However, blood culture is an imperfect reference method, suffering from a number of limitations including a prolonged time to pathogen identification, effects of variable blood volume, and lack of growth for fastidious pathogens or in the presence of prior antimicrobial therapy [62]. One limitation that can be addressed by molecular methods is the time to definitive identification.

A number of commercial molecular testing products are available for the identification of organisms and resistant determinants directly from positive blood culture bottles. This approach takes advantage of the culture amplification of bacteria from blood while adding molecular methods to lessen the time to identification. FDA-cleared tests for use directly with positive blood culture bottles include AdvanDx PNA-FISH (Woburn, MA), Cepheid (Sunnyvale, CA), Biofire FilmArray BC-ID (Salt Lake City, UT) and Nanosphere BC-GP and BC-GN panels (Northbrook, IL). The molecular targets for each of these products are listed in Table 49.3. The use of MALDI-TOF MS in direct pathogen detection directly from positive blood cultures also is being investigated [65, 66]. Recent data show identification rates of

approximately 85 %, while reducing time to identification by more than a day [67]. Several studies have demonstrated the cost-effectiveness of utilizing rapid detection of organisms from positive blood culture bottles [8, 9, 11].

Molecular Epidemiology

Pulsed field gel electrophoresis (PFGE) is the gold standard for molecular epidemiology studies of the majority of organisms [68]. In brief, bacterial cells are immobilized in agarose and subjected to proteolytic degradation followed by restriction endonuclease digestion. The resulting genomic fragments are separated by PFGE which allows for better resolution of high molecular weight products [69]. PFGE is a critical tool for infection control and public health specialties, as a proven reproducible method to show strain relatedness and identify outbreaks. Other common approaches to molecular epidemiology include amplified fragment length polymorphism (AFLP) analysis and multi locus sequence typing (MLST) [70]. AFLP analysis is based on the same theory as PFGE: differences in DNA sequence can be identified by differences in restriction endonuclease patterns. The major difference between AFLP analysis and PFGE is that PFGE looks at the entire genome of an organism, while AFLP analysis emphasizes regions of the genome known to have high rates of polymorphisms. MLST analysis is done by amplifying and sequencing a small set of known housekeeping genes (usually 7–14) that have a standard rate of genetic variability.

These labor-intensive, and often expensive, approaches to molecular epidemiology have their disadvantages. Although PFGE has high discriminatory power, it is not very reproducible even amongst members of the same laboratory. This variability makes longitudinal comparisons difficult and often requires the same strains to be run repeatedly and/or implementation of a standard strain to normalize banding patterns. Although MLST analysis is very reproducible, it lacks the discriminatory power that more genome wide approaches such as AFLP analysis and PFGE offer. AFLP analysis tries to combine the discriminatory power of PFGE with the reproducibility of MLST analysis, with some success, but this approach is not applicable to all organisms [68].

MALDI-TOF MS represents a promising development for the field of molecular epidemiology, providing a relatively fast and easy method of comparing strain relatedness, with minimal hands-on time. MALDI-TOF MS has the advantage of interrogating the entire proteome of a microorganism, although the protein size range analyzed is typically only 2–20 kDa. Researchers have looked at the ability of MALDI-TOF MS to distinguish bacterial subspecies of organisms such as *Salmonella* [71, 72]. Only a few studies have been performed that compare the ability of a MALDI-TOF MS system directly to PFGE and assess its ability to determine absolute strain relatedness [73]. MALDI-TOF MS has been used to identify clonal populations of MRSA with some success [74], but the accuracy of this has been debated [75]. It remains to be seen, however, if the level of resolution of MALDI-TOF MS fingerprinting is enough to allow this technology to replace PFGE in the epidemiologic investigations of microorganisms.

Future Perspectives

Advances in molecular biology in the last 10–15 years have made an astounding impact on clinical laboratory testing for infectious diseases. Notably, TB can be confirmed in 24 h as opposed to 6–8 weeks, sexually transmitted infections such as those caused by *C. trachomatis* and *N. gonorrhoeae* can be rapidly and accurately identified improving treatment and prevention of transmission, and organisms with important infection control implications such as *B. pertussis*, MRSA, and VRE, can be quickly identified leading to appropriate therapy and/or precautions. The applications of molecular technology in clinical microbiology are endless, but disadvantages also abound. A molecular infectious disease laboratory is established only with considerable cost and expertise. Further, we are still learning what many NAA test results mean in terms of infectious etiology and clinical significance [76]. Is the mere presence of a microorganism's DNA convincing evidence of disease causation? Additional clinical and scientific evidence may be needed to validate the clinical relevance molecular-based results.

Though there is still much to be learned about the appropriate application and interpretation of molecular infectious disease testing, numerous exciting opportunities are on the horizon. The use of real-time PCR testing in the clinical laboratory has revolutionized diagnostic microbiology. The expanding capacity of multiplex technologies is allowing the simultaneous detection of over 20 analytes in just over an hour (BioFire Diagnostics). Perhaps the technology with the greatest impact on clinical microbiology is the use of MALDI-TOF MS not only for the identification of organisms, but also their potential resistance profiles and strain typing. Lastly, as next-generation sequencing becomes more affordable and accessible to clinical laboratories, clinical investigators will be able to ask questions about pathogenesis and microbiome changes in real time. Never before has clinical microbiology changed at the rapid pace we are currently experiencing. We must remember that the power of molecular technologies should be coupled with well-controlled and clinically relevant diagnostic approaches to have the greatest impact on patient care.

Gastrointestinal Infections

50

Eileen M. Burd and Benjamin H. Hinrichs

Abstract

Establishing a specific etiology for gastrointestinal infections can be challenging because of the common clinical features and wide variety of causative microorganisms. In many cases, the etiologic agent cannot be determined using traditional diagnostic methods and may result in unnecessary antibiotic use or prolonged periods of illness. Molecular tests provide many advantages over traditional laboratory methods but, with the exception of a few analytes, are still largely in the developmental phase for gastrointestinal pathogens and are not widely used. The main advantages of molecular tests include increased sensitivity and the ability to detect agents which will not grow in culture. To test for all possible gastrointestinal pathogens at one time would require a large panel that would include a variety of bacterial, viral and parasitic agents. Challenges inherent in developing diagnostic molecular panels include ensuring that all variants of a particular microorganism can be detected as well as the rapid evolution of pathogens. In this chapter, the diagnostic merit of molecular tests as well as available tests will be presented for the major groups of gastrointestinal pathogens.

Keywords

Infectious gastroenteritis • Diarrhea • Bacterial gastroenteritis • Viral gastroenteritis • Parasitic gastroenteritis • Laboratory diagnosis • Polymerase chain reaction • Gastrointestinal pathogens panel

Introduction

Gastrointestinal infections are a common global health problem. They most often affect the stomach or intestines and generally result in diarrhea. Most gastrointestinal infections are not serious and resolve without treatment after a few days. In select populations, however, diarrheal diseases carry a high degree of morbidity and mortality. The elderly, young children, and people with chronic illnesses or compromised immune systems can become acutely dehydrated and require medical attention.

Many bacteria, viruses, and parasites can infect the gastrointestinal system. Since symptoms are similar, differentiation among the various etiologies is difficult. The microorganisms that cause gastrointestinal infections vary with the geographic region, degree of economic development, level of sanitation, and hygienic standards. In developed countries like the USA, outbreaks of diarrhea are most often a result of food poisoning. Many common gastrointestinal infections are caused by bacteria, including *Bacillus cereus*, *Campylobacter*, *Salmonella*, and enterotoxigenic *Escherichia coli* that are commonly acquired by eating undercooked foods.

Highly infectious viruses, such as norovirus, can cause gastroenteritis and account for many foodborne illness outbreaks. Gastrointestinal viruses are relatively stable in the environment and can spread rapidly through person-to-person or fomite contact, particularly in enclosed communities, such as hospitals, dormitories, daycare centers, and cruise ships.

Gastrointestinal parasite infections are typically acquired from ingestion of contaminated food or water. The parasite *Giardia lamblia* is often consumed by hikers who drink untreated stream water. *Cryptosporidium* has been associated with drinking water or recreational water. Outbreaks of *Cyclospora* and *Cystoisospora* (formerly *Isospora*) have been associated with consumption of contaminated food or water. These parasites are more common in tropical and subtropical areas of the world and people traveling to countries where the disease is endemic may be at increased risk for infection.

Identification of the causative agent in clinically significant gastrointestinal infections is important so that appropriate treatment, if any, can be provided. Most gastrointestinal infections will resolve without treatment other than rehydration to replenish lost fluids. Antibiotics are not normally prescribed unless a person is immunocompromised since using any antibiotic or the wrong antibiotic can worsen some infections, prolong the infection, or increase the risk of relapse. Antibiotics may be given for certain bacteria, specifically *Campylobacter*, *Shigella*, and *Vibrio cholerae*, but are not used for uncomplicated cases of *Salmonella* or toxigenic *E. coli*. Gastrointestinal parasitic infestations are treated with appropriate antiparasitic medication to help eliminate the parasite.

Molecular methods can provide rapid and sensitive detection of gastrointestinal pathogens. Molecular amplification is greatly complicated by the presence of a complex and abundant gut microflora and high concentrations of potential PCR inhibitors in diarrheal stool specimens [1]. Approaches to reduce PCR inhibition include dilution of extracted nucleic acids, treatment of samples with chelating agents (Chelex 100, Bio-Rad Laboratories, Hercules, CA), or adding detergents or denaturing chemicals during extraction. Inclusion of amplification facilitators such as bovine serum albumin or betaine also can increase amplification and overcome low levels of contaminants that co-purify with nucleic acids. Due to the high number of possible enteric pathogens with common clinical presentations, multiplexed molecular tests are advantageous. US Food and Drug Administration (FDA)-approved or -cleared molecular tests are available for some gastrointestinal pathogens in single test or multiplex formats.

For some analytes, reference materials are commercially available and can be used for development of molecular tests, limit of detection studies, cross-reactivity studies, positive and negative controls, training, lot-to-lot comparison of reagent test kits, and other purposes. When reference materials are not commercially available, characterized organisms recovered in clinical or research laboratories may be used. Similarly, proficiency testing surveys are available for many gastrointestinal pathogens, including from the College of American Pathologists (Northfield, IL), the Wisconsin State Laboratory of Hygiene (Madison, WI), and the American Proficiency Institute (Traverse City, MI). When proficiency testing surveys are not commercially available, the laboratory director is responsible for arranging at least semi-annual alternative assessment to evaluate the reliability of analytic testing. Appropriate alternative assessment procedures include split sample analysis with a reference or other laboratory, split samples with an established in-house method such as histology, or clinical validation by chart review. In addition to defining the alternative assessment procedures, the laboratory director must set the criteria for successful performance and ensure documentation of all activities.

Bacterial Pathogens

Bacterial Gastroenteritis

Description of Pathogens

Bacterial gastroenteritis is very common and can affect adults and children. Isolated cases of bacterial gastroenteritis can be seen, but illness usually occurs in outbreaks associated with a group of people who ate the same contaminated food. Bacterial diarrhea is particularly common among people from industrialized countries who travel to developing countries. In developing countries, epidemics of bacterial gastroenteritis with significant associated mortality often arise in areas where sanitation and hygienic practices are poor.

Many bacterial pathogens are well-recognized causes of gastroenteritis. In industrialized countries, *Campylobacter*, *Salmonella*, *Shigella*, and Shiga-toxin producing *Escherichia coli* are the leading causes of bacterial gastroenteritis. Other etiologic agents include *Aeromonas*, *Plesiomonas*, *Listeria*, *Clostridium*, *Staphylococcus aureus*, *Yersinia*, *Vibrio*, and others.

Some enteric pathogens produce characteristic symptoms (e.g., "rice water" stools produced by *Vibrio cholerae*) and the clinical features and pathogenic aspects of a gastrointestinal illness can sometimes be suggestive of a specific etiology. Most often, however, the presenting clinical features do not reliably suggest a particular etiology and laboratory tests are needed to identify the specific pathogen.

In general, these bacterial pathogens can be readily cultured from freshly collected stool specimens of infected

patients using a variety of selective and specialized media. Clinical laboratories generally use a limited set of media to recover the most common bacterial pathogens (e.g., *Salmonella*, *Shigella*, and *Campylobacter*) and other culture media are used to identify less common agents on special request (e.g., based on travel history, exposure, etc.). Culture and identification of enteric pathogens is cost-effective but can take several days to provide a diagnosis. Culture has some limitations and it is especially difficult to distinguish nonpathogenic from pathogenic strains of *E. coli*. Recent recommendations suggest that, because of the variety of serotypes and difficulty of distinguishing pathogenic forms from normal flora, laboratories should detect enterotoxigenic *E. coli* using immunoassays that detect the toxin in addition to culture [2].

Clinical Utility of Testing

Bacterial gastroenteritis usually is self-limited, but treatment is required in some cases and improper management can lead to a prolonged course. Identification of an etiologic agent allows for more effective targeted treatment which can reduce overall medical costs, and is useful to differentiate bacterial gastroenteritis from other diseases, such as malabsorption syndromes, inflammatory bowel disease, appendicitis, Crohn's disease, diverticulitis, and other enteropathies, that can present with similar symptoms. Since bacterial gastroenteritis can involve groups of people and a common food source, definitive identification of an etiologic agent can be helpful in prompting epidemiologic investigation and testing of potentially contaminated food by public health laboratories. Current stool culture-based tests for bacterial gastrointestinal pathogens typically require several day turnaround times and may yield poor results, especially if a patient has received antibiotic therapy. Molecular tests, especially multiplexed panels, provide accurate diagnosis of at least the most common causes of bacterial diarrhea from a single specimen in one day.

Available Assays

The ProGastro® SSCS® Assay (Hologic Gen-Probe, San Diego, CA) is an US FDA-cleared multiplex real-time PCR test for five common bacterial gastrointestinal pathogens. The test detects *Salmonella*, *Shigella*, *Campylobacter* (*C. jejuni* and *C. coli* only) nucleic acids and Shiga Toxin 1 (stx1) and Shiga Toxin 2 (stx2) genes. The test includes internal controls and is run on a SmartCycler II (Cepheid, Sunnyvale, CA) real-time PCR instrument with results delivered in 4 h.

The xTAG® Gastrointestinal Pathogen Panel (xTAG® GPP, Luminex Corporation, Austin, TX) is another US FDA-cleared, qualitative, multiplex test that simultaneously detects and identifies some viral and parasitic gastrointestinal pathogens in addition to the major bacterial pathogens in a single sample. The bacterial pathogens and toxins that can be detected using the panel include *Salmonella*, *Shigella*, *Campylobacter*, enterotoxigenic *E. coli*, Shiga-like toxin, and toxigenic *Clostridium difficile*. The assay also detects rotavirus A, norovirus GI/GII, *Giardia*, and *Cryptosporidium*. Results are interpreted as presumptive and must be confirmed by US FDA-cleared tests or other acceptable methods. The CE-marked panel available in Canada and Europe detects *Yersinia enterocolitica*, *Vibrio cholera*, adenovirus 40/41, and *Entamoeba histolytica* in addition to those available in the US FDA-cleared panel.

The BioFire FilmArray™ (bioMerieux, Durham, NC) Gastrointestinal (GI) Panel is US FDA-cleared and detects 23 bacterial, viral, and protozoal pathogens, including some not present on other panels. Analytes on the panel include *Aeromonas*, *Campylobacter*, *Clostridium difficile* (Toxin A/B), *Plesiomonas shigelloides*, *Salmonella*, *Yersinia enterocolitica*, *Vibrio*, *Vibrio cholera*, Enteroaggregative *E. coli*, Enteropathogenic *E. coli*, Enterotoxigenic *E. coli*, Shiga-like toxin-producing *E. coli*, *E. coli* O157, *Shigella*/Enteroinvasive *E. coli*, Adenovirus F 40/41, Astrovirus, Norovirus GI/GII, Rotavirus A, Sapovirus, *Cryptosporidium*, *Cyclospora cayetanensis*, *Entamoeba histolytica*, and *Giardia lamblia* along with internal controls to ensure that all processes have been performed successfully. A stool sample collected in Cary Blair transport medium is inoculated into a reaction pouch that contains all of the reagents necessary for the entire reaction. Separate nucleic acid extraction is not required. The pouch is placed in the FilmArray instrument and nucleic acids are extracted and purified, followed by nested multiplex PCR. The first-stage PCR is a single, highly multiplexed reaction and the second-stage PCR reactions detect the products from the first stage PCR. Endpoint melt curve analysis is used to identify the products that are generated. The instrument tests one sample at a time with hands-on time of approximately 2 min and results available in approximately 1 h.

Diatherix Laboratories, an independent CLIA-certified clinical reference laboratory located in the Hudson-Alpha Institute for Biotechnology in Huntsville, Alabama, offers testing for gastrointestinal pathogens using a proprietary technology called target enriched multiplex polymerase chain reaction (Tem-PCR). The bacterial pathogens included in the panel include *Clostridium difficile*, *Clostridium difficile* toxin B gene, *Campylobacter jejuni*, *Escherichia coli* strain 0157, *Listeria monocytogenes*, *Salmonella enterica*, *Staphylococcus aureus*, *Vibrio cholera*, and *Vibrio parahaemolyticus*.

Molecular tests are expected to play an increasingly important role in the diagnosis of gastrointestinal illnesses. Because of the complexity of gastrointestinal pathogens and

the emergence of variants of these pathogens, future clinical molecular tests will likely include new approaches such as bead-based microarrays, microfluidic systems, and other methods that simultaneously target many more pathogens than current methods allow.

Interpretation of Results

Interpretation of positive results is not generally problematic. Because the asymptomatic carriage rate is extremely low, detection of specific bacterial pathogens in stool in the absence of other enteric pathogens can be considered diagnostic.

Laboratory Issues

Bacterial culture may still be needed for cases where antibiotic susceptibility testing is required. Antimicrobial therapy is indicated for some cases of gastrointestinal illness due to *Salmonella*, *Shigella*, *Aeromonas*, *Yersinia*, and *Vibrio* and some others, but not for *Pseudomonas*, *S. aureus*, or toxigenic *E. coli* [3]. Because of increasing resistance and strain variability, susceptibility testing is recommended to guide therapy.

Reference materials are available from several vendors. Previously characterized positive stool samples or negative samples spiked with well-characterized organisms recovered in the clinical laboratory can be used. Dried genomic nucleic acids are available for some analytes from the American Type Culture Collection (ATCC) (43504D, Manassas, VA) or BEI Resources (Manassas, VA) which is managed by ATCC. The NATtrol™ (ZeptoMetrix Corp, Buffalo, NY) verification set contains all of the analytes in the BioFire GI panel.

Proficiency testing programs that are compatible with molecular methods and accommodate most of the analytes on gastrointestinal pathogen panels are available from several organizations. A combination of programs might be needed to fully accommodate entire testing panels. The College of American Pathologists (Northfield, IL) offers a Gastrointestinal Panel for Molecular Multiplex Testing (GIP) survey that includes *Campylobacter*, *Clostridium difficile* toxin AB, *Cryptosporidium*, Enterotoxigenic *E. coli*, *Giardia*, Norovirus GI/GII, Rotavirus A, *Salmonella*, Shiga-like toxin producing *E. coli* SXT-1 and SXT-2, and *Shigella*. The Wisconsin State Laboratory of Hygiene (Madison, WI) offers a Comprehensive (MC) Bacteriology survey that includes *C. difficile* toxin or antigen as well as enteric pathogen identification. Separate surveys include *C. difficile* (CD), Shiga Toxin (SHG), and Enteric Pathogens (NP) including *Aeromonas*, *Campylobacter*, *E. coli* O157:H7, *Plesiomonas*, *Salmonella*, *Shigella*, *Vibrio*, and *Yersinia*. The American Proficiency Institute (Traverse City, MI) has several programs available that include *Campylobacter*, toxigenic *Clostridium difficile*, Rotavirus, *Giardia*, and *Cryptosporidium* in addition to bacteriology and virology programs.

As molecular tests become more widely used, accommodation will need to be made for reporting of positive results to public health departments. Most state public health departments require notification when certain infectious agents, including many gastrointestinal pathogens, are suspected or identified. This reporting allows public health departments to investigate outbreaks and conduct surveillance studies to assess changes and trends in disease occurrence. For some gastrointestinal bacteria such as *Salmonella* and Shiga-toxin-producing *E. coli*, health departments usually require a culture of the organism to be submitted for definitive identification, typing studies, etc. that help identify common foodborne sources. This policy will need to be modified if molecular testing for bacterial gastrointestinal pathogens becomes widely used in clinical laboratories.

Clostridium difficile

Description of Pathogen

Clostridium difficile is a spore-forming, Gram-positive anaerobic bacillus that is carried by some individuals as a component of the normal intestinal microbiota. Pathogenic strains produce toxin A and/or toxin B, which damage the intestinal mucosa. Toxigenic *C. difficile* is associated with nearly all cases of antibiotic-related colitis and 15–20 % of antibiotic related diarrhea [4, 5].

C. difficile infection (CDI) has become a scourge of hospitals worldwide and is estimated to account for an excess $1 billion to $3.2 billion per year of healthcare costs in the USA [6, 7]. While advanced age and length of hospitalization are directly related to increased risk of CDI, exposure to antibiotics remains the most significant modifiable risk factor [8]. Exposure to antibiotics and subsequent loss of endogenous enteric microbiota is believed to create a favorable environment for the growth of *C. difficile*. While reports of *C. difficile* colonization in both healthy children and adults suggests the possibility of an endogenous source of infection [9, 10], epidemiologic studies have established the significance of the organism as a transmissible nosocomial pathogen [8, 11].

Disease is caused by the production of toxins A and B, which are encoded by the genes *tcdA* and *tcdB*, respectively. Not all strains carry these genes, and demonstration of the ability to produce toxin is an essential criterion for the diagnosis of CDI. Recent studies highlight the importance of toxin B over toxin A in disease pathogenesis [12], and most clinical assays focus on the detection of *tcdB* gene sequences. Two regulatory genes, *tcdC* and *tcdD*, are hypothesized to negatively influence the expression of *tcdA* and *tcdB*, and together with the toxin genes are part of the chromosomally encoded region known as the pathogenicity locus (PaLoc) [8].

Since 2001, several US and Canadian hospitals reported outbreaks of CDI associated with increased disease severity [13, 14]. Epidemiologic studies revealed a high percentage

of cases were caused by a strain referred to as BI/NAP1/027, named in reference to typing results for restriction endonuclease analysis (REA), pulsed field gel electrophoresis (PFGE), and PCR-ribotyping, respectively. The BI/NAP1/027 strain carries 18-bp and 1-bp (nt 117) deletions within the *tcdC* gene, and these deletions are speculated to result in the formation of an abnormal *tcdC* protein with a loss of regulatory function [13]. The resultant loss of negative regulation may lead to an increase in toxin formation and greater virulence [13]. Supporting this theory is the observation that isolates of the BI/NAP1/027 strain produce increased amounts of toxin A and B in vitro [15]. An additional toxin known as the binary toxin CDT is present in the BI/NAP1/027 strain as well as 6 % of *C. difficile* isolates, and is encoded by two chromosomal genes, *cdtA* and *cdtB*, located outside of the PaLoc [13]. Although production of the binary toxin is associated with the more virulent BI/NAP1/027 strain, its role in pathogenesis is not well established [8, 16].

Clinical Utility of Testing

Rapid and accurate diagnosis of CDI is critical not only for the timely treatment of individual patients, but also for preventing the spread of nosocomial disease. The diversity of tests available makes possible a number of diagnostic algorithms. None of these testing strategies has performed optimally to date, leading a number of investigators to suggest the adoption of the highly sensitive and specific PCR-based assays. Several studies have evaluated the effects of implementing nucleic acid testing. Algorithms examined include PCR assays as confirmatory tests of glutamate dehydrogenase (GDH)-positive samples, as reflex tests for GDH-positive, toxin-enzyme immunoassays (EIA) negative samples, and as stand-alone assays for direct testing of stool samples. A comparison of these testing algorithms to those using toxin-EIA only, GDH followed by toxin-EIA, and GDH/toxin-EIA followed by cell culture cytotoxin neutralization (CCCN) testing of toxin-EIA negative samples indicates a clear trade-off between sensitivity and cost [17]. The cost per test for all strategies using PCR-based assays was significantly greater than the most expensive non-PCR-based testing algorithm ($35.22 vs $24.41, respectively) [17]. However, strategies using PCR as confirmation of GDH-positive samples or as a reflex test for GDH-positive, toxin-EIA negative samples detected an additional 89 toxigenic *C. difficile* samples over a 1 year period that were missed by algorithms using traditional testing methods [17]. Furthermore, stand-alone, direct PCR testing of stool samples detected an additional 138 positive specimens missed by even the most sensitive non-PCR-based testing algorithm. Importantly, all diagnostic strategies using PCR provided results for the majority of samples (>83.7 %) in less than 1 h and in less than 5 h for the remainder [17]. These rapid turnaround times are in contrast to algorithms relying on CCCN as a reflex test for GDH-positive, toxin-EIA negative samples, which required as long as 48 h for 12.3 % of samples tested [17].

An optimal testing strategy balances the number of CDI cases detected with total costs and turnaround time. Although the additional costs of algorithms employing PCR are significant, use of these assays would likely allow for the earlier detection of disease. In turn, earlier detection of disease could prevent the spread of nosocomial infection and decrease the total number of CDI cases. In addition, rapid detection allows for the timely institution of treatment and possibly shortened hospital stays. The assessment of total cost, therefore, must consider both expenses related directly to testing in addition to costs savings realized as a result of lowering the incidence of nosocomial disease and decreasing time of hospitalization.

In an effort to determine how different diagnostic algorithms might affect isolation practices of patients with suspected CDI, Tenover et al. applied the findings of several studies to a theoretical model of 1,000 patients with 10 % disease prevalence [16]. The results confirm the poor performance of strategies relying solely on GDH/toxin-EIA testing as the number of patients placed in isolation with true CDI nearly matches the numbers of patients without the disease [16]. Furthermore, 45 patients with CDI are not identified, and therefore, are not placed into proper infection control isolation [16]. Algorithms that reflex to toxigenic culture or CCCN after GDH/toxin-EIA testing detect more cases of CDI, but still produce high numbers of false-positive results (55 patients). Using toxigenic culture as a reflex test produced values for sensitivity and specificity statistically equivalent to PCR-based reflex testing; however, the length of time required to produce final results would likely lead to excessive costs. Using PCR-based assays as stand-alone tests detected the greatest number of CDI cases (95 %), and led to the unnecessary isolation of only 36 patients [16]. While these results further confirm the superior diagnostic performance of nucleic acid testing either as a reflex test for GDH-positive, toxin-EIA negative samples or as a stand-alone method, the authors of the study recommend additional investigations examining the cost-effectiveness of these strategies [16].

A potential concern for diagnostic algorithms using GDH as a screening test is highlighted by a report from Larson et al who identified four (1.9 %) of 211 GDH-negative samples with the *tcdB* gene by direct PCR testing [17]. These four apparent false-negative samples also were negative by CCCN, but confirmed as containing toxigenic *C. difficile* by toxigenic culture. The results are consistent with studies demonstrating lower sensitivities and negative predictive values for an algorithm combining GDH and PCR compared to utilizing just PCR [18].

While not contributing directly to patient care, typing methods have provided important insights into CDI epidemiology. In addition to aiding determinations of infection source, reservoir, and mode of transmission, typing methods allow investigators to correlate abnormally severe clinical behavior with putative virulence factors. Both phenotypic and genotypic methods are used; however, phenotypic methods are generally less reproducible and some strains have not been able to be phenotyped [19].

Available Assays

The optimal means of diagnosing CDI is still evolving, and current recommendations put forth by several professional organizations are conflicting [8, 20]. In the past, CCCN was regarded as the gold standard because of the ability to directly identify the presence of toxin B. However, the inability of CCCN to detect a large number of CDI cases is well documented, and the clinical utility is further diminished by a lengthy turnaround time (24–48 h) [17, 21]. Bacterial culture followed by a sensitive and specific toxin assay performed on the isolated organism (toxigenic culture) has replaced CCCN as a reference method in many studies [8, 20, 22]. Toxigenic culture has demonstrated superior sensitivity compared to CCCN, but because toxin production is assessed only after the organism has been grown in vitro, the clinical meaning is not clear [20]. Unfortunately, similar to CCCN, toxigenic culture requires considerable technical expertise, and has an average turnaround time of 3–7 days [23].

EIA for the detection of toxins A and B (toxin-EIA) are rapid and easy to use alternatives to culture-based testing, and are currently the most commonly used tests in the USA [8, 21]. However, recent studies comparing their performance to toxigenic culture indicate sensitivities ranging from 32–67 % [24, 25], thus preventing their use as a reliable screening or stand-alone test [8, 20]. EIA tests are available for the detection of GDH, a constitutively expressed enzyme produced by nearly all *C. difficile* strains as well as some non-*C. difficile Clostridium* sp. [16, 26]. These GDH EIAs demonstrate sensitivities of greater than 90 %, and diagnostic algorithms often use these assays as initial screening tests [26]. However, GDH EIAs detect both toxigenic and non-toxigenic strains, and GDH-positive samples must be confirmed with an assay demonstrating toxin production. Options for confirmation include toxigenic culture, CCCN, and toxin-EIAs. However, due to the low sensitivities of CCCN and toxin-EIAs, a number of cases would likely be missed.

Molecular tests have emerged as additional options for both confirmatory and stand-alone testing. These methods generally demonstrate excellent sensitivities and specificities, and most assays are capable of delivering results in 1–3 h [16]. Several tests are US FDA-cleared, and additional assays will likely become commercially available in the near future. At this time all US FDA-cleared assays are qualitative, although quantitative testing is technologically possible with real-time PCR. Most US FDA-cleared assays are based on real-time PCR. However, other novel methods such as helicase-dependent amplification (HDA) and loop-mediated isothermal amplification (LAMP) also are employed. In addition, the majority of commercially available real-time PCR assays target solely the *tcdB* gene. US FDA-cleared multiplex PCR assays target *tcdB* as well as variable *tcdA*, *tcdC*, and *cdt* gene sequences and the single base pair deletion at nucleotide 117 in the *tcdC* gene associated with the 027/NAP1/B1 strain. Initial studies evaluating these US FDA-cleared assays are promising; however, the 2010 Update by the Society for Healthcare Epidemiology of America and the Infectious Diseases Society of America stated the need for further studies before recommending molecular assays for routine testing [8]. Lastly, CDI screening also may be performed using the US FDA-cleared xTAG® Gastrointestinal Pathogen Panel (Luminex Corporation), a multiplex test that simultaneously detects 11 gastrointestinal pathogens including *C. difficile* and other major bacterial, viral, and parasitic pathogens. Published reports evaluating the US FDA-cleared version of this assay are currently lacking.

As stated above, most real-time PCR assays target *tcdB*; however, interest in detecting the hypervirulent BI/NAP1/027 strain has spurred the development of assays that evaluate *tcdC* [12]. Some investigators contend that *tcdC* may be used as a surrogate target for *tcdA* and *tcdB*, and excellent correlation between the presence of *tcdC* and *tcdA* and/or *tcdB* has been demonstrated [25]. The authors also report the ability to detect deletions in *tcdC*, including the 18-bp deletion associated with the BI/NAP1/027 strain. Nevertheless, the assay was unable to discriminate the 18-base pair (bp) deletion from a 39-bp *tcdC* deletion not currently associated with an epidemic strain, and therefore, cannot be used to reliably detect the presence of the BI/NAP1/027 strain [25].

The US FDA has cleared assays using non-PCR amplification methods such as LAMP and HDA. LAMP assays amplify target DNA isothermally, and identify successful amplification by detecting an increase in turbidity due to the build-up of a reaction by-product. HDA assays also amplify isothermally and use helicase enzymes to separate DNA strands rather than thermal denaturation [27]. These assays are attractive to laboratories that are not able to purchase expensive thermal cyclers or detection systems. Like real-time PCR methods, LAMP- and HDA-based assays are rapid and demonstrate excellent sensitivities and specificities [27–29]. The *illumi*gene *C. difficile* assay is US FDA-cleared for testing of symptomatic children ages 1–2 years. Other US FDA-cleared nucleic acid detection assays have not received clearance for this age group. As asymptomatic colonization

of children under the age of two is well documented [9], testing of this age group is controversial.

Finally, genetic typing methods for epidemiologic analysis may be broadly categorized into methods using REA, PCR, or direct sequencing [19]. These methods require DNA extracted from a single clone, and therefore, culture should be obtained when there is concern either of an outbreak or of a particularly virulent toxigenic strain [19]. Genetic typing techniques have the ability to discriminate and characterize a broad range of epidemic and non-epidemic *C. difficile* strains; however, currently there is focused interest in the epidemiology of the BI/NAP1/027 strain. Two multiplex PCR assays that detect the single bp deletion at nucleotide 117 in the *tcdC* gene associated with this hypervirulent strain have recently been US FDA-cleared. In both cases, detection of the BI/NAP1/027 strain is US FDA-cleared for epidemiologic investigations only.

Interpretation

A positive real-time PCR test is generally diagnostic of toxigenic *C. difficile* in a patient displaying typical signs and symptoms of CDI. While it is possible that a patient may be colonized with toxigenic *C. difficile* and suffer diarrhea caused by a different etiology, this situation is likely to be rare [16].

PCR may detect toxigenic *C. difficile* even though non-toxigenic *C. difficile* or negative growth is reported by culture. Many of these cases are positive by GDH EIA, toxin-EIA, or CCCN, and thus are regarded as true positives. Culture may fail to detect growth because of significant time delays between sample collection and testing, concurrent antibiotic treatment at time of collection, or laboratory issues as discussed below [18].

Positive predictive values for real-time PCR assays may be as low as 84 %, and demonstrate that not all positive results are indicative of CDI [18]. Studies reporting the occurrence of isolated PCR-positive results also suggest PCR-based assays may be too sensitive. Additional studies correlating the clinical outcomes of patients who test negative by conventional methods but positive by PCR are needed to improve diagnostic accuracy.

The occurrence of a positive PCR result in an asymptomatic patient indicates colonization with toxigenic *C. difficile* and is well documented [10]. For this reason the testing of asymptomatic patients, except for epidemiologic purposes, is not recommended [9].

Negative PCR results generally indicate the absence of CDI, as evidenced by high negative predictive values for these assays. Recommendations made by the European Society of Clinical Microbiology and Infectious Diseases state that a single negative result from a *tcdB* PCR assay, a GDH EIA, or toxin-EIA may be used to rule out the presence of toxigenic *C. difficile* [20]. While negative PCR results may occur in samples testing positive by conventional detection methods, this is an uncommon occurrence and may be due to one of the reasons discussed below.

Laboratory Issues

The sensitivity of real-time PCR assays may be as low as 77.3 % and negative results are speculated to occur for a number of reasons [22]. Samples negative by PCR, but positive for toxigenic isolates may contain substances inhibitory to PCR amplification. The detection of PCR inhibitors is aided by the incorporation of internal controls into all US FDA-cleared real-time PCR assays. Other investigators propose that negative PCR tests may be due to sampling error of stool, a known heterogeneous testing medium, when low numbers of organisms are present [18, 30].

A concern regarding the clinical significance of PCR stems from the fact that PCR merely detects the presence of a gene and does not evaluate gene expression. While it is theoretically possible for PCR to detect *C. difficile* carrying *tcdB* that is not expressed, testing only unformed stool specimens from patients with a clinical suspicion of CDI may help avoid this issue [16]. So far, no published studies have evaluated this point directly.

Real-time PCR assays targeting *tcdB* are believed to comprehensively detect all current strains of toxigenic *C. difficile* as *tcdB* negative strains or strains with significant deletions in *tcdB* do not exist naturally [12, 31]. Strain-to-strain *tcdB* sequence variability resulting in poor primer binding is occasionally cited as a concern for the ability of toxin B PCR assays to sensitively detect the wide range of *C. difficile* strains. While significant sequence variation within the *tcdB* gene is reported [31], most currently targeted *tcdB* sequences appear conserved across the range of strain types [16]. Therefore, the effect of *tcdB* sequence variation on sensitivity of toxin B PCR assays is expected to be minimal [16].

Also of concern is the potential evolution of a novel toxigenic *C. difficile* strain with an altered *tcdB* sequence as a result of genetic drift. Although most toxigenic *C. difficile* strains contain an intact *tcdB* gene, the detection of a strain deficient in at least a portion of the *tcdB* gene is reported in a case of recurrent CDI [32, 33]. While the report of a clinically significant *tcdB* deficient strain reinforces the need to be vigilant for the development of *tcdB*-negative, *tcdA-positive* strains affecting the clinical performance of toxin B PCR assays, the occurrence of such variant strains is currently rare [22, 33]. Multiplex real-time PCR assays, with the ability to simultaneously detect several different sequence targets (e.g., *tcdA* and *tcdB*, *cdtA*, *cdtB*, and *tcdC*) may decrease the likelihood of detection failure due to primer sequence mismatches [23].

The recognition of clinically significant toxin A negative, toxin B positive strains also is cited as a concern for the ability of LAMP assays to comprehensively detect all CDI cases.

Although four toxin A negative, toxin B positive strains are currently recognized, only one strain, toxinotype VIII, has been associated with significant numbers of CDI cases [34]. The *tcdA* gene of toxinotype VIII contains both a 1.8 kb deletion in addition to a nonsense mutation resulting in a truncated toxin A protein [31, 34]. Despite the modified toxin A gene sequence of toxinotype VIII, a recent study found that three strains of toxinotype VIII tested on the *illumi*gene *C. difficile* assay were detected [35]. Several studies report samples that are PCR-positive, but negative by toxigenic culture.

Although toxigenic culture is a more sensitive reference method than CCCN, instances of detection failure are documented [18]. Reasons for detection failure may be clinical as mentioned above, but also may involve factors related to laboratory handling of specimens. Results of toxigenic culture for *C. difficile* may be adversely affected by long delays between collection and testing of specimens, the failure to enrich for spores, or the loss of spore viability during the spore enrichment process affecting only particular strains [18, 22]. In addition, culture is speculated to occasionally fail to detect toxigenic strains as a result of overgrowth by a non-toxigenic strain, as studies have reported the presence of multiple strain types in patient samples [22, 36].

A *C. difficile* verification panel that includes ribotype 027 and *C. sordellii* as a negative control is commercially available (ZeptoMetrix Corp, Buffalo, NY). A panel of 8 *C. difficile* strains, each with a different toxinotype as well as freeze-dried, well-characterized *C. difficile* strains and genomic DNA from those strains are available from ATCC (Manassas, VA). The ACCURUN 501 *C. difficile* Control (SeraCare Life Sciences, Gaithersburg, MD) contains inactivated organisms in a human synthetic stool matrix. The control set contains *C. difficile* NAP1/027/B1 hypervirulent strain, two toxigenic *C. difficile* strains, and *C. sordelli* as a negative control. Proficiency testing samples for *C. difficile* molecular tests are available from the College of American Pathologists, the Wisconsin State Laboratory of Hygiene, and the American Proficiency Institute.

Tropheryma whipplei

Description of Pathogen

The etiological agent of Whipple's disease is *Tropheryma whipplei*, a bacterium present in the environment, sewage, human stool, and saliva, but whose entire ecological distribution is yet to be characterized [37, 38]. In accordance with these findings, a fecal-oral route of transmission has been proposed [38]. Evidence also exists for the ability of the organisms to asymptomatically colonize the upper gastrointestinal tract, as PCR has identified *T. whipplei* DNA in the saliva and gastric juice of 35 % and 11.4 % of individuals, respectively, without evidence of Whipple's disease [39, 40].

Whipple's disease, however, is rare, and only an estimated 1,000 cases have been described [38]. Its pathogenesis is poorly understood, and while genetic risk factors have been proposed, none have been confirmed [38]. The most common presentation of disease includes symptoms related to malabsorption such as diarrhea and weight loss, although a long history of nonspecific complaints, often including arthralgias, is typical [38, 40]. These vague and chronic symptoms may last an average of 6 years before clinical signs more characteristic of the disease appear [38]. Atypical cases lacking classic gastrointestinal symptoms and involving the cardiovascular system and the central nervous system (CNS) as well as other organ sites may occur in up to 15 % of those affected [38]. The long time period before typical symptoms are manifested in addition to the high percentage of unusual presentations often results in a delay of treatment. Early diagnosis and the initiation of antibiotics are critical to avoiding long-term morbidity, and, therefore, improved detection methods are needed.

Clinical Utility of Testing

The diagnosis of Whipple's disease is made primarily by histological examination of tissue biopsies; however, since the 1990s, PCR has played an increasing role in diagnosis. Culture and serological methods have recently been developed as diagnostic tools; however, their availability is limited [37, 38]. In the past, electron microscopy (EM) was commonly used to demonstrate the characteristic trilaminar bacterial cell wall; however, its utilization is declining [41].

The optimal use of PCR in establishing a diagnosis of Whipple's disease is debated. Some reports recommend PCR testing in parallel with the procurement of biopsies, citing the lack of optimal specificity of histology and PCR when used alone [38]. Others advocate the use of PCR only when biopsies fail to indicate disease, although this is not supported by the low rate of PCR positivity in histologically negative duodenal biopsies [42].

Intestinal biopsies from patients without gastrointestinal symptoms may be negative by PCR, and thus clinical symptoms in atypical cases should guide the selection of samples for PCR analysis [42]. In addition to duodenal biopsies, PCR testing has proven useful when performed on a number of different specimen types including lymph nodes, cardiac valves, synovial fluid, cerebrospinal fluid (CSF), and vitreous humor [37]. CSF has tested positive by PCR methods in several patients without CNS symptoms, and may indicate the need for antibiotics with good CNS penetration [41]. While saliva, feces, and blood may be positive in patients with Whipple's disease, higher rates of background positivity makes the utility of testing these specimens uncertain [37, 43, 44].

No biological marker or test is currently available to determine the required duration of treatment for Whipple's disease [38]. Nevertheless, monitoring response to treatment using PCR appears to have utility for predicting outcome [41, 44]. PCR positivity after treatment correlated with a higher likelihood of relapse; however, the positive predictive value was only 58 % [45]. Likewise, while negative post-treatment PCR results have been associated with remission, a significant number of patients without detectable *T. whipplei* DNA in intestinal biopsies have developed recurrent disease [46].

Molecular methods for genetic subtyping of *T. whipplei* are limited to the research setting, as currently no correlations are established between subtype and geographic location or specific clinical manifestations [44].

Available Assays

Duodenal biopsies demonstrating expansion of the lamina propria by macrophages filled with Periodic acid-Schiff (PAS)-positive bacterial fragments is the classic histological finding of Whipple's disease, and is observed in the majority of Whipple's disease patients [40]. While relatively specific when identified in a patient with typical Whipple's symptomatology, the protean symptoms of this pathogen necessitate the consideration of other infectious diseases, such as *Mycobacterium avium* complex and *Rhodococcus equi*, as well as noninfectious disorders, all of which may have overlapping histological appearances [41, 44]. Biopsies obtained from other anatomic sites demonstrating macrophages filled with PAS-positive material are even less specific, and must be interpreted with caution [37, 40, 44]. Immunohistochemistry for *T. whipplei* performed on paraffin-embedded tissues has recently been developed and has greatly improved both the sensitivity and specificity of histological diagnosis [38]. Lastly, intestinal biopsies may be non-contributory due to the patchy nature of disease and the possibility for diagnostic material to be confined deep within the submucosa and not usually evaluated in superficial mucosal biopsies [41, 44].

The existence of disorders with overlapping histological findings and the possibility for biopsies to miss disease supports the diagnostic role of PCR-based methods. While reports of sensitivity are limited, several studies document PCR positivity in nearly all cases of histologically proven disease [42, 45]. Detection of *T. whipplei* DNA from negative intestinal biopsies by PCR-based tests highlights the diagnostic sensitivity and utility of molecular methods [42, 44].

Molecular detection of *T. whipplei* is primarily using PCR methods including conventional [45], nested [39], semi-nested [47], and real-time PCR [48–50]. Primers targeting 16S rDNA, 16S-23S rDNA intergenic spacer, 23S rDNA, and *rpo*B sequences are commonly used [44]. Assay sensitivity and specificity varies according to the amplification target and the PCR method.

Conventional PCR assays provide qualitative results, and detection techniques are time consuming, requiring 2 or more days to perform. Ethidium bromide-stained gel electrophoresis may be used to detect amplified bands of characteristic size; however, an additional confirmatory identification step is recommended [38]. Options include Southern hybridization using sequence-specific fluorescent oligonucleotide probes or direct sequencing techniques [38]. Nevertheless, these assays can perform adequately, and a study evaluating a conventional PCR assay using paraffin-embedded tissue from patients with histologically confirmed Whipple's disease demonstrated a sensitivity and specificity of 96.6 % and 100 % respectively [45].

Semi-nested or nested PCR methods generally allow for a lower limit of detection than conventional PCR assays; however, these methods are associated with a higher risk of contamination due to the required handling of amplification products [44]. An additional disadvantage of these methods includes their longer turnaround time compared to real-time PCR methods.

Real-time PCR methods are more rapid and less prone to contamination than conventional, semi-nested, and nested PCR assays. In addition, real-time PCR assays provide quantitative results, which help differentiate true infection from contamination or low-level colonization [49]. A study comparing the performance of a LightCycler® (Roche Molecular Systems, Branchburg, NJ) real-time PCR assay to a conventional PCR assay demonstrated good correlation of results; however, the turnaround time was significantly shorter for the real-time PCR assay (3.5 h vs 2–3 days) [48].

No tests are FDA-cleared or -approved for the detection of *T. whipplei*; however, amplification of *T. whipplei* DNA by PCR in blood, CSF and tissues is available from some reference laboratories.

Interpretation of Results

A positive PCR result in the setting of classic Whipple's disease symptoms and biopsy findings is generally confirmatory. Correlating positive PCR results with clinical findings is especially important in atypical presentations and when histology is non-contributory. The need for clinical correlation is highlighted by occasional studies identifying the presence of organisms in asymptomatic adults. Most of these studies produced results using nested and semi-nested PCR assays [39, 43], which are associated with a high contamination risk [44]. Such unexpected positive results could be due to environmental contamination, asymptomatic colonization, or nonspecific amplification of non-*T. whipplei* DNA. These findings have not been confirmed as several other studies have found that PCR performed on intestinal biopsies is consistently negative in patients undergoing endoscopy to investigate conditions other than Whipple's disease [42, 49]. The ability for real-time PCR to produce

quantitative results may allow differentiation of true infection from contamination or asymptomatic colonization [49]; however, specific ranges have not been determined.

Negative PCR results in patients diagnosed with Whipple's disease histologically may be due to DNA degradation as a result of the DNA extraction process, the presence of PCR inhibitors, or damaged DNA from formalin-fixation [44]. In addition, negative PCR results may prompt consideration of other infectious etiologies capable of producing histological findings similar to Whipple's disease [44].

Laboratory Issues

As mentioned above, DNA degradation during extraction from tissues and other clinical samples may cause false-negative results. Choosing and validating an appropriate extraction method, therefore, is critical, and commercial extraction kits include chaotropic lysis (Isoquick Kit, Orca Research, Bothell, WA, USA), Pure-Gene protocol (PureGene Kit, Flowgen Instruments Ltd., Lichfield, UK), and QIAamp DNA binding columns (QIAGEN, Hilden, Germany) [44]. Extraction efficiency may be evaluated using primers targeting human gene sequences as internal controls.

PCR inhibitors may cause false-negative results. Similar to the evaluation of extraction efficiency, the presence of PCR inhibitors may be identified using primers targeting ubiquitous human genes as internal controls [44].

PCR testing can be performed retrospectively on paraffin-embedded tissue biopsies; however, the use of fresh or frozen specimens provides more sensitive results [42].

Suspensions of organism are often used as reference material but are not currently commercially available. Proficiency testing surveys also are not commercially available.

Helicobacter pylori

Description of Pathogen

Helicobacter pylori is a spiral-shaped and flagellated, Gram-negative bacterium that can be found in the stomach of some individuals. The *H. pylori* genome is approximately 1.64–1.67 million bp with 1,515–1,590 predicted protein-coding sequences. *H. pylori* has unusually high levels of genetic variation between strains due to a natural DNA uptake system that can incorporate very large fragments of exogenous DNA into the *H. pylori* genome.

H. pylori infection is a leading cause of gastric and duodenal ulcers, and is strongly associated with gastric malignancies such as gastric adenocarcinoma and gastric mucosa-associated lymphoid tissue (MALT) lymphoma [51]. While the clinical course of infection may be variable and depends on both host and microbial factors, the organism most often produces a chronic infection manifested as chronic gastritis [51, 52]. Treatment aims to completely eliminate the organism, and eradication cures the majority of both duodenal and gastric ulcers. Although treatment results in regression of most low-grade gastric MALT lymphomas [53, 54], treatment effectiveness in reducing the risk of gastric adenocarcinoma is less clear [51, 53].

H. pylori infection rates are greatest in developing countries due to lower socioeconomic conditions; however, prevalence estimates in the USA are high, reaching 30–40 % [55]. Strains demonstrating antibiotic resistance limit the effectiveness of standard eradication regimens, which usually include clarithromycin, either amoxicillin or metronidazole, and a proton-pump inhibitor (PPI) [51, 56]. Prevalence of clarithromycin resistance is estimated to be 10–15 % in the USA, and resistance results in a 70 % reduction in the eradication rate [56]. While resistance to metronidazole occurs more frequently (20–40 %), eradication rates of resistant strains are decreased by only 25 % [56]. Strains resistant to amoxicillin and second-line antibiotics such as tetracycline are much less common, but their presence could alter the effectiveness of rescue therapies [56].

The high prevalence of *H. pylori* infection and antibiotic resistance, in addition to the clear benefit of eradication therapy necessitates the use of reliable diagnostic tests. Molecular methods consisting primarily of PCR-based assays are both rapid and sensitive, and while useful for the general diagnosis of *H. pylori* infection may also play an important role in special clinical situations such as acute bleeding. Furthermore, although antibiotic resistance may be detected effectively using conventional phenotypic testing of *H. pylori* cultures, genotypic susceptibility testing of cultures and biopsy specimens offers a fast and reliable alternative.

Clinical Utility of Testing

Diagnostic testing for *H. pylori* is indicated in patients with either active or previously documented peptic ulcer disease, low-grade gastric MALT lymphoma, and in certain cases of dyspepsia not yet investigated by endoscopy [57]. The diagnosis of *H. pylori* infection may be established using a wide variety of diagnostic tests and the choice of test is largely determined by clinical factors such as whether or not the patient requires upper gastrointestinal endoscopy [57].

Tests utilized with endoscopy and regarded as invasive include culture, histology, rapid urease tests (RUTs), and PCR assays performed on biopsy material. Noninvasive tests not requiring endoscopy include serology, the urea-breath test (UBT), and stool tests such as antigen assays and PCR. Each test has particular disadvantages and comparing diagnostic performance is made difficult by the fact that no single test method is regarded as the gold standard. As a substitute for a gold standard, studies comparing different assays often designate true positives as those samples yielding positive results with two or more testing methods.

While certain non-molecular methods such as the UBT, histology, and RUTs offer sufficient sensitivity for routine testing, PCR-based molecular methods performed on tissue biopsies offer even greater sensitivity and may identify true positives missed by RUT and histology [58–62]. This increased sensitivity has the greatest utility in evaluating patients with bleeding peptic ulcers where non-molecular assays perform poorly [58, 63, 64]. Real-time PCR assays may also improve patient care by offering quantitative results. High bacterial densities are associated with lower eradication rates, and, therefore, quantitative measurements by real-time PCR may be used to identify patients who could benefit from a modified, more intense treatment regimen [65]. In addition, PCR-based assays for the detection of *H. pylori* DNA in fecal specimens represent potentially simple and noninvasive methods for establishing the existence of infection and for proving successful eradication. However, interpreting results of these tests requires the clinician to be aware of complicating factors that are specific to assays performed on stool. These issues are discussed in detail below.

While culture is currently the gold standard for antibiotic susceptibility testing, the sensitivity of these methods may be reduced due to the fastidious nature of *H. pylori*, overgrowth of cultures by bacterial contaminants, and by low numbers of viable *H. pylori* organisms in the post-treatment period [66]. In addition, cultures may take several days for growth. Fortunately, effective and rapid genotypic susceptibility testing methods are available and may be applied to both culture and biopsy specimens.

Numerous studies have looked for an association between the presence of virulence or pathogenic factors and severity of disease. The *cagA* and *vacA* genes are most commonly implicated, and certain alleles of these genes are associated with more severe gastritis as well as higher rates of peptic or duodenal ulcer disease and gastric adenocarcinoma [67–69]. While these pathogenic factors can be detected by molecular methods, including conventional and multiplex PCR, the clinical utility of testing is questionable [70–72]. Confounding variation in host genetic and environmental factors, in addition to discrepant results when comparing different geographic regions and ethnicities, undermines a clear relationship between the presence of pathogenic factors and disease severity [73, 74]. The lack of a clear association has prevented development of clinical guidelines recommending testing of these pathogenic factors for patient care [75].

Available Assays

Several laboratory developed tests (LDTs) for the detection of *H. pylori* DNA in tissue biopsies and stool have been described and include amplification methods such as conventional, nested, multiplex, and real-time PCR, as well as FISH. No US FDA-cleared tests are available. Amplification targets include genes related to the production of virulence factors such as urease (*ureA*), phosphoglucomutase (*glmM*, formerly named urease C (*ureC*)), and *vacA*, as well as species-specific sequences of 16S rRNA and 23S rRNA. Other genes targeted include the sequences encoding the 26-kDa species-specific protein antigen (SSA) and heat shock protein (HSP60), as well as random *H. pylori* genome sequences. Sensitivity and specificity of the assays are determined largely by target gene and primer choice, but also depend on the type of PCR method. Conventional PCR assays provide qualitative results and perform the same or better than conventional detection methods [58]. Detection of PCR amplicons is usually achieved with ethidium bromide-stained gel electrophoresis. Such detection methods require the open handling of PCR products, and, therefore, have a greater risk of contamination than real-time PCR methods.

Real-time PCR methods provide quantitative results, are generally more rapid and sensitive than conventional PCR assays, and also involve less contamination risk [60]. Assays using a hemi-nested or nested design generally allow for a lower limit of detection than conventional PCR assays [76, 77], and achieve similar levels of detection when compared to quantitative RT-PCR (RT-qPCR) assays [61]. Disadvantages of nested and semi-nested designs compared with RT-qPCR include more technologist time and a higher risk of contamination due to handling of amplification products [61].

Multiplex PCR methods combining several different primer targets demonstrate greater sensitivity than conventional testing methods [59]. In addition, a multiplex assay for the detection of both *H. pylori* and *Helicobacter heilmannii-like* organisms may be useful for determining prevalence of disease due to the latter, less common organism [78].

PCR-based assays for the detection of *H. pylori* DNA in fecal specimens frequently use in-house developed capture-probe systems or QIAamp DNA extraction stool kits (Qiagen, Germantown, MD) to obtain purified DNA and to reduce PCR inhibitors [56]. Capture-probe techniques use biotinylated oligonucleotide probes targeting the *H. pylori* 16S rRNA gene [56]. After overnight incubation, the desired gene fragment is harvested using paramagnetic polystyrene beads coated with streptavidin [56, 79]. Gene-capture methods used with conventional PCR targeting 16S rRNA *H. pylori*-specific sequences have demonstrated sensitivities ranging from 75 to 100 % [79, 80]. The QIAamp DNA stool kit has been shown to perform well when used in a semi-nested PCR assay targeting 23S rRNA gene sequences, but results have varied when detecting other genes [56, 81]. Lastly, a filtration-based extraction technique used by Russo et al. demonstrated excellent sensitivity (95.6 %) and specificity (100 %) using a conventional PCR assay with *ureA* primers [82].

Most antibiotic resistance among *H. pylori* strains is due to chromosomal mutations, and therefore, amenable to detection

Table 50.1 *H. pylori* antibiotic resistance mutations detectable by described assays

Antibiotic	Resistance gene	Nucleotide change	Amino acid change
Clarithromycin	23S rRNA	A2142G	NA
		A2143G	NA
Ciprofloxacin	gyrA	C(T) to A	N87K
		C(T) to G	N87K
		A to G	D91G
		G to T	D91Y
		G to A	D91N
Tetracycline	16S rRNA	A926G	NA
		A926C	NA
		A926T	NA
		A928C	NA

NA not applicable

by molecular means (see Table 50.1). *H. pylori* resistance to clarithromycin and other macrolides is caused by point mutations at two nucleotide sites (A2142G and A2143G) within the 23S rRNA gene resulting in decreased ribosomal binding of the antibiotic [52]. Clarithromycin resistance mutations may be detected using several different molecular methods such as restriction fragment length polymorphism (RFLP), pyrosequencing, fluorescence in situ hybridization (FISH), and real-time PCR [56]. PCR followed by RFLP and real-time PCR methods are used most often [56].

RFLP-based assays for the detection of clarithromycin resistance take advantage of the fact that antibiotic resistance mutations create restriction sites within the 23S rRNA gene not present in susceptible strains. Conventional PCR using 23S rRNA specific primers produces amplicons, which when cleaved with restriction endonucleases and visualized by agarose gel electrophoresis create a pattern composed of two bands instead of one. While conceptually simple, these methods are more time consuming than real-time PCR assays.

Real-time PCR methods can detect clarithromycin resistance mutations directly from biopsy specimens with excellent sensitivity and rapid turnaround times of 1–4 h [66, 83–85]. An assay described by Gibson et al. uses fluorescent-labeled probes complementary to the clarithromycin-sensitive 23S rRNA gene sequence [86]. Resistance mutations result in mismatched bases between the probe and target, and melting curve analysis reveals a lower peak melting temperature for the mismatched hybrid than a fully complementary probe and target hybrid [86]. This assay has good concordance with culture-based methods [66, 84], but also identified susceptibilities for an additional 28 patients whose cultures were negative. Of the 28 additional susceptibility results rendered, 21 had resistance genotypes. Another assay design using a biprobe system was tested on 200 patients who failed eradication therapy. The assay detected resistance genotypes with a sensitivity and specificity of 98.4 % and 94.1 %, respectively, when compared to culture-based testing [85]. Clarithromycin-resistant genotypes can also be detected in stool samples using real-time PCR methods; however, the sensitivity is lower [87]. Real-time PCR assays have also been developed to detect point mutations in the quinolone resistance-determining region of the *gyrA* gene resulting in resistance to ciprofloxacin and point mutations in the 16S rRNA gene conferring decreased susceptibility and resistance to tetracyclines [88, 89]. The assay for determining fluoroquinolone resistance identifies mutations using two hybridization biprobes designed to detect the most frequently occurring mutations at amino acid positions 87 or 91 [88]. Tetracycline resistance is detected using 16S rDNA primers and a fluorescently labeled probe complementary to the wild-type 16S rDNA allele. In both assays, melting curve analysis differentiates amplicons with resistance mutations from those with wild-type sequences [89]. While various mutations in the NADPH nitroreductase gene (*rdxA*) are associated with metronidazole resistance, detection of these mutations is not a reliable indicator of resistance [90].

Histopathologic diagnosis of *H. pylori* infection is a sensitive and specific method (>95 % and 100 %, respectively) under optimal conditions, yet ancillary molecular techniques such as FISH may help in difficult cases [56]. Visualization of the characteristic bacterial forms may be difficult when reduced numbers of bacteria are present, such as when biopsies are obtained after eradication therapy or if the patient has been on long-term acid suppression therapy with PPIs. These same conditions may change the typical morphology of *H. pylori* from a comma or S-shaped bacillus to a coccoidal form, obscuring a visual diagnosis. Several studies using fluorescently labeled, species-specific probes have demonstrated the ability of FISH to reliably detect *H. pylori* [91, 92]. Additionally, clarithromycin-resistant strains also can be detected using FISH performed on formalin-fixed tissue sections [92]. Fluorescent-labeled oligonucleotide probes designed to detect the most common mutations determining clarithromycin resistance are both sensitive and specific when compared to culture-based susceptibility testing [91]. FISH testing, however, may produce results more rapidly than culture.

Interpretation of Results

PCR tests can achieve equal or better performance when compared to non-molecular tests [58–62]. The sensitivity is highly dependent on the target gene and is discussed in greater detail in the "Laboratory Issues" section below.

The specificity of different PCR test methods varies and determining specificity is complicated by the lack of gold standard. Real-time PCR assays applied to tissue biopsies have detected *H. pylori* at low densities that were missed by histology, UBT, and RUT suggesting that the poorer sensitiv-

ity of these non-molecular assays is due to low numbers of organisms [61]. However, due to the high sensitivity of PCR-based methods and the amplification of DNA from nonviable organisms, isolated positive PCR results in the post-treatment period must be interpreted with caution. Positive results in this setting may represent continued presence of organisms at low levels or nonviable organisms, and, therefore, PCR may not have utility in determining eradication failures in the post-treatment period. Isolated positive PCR results in untreated patients may reflect true infection with a low *H. pylori* density, but may also be due to nonspecific amplification of non-*H. pylori* bacterial DNA [93]. Due to these factors, PCR-based methods should not be used as the sole diagnostic test.

Like PCR testing of biopsy specimens, the specificity of results obtained from PCR testing of stool samples may be decreased due to amplification of nonviable organisms. Studies examining the use of PCR-based testing of stool for determining eradication success rates in the early post-treatment period are conflicting [80, 94]. While negative PCR results within 12 days of treatment were obtained for a small group of infected patients, another study demonstrated false-positive results occurring in half the patients 1 month after treatment [94, 95]. False-positive PCR results decrease after longer follow-up periods, and approach zero after 12 weeks of therapy [94]. In addition, analytical specificity of PCR testing on stool samples may be reduced due to the presence of non-*pylori Helicobacter* species present in fecal material [56]. While clinical specificity for PCR-based assays is determined by comparison with UBT, culture, and RUTs, determinations of analytical specificity by testing of non-*pylori Helicobacter* species is rarely performed [96].

Antibiotic resistance genotype testing using real-time PCR can produce results indicating the presence of more than one genotype [85]. These results are interpreted as representing a mixed population and combinations of one or more distinct mutant strains among wild-type strains have been detected [85]. While some studies have detected mutant strains in the presence of wild-type strains down to a level of 10 % [85], other studies cite failed resistance detection due to high levels of susceptible strains [87].

Laboratory Issues

Sensitivity and specificity of PCR-based methods are greatly dependent on primer choice and target gene. Additionally, significant inter-study variation in sensitivity and specificity exists for several of the commonly used primers. Nucleotide differences among distinct *H. pylori* strains may partly explain this test performance variability [77]. A study comparing the diagnostic performance of several different primers demonstrated poor specificity for SSA gene primers and unsatisfactory sensitivity for the *ureA* gene and random *H. pylori* genome sequences [76]. While this study concluded that *glmM* gene PCR performed best, other studies have reported lower specificities [60, 77]. Assays using 16S rRNA sequences generally report excellent sensitivities, but the specificity of these primers is questionable. Several authors argue that 16S rRNA primers are inappropriate because of sequence conservation among different bacterial genera as well as the possibility for non-specific amplification of human DNA [76, 77]. Assays targeting *vacA* have reported moderate sensitivity (89.5 %) but excellent specificity (99.0 %) [84]. The HSP60 gene is thought to be both well conserved and demonstrates species-specific variation [77]. A nested assay design using primers targeting HSP60 claims to have sensitivity and specificity approaching 100 % [77].

Determining whether tissue to be used for PCR assays is preserved by formalin fixation or cryopreservation represents an important variable in testing, but may ultimately be decided by proximity of laboratory and endoscopy suite. Both formalin-fixed and frozen tissue specimens may be used for PCR-based testing, although frozen samples are far superior [56]. Formalin fixation causes DNA to fragment; however, assays using formalin-fixed tissues may still perform acceptably if short DNA sequences are targeted.

PCR assays applied to stool specimens suffer from inconsistent results attributable to substances inhibitory to PCR amplification, low numbers of *H. pylori* organisms within fecal samples, as well as degradation of DNA during intestinal transit [53, 56]. To avoid false-negative results, complex purification and extraction steps to eliminate PCR inhibitors are required before DNA amplification. Performance of the different biochemical, immunologic, and physical purification methods varies due to degradation of target DNA and incomplete removal of inhibitors [96]. Frozen stocks of *H. pylori* strain NCTC 11637 and dried genomic DNA from that strain (American Type Culture Collection 43504D, Manassas, VA) as well as titered cultures of *H. pylori* (ZeptoMetrix Corp, Buffalo, NY) are commercially available reference materials. Proficiency testing exercises are not commercially available.

Viral Agents

The most common causes of viral gastroenteritis include adenovirus serotypes 40 and 41, rotavirus, astrovirus, and caliciviruses (noroviruses, sapoviruses). Conventional detection of these viruses is based on antigen detection and EM. Molecular methods have been primarily used for epidemiologic or research purposes but have also demonstrated significant improvement in the diagnosis of viral gastroenteritis and are becoming available in clinical laboratories.

Other viruses less frequently implicated as causes of acute gastroenteritis include coronaviruses and toroviruses.

In addition, viruses such as cytomegalovirus and herpes simplex virus are opportunistic causes of enteric disorders in patient infected with the human immunodeficiency virus (HIV) or with compromised immunity but are diagnosed by examination or testing of gastric or intestinal biopsy tissues rather than examination of stool.

Adenovirus

Description of Pathogen

Adenoviruses are nonenveloped viruses with a linear, nonsegmented, double-stranded DNA genome surrounded by an icosahedral protein capsid. The genome size varies among adenoviral groups and is between 26,000 and 45,000 nucleotides which theoretically provides the capacity for 22–40 genes. The genome consists of immediate early (E1A), early (E1-E4), intermediate, and late genes (L1-L5).

Adenoviruses are classified into five genera including Atadenovirus, Aviadenovirus, Ichtadenovirus, Mastadenovirus, and Siadenovirus. The adenoviruses that infect humans belong to the genus *Mastadenovirus*. Seven species of human adenovirus (A through G) within the genus *Mastadenovirus* are currently recognized. Species designations are determined by immunologic properties as well as DNA homology and oncogenicity [97]. Each species group contains several serotypes classified by neutralization reactions to specific antisera [97]. At present, over 50 serotypes have been described [98]. Serotype groups may be further subdivided into genomic types. Genotypes are assigned lowercase letters to differentiate them from the prototype strain as indicated by the letter "p" [97]. Interspecies DNA sequence variation may be as low as 4 % whereas genotypes within an adenovirus species may be 50 % to nearly 100 % homologous [99, 100]. Intraspecies recombination resulting in intermediate strains has been reported [101].

Species F serotypes 40 and 41 are the most frequent adenovirus serotypes isolated from patients with gastroenteritis and are referred to as the "enteric adenoviruses." These serotypes are second only to rotavirus as the most common cause of acute diarrheal illness in children [102]. Adenoviruses of all serotypes are implicated in approximately 5–15 % of childhood diarrhea cases [97]. Gastroenteritis due to adenovirus occurs worldwide and the incidence does not demonstrate significant seasonal variation [103]. More than one serotype or species may be isolated in a given patient [104]. Serotypes infrequently associated with gastroenteritis include 1, 2, 3, 5, 7, 12–18, 21, 25, 26, 29, 31, and 52 [102].

Transmission is thought to occur by fecal-oral spread and the mean incubation period for gastroenteritis is 3–10 days [97, 103]. After clinical symptoms improve, enteric adenoviruses are shed in stool rarely for longer than a few days compared to patients with respiratory infections not involving enteric adenoviruses who may shed for 3–6 weeks and as long as 18 months [97]. The duration of viral shedding in the gastrointestinal tract may be prolonged in immunocompromised individuals [97]. Adenoviruses can also be shed in the stool of individuals with asymptomatic infections which are common, particularly in children [97].

Clinical symptoms include watery, non-bloody diarrhea accompanied by mild fever, vomiting, and abdominal pain. Gastroenteritis in immunocompetent patients usually resolves without complication; however, rare fatalities are documented [97].

Gastrointestinal infections in immunocompromised patients occur most often in hematopoietic stem cell (HSCT), bone marrow (BMT), and solid organ (SOT) transplant patients. Infections in these patients are frequently severe and can become disseminated. In pediatric allogeneic HSCT patients, detectable virus in stool almost always precedes systemic adenovirus infection [105]. Adenovirus species isolated most frequently in HSCT and BMT patients with gastrointestinal disease include species A (serotype 31), B (serotype 7), and C (serotype 2) [106]. The incidence of adenovirus infections in patients with HIV infection or acquired immunodeficiency syndrome (AIDS) has dropped due to effective treatment of the HIV infection with highly active antiretroviral therapy [10]. Serotypes within species D cause the majority of gastroenteritis in HIV-positive patients and include serotypes 9, 17, 20, 22, 23, 26, 27, and 42–51 [106].

Clinical Utility of Testing

Diagnosis of adenovirus gastroenteritis is primarily determined through testing of stool samples although tissue biopsy specimens also may be used. Conventional methods used to identify the presence of adenovirus in stool samples include shell vial cultures, direct fluorescent antibody assays, EIAs, and EM. Disadvantages of culture methods include delays of up to weeks and false-negative results with difficult to culture AV serotypes such as 40 and 41 [99]. Immunofluorescent and immunochromatographic methods, while rapid, are insensitive [107]. EM also is insensitive and is not routinely used in clinical laboratories. Indirect diagnosis using serology is limited by poor sensitivity especially in immunocompromised patients and by high seroprevalence among children preventing the ability to identify acute disease [107, 108]. Despite these diagnostic limitations, conventional methods may be sufficient to detect infection in immunocompetent patients with localized or benign gastrointestinal symptoms [109].

Adenovirus infection may become severe in immunocompromised patients and the ability to begin early treatment, such as reduction of immunosuppression or cidofovir therapy, requires rapid and sensitive diagnostic techniques [107]. Several PCR-based assays have been validated for

stool specimens and are comparable or better than conventional methods [110–112]. Both qualitative and quantitative PCR assays are used. Qualitative assays vary in serotype detection of all or only some serotypes. While qualitative PCR methods are sensitive, quantitative assays assess stool viral load and proliferation kinetics. These parameters may become important in assessing the need for preemptive treatment of adenovirus infection in pediatric HSCT patients by detection of significant levels of virus in stools before the onset of viremia and disseminated infection in the majority of these patients [105, 113].

Multiplex assays differ in their clinical application. One particular assay provides qualitative, yet species-specific results [114], while others offer quantitative results and detect adenovirus in combination with other important gastrointestinal pathogens. Quantitative assays may be useful for determining which pathogen is responsible for disease in cases of mixed infections [115, 116].

In most cases, determination of adenovirus serotype is unnecessary for clinical management [117]. By contrast, serotyping is important for epidemiology studies, when investigating an especially severe infection, and in predicting clinical outcome [106]. Isolation of specific adenovirus serotypes from the gastrointestinal tract, such as 1, 2, 5, and 6, may raise concern for the possibility of disseminated disease since these serotypes have been documented to cause systemic infections in immunocompromised patients [107]. On the other hand, serotypes 40 and 41, while frequently isolated in cases of gastroenteritis, have not been recovered from immunocompromised patients with disseminated infections [107]. While conventional serotyping methods may take up to several weeks [97], molecular methods such as PCR have improved turnaround times and allow for the characterization of isolates at the species, serotype, and genotype level [107]. Molecular and serological typing results usually are concordant [97].

Available Assays

Tissue biopsies may be submitted for culture or for histological examination using hematoxylin-and-eosin or Wright-Giemsa stains and immunohistochemistry. Molecular techniques such as in situ hybridization may aid diagnosis by confirming characteristic microscopic findings [118]. Alternatively, biopsy specimens may be submitted directly for molecular testing using conventional or real-time PCR [102, 119].

Molecular methods offer increased sensitivity and shorter turnaround time compared with conventional methods [110–112]. Different PCR methods for the detection of adenovirus in stool or tissue biopsies include conventional PCR, real-time PCR, and multiplex PCR. Most clinical laboratories use LDTs because no US FDA-cleared tests are available for stool testing. Regardless of the PCR method, degenerate or non-degenerate primers and probes targeting the hexon or fiber genes or the VA RNA-encoding regions are typically used. These regions display homology across serotypes for consistent binding of primers and probes, yet also include hypervariable regions suitable for differentiating serotypes.

Conventional PCR assays range in their detection abilities. Some systems detect and report specific serotypes [110, 120, 121], while others report genus- or species-specific results and purport to detect all serotypes [107, 117]. These assays are qualitative and usually have a 1–2 day turnaround time. Methods used to detect PCR amplicons include ethidium bromide-stained gel electrophoresis, Southern blotting, or liquid phase hybridization quantitated by time resolved fluorometry [122]. These detection methods are time- and labor-intensive and necessitate handling of PCR products, thus potentiating the risk of contamination.

Real-time PCR methods offer quantitative results and are more rapid and involve less contamination risk than conventional PCR assays [102, 119, 123, 124]. Several LDTs and one commercial assay are validated for use on stool specimens. While some methods rely on a single probe and primer pair, most utilize more than one set of primers and multiple probes. Weighing of stool specimens before DNA extraction allows results to be quantitated in copies per gram of stool. This standardization permits assessment of serial stool specimens for viral load kinetics and facilitates comparison of results between assays.

Several multiplex PCR assays have been validated for stool testing and differ in their clinical applications and detection methods. One particular method allows for identification of all six adenoviral species in a single reaction mixture using species-specific hexon primers [110]. Species-specific results are visualized by agarose gel electrophoresis, which shows a different amplicon length for each species [110]. Other multiplex assays offer quantitative results and combine adenovirus detection with other common gastrointestinal viral pathogens [115, 116]. Detection techniques differ and involve either fluorescent-labeled sequence-specific probes or sequence-specific capture probes bound to microspheres, which are interrogated by flow cytometry.

Conventional typing may take weeks making such methods impractical for clinical use. Molecular typing methods greatly improve turnaround time and several assays have been tested for use with stool samples. Strategies for producing serotype or genotype specific results vary by assay, and may be performed from cultured isolates or directly from clinical specimens [125, 126]. Traditional molecular typing methods rely on REA and may be performed on adenoviral genome DNA or following PCR amplification of specific regions [117, 127]. Genotype or serotype is inferred from the band pattern on agarose gel electrophoresis. REA methods are still used to identify new strains or for type identification

of an isolate causing severe disease [106]. Sequence-based typing may be used to determine both serotype and genotype and is usually performed after PCR amplification of hypervariable regions [128]. Generated sequences are compared to banked sequences of known serotypes.

Interpretation of Results

Similar to other clinical situations where highly sensitive molecular assays are applied, PCR methods used in the diagnosis of adenovirus gastroenteritis offer improved sensitivity over conventional methods, but may provide positive results in the absence of disease. The ability for adenoviruses to cause asymptomatic infection and the tendency for nonenteric adenoviruses to be shed in the stool for weeks to months after resolution of clinical symptoms make interpretation of positive results in patients without symptoms difficult [97, 103].

Diagnosis of adenovirus gastroenteritis in immunocompetent patients is straightforward when PCR results are positive for an enteric adenovirus species or serotype in the presence of characteristic symptoms. Viral shedding in the absence of symptoms is unusual for enteric adenoviruses, especially in immunocompetent individuals.

Shedding of nonenteric serotypes for long periods of time occurs more frequently in immunocompromised patients and makes it difficult to determine conclusively that a detected adenovirus serotype is the cause of the patient's symptoms. Persistent viral shedding from a previous adenovirus infection may be difficult to distinguish from a newly acquired asymptomatic infection, which occurs often in the immunocompromised patient population. Further complicating interpretation in immunocompromised individuals is the frequent occurrence of coinfections.

The ability to determine serotype by sequencing is limited by incomplete reference databases containing sequence information for only certain serotypes [107]. The completeness of the reference database depends on the genome region sequenced. Serotype determination by methods relying on enzyme restriction patterns is limited to serotypes whose restriction patterns have been previously described. These methods are further hampered by the genetic variability created over time by recombination events between viruses of different serotypes. Such variation may alter cleavage sites and create unrecognizable restriction enzyme patterns. Infections caused by one or more serotypes may also create uninterpretable results.

As mentioned above, quantitative testing of stool allows clinicians to monitor stool viral load and proliferation kinetics. The mere presence of adenovirus in stool is common in pediatric HSCT patients, and does not necessitate treatment, as the majority will clear the virus spontaneously [129]. Quantitative measurements, however, have allowed investigators to identify rising stool viral loads in the majority of pediatric HSCT patients who go on to develop adenovirus viremia and disseminated disease [105, 113]. Quantitative serial stool measurements, therefore, may serve as a useful tool for predicting when early treatment is warranted and could prevent the overuse of the nephrotoxic antiviral drug cidofovir [113].

Laboratory Issues

Detection of all adenovirus serotypes is important because serotypes other than enteric adenoviruses cause a significant number of gastroenteritis cases in immunocompromised patients. The high degree of genetic heterogeneity among adenovirus serotypes makes detection of all known serotypes by a generic PCR assay difficult [106]. Genetic diversity also complicates identification of regions with sufficient homology to allow for uniform annealing of primers and probes in all serotypes. Currently, most assays use primers and probes that bind to the highly conserved hexon gene, which has only approximately 50 % nucleotide homology between serotypes (NCBI database, [105]). Uniform annealing of primers and probes is even more important for quantitative assays, to ensure equal amplification efficiency of all serotypes [108]. Concern that nucleotide mismatches between target and primer or probe would result in decreased sensitivity of detection for many serotypes has led to more optimal assay designs utilizing multiple primer and probe sets [123]. Lastly, multiplex assays that detect multiple viral pathogens can detect coinfections, although the test performance for adenovirus was occasionally negatively affected by coamplification of other viruses [116].

DNA from both adenovirus 40 and adenovirus 41 is available from ATCC (Manassas, VA). The Zeptometrix NATtrol™ gastrointestinal pathogens verification panel includes adenovirus among the other analytes. The Stool Pathogen Panel (SP) proficiency survey from the College of American Pathologists includes challenges for adenovirus 40/41.

Rotavirus

Description of Pathogen

Rotaviruses are non-enveloped viruses in the *Reoviridae* family, named because of their characteristic wheel-like appearance by EM. Rotaviruses are very stable in the environment and can remain infectious for several weeks. They have a triple-layered structure with concentric capsid layers that surround a core which contains the genome. The surface of the outermost capsid layer contains two major structural viral proteins, VP4, a protease-cleaved protein (P protein), and VP7, a glycoprotein (G protein). The middle

layer of the capsid contains structural protein VP6. The inner capsid layer contains proteins VP1, VP2, and VP3. The rotavirus genome consists of 11 segments of double-stranded RNA with a complete genome length of 16,500–21,000 nucleotides. The genomes can reassort during dual infection of a single cell which results in co-circulation of a wide variety of strains.

Rotaviruses are classified into serogroups A through G based on the antigenic characteristics the VP6 protein. Only groups A, B, and C infect humans and animals. The remaining rotavirus groups have been found only in animals. The Group A human rotaviruses cause the majority of viral gastrointestinal infections in children. Group B rotaviruses were first identified as causing adult diarrhea in a large waterborne epidemic in China. Serologic evidence indicates that Group B rotavirus is also present in the UK and the US, and genome profiles consistent with Group B rotavirus have been detected as causes of diarrhea in India [130]. Group C rotaviruses are an emerging cause of gastroenteritis in both children and adults and have been identified in sporadic cases and outbreaks worldwide. The Group A rotaviruses are further classified into serotypes based on neutralizing serologic reactions against the P (VP4) and G (VP7) proteins. Also, because the two gene segments that encode the P and G proteins segregate independently, a genotyping system has been developed based on the sequences of both genes. The most prevalent Group A rotavirus genotypes in humans are G1P[8], G2P[4], G3P[8], G4P[8], and G9P[8]. A Rotavirus Classification Working Group has been formed to assist in classification of any newly described rotavirus genotypes based on sequence information for all 11 genomic RNA segments.

Rotavirus is endemic worldwide and is the single most common cause of diarrhea among infants and young children [131]. Most rotavirus infections are self-limiting but some children become very ill with severe vomiting, diarrhea, and life-threatening loss of fluids that requires hospitalization. Death due to rotavirus infection is relatively rare in the USA but is a significant concern in developing countries. Rotaviruses are estimated to cause more than half a million infant and young children deaths worldwide every year [131].

In the USA and other countries with temperate climates, annual outbreaks of rotavirus infection occur during winter and spring, with fewer cases in summer. However, with the introduction of rotavirus vaccines, the seasonality has shifted and the winter–spring trend in peak rotavirus activity is no longer consistently observed [132]. Seasonal variation is not seen in tropical climates.

Rotaviruses are shed in large quantities in the stools of infected children beginning 2 days before the onset of diarrhea and for up to about 10 days after the onset of symptoms. Immunocompromised individuals may shed detectable rotavirus for more than 30 days after infection. Rotaviruses are highly communicable, with a small infectious dose of less than 100 virus particles [133]. Rotaviruses are spread by fecal-oral transmission, both through close person-to-person contact and through fomites, and are common causes of diarrheal outbreaks in families, in childcare centers, and other institutions, and among hospitalized children [134]. The incubation period for rotavirus illness is about 2–3 days. Immunity after infection is incomplete, but repeat infections tend to have milder signs and symptoms than the initial infection.

A rotavirus vaccine is now included in the American Academy of Pediatrics recommended immunization schedule for infants. Two vaccines, RotaTeq® (Merck & Co., Inc., West Point, PA) and Rotarix® (GlaxoSmithKline, London, UK) were introduced in 2006 and 2008, respectively, and are currently licensed for use in the USA. A previous rotavirus vaccine was taken off the market in 1999 because of an increased risk for intussusception, which does not occur with either RotaTeq or Rotarix.

Adults and older children also can be infected with rotaviruses. Infection in adults is often subclinical or very mild. Clinically evident cases are most often seen in immunocompromised patients, the elderly, and travelers to developing countries [135].

Clinical Utility of Testing

Rotavirus infection cannot be diagnosed by clinical presentation because the clinical features of rotavirus gastroenteritis do not differ from those of gastroenteritis caused by other pathogens. Confirmation of rotavirus infection by laboratory testing is used for surveillance but also is useful in clinical settings to avoid inappropriate use of antimicrobial therapy.

Since rotavirus is present in high concentrations in the stool of infected children, stool is the preferred specimen for diagnosis. Rotaviruses can be cultured in Madin-Darby bovine kidney (MDBK), fetal African green monkey kidney cells (MA104 cell line), and some other cell lines in media containing trypsin or pancreatin, but culture is relatively inefficient and not performed in clinical laboratories. The most widely available method for detection of rotavirus antigen in stool is EIA directed at the VP6 antigen common to all group A rotaviruses. Several commercial EIA kits are available, which are inexpensive, easy to use, rapid, and sensitive (approximately 90–100 %). Latex agglutination is less sensitive and specific than EIA but is still used in some settings. Immunochromatographic point of care tests have reported sensitivities of 94–100 % and specificities of 96–100 % compared with clinical laboratory tests [136]. Other techniques, including EM, reverse transcription-polymerase chain reaction, nucleic acid hybridization, sequence analysis, and culture are used primarily in research settings.

Molecular methods have been used primarily for characterization of G and P genotypes in epidemiologic studies

and to evaluate the impact of vaccination [137, 138]. RT-PCR has increased detection rates for rotavirus A by up to 48 % compared to EIA or EM [139]. Sensitivity of RT-PCR tests is estimated at 10^4 rotavirus particles per milliliter of stool, while EIA methods detect 10^6 rotavirus particles per milliliter of stool. While increased sensitivity is usually seen as a benefit, some have considered RT-PCR assays too sensitive for the detection of rotaviruses due to their ability to detect asymptomatic infections, which are common in infants and young children [140, 141].

Available Assays

Some commercial tests designed for testing food sources or environmental samples are available as research use only kits. Most reports of molecular tests used for diagnosis of human rotavirus infections are LDTs. The xTAG GPP gastrointestinal pathogen panel test kit (Luminex Corp., Austin, TX) is an US FDA-cleared qualitative RT-PCR multiplexed test that can be performed in about 5 h and simultaneously detects the most common parasitic, bacterial and viral gastrointestinal pathogens, including rotavirus Group A.

Interpretation of Results

Asymptomatic carriage of rotavirus can be detected by molecular tests and needs to be considered when interpreting positive results in clinical specimens [140, 141]. Asymptomatic carriage vs true mixed infection also needs to be considered in the rare event that rotavirus is detected in combination with another gastrointestinal pathogen in the same clinical sample or during an episode of diarrhea. Laboratories should be aware that rotaviruses can be detected by RT-PCR in clinical specimens for about 10 days after resolution of an acute diarrheal episode in healthy children [137].

Laboratory Issues

Ideally, diagnostic RT-PCR tests would be able to detect all three genogroups of human rotaviruses. Except for epidemiologic purposes, identification of the specific genogroup is probably not necessary. Laboratories should be aware that rotavirus RNA has been detected in serum, CSF, and throat swab specimens [142, 143].

The NATtrol™ (ZeptoMetrix Corp, Buffalo, NY) verification set includes reference material for rotavirus among other analytes. Human rotavirus in diarrheal stool samples is available from ATCC (Manassas, VA). The Gastrointestinal Panel for Molecular Multiplex Testing (GIP) and the Stool Pathogens (SP) survey, both from the College of American Pathologists, include proficiency testing challenges for rotavirus among other gastrointestinal pathogens.

Astrovirus

Description of Pathogen

Astroviruses are small, round, non-enveloped viruses with icosahedral cubic capsids that have a characteristic five or six-point star-like surface structure when viewed by EM. Astroviruses contain three structural proteins (VP26, VP29, and VP32). The genome is composed of non-segmented, positive-sense, single-stranded RNA. The total genome length is 6,800–7,900 nucleotides, excluding the poly (A) tract at the 3′ end and the genome has been sequenced.

The family *Astroviridae* contains two genera: *Mamastroviruses* which infect numerous types of mammals and *Avastroviruses* which infect birds (e.g., ducks, chickens, turkeys). Within each genus are species of astroviruses, which, according to International Committee on Taxonomy of Viruses guidelines, are named based on the host in which they replicate. The astroviruses are further subclassified within each species into serotypes. Three species of astroviruses are found in human stool: HAstV (serotypes 1–8), AstV-MLB, and HMOAstV (serotypes A to C). These species are more closely related to animal astroviruses than to each other, indicating phylogenetically separate origins of human astroviruses [144].

Simultaneous circulation of multiple types of astrovirus is not rare [144]. Human astrovirus serotype 1 (HAstV-1) is the most prevalent serotype detected worldwide. However, serotype 3 produces higher quantities of virus in stool and appears to cause a larger proportion of cases of persistent gastroenteritis [145].

Human astroviruses are endemic worldwide. Studies using sensitive detection techniques, such as RT-PCR, have demonstrated that astrovirus infection is a more common and important cause of viral gastroenteritis than previously known. Symptomatic illness is most common in children < 2 years of age, although infection in immunocompromised individuals and outbreaks among adults and the elderly have also been reported. Astroviruses are highly stable in the environment and are resistant to a wide range of detergents and lipid solvents. The fecal-oral route is thought to be the most common means of transmission and contaminated food, water, and fomites are common sources of virus. As with many other viral causes of gastroenteritis, astrovirus infection has a peak incidence in winter in temperate climates and is associated with the rainy season in tropical regions. Astrovirus is thought to replicate in the intestinal tissue of the jejunum and ileum and generally causes mild, self-limiting illness of short duration. Prevalence is likely under-estimated since surveillance and seroprevalence studies have demonstrated that astrovirus infection is common and is largely asymptomatic.

Immunity to astrovirus infection is not well understood. Prevalence of symptomatic infection among young children and institutionalized elderly populations suggests that antibody is acquired early in childhood, provides protection through adult life, and begins to decline later in life [146]. Heterologous protection does not occur across the human astrovirus serotypes [147].

Clinical Utility of Testing

No vaccine or anti-viral treatment is available for prevention or treatment of astrovirus infection, but diagnosis may be important to avoid unnecessary antibiotic use. Establishing an etiology also may be important in hospitalized patients for infection control purposes to prevent nosocomial spread [148, 149]. Further, diagnosing astrovirus gastroenteritis in patients with malnutrition, immunodeficiency, and underlying gastrointestinal disease, may be important because of the increased likelihood of complications that require hospitalization in these populations. The impact of astrovirus infection on the morbidity of infants and children may become increasingly important as the rotavirus vaccine becomes more widely used and the burden of rotavirus is reduced.

Available Assays

Astroviruses have been adapted to cell culture using CaCo-2 human colonic carcinoma cells in some research settings, but are not cultured for clinical diagnostic purposes. EM and immune EM (IEM) have been effectively used to detect astroviruses in clinical stool specimens but are not available in many clinical laboratories. Also, identification by EM can be difficult since only a small portion of astrovirus particles (about 10 %) display the characteristic star-like morphology [150].

EIA tests have been developed for the qualitative detection of astrovirus antigen in clinical specimens and are commercially available in Europe (e.g., RIDASCREEN® Astrovirus test, R-biopharm AG, Darmstadt, Germany, IDEIA™ Astrovirus, Dako Diagnostics Ltd, Ely, UK) but are not US FDA-cleared for diagnostic use in the USA.

Commercial real-time RT-PCR kits are available for testing environmental and food samples. Molecular assays are considered to be an improved diagnostic method over EM and EIA [151], but US FDA-cleared diagnostic tests for astrovirus are not available. Specifications for LDTs for detection of astrovirus in clinical samples using highly sensitive group-specific RT-PCR primers targeted to conserved genomic regions coding for the nonstructural proteins and untranslated regions are available [151]. Reported detection limits for these assays vary from 1 to 10 viral copies depending of the quality of the analyzed nucleic acid. Some tests utilize primers from the capsid coding region which can be less sensitive, but provide type information [151].

Interpretation of Results

Shedding of astrovirus is generally limited to about 1 week in immunocompetent individuals, but as with other viruses that cause gastroenteritis, prolonged shedding of astrovirus (e.g., 4 weeks) has been observed in immunocompromised patients [148, 152]. Although asymptomatic infection is common, determining the significance of astrovirus detection should not be problematic in most clinical settings since presumably only diarrheal stools from symptomatic patients would be tested.

Laboratory Issues

Astrovirus infections are generally limited to the gastrointestinal tract; however, astroviruses have been detected in plasma as a cause of febrile illness and in brain tissue of an immunocompromised patient [153]. Human gastrointestinal astrovirus infections have been limited to the eight closely related serotypes described above. Recently, several highly divergent astrovirus serotypes (MLB1, MLB2, VA1, VA2, and VA3) have been detected in stool samples from patients with and without diarrhea [153]. An association with gastrointestinal disease has not been definitively made for these newly described astroviruses [153]. Reference material and proficiency testing challenges are not currently commercially available.

Caliciviridae (*Noroviruses, Sapoviruses*)

Description of Pathogen

Human caliciviruses belong to the family *caliciviridae* and are small, round, non-enveloped viruses with a single-stranded, positive-sense RNA genome. The family currently includes the genera *Norovirus* (previously Norwalk and Norwalk-like viruses), *Sapovirus* (previously Sapporo and Sapporo-like viruses), *Lagovirus*, *Vesivivirus*, and the newly proposed *Becovirus* and *Recovirus*. The noroviruses and sapoviruses have recognized roles as causes of acute gastroenteritis in humans. Within each genus, strains are further grouped into genogroups and genotypes or clusters.

The noroviruses are partitioned into genogroups GI to GVII, each further subdivided into genotypes and subgenotypes. Porcine, bovine, and murine noroviruses belong to genogroups II, III, and V, respectively. The majority of human norovirus outbreaks are caused by genogroup II genotype 3 (GII-3) and genogroup II genotype 4 (GII-4) viruses. Human norovirus are thought to be specific to humans and transmission from an animal reservoir has not been described. However, at least three clusters of porcine noroviruses in genogroup II are genetically closely related to the human noroviruses in genogroup II, introducing the potential for zoonotic transmission [154].

The sapoviruses are similarly partitioned into five genogroups (GI to GV) with genotypes in each group. Human sapoviruses belong to genogroups GI, GII, GIV, and GV. GIII contains the porcine strains. Caliciviruses appear to naturally undergo recombination during normal replication of the virus, leading to the emergence of a continuous array of new variants [155].

Human caliciviruses are cannot be grown in standard in vitro cell culture assays and their role as agents of gastrointestinal diseases was under appreciated because clinical tests for the detection of caliciviruses were not commonly available. Molecular methods such as RT-PCR have revealed that caliciviruses are broadly distributed worldwide and are very common causes of epidemic and sporadic gastroenteritis in both children and adults [156]. The study of noroviruses is significantly more advanced than that of sapoviruses. Noroviruses are recognized as the leading cause of epidemic gastroenteritis, often causing large water- or food-borne outbreaks in all ages, while sapoviruses are implicated mainly in pediatric gastroenteritis [157].

Caliciviruses are presumed to replicate primarily in the upper intestinal tract and histopathologic lesions are seen in the jejunum of infected individuals. Symptoms of calicivirus infection are popularly known as "stomach flu" and include vomiting, abdominal cramps, diarrhea, headache, and fever. Symptoms generally last 1–4 days and most people recover completely without treatment. Infants, older adults and people with underlying disease can become severely dehydrated and require medical attention. Asymptomatic infections with shedding of virus are common, and could be the source of some outbreaks [158]. Protective immunity is thought to be short-lived and individuals who have been infected may or may not be immune to reinfection. Studies of immune response are complicated by the ability of the virus to produce naturally occurring variants which are difficult for the immune system to recognize.

Caliciviruses are stable in the environment and can survive freezing, heating to 60 °C, and in chlorinated water up to 10 ppm. They can also survive for several days on many types of surfaces (e.g., door knobs, counter tops, pens, and telephones). Caliciviruses are highly contagious with an estimated infectious dose as low as 10–100 virus particles [159]. These characteristics facilitate rapid spread of caliciviruses, especially in households and institutional settings such as schools, day care centers, hospitals, nursing homes, restaurants, and cruise ships [160]. Calicivirus infections occur year round, although a winter seasonal peak is frequently observed [161].

Transmission is thought to occur mainly through fecal-oral routes. Evidence also suggests that caliciviruses may be transmitted by close exposure to aerosols generated during vomiting episodes in infected individuals. The most frequent cause of norovirus infection appears to be consumption of food or beverages that are contaminated either at their source or by infected food handlers. Uncooked shellfish, particularly oysters, as well as raspberries and precooked foods, such as salad, ham, and sandwiches, are among the common foods that have been responsible for outbreaks [161]. Outbreaks resulting from contamination of municipal water are rare, but water-borne outbreaks associated with community or family water systems have been documented. Sapoviruses have been associated with food-borne outbreaks, but much less frequently than noroviruses. Sapovirus infections are not associated with eating seafood. Nosocomial infections due to caliciviruses are increasingly recognized and may be quite common.

Clinical Utility of Testing

Laboratory diagnosis of calicivirus infection is difficult and clinical diagnosis is often used, especially when other agents of gastroenteritis have been ruled out. Detection of caliciviruses may be important because of their biologic, physicochemical, and epidemiologic features, which present significant challenges for infection control in hospital environments. The regular turnover of patients leaving the hospital and being replaced by new patients provides an opportunity for introduction of the virus from the community and subsequent transmission within the hospital environment.

Available Assays

Although Norovirus has been adapted to grow in a complex 3D culture system in research settings, attempts to culture human caliciviruses in routine cell lines have failed to yield replicating virus, even with addition of a wide variety of culture supplements.

Caliciviruses can be detected fairly rapidly in stool specimens from patients with diarrhea using direct EM. Detection by direct EM requires virus concentrations of at least 10^6 virus particles per milliliter of stool, making EM relatively insensitive, even after processing of the specimen to concentrate the virus particles [158]. IEM improves the sensitivity of direct EM by 10- to 100-fold, but this technique is infrequently used. False-negative results can occur if antibody is present in excess and masks detection of the virus [160]. Use of EM is limited due to the need for expensive equipment, experienced technologists and a significant amount of labor per specimen [162].

The cloning of the Norwalk virus genome and subsequently of other human caliciviruses has allowed the development of other methods for diagnosis. EIAs to detect virus in stool specimens using polyclonal hyperimmune animal sera can detect the presence of 10^4–10^6 intact virus particles/ml of stool [160, 163], but are considered to have inadequate

sensitivity to be used for diagnosis, especially of sporadic cases [164]. Serologic EIAs to detect specific antiviral antibodies generally are used to detect a fourfold increase in antibody levels between acute and convalescent serum specimens. The hyperimmune antisera and recombinant antigens needed to produce these EIAs are not widely accessible and US FDA-approved diagnostic assays have not been produced. The assays are available at some public health laboratories and are primarily used for epidemiologic purposes.

Since caliciviruses cannot be grown in vitro, EM is available only in highly specialized facilities, and serology assays are insensitive, the potential utility of RT-PCR-based techniques is considerable. The highly variable nature of calicivirus genomes presents a significant challenge to designing molecular assays for diagnostic use. The literature contains details of a variety of RT-PCR assays that have been used for the detection of human caliciviruses in diagnostic studies as well epidemiologic investigations of food, water, and other environmental samples. Some of the assays are designed to detect sapoviruses without cross-reactivity with noroviruses or rotaviruses. Among them is a quantitative real-time PCR assay using primers against the junction of the RNA-dependent RNA polymerase/capsid genes that has been described to detect sapovirus genogroups I, II, and IV with an analytical sensitivity of ten copies of viral cDNA per reaction [165]. Conventional qualitative RT-PCR assays that detect all genogroups of human sapoviruses have also been developed [166]. Nested RT-PCR assays that claim to be more sensitive than conventional PCR that detect and differentiate all genogroups of human sapovirus have been reported using primers against the RNA-dependent RNA polymerase region [167] or the capsid-protein coding region [168]. Molecular assays using various protocols and primer sets to detect noroviruses have been similarly described. Only a small region of approximately 50 base pairs at the polymerase (ORF-1)/capsid (ORF2) junction of the norovirus genome appears to be sufficiently conserved to detect all within-genogroup variants [169–171]. Additional assays have been published that use multiple primers in a multiplex format to amplify the capsid region of the respective viral targets to simultaneously detect norovirus genogroups I and II, sapoviruses, and astroviruses [172].

The public health laboratories in all 50 states of the US, are able to test for norovirus RNA by RT-PCR in stool and emesis specimens, as well as environmental samples. The public health laboratories sponsor CaliciNet, a national network that tracks the different sequences of norovirus strains found in clinical and environmental samples to aid in assessment of relationships between strains in epidemiologic investigations and provide identification of emerging strains.

Several CE-marked molecular tests are available in Europe for the specific detection of Norovirus genogroups I and II in stool samples, including the MutaPLEX® Norovirus real-time RT-PCR kit (Immundiagnostik AG, Bensheim, Germany), the RealStar® Norovirus RT-PCR kit (Altona Diagnostics, Hamburg, Germany), the AmpliSens® *Norovirus* genotypes 1, 2-EPh PCR kit (Ecoli s.r.o., Slovak Republic), the SmartNorovirus (Cepheid, Maurens–Scopont, France) and the Xpert® Norovirus (Cepheid, Sunnyvale, CA). The xTAG GPP gastrointestinal pathogen panel test kit (Luminex Corp., Austin, TX and Milan, Italy) is a qualitative multiplex molecular test that uses the Luminex xTAG® Technology and the xMAP® Technology platform to simultaneously detect the most clinically important bacterial, viral, and parasitic gastrointestinal pathogens, including Norovirus types I and II from a single specimen. The xTAG GPP panel is US FDA-cleared for use in clinical laboratories in the USA and also has regulatory approval in Europe and Canada. The BioFire GI Panel (bioMerieux, Durham, NC) fully automated GI panel also includes detection of Norovirus genogroups I and II as well as sapoviruses.

Interpretation of Results

The increased sensitivity afforded by RT-PCR may make interpretation of results confusing, especially during the management of outbreaks. Norovirus can be detected in stool samples before symptoms occur and continue to be detected for a few days to several weeks after symptoms resolve.

Laboratory Issues

Ideally, diagnostic RT-PCR tests would be able to detect and distinguish the clinically significant genera of human caliciviruses. False-negative results may occur due to the sequence diversity of newly emergent variants which existing primer pairs may not detect. Identification of the specific genogroup is helpful for epidemiologic investigations but is probably not necessary in clinical laboratories. Norovirus is most easily detected in stool specimens obtained during the acute phase of illness (48–72 h after the onset of symptoms) when large numbers of virus are present. Norovirus RNA also has been reported in human serum [173] and in CSF [174].

Quantified, synthetic Norovirus GI and GII RNA standards are available from ATCC (Manassas, VA). The NATtrol™ (ZeptoMetrix Corp., Buffalo, NY) verification set contains reference material for noroviruses and sapoviruses in addition to a variety of bacteria and parasites.

The Gastrointestinal Panel for Molecular Multiplex Testing (GIP), as well as the Stool Pathogens (SP) survey, both from the College of American Pathologists, have Norovirus GI/GII as analytes on the panel, but do not currently include sapoviruses.

Parasitic Pathogens

Protozoa and helminth parasites can infest the gastrointestinal tract and are typically shed in the stool. Parasitic infections are prevalent in Central and South America, Africa, and Asia but are much less common in Australia, Canada, Europe, Japan, New Zealand, and the USA. In developed countries, parasitic infections are most frequently encountered among immigrants and travelers returning from endemic regions and occasionally among individuals who have not traveled, particularly those with AIDS or other causes of immunodeficiency.

Description of Pathogens

Many intestinal parasites may need to be considered in the differential diagnosis of gastrointestinal disease depending on the geographic area visited, specific history of exposure, and individual risk. The most common pathogenic protozoan parasites in developed countries are *Giardia lamblia* and *Cryptosporidium hominis*/*C. parvum* and are seen in travelers returning from endemic areas. *Entamoeba histolytica* is a much less common cause of gastrointestinal illness but early diagnosis is important because of the potential to cause dysentery and invasive extraintestinal disease. Many other intestinal parasites such as *Enterobius vermicularis*, *Cyclospora* sp., *Ascaris* sp., *Cystoisospora* sp., microsporidia, *Trichuris* sp., hookworms, *Strongyloides* sp., tapeworms, flukes, and others are associated with acute and chronic illness in the USA, particularly in socioeconomically poor areas and among immunocompromised individuals. Surveillance using molecular assays is causing reconsideration of the role of some parasites such as *Blastocystis hominis*, *Dientamoeba fragilis*, *Entamoeba coli*, and *E. hartmanii* that were previously considered to be associated with harmless asymptomatic infection but are now thought to have the potential to cause symptomatic illness [175].

Clinical Utility of Testing

Gastrointestinal parasitic infections are not common but cause significant morbidity and mortality, particularly in developing countries and in individuals who are immunocompromised or have other underlying medical conditions. Diagnosis of parasitic disease often is delayed when patients present with vague gastrointestinal symptoms or because of the inability of existing diagnostic methods to detect the causative organism when there is irregular morphology, a low parasite load, or intermittent shedding. When diagnosis is delayed, patients are more likely to have developed more severe symptoms at the time of diagnosis. Delayed diagnosis also allows for increased opportunity to spread infection to others. Prompt diagnosis permits initiation of effective treatment and implementation of infection control measures.

Available Assays

Clinical laboratory detection is routinely performed by microscopic examination of stool specimens using wet mounts and permanent stained slides. Because there is marked fluctuation in the shedding of parasites from day to day, the diagnostic yield of examining a single stool specimen is low (50–60 %); therefore, to improve sensitivity, a total of three stool specimens should be collected every other day or at least on separate days within a period of no more than 10 days [176]. Some parasitic enteropathogens (i.e., *Cyclospora*, *Cystoisospora*, and microsporidia) are difficult to detect in stool and require the use of special stains.

The specificity of microscopic examination is theoretically perfect, but depends on the skill of the microscopist. The sensitivity of microscopic examination also depends largely on the skill of the microscopist and can be low for some parasitic diseases. Concentration techniques are used routinely and improve sensitivity. Since microscopy is very labor-intensive, US FDA-approved immunoassays are available for detecting *Entamoeba histolytica*, *Giardia*, or *Cryptosporidium* antigens in stool, and numerous studies confirm that antigen immunoassays are more sensitive than microscopic examination [177]. Antigen immunoassays have added benefits of being rapid and are technically simple to perform. The sensitivity of microscopy and immunoassay examinations for ova and parasites is low enough that empiric treatment is often given when clinical suspicion is high but tests are negative. Use of X-ray contrast material, laxatives, antacids, or antibiotics (especially tetracyclines and metronidazole), and various other substances can interfere with detection of parasites and delay the diagnosis by as much as several weeks. Due to the nature of the infection, sigmoidoscopy or colonoscopy to obtain duodenal aspirates or biopsy specimens may be necessary for detection of some parasites such as *Cryptosporidium*, microsporidia, or *Giardia*. Even these invasive methods of testing can give false-negative results due the patchy nature of organism distribution in the gastrointestinal tract.

Molecular tools similar to those used for other pathogens are increasingly being used to study parasite polymorphisms and the epidemiology of parasitic diseases. Molecular tests are slowly entering the diagnostic arena and may become more commonly used when US FDA-approved or -cleared tests become available. Current non-molecular diagnostic processes for detection of gastrointestinal parasites can be slow and confusing, while molecular tests have the potential to greatly facilitate diagnosis.

Commercially developed laboratory tests beyond microscopy have been limited to a few well-recognized parasitic pathogens. Individual assays using PCR amplification of parasite DNA sequences extracted from stool or biopsy specimens have been developed for a number of specific

gastrointestinal parasites, but are largely research tools and are not commercially available. Molecular detection of *Cryptosporidium* sp., *Cyclospora cayetanensis*, *Giardia lamblia*, microsporidia, *Entamoeba histolytica*, and *E. dispar* is performed at the Centers for Disease Control and Prevention and may be available at some public health or other reference laboratories.

Multiplex tests are more practical for routine clinical laboratory use and assays for various combinations of parasitic targets have been described in the literature for successful detection of the target organisms in diarrheal stool specimens. The US FDA-cleared xTAG® Gastrointestinal Pathogen Panel (xTAG GPP, Luminex Corporation, Austin, TX) contains primers for the amplification of *Giardia* and *Cryptosporidium* along with other nonparasitic gastrointestinal pathogens. The version of the test marked for diagnostic use in Canada and Europe also detects *Entamoeba histolytica*. The US FDA-cleared BioFire FilmArray™ (bioMerieux, Durham, NC) Gastrointestinal (GI) Panel includes detection of *Cryptosporidium*, *Cyclospora cayetanensis*, *Entamoeba histolytica*, and *Giardia lamblia* in addition to bacterial and viral gastrointestinal pathogens.

Interpretation of Results

In most cases, positive molecular test results in symptomatic patients will correlate with disease. Whereas microscopic examination requires the presence of whole intact parasite for visualization, PCR can only detect the presence of the parasite DNA and cannot distinguish between live, damaged, or dead organisms. Also, the length of time that parasite DNA can be detected after clearance of the organism from the body has not been studied for gastrointestinal parasites, and the possibility that positive results obtained by PCR analysis might be due to lingering parasite DNA may need to be considered, depending on the clinical situation. In addition, asymptomatic carriage is common and must be considered when drawing conclusions about positive results if molecular tests are being used for screening purposes, such as for travelers returning from endemic regions or foreign adopted children.

Laboratory Issues

Stool specimens submitted for microscopic ova and parasite examination are generally placed in preservatives to stabilize parasite morphology and prevent further development of certain helminth eggs and larvae. Preservatives can interfere with PCR-based tests since they act by producing cross-links between nucleic acids and proteins which can obstruct DNA extraction and block PCR amplification. Preservatives also have the potential to cause fragmentation of nucleic acids which could interfere with target amplification. Specimens for molecular tests must be collected without preservatives and kept refrigerated or frozen prior to testing.

Microscopic examination is the most comprehensive method for detection of parasites and has the advantage of allowing detection of any parasite that might be present. Molecular tests are more sensitive but are not developed to the point where microscopy will be completely replaced by PCR. The introduction of real-time PCR assays, especially those that combine several targets into multiplex assays, offers the possibility of using DNA-based detection techniques as a component of a diagnostic approach. However, one of the constraints of multiplex assays is the restriction in the number of parasitic targets that can be detected simultaneously. Additional pathogenic parasites that are not targeted in the molecular assays will still need to be tested for by traditional microscopy or antigen detection methods.

Native genomic DNA and/or whole organisms for culture are available for *Giardia*, *Cryptosporidium* and *Entamoeba histolytica* from ATCC (Manassas, VA) and BEI Resources (Manassas, VA). The NATtrol™ (ZeptoMetrix Corp, Buffalo, NY) verification set contains those same protozoan analytes and also includes *Cyclospora*. Challenges for the molecular detection of *Giardia* and *Cryptosporidium* are available as part of the GIP proficiency survey from the College of American Pathologists.

Future Directions

Since the methods used for pathogen discovery have dramatically improved, emerging gastrointestinal pathogens, such as parechoviruses [178], as well as variants of known pathogens are being recognized at a rapid rate. The rapidly changing catalogue of clinically relevant gastrointestinal pathogens makes development of US FDA-approved/cleared tests difficult.

Clinical laboratories may have difficulty determining when to bring a molecular test into the laboratory. Higher cost is sometimes a deterrent but other considerations are whether a laboratory diagnosis would change patient management, improve outcomes, improve workflow, and/or lower associated healthcare costs. Sometimes molecular tests are so far superior to existing diagnostic tests that the issue is not whether a clinical laboratory can afford to offer a molecular test, but rather whether the laboratory can afford not to when the total cost of healthcare is considered.

Sexually Transmitted Diseases

51

Jeanne A. Jordan

Abstract

Sexually transmitted infections are a major public health problem. The Centers for Disease Control and Prevention estimates over 20 million new infections occur each year in the USA alone, resulting in medical costs of $16 billion. Successful screening programs and accurate assays are therefore key to identifying infected individuals so that treatment and partner notification can be conducted to prevent the further spread of STIs. This chapter on STIs focuses on four of the most prevalent infections: *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Trichomonas vaginalis*, and human papillomavirus.

Keywords

Sexually transmitted diseases • *Chlamydia trachomatis* • *Neisseria gonorrhoeae* • *Trichomonas vaginalis* • Human papillomavirus • Clinical molecular testing • Nucleic acid amplification testing

Introduction

Sexually transmitted infections (STIs) are a major public health problem. The Centers for Disease Control and Prevention (CDC) estimates over 20 million new infections occur each year in the USA alone, resulting in medical costs of $16 billion. Successful screening programs and accurate assays are therefore key to identifying infected individuals so that treatment and partner notification can be conducted to prevent the further spread of STIs. This chapter on STIs will focuses on four of the most prevalent infections: *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Trichomonas vaginalis*, and human papillomavirus.

C. trachomatis and *N. gonorrhoeae*

C. trachomatis (CT) and *N. gonorrhoeae* (NG; also abbreviated GC for gonococcus) are presented together, not because of their similarities in disease presentation, but because of the current trend in screening samples for both simultaneously. Historically, these organisms were identified using very different laboratory methods: CT by tissue culture and NG by growth on specialized bacterial medium. However, today these two STIs are primarily diagnosed using nucleic acid amplification testing (NAT), the focus of this chapter, rather than by culture or immunoassay.

C. trachomatis

Description of the Organism

C. trachomatis is a gram-negative, obligate intracellular bacterium of global public health significance. Infection with CT is associated with three different disease presentations: (1) trachoma, an infection of the eye, which if left untreated causes irreversible blindness (associated with infections of

D.G.B. Leonard (ed.), *Molecular Pathology in Clinical Practice*, DOI 10.1007/978-3-319-19674-9_51

CT serovars A, B, B1, and C); (2) genital infections in both women and men, which can cause serious complications in both sexes (associated with serovars D-K); and (3) lymphogranuloma venereum (LV), also considered an STI, which if untreated can lead to enlargement and ulceration of the external genitalia as well as lymphatic obstruction (associated with serovars L1, L2, and L3) [1]. This chapter focuses on the diagnosis of those serovars causing genital infections.

Clinical Utility

Worldwide, genital CT causes more cases of STI than any other bacterial pathogen, and as such, represents a major reproductive health problem. The World Health Organization (WHO) estimates that annually there are 89 million new cases of genital CT globally, with more than 4 million cases occurring annually in North America alone. In 2010, the CDC reported regional positivity rates in US women ≤25 year old being tested in family planning clinics that ranged from 5.5 to 11.3 %. In that same 2010 report, the rate of CT infection in US women was 610.6 per 100,000 [2].

In the USA alone, the CDC estimates that there were over 1.3 million new cases of CT in 2010. The population most affected by these STIs is young women ≤25 years of age. However, rates of CT and/or NG infection are also on the rise in men who have sex with men (MSM). In the MSM population, the infection can present in genital, anal, and/or pharyngeal sites, and as such non-urine based samples must be considered if infections are to be detected and treated.

CT is a major cause of secondary infertility in females, due to its association with cervicitis, endometritis, and urethritis, which can lead to scarring of the affected tissues. Between 10–40 % of CT infections in females will result in pelvic inflammatory disease (PID), with sequelae including ectopic pregnancy, tubal factor infertility, and chronic pelvic pain [3]. The risk of developing any one of these sequelae increases with the number of PID episodes that an individual experiences. Additionally, pregnant women infected with CT are at risk of transmitting the infection to their newborn infants resulting in newborn conjunctivitis or pneumonia. In males, genital CT infection is associated with nongonococcal urethritis (NGU), epididymitis, prostatitis, proctitis, and Reiter syndrome [1, 4]. Reiter syndrome is an inflammatory disease usually following an infection and affecting the joints, urinary tract, and eyes, as well as ulceration of the skin and mouth.

The individuals at greatest risk of genital CT infections are adolescents and young adults, ages 15–24 years, which is similar to the age of prevalence for human papillomavirus (HPV). Intervention based on selective screening for genital CT infection has reduced its prevalence, as well as the incidence of PID and ectopic pregnancy. These improved outcomes have occurred with the implementation of NAT, use of less-invasive and better-tolerated collection techniques, and development of transport systems that stabilize nucleic acid. Molecular testing for STIs is an advantageous approach, especially in the high-prevalence or high-risk patient populations.

CT infections commonly are asymptomatic in both women and men, with up to 70 % of infected females and 50 % of infected males lacking symptoms. This results in a significant number of individuals not seeking treatment, further transmitting the infection, and at risk of developing complications from the infection. Mass screening programs in Europe have led to a significant reduction in CT prevalence. However, to be successful, these programs must be practical and acceptable to the targeted patient populations. Acceptable screening programs include using self-collected vaginal specimens or first-void urines that can be stably shipped at ambient temperatures. This strategy has the advantage of limiting the number of physician office visits for individuals, thereby increasing compliance.

Urine samples are recommended when screening men for CT. However, other sites including rectal and pharyngeal screening also should be obtained if there is a history of anal and/or oral sex practices. The CDC recommends NAT for CT screening of all non-genital sites. Because this practice may be off-label use of an FDA-cleared test, the laboratory is responsible for validation of the test performance with non-genital site specimens prior to clinical use.

N. gonorrhoeae

Description of the Organism

N. gonorrhoeae (NG) is a gram-negative, oxidase-positive, intracellular diplococcus. Microscopically, the microorganism has a characteristic kidney or coffee bean appearance.

NG is a fastidious organism, being highly susceptible to temperature extremes and desiccation, which results in less-than-satisfactory isolation by culture, especially when off-site specimen transportation is required before culture [5].

Clinical Utility

The fastidious nature of NG has led to a transition from culture toward molecular testing [6]. Interestingly, experiences with NG testing have led some investigators to conclude that NAT for NG does not appreciably increase the number of positive specimens compared to culture methods, if optimal transport conditions have been maintained. However, NAT allows for the use of alternative, less-invasive specimens such as urine and self-collected vaginal swabs for NG detection. This strategy avoids the need to collect urethral or endocervical specimens, which should increase compliance for testing.

Like CT, the incidence of NG is highest among adults < 25 years of age. NG remains second only to CT infection in the number of bacterial cases of a reportable STI. Worldwide, approximately 62 million new cases of NG occur annually. In the USA in 2010, there were 100.8 cases of NG per 100,000 population, with an overall 309,341 cases reported to the CDC [2]. NG-associated urogenital tract infections, as for CT, can be silent and lack symptoms altogether, or the infection can present with mild-to-severe symptoms. In men, symptoms include acute urethritis and discharge, which if left untreated can lead to the following complications: epididymitis, prostatitis, or urethral strictures. In women infected with NG, symptoms can include endocervical inflammation and discharge, which if not treated can lead to abscess formation, salpingitis, or PID. In women, complications of NG infection include risk of infertility and ectopic pregnancy. Disseminated NG infection, although uncommon (approximately 1 % of cases), usually has a poor outcome, which includes bacteremia, skin rash, and asymmetrical septic polyarthritis. Over time, NG has developed resistance to antibiotics, including fluoroquinolone [7, 8], leaving the cephalosporins as the only class of recommended antibiotics remaining for treatment of NG infections.

Available Tests

Prior to the introduction of molecular testing, CT and NG were detected from clinical specimens primarily by culture. For CT, more rapid tests were developed to facilitate shorter turnaround times and included enzyme immunoassays (EIA) to detect either the lipopolysaccharide or major outer membrane protein antigen and direct fluorescence assays that used genus-specific or species-specific monoclonal antibodies [1]. For NG, direct gram stain and culture have been used routinely. Guidelines for CT and NG screening now include molecular testing as a recommended test method [2].

More molecular test platforms have been cleared by the US Food and Drug Administration (FDA) for detecting CT and/or NG than for any other infectious pathogen. These platforms include both non-amplified (e.g., the PACE DNA probe assay, Gen-Probe, San Diego, CA) and amplified testing methods. The non-amplified probe-based assays are not discussed further in this chapter.

The popularity of using NAT for CT and NG can be partially explained by market pressures; the sheer volume of STI testing performed annually drives commercial interests. In addition, a wide variety of validated specimen types have been approved for use with these testing platforms, both in symptomatic individuals and in asymptomatic individuals, which helps to facilitate compliance in high-risk groups for this ever-growing public health concern.

Table 51.1 lists seven FDA-cleared NAT platforms for CT and NG; four use target amplification and one uses signal amplification methods. The table summarizes the test methods, purification strategies, amplification and detection schemes, and types of contamination controls and internal amplification controls included in the test kit. The sample preparation protocols vary widely for these kits and range from using crude cell lysates to purified nucleic acid for testing. The different sample types used and the extent of sample purification affect the rates of inhibition and thus the need to include an internal amplification control.

Interpretation of Test Results

Tables 51.2, 51.3, 51.4, 51.5, 51.6, 51.7, and 51.8 describe in detail NAT platforms for CT and NG, including the genes targeted, the recommended clinical specimens, optimal specimen transport and storage conditions, specimen processing requirements, test interpretations, workflow issues, and other features of these test methods. Many investigators have published performance data using these platforms [9–22].

Laboratory Issues

Recommended Specimens for Testing

The recommended specimen types for NAT testing for CT/NG include vaginal swabs from women and urine specimens from men; both specimens are collected non-invasively, which improves testing acceptability in the at-risk populations [2].

Inhibitors and Internal Controls

Amplification inhibition is common for urogenital specimens, with consequent negative effects on test results [23]. The percentage of specimens containing amplification inhibitors ranges from 1 – 5 % for urines and as much as 20 % for cervical swabs. Initial studies found that inhibition could be reduced or eliminated if specimens were first refrigerated overnight or frozen and thawed before testing, pointing to the labile nature of some inhibitors. However, other inhibitors are quite stable and thus more difficult to neutralize. Many of the commercially available platforms include an internal control (IC) to identify specimens containing inhibitors. Testing algorithms state that when the internal control fails, the results of a specimen without detectable CT and/or NG cannot be reported as negative due to the likelihood that amplification inhibitors are present in the specimen.

Table 51.1 Characteristics of selected NAT platforms for *Chlamydia trachomatis* and *Neisseria gonorrhoeae*

Manufacturer	Assay method	Sample preparation	Amplification strategy	Detection strategy	Contamination controls	IC
Becton Dickinson	SDA	DNA extraction via para-magnetic particle technology	Target	Fluorescence	Closed System	Yes
					Routine environmental monitoring suggested for detecting contamination	
					Clean area using fresh 1 % (v/v) sodium hypochlorite, DNA AWAY, or 3 % (w/v) hydrogen peroxide	
Qiagen	Digene HC2	Hybrid capture from crude cell lysate	Signal	Chemiluminescence	Clean wash apparatus and tubing with 0.5 % sodium hypochlorite solution to prevent contamination from alkaline phosphatase. Check wash buffer and Reagent 2 for contamination	No
Hologic Gen-Probe	TMA and DKA	Target capture from crude cell lysate	Target	Chemiluminescence	Separate the various working areas; use unidirectional work-flow; decontaminate surfaces and pipettors with 2.5–3.5 % sodium hypochlorite; establish intervals for contamination monitoring	No
Roche Diagnostics	PCR	Crude cell lysate	Target	Colorimetric	AmpErase enzyme pre-amplification treatment to destroy previously generated amplicons; dUTP incorporation during amplification; unidirectional workflow; clean area using 0.5 % sodium hypochlorite	Yes
Roche Diagnostics	PCR	DNA extraction via magnetic glass particles	Target	Fluorescence	AmpErase enzyme pre-amplification treatment to destroy previously generated amplicons; dUTP incorporation during real-time PCR amplification	Yes
Abbott	PCR	DNA extraction via magnetic particle extraction technology on m2000sp	Target	Fluorescence	Routine environmental monitoring suggested for detecting contamination, if detected use 0.1 % v/v sodium hypochlorite followed by 70 % ethanol	Yes
Cepheid	PCR	DNA extraction performed within cartridge across a glass fiber affinity column	Target	Fluorescence	Individual, self-contained cartridges minimize cross-contamination	Yes

DKA dual kinetic assay, *HC2* hybrid capture 2, *IC* internal control, *NASBA* nucleic acid sequence-based amplification, *NAT* nucleic acid amplification testing, *PCR* polymerase chain reaction, *SDA* strand displacement amplification, *TMA* transcription-mediated amplification

Table 51.2 BectonDickinson ProbeTec™ ET CT/NG SDA assays run on viper system with XTR technology: parameters and test interpretation for CT/NG detection

Target	CT: Cryptic plasmid	
	NG: PivNg gene	
Specimens	Female and male urine	
	Endocervical, vaginal, and male urethral swabs	
	Endocervical liquid-based cytology	
Specimen handling	Urines: if collected unpreserved, store at 2–8 °C and process within 7 days of collection. If transferred to Q^X UPT within 8 h of collection, store at 2–30 °C and process within 30 days.	
	Endocervical swabs and male urethral swabs: transport swabs at 2–30 °C and process within 30 days.	
	Dry vaginal swabs: transport at 2–30 °C and process within 14 days of collection.	
	Vaginal swabs expressed in Q^X swab diluent: transport at 2–30 °C and process within 30 days.	
	Liquid based cytology specimens: transport and stored in original vials for up to 30 days at 2–30 °C.	
Test interpretation	CT/NG Q^X MaxRFU	Interpretation
CT/NG Q^X Pos control	≥125	QC Pass
CT/NG Q^X Pos control	<125	QC Fail
CT/NG Q^X Neg control	<125	QC Pass
CT/NG Q^X Neg control	≥125	QC Fail
CT/NG test result	≥125	CT Pos
CT/NG test result	<125	CT Neg
Other features	Positive control tubes contain approximately 2,400 copies each of pCTB4 and pNGint3 linearized plasmids. If the CT-specific signal is ≥125 MaxRFU then the extraction control value is ignored, but if it is <125 MaxRFU then the extraction control value is utilized by the algorithm for test result interpretation.	
Issues	Two *N. cinerea* and 2 *N. lactamica* strains cross-react in the NG Q^X assay. Blood in swab-based specimens exceeding 60 % may cause extraction control failures.	

MaxRFU maximum relative fluorescent units, *Neg* negative, *Pos* positive, *SDA* strand displacement amplification, *CT Chlamydia trachomatis*, *NG Neisseria gonorrhoeae*

Table 51.3 Qiagen HC2 assays (CT/NG dual ID HC2 DNA test, CT ID HC2 DNA test, and NG ID HC2 DNA test): parameters and test interpretation for CT/NG detection

Target	CT: 4 % of genome by CT RNA probe cocktail and 100 % of cryptic plasmid		
	NG: 0.5 % of genome by NG RNA probe cocktail and 100 % of cryptic plasmid		
Specimens	Cervical specimens (cervical brush in Specimen Transport Medium), or female swab specimen collection kit (Dacron swab and Specimen Transport Medium)		
Specimen handling	Cervical brush: Can be held for up to 2 weeks at room temperature and ship unrefrigerated to the laboratory. At the laboratory, specimens can be stored at 2–8 °C if testing is to be completed within 1 week, or stored at −20 °C for up to 3 months.		
	Swabs: Transport swabs at 2–27 °C; process within 4 days.		
Test interpretation	<1.00 RLU	Negative	CT and/or NG not detected
	≥1.00 RLU	Positive	CT and/or NG detected
Workflow issues	Positive results with the CT/NG Dual ID HC2 DNA test require follow up testing of the same specimen with the individual CT ID HC2 DNA Test and the NG ID HC2 DNA Test.		
Other features	Specimens may be tested manually or using the Rapid Capture System instrument for high-volume testing.		
	Cervical brush used with non-pregnant women only. Collect specimens from pregnant women using the HC Female Swab Collection Kit only.		
Issues	Presumptive cross-reactivity to certain other DNA sequences, such as pBR322 or pGEM in high concentration. Cross-reactivity observed with *C. psittaci, N. lactamica, N. meningitis, N. cuniculi*, and *N. mucosa.*		

HC2 hybrid capture 2, *ID* identification, *RLU* relative light units

Table 51.4 Hologic Gen-Probe Aptima Combo 2 assays run on Tigris DTS or panther system (TMA and DKA Technologies): parameters and test interpretation for CT/NG detection

Target	CT: 23S rRNA		
	NG: 16S rRNA		
Specimens	Female and male urine		
	Endocervical, vaginal, and male urethral swab		
	Liquid-based cytology (LBC) samples		
Specimen Handling	Swab-based specimens: transport at 2–30 °C and process within 60 days of collection.		
	Urines: transport urine in APTIMA urine transport tube at 2–30 °C and test within 30 days of collection.		
	LBC samples: once the LBC solution has been transferred to an APTIMA specimen transfer tube, test within 30 days of collection when stored at 2–8 °C or within 14 days when stored at 15–30 °C.		
	Transport all specimen types in the proper collection devices.		
Test interpretation	Signals in relative light units (RLU ×1,000)		
CT Test results	Negative	Equivocal	Positive
CT only	1 to <25	25 to <100	100 to <4,500
CT and NG	1 to <85	85 to <250	250 to <4,500
CT indeterminate	1 to <85	85 to <4,500	NA
NG test results	Negative	Equivocal	Positive
NG only	1 to <60	60 to <150	150 to <4,500
NG and CT	1 to <85	85 to <250	250 to <4,500
NG indeterminate	1 to <85	85 to <4,500	NA
Workflow issues	Simultaneous amplification and detection of CT and NG via differences in kinetic profiles of the probes; CT signal has rapid "flasher" kinetics, while NG signal has slower "glower" kinetics.		
	DTS options include manual assay or Tecan-assisted assay, or use of the TIGRIS DTS System.		
Other features	No known cross-reactivity with nongonococcal *Neisseria species*.		
Issues	Assay was not evaluated in low CT prevalence populations. Performance of vaginal swab specimens has not been evaluated in pregnant women or in women <16 years of age.		

CT Chlamydia trachomatis, *DKA* dual kinetic assay, *DTS* direct tube sampling, *LBC* liquid-based cytology, *NA* not applicable, *NG Neisseria gonorrhoeae*, *RLU* relative light units, *TMA* transcription-mediated amplification

False-negative NAT results

A new strain of *C. trachomatis* containing a 377 base pair deletion within its cryptic plasmid was described [24]. The deletion was found to be located within the target sequence of the Roche Cobas assay, resulting in false-negative results for this CT strain [24]. This would impact the epidemiologic surveillance data in areas where this strain circulated. Once identified, several manufacturers, including Roche, altered the design of their NAT, incorporating dual targets for CT detection.

Cross-Reactivity with Nongonococcal Neisseria Species and False-Positive Results

The specificity for some NAT platforms is problematic due to cross-reactivity with certain nongonococcal species of Neisseria [21, 25, 26]. This problem was thought to arise from the intraspecies and interspecies genetic recombination that occurs between Neisseria species, which can result in false-positive NAT results with certain of the commensal Neisseria species [19]. Of eight nongonococcal species tested, false-positive results were seen with *N. cinerea* and *N. lactamica* using the BD ProbeTec assay, with *N. subflava* and *N. cinerea* using the Roche Cobas assay, and with *N. lactamica*, *N. meningitis*, *N. cuniculi*, and *N. mucosa* using the Qiagen assay. Since *N. cinerea*, *N. lactamica*, *N. subflava*, and *N. sicca* isolates have been recovered from genital mucosa, genital specimens may result in false-positive results as is also true for pharyngeal specimens. A recent study evaluated the cross-reactivity patterns of six NAT tests designed to detect *N. gonorrhoeae* to nongonococcal strains. The study clearly demonstrated cross-reactivity from all six NATs, with false-positive reactions for the 234 isolates tested ranging from 1–14.1 %. The Cobas amplicor and ProbeTec tests showed the highest number of false-positive results at 14.1 % and 11 %, respectively [21].

Confirmatory Testing

When selecting a testing platform, the prevalence of infection in the population being tested is of significance. The analytical performance of any test is dependent on the prevalence of infection, with the risk of generating false-positive results being inversely related to the prevalence. These issues have fueled the debate over the need for confirmatory testing for positive test results for CT and NG, as both are reportable infections, with the potential for psy-

Table 51.5 Roche Cobas Amplicor CT/NG test and Cobas CT/NG test: parameters and test interpretation for CT/NG detection

Targets	CT: Cryptic plasmid				
	NG: M-Ngo PII (Cytosine DNA methyltransferase)				
Specimens	Female and male urine (CT only)				
	Endocervical and male urethral swabs (CT/NG)				
Specimen handling	Transport swabs and urine at 2–8 °C. Store swabs and urine at: 2–8 °C, process within 7 days of collection; −20 °C, process within 30–60 days of collection.				
Test interpretation					
For CT	IC	A450, A660	CT result	IC result	Interpretation
	Without	<0.2	NA	NA	Negative
		>0.2 to <2.0	NA	NA	Equivocal
		>2.0	NA	NA	Positive
	With	<0.2, ≥0.2	Negative	Positive	CT not detected
		<0.2, <0.2	Negative	Negative	Inhibitory specimen
		>0.2 to <2.0	Equivocal	Any	Equivocal
		≥2.0, Any value	Positive	Any	CT detected
For NG	IC	A450, A660	NG result	IC result	Interpretation
	Without	<0.2, NA	NA	NA	Negative
		≥0.2 to <3.5, NA	NA	NA	Equivocal[a]
		≥3.5, NA	NA	NA	Positive
	With	<0.2, ≥0.2	Negative	Positive	NG not detected
		<0.2, <0.2	Negative	Negative	Inhibition
		≥0.2 to <3.5, 0.2-3.5	Equivocal	Any	Equivocal[a]
		≥3.5, any	Positive	Any	NG detected
Workflow issues	Simultaneous amplification of CT/NG/IC with separate detection reactions.				
Other issues	IC is a plasmid-containing CT primer binding site and randomized internal sequence. The IC test was designed to permit detection of substances interfering with PCR if present at >20 copies/test. Reactions containing substances at lower concentrations may still result in inhibition, but not at detectable levels, and therefore result in a false-negative result for the target.				
	May detect nonpathogenic isolates of *N. subflava* and *N. cinerea*.				

[a]Equivocal result: Another aliquot is to be tested in duplicate and an interpretation made based on the results of at least 2 of 3 results using 2.0 A660 as the cutoff. See packet insert for details

A450 Absorbance 450, *A660* Absorbance 660, *CT Chlamydia trachomatis*, *DTS* direct tube sampling, *IC* internal control, *LBC* liquid-based cytology, *NA* not applicable, *NG Neisseria gonorrhoeae*, *PCR* polymerase chain reaction, *RLU* relative light units

Table 51.6 Roche Cobas 4800 System CT/NG Real-time PCR Test: Parameters and Test Interpretation for CT/NG Detection

Targets	CT: 2 targets used : one cryptic plasmid common to all CT serovars and one chromosomal DNA target in the *ompA* gene
	NG: 2 targets within the highly conserved DR-9 region
Specimens	Females: Self-collected vaginal swab collected in a clinical setting
	Males: urine specimen
Specimen handling	Transport self-collected vaginal swabs and male urine specimens stored in manufacturer's specific collection devices at 2–30 °C, stable for 12 months. Transport neat urine specimen at 2–30 °C, stable for 24 h.
Test interpretation	
CT POS, NG POS	Positive for both CT and NG DNA
CT NEG, NG NEG	Neither CT nor NG DNA was detected
CT POS, NG NEG	Positive for CT, NG DNA not detected
CT POS, NG invalid	Positive for CT, retest original specimen for NG
CT NEG, NG POS	CT DNA not detected, positive for NG
CT invalid, NG POS	Retest original specimen for CT, positive for NG
CT invalid, NG NEG	Retest original specimen for CT, NG not detected
CT NEG, NG invalid	CT DNA not detected, retest original specimen for NG
Invalid	Retest original specimen for both CT and NG
Failed	Retest original specimen for both CT and NG
Workflow issues	Batch sizes can either be 24/run or 96/run
Other issues	CT/NG IC consists of 2 recombinant plasmid DNAs one each specific for CT or NG genomic target sequences. The IC is also the sample processing control.
	Visibly bloody or dark brown-appearing vaginal swab samples or urine samples should not be processed. Highly viscous vaginal swab samples should have the swab removed and the sample vortexed before processing.

CT Chlamydia trachomatis, *NEG* negative, *NG Neisseria gonorrhoeae*, *POS* positive

Table 51.7 Abbott real-time CT/NG assay run on the m2000 System: parameters and test interpretation for CT/NG detection

Target	CT: Two DNA probes targeting the cryptic plasmid	
	NG: One DNA probe targeting the Opa gene	
Specimens	From symptomatic individuals: female endocervical swab, clinician-collected vaginal swab, and self-collected vaginal swab; male urethral swab; female and male urine specimen.	
	From asymptomatic individuals: clinician-collected vaginal swab and self-collected vaginal swab; female and male urine specimen.	
Specimen handling	Specimens must be collected using the Multi-Collect Specimens Collection Kit and may be stored and transported at 2–30 °C for up to 14 days. Longer storage requires storage at ≤ −10 °C for up to 90 days.	
Test interpretation	CT samples with no evidence of amplification	Negative for CT
	CT samples with a cycle number ≤ the assay CO	Positive for CT
	CT samples with a cycle number > than the assay CO	Equivocal for CT
	NG samples with no evidence of amplification, or with a cycle number > than the assay CO	Negative for NG
	NG samples with a cycle number ≤ to the assay CO	Positive for NG
Workflow issues	A sample with an initial interpretation of "Equivocal" for CT must be retested. An "Equivocal" interpretation does not apply to NG samples.	
Other features	The second set of CT-specific primers recognizes the new variant of CT (nvCT) [24]. The NG primers used do not cross-react with non-NG strains of Neisseria. The Abbott RealTime CT/NG assay will not detect plasmid-free *C. trachomatis* variants. Treatment success or failure should not be determined using this test. A negative result does not exclude the possibility of an infection, as results are dependent upon sample adequacy and absence of inhibitors.	

CO cutoff, *CT Chlamydia trachomatis*, *NG Neisseria gonorrhoeae*

Table 51.8 Cepheid Xpert real-time CT/NG assay

Target	CT: One chromosomal sequence	
	NG: Two chromosomal sequences	
Specimens	Symptomatic and asymptomatic females: first catch urine specimen, endocervical swab, self-collected vaginal swab collected in clinical setting.	
	Symptomatic and asymptomatic males: first catch urine specimen.	
Specimen Handling	Specimens must be collected in the specific manufacturer's transport devices	
	Swabs can be transported at 2–30 °C and are stable for up to 60 days at that temperature range	
	Urine specimen can be transported at 2–15 °C and are stable for up to 45 days, or transported at 2–30 °C and are stable for up to 3 days	
Test interpretation	CT detected; NG detected	Positive for CT1, NG2, and NG4 targets
	CT detected; NG not detected	Positive for CT1 target, Negative for NG2 and/or NG4 targets
	CT not detected; NG detected	Positive for NG2 and NG4 targets, Negative for CT1 target
	CT and NG not detected	Negative for CT1, and NG2 or NG4 targets
	Invalid	Sample adequacy control and/or sample processing control failed
	Error	Probe check control failed
	No result	Insufficient data collected
Other features	Built-in controls within each cartridge include a sample processing control, sample adequacy control and a probe check control.	
Workflow issues	Extraction, amplification and detection all occur within the cartridge.	

CT Chlamydia trachomatis, *NG Neisseria gonorrhoeae*

chosocial and/or medicolegal consequences for a false-positive or a true-positive result [27]. The newest 2010 CDC Guidelines for STI testing do not contain language recommending routine repeat testing of initial positive results [2]. NAT testing for CT/NG is the preferred diagnostic method of choice in evaluating adults and adolescents as victims of sexual assault [2].

Contamination Controls

The advent of NAT, with its exquisite sensitivity, has given birth to a whole new mind-set for cleanliness in the molecular testing laboratory. No longer is disinfection of the benchtop after a day's work adequate. New standards strive to remove or prevent amplicon contamination in the laboratory environment. Strategies includes daily cleaning of labora-

tory surfaces with a dilute bleach solution, and frequently replacing disposable gloves and gowns while working in the pre- and post-amplification area(s). Create and enforce a regular schedule for performing wipe testing to monitor for amplicon contamination. For many of the current NAT platforms, pre- and post-amplification steps should be performed, if possible, in separate rooms with positive and negative airflow, respectively. Alternatively, contamination can be greatly reduced when using a fully automated, closed real-time NAT system that incorporates sample preparation, nucleic acid amplification, and detection in a single closed reaction.

Validating Off-Label Use of CT/NG Tests

In at-risk populations, it is important to be able to detect rectal and/or oropharyngeal CT/NG infections using a NAT platform. To date, manufacturers of NAT tests for CT/NG have not included rectal and/or oropharyngeal specimens in their evaluations or clinical trials. Therefore, these applications are not described in the manufacturer's packet insert and must be validated by individual laboratories.

Future Directions

Continued Use of Self-Collected, Noninvasive Specimen Types

Reaching high-risk populations for STI screening will improve with policies that emphasize the use of noninvasively collected specimens, including self-collected vaginal swabs and first-void urine specimen [28]. This is especially true when attempting to reach the young adult patient population, age range from 14 – 24 years, where the prevalence of CT and NG infections is highest and the willingness to undergo a pelvic examination or urethral swab collection is lowest.

Liquid-Based Cytology Cervical Specimens for CT/NG NAT Testing

Testing for STIs using Pap smear specimens has become more common but only after critical issues were addressed that enabled liquid-based cytology samples to be used for STI testing [14]. One of the most important solutions developed was the concept of using a "pre-aliquot," prior to handling of the specimen in cytology, which solved the issue of cross-contamination from other specimens, as well as the ethical issue of waiting to perform the infectious disease testing until after the cytology screening is completed. Successful implementation of this strategy was not easy and required dialogue and cooperation between laboratories, pathologists, manufacturers, and regulatory bodies.

Antibiotic Resistance Testing Using NAT for Cephalosporin-Resistant *N. gonorrhoeae*

Resistance to penicillin, tetracycline, and fluoroquinolones is now common among *N. gonorrhoeae* isolates [7, 8, 29]. Now emergence of cephalosporin-resistant *N. gonorrhoeae* has been described in several countries around the world. Being able to screen for antimicrobial resistance using a NAT platform would be very useful from a public health perspective.

Trichomonas Vaginalis

Description of the Organism

Trichomonas vaginalis (TV) is a flagellated protozoan and the only species within its genus that can infect squamous epithelial cells of the human urogenital tract [30]. TV infection is considered to be a nonulcerative STI but is associated with severe local inflammation. In women, symptoms may include vulvar irritation and vaginal discharge, which appears frothy, mucopurulent, and yellow-green in color. During a TV infection, the vaginal pH is often abnormally elevated (pH>4.5). Complications of TV infection in untreated women include endometritis, infertility, and cervical erosion. In men infected with TV, symptoms may include profuse purulent urethritis and a form of NGU, with complications including chronic prostatitis, urethral strictures, epididymitis, and/or infertility if the infection is untreated [31, 32].

Clinical Utility

Detection of TV infections in males has received far less attention than these infections in females. However, with the advent of NAT, this understudied infection in men has become more appreciated, and thus research studies have provided important information on its prevalence, clinical symptoms, sequelae, and the most appropriate specimen to collect for proper diagnosis. TV has a greater role in NGU than previously thought [33]. As with diagnosing TV infections in female patients, direct microscopic examination of urethral discharge has poor sensitivity for detecting TV in male patients.

Worldwide, TV infection accounts for approximately 276.4 million cases annually [34], which is greater than the number of cases of *C. trachomatis*, *N. gonorrhoeae*, and syphilis combined. In the USA, the annual incidence of TV infection is estimated to be approximately 8 million cases [2]. However, because TV infection is not a report-

able disease, this number may be an underestimate. Unlike CT and NG, where prevalence is higher in adolescents and young adults, TV is more equally distributed among all age groups.

Detecting TV in an individual is considered by healthcare providers to be a red flag for high-risk sexual behavior and is frequently present along with other STIs in the same individual. Diagnosing TV is difficult, because 50–70 % of all infected individuals are asymptomatic. Without a sensitive assay, infected individuals left untreated continue to act as a reservoir for ongoing disease transmission within the community.

TV infection is associated with two important sequelae: (1) an increased risk of acquiring human immunodeficiency virus (HIV); and (2) an increased risk of perinatal morbidity and mortality [35–38]. HIV transmission is enhanced by the local inflammatory reaction containing CD4-positive T cells within the genital tract that is present with TV infections. In women, TV infection is strongly associated with an abnormal vaginal ecology. Harboring TV may contribute to the change in vaginal flora, which is associated with decreased lactic acid production and subsequent increase in vaginal pH. Lactic acid production and the normally low pH of the genital tract environment help to inactivate HIV. Therefore, a change in the vaginal environment to a less hostile environment promotes an increased survival of HIV. If this hypothesis is correct, then controlling TV infections could lower HIV acquisition.

The increased risk of perinatal morbidity and mortality with TV infection is associated with premature rupture of membranes, preterm delivery, and low-birth-weight infants in pregnant women infected with TV [39]. Although controversial, these associations suggest a need for increased efforts to detect and treat this infection in pregnant women [40].

Screening for TV infection is less common than screening for CT and NG infections; often the practice is limited to public health clinics and obstetrical practices. Successful control of TV infections would be aided greatly by increased screening of high-risk populations, performing contact follow-ups with sexual partners, and using a more sensitive diagnostic assay. Improved detection of TV by using NAT, as is the case for CT, would be predicted to reduce the incidence of TV infection and assist in reducing HIV transmission and possibly even poor pregnancy outcomes [41].

Available Tests

Historically, the most common diagnostic method for TV in urogenital discharge was direct microscopic examination, broth culturing, or both. Direct microscopic examination of genital discharge material on a slide is certainly the most rapid and inexpensive method to use, but lacks adequate sensitivity, which is reported to be approximately 40–70 % [42]. The low level of sensitivity with microscopic examination may be due in part to the rapid loss of the characteristic protozoan motility once the organism is removed from a 37 °C environment. Loss of motility is accompanied by change in morphology; non-motile TV organisms round up and are difficult to differentiate from leukocytes, being similar in size.

Currently, broth culturing is the gold standard for detecting TV [43]. Successful growth in culture can be achieved with as few as 300–500 TV organisms per milliliter of vaginal fluid, but culturing requires 2–7 days of incubation and daily microscopic examination. Culture methods have sensitivities that range between 50 - 80 % but require specialized medium such as Diamond's broth, Tricosel medium, or the In-Pouch system (Biomed Diagnostics, Inc. White City, OR). These specialized media may not be available in the physician's office. In addition, some TV isolates do not grow in culture due to strain requirements, low numbers of organisms, or damaged/nonviable organisms.

These limitations led laboratories to develop NAT for TV DNA using a range of testing platforms, including conventional and real-time NAT assays [44–51]. To date, the most commonly cited NAT tests are laboratory-developed tests (LDTs). Table 51.9 lists the more common targets for LDT TV-specific assays, with the most sensitive assays being those targeting repetitive DNA sequences.

Interpretation of Test Results

Currently, a single FDA-cleared TV NAT test is available, the Hologic Gen-Probe APTIMA Trichomonas vaginalis assay that can be run on both the TIGRIS DTS and the PANTHER System. In 2011, one commercially available TV-specific NAT was FDA cleared. The Aptima *Trichomonas vaginalis* test (developed at Gen-Probe Inc.) detects 16S rRNA using TMA [52–54]. This assay fills a significant void in NAT STI screening algorithms. Tables 51.10 and 51.11 describe the details of this assay including interpretation of the test results.

Table 51.9 Summary of common laboratory-developed tests for *Trichomonas vaginalis* specific targets using NAT

Primer pair [Reference]	DNA target	Amplicon (bp)
TVK3, TVK7 [97]	Repetitive DNA	312
TVK3, TVK4 [97]	Repetitive DNA	350
BTUB2, BTUB9 [98]	Beta Tubulin	112
TV1, TV2 [99]	18S rRNA gene	312
TV-E650 [100]	E650	650
TVA5, TVA6 [99]	Ferredoxin gene	102

NAT nucleic acid testing

If a TV LDT generates a numerical value, then the rationale for establishing the positive and negative cutoff values for the assay as well as possibly an equivocal zone are required. The LDT standard operating procedure must define when to perform repeat testing on the original specimen and when to report a result as indeterminate. If culture-based testing is performed as the "gold standard" test, culture-negative, NAT-positive results for the same specimen must be assessed by an independent method. Lastly, an alternative proficiency testing program is required when external programs are not available.

Laboratory Issues

Before 2011, laboratories wanting to perform TV NAT would need to develop, validate, and implement diagnostic testing, as no commercial test was available. This would include establishing interpretation criteria for an LDT. Several important issues should be addressed when developing and validating a NAT for TV. Validating an LDT should include establishing the limit of detection (LOD), as well as determining the analytical performance characteristics including sensitivity, specificity, and positive and negative predictive values.

Target Selection

For TV NAT LDTs, the primers and probes should be assessed with specimens containing other organisms or specimen spiked with specific organisms similar to TV, which may cross-hybridize and result in a false-positive result. Specifically, other *Trichomonas* species, such as *T. tena*, as well as other organisms that may be present within the urogenital tract specimen, including human genomic DNA, should be tested. The TV-specific primer pairs and probes described in the literature recognize different gene targets that vary in their copy number. In general, choosing a gene target that is present in multiple copies per genome is usually preferable to choosing a single-copy gene target to improve the sensitivity of the test.

Internal Control

Both vaginal swabs and urine specimens can contain significant levels of inhibitors that interfere with the NAT reaction.

Table 51.10 Summary of the APTIMA *Trichomonas vaginalis* assay run on the TIGRIS DTS system

Manufacturer	Assay method	Sample preparation	Amplification strategy	Detection strategy	Contamination controls	IC
Hologic GenProbe	TMA and HPA	Target capture via capture oligomer	16S rRNA Target	Chemiluminescence	Closed System	No
					Routine environmental monitoring suggested for detecting contamination	

DTS direct tube sampling, *HPA* hybridization protection assay, *IC* internal control, *TMA* transcription mediated amplification

Table 51.11 Hologic Gen-Probe APTIMA *Trichomonas vaginalis* assay (target capture, transcription-mediated amplification (TMA) and hybridization protection assay (HPA) technologies): parameters and test interpretation for TV detection

Target	16S ribosomal RNA		
Specimens	Female urine specimen		
	Endocervical or vaginal swab		
	Endocervical sample collected in PreservCyt solution		
Specimen handling	Swab-based specimen: Transport at 2–30 °C and process within 60 days of collection.		
	Urine specimen: Transport urine specimen in APTIMA urine transport tube at 2–30 °C and test within 30 days of collection. Urine specimen still in primary collection containers must be transported to laboratory at 2–30 °C and transferred into the APTIMA urine specimen transport tube within 24 h of collection.		
	LBC samples: Transport and store LBC samples at 2–30 °C for up to 30 days. LBC samples must be transferred into an APTIMA specimen transfer tube, after transfer, specimens may be stored an additional 14 days at 15–30 °C or 30 days at 2–8 °C.		
Test interpretation	Signals in relative light units (RLU ×1,000)		
TV test results	Negative for TV	Positive for TV	Invalid Results
	0 to <100	100 to <2,400	0 or ≥2,400
Other features	DTS options include manual assay, Tecan-assisted assay, or TIGRIS DTS System		
	No cross-reactivity was observed with any of the organisms tested. Sensitivity of the assay to detect *T. vaginalis* at 2.5 TV/ml was negatively affected by the presence of *T. tenax* and *P. hominis*. Assay performance has not been evaluated in the presence of *Dientamoeba fragilis*. Assay has not been validated for use with self-collected vaginal swab samples. Performance of vaginal swab specimens has not been evaluated in pregnant women or in women <14 years of age. Therapeutic success or failure cannot be determined using this assay.		

DTS direct tube sampling, *LBC* liquid-based cytology, *RLU* relative light units, *TV* Trichomonas vaginalis

For interpreting negative results, an IC is important to include in the assay, especially if the input material being tested is a crude cell lysate. More details on inhibitors can be found within the CT and NG section of this chapter.

Specimen Collection

The optimal specimen to collect differs for women and men. For women, the specimen of choice is vaginal discharge collected using a Dacron-tipped, plastic-shaft swab, while for men the sediment from the first-void urine is superior to a urethral swab specimen. For increased analytical sensitivity, only the first 20–30 ml of the first void urine should be collected. Each specimen type to be tested needs to be validated prior to clinical testing. Validating the specific sample processing methods is crucial for ensuring good sensitivity.

Specimen Transport

Trichomonas vaginalis expresses and secretes numerous proteases. For greatest target stability, specimens should be transported at temperatures below room temperature (2–8 °C) or in a specimen transport device that stabilizes the nucleic acid. Each specimen transportation system or device used as well as the specimen storage conditions need to be validated prior to clinical testing.

Future Directions

Multiplex Testing for CT, NG, and TV

Multiplex testing for CT and NG has been available for years. Recently, increased attention has been given to including TV as a target. With the prevalence of TV being greater than that of CT and NG combined in many regions, along with the association of TV infection with increased risk of HIV acquisition, inclusion of TV in a multiplex STI panel is a reasonable idea. Depending on the prevalence of other STIs within a patient population or geographic area, additional targets may be considered applicable for a multiplex STI panel.

Greater Use of Noninvasive Specimens

As with CT and NG detection, collection of first-void urines or self-collected vaginal swab specimens may improve patient compliance for TV testing [28]. This approach may in turn help to identify the asymptomatic, infected individuals and reduce transmission to sexual partners.

Monitoring Trends in Developing Metronidazole Resistance in TV Isolates

Metronidazole and tinidazole are the only recommended drugs for treating individuals infected with TV. Routine testing of TV isolates for antimicrobial drug resistance is not available in most clinical laboratories, but is available through the Centers for Disease Control and Prevention (CDC). Recently, the CDC assessed the prevalence of in vitro drug resistance in six US cities and found low-level resistance to metronidazole in 4.3 % of isolates and no tinidazole resistance [55]. Because of the reliance on a single class of antimicrobial drugs to treat TV infection, the CDC recommends that periodic surveillance for TV drug resistance be carried out and that in vitro, culture-based antimicrobial resistance testing be considered for TV isolates from women having a history of failed treatments [2].

Human Papillomavirus

Description of the Organism

HPVs are small, non-enveloped viruses with a double-stranded, circular DNA (approximately 8 kilobases [kb]) genome and very limited cell tropism. To date, approximately 120 different types of HPV have been identified [56]. HPV can infect and replicate in the nuclei of only certain squamous epithelial cells, which are classified as either cutaneous or mucosal in nature. In general, the cutaneous types of HPV infect keratinizing epithelium, while mucosal types infect non-keratinizing epithelium. This section focuses on the approximately 60 types of anogenital HPV, which can be spread through sexual contact.

Clinical Utility

HPV is one of the most common sexually transmitted infections. More than 5 million new cases are estimated annually in the USA, with more than 20 million men and women currently infected. The prevalence of HPV is highest among sexually active young women ages 15–25 years [2].

The sexually transmitted HPV types can be further classified by their risk of disease progression. Infection with a low-risk HPV is commonly associated with condyloma acuminata or genital warts, and is considered benign or low-risk for progression to malignancy [57, 58]. In contrast, infection with a high-risk HPV can be associated with cervical cancer in women and penile cancer in men [59]. To a lesser extent high-risk HPV has been associated with anal, vulvar, and vaginal cancers (http://apps.who.int/hpvcentre). High-risk (HR) HPV types play a major role in the pathogenesis of epithelial cell cancers of the anogenital tract, due to viral induction of epithelial cell proliferation [60, 61]. Currently, most commercial assays include 14 HR HPV types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, and 68). The first 12 of these 14 HPV types are considered oncogenic, with the latter 2 HPV types along with HPV 26, 53, and 72 being considered possible oncogenic types [57, 58]. The International Agency for Research on Cancer (IARC) designates HR HPV types.

While most men and women infected with anogenital HPV types will not develop cancer, a small subset will; a process that may take decades to occur [62, 63]. Certain cofactors may be important in disease progression as well, including the individual's immune status, certain human leukocyte antigen (HLA) types, smoking, nutritional status, or possibly coinfection with HIV type 1, herpes simplex virus, or CT [64–68]. Women 30 years of age or older who are persistently infected within the cervix with HR HPV are at an increased risk for developing cervical cancer. Thus, HPV acquisition during adolescence may have long-term consequences for health later in adulthood [69, 70].

Most high-grade cervical lesions are caused by persistent infection with one of the HR HPV types, with HPV 16 and HPV 18 being associated with at least 70 % of cases in the USA [71] Based on these findings, the 2009 American Society for Colposcopy and Cervical Pathology (ASCCP) consensus conference approved a strategy that included HPV 16/18 genotyping when managing women ≥ 30 years of age who are positive for HR HPV upon routine screening with negative cytology [72].

Worldwide, cervical cancer is the second most common female cancer, with approximately 529,828 women developing cervical cancer each year [59, 73]. In the USA in 2010, the American Cancer Society estimated that there were approximately 12,200 new cases of cervical cancer and 4,210 deaths [74]. Cervical cancer is a highly preventable disease if detected and treated early. Infection with HR HPV is associated with the appearance of clinical lesions. HPV is considered to be a necessary requirement for invasive cervical cancer [75]. Abnormal cell growth or cervical dysplasia is an early manifestation of HPV infection. The characteristic cellular changes caused by HPV infection can be detected on Pap smear evaluations or in cervical biopsies. The morphologic changes of dysplasia are classified as atypical squamous cells of undetermined significance (ASCUS), low-grade squamous intraepithelial lesion, or high-grade squamous intraepithelial lesion [76, 77].

Annually, approximately 2 million Pap tests performed in the USA are interpreted as an ASCUS-grade result. ASCUS rates typically fall within the range of 5–10 % but can be as high as 20 % in younger women. Current recommendations include reflex testing of Pap specimens for HR HPV with an ASCUS-grade result; patients testing negative for HPV DNA can be followed according to routine practice, while those testing positive for HR HPV should be referred to colposcopy, as progression to high-grade disease is probable [78, 79]. Patients with abnormal Pap smears whose specimens contain HR HPV DNA require close medical follow up [80–83].

In 2009, the Cytopathology and Technology Education Consortium developed a consensus statement that includes wording for the appropriate and inappropriate uses of HPV testing [84]. Laboratory directors of laboratories performing HPV testing should utilize these valuable guidelines. Currently in the USA, most laboratories performing HR HPV testing commonly receive specimens for the following two appropriate indications:

1. As a reflex test when managing women ≥21 years of age with cytologic result of ASCUS.
2. During routine cervical cancer screening for women ≥30 years of age in conjunction with cervical cytology testing.

In general, HR HPV testing during routine screening in women <30 years of age is considered inappropriate, and there is no role for low-risk HPV testing in routine cervical cancer screening or when evaluating women with abnormal cervical cytology.

Available Tests

In 2003, the FDA approved the Digene Hybrid Capture 2 (hc2) assay [85] with indicated uses that included (1) screening specimens from patients with an ASCUS-grade Pap test result to determine the need for colposcopy [78, 83]; and (2) primary screening tool in conjunction with a Pap test for women 30 years and older [81]. Recommended specimen types for this assay include cervical swabs and liquid-based cytology specimens. The recommended collection devices and transport media include cervical brushes and cervical biopsies transported in specimen transport medium, or a cervical broom transported in Cytyc Preserv-Cyt solution.

Since the Digene HC2 test was first approved, several other tests have been approved by the FDA and introduced into the market. These include one additional signal amplification assay for detecting HPV DNA (Cervista HV test from Hologic), and two target amplification assays that detect either DNA (Roche Cobas HPV test) or RNA (GenProbe Aptima HPV test). Tables 51.12, 51.13, 51.14, 51.15, and 51.16 illustrate the chemistries used, and the HR HPV types detected. Most of these molecular HR HPV tests have been evaluated and found to have excellent clinical sensitivities and negative predictive values, but perform less well in terms of clinical specificity and positive predictive value [86–90].

HPV 16/18 Genotyping

Genotyping has increasingly become a recommendation since studies published by the National Cancer Institute described a 20 % risk of progressing to cervical intraepithelial neoplasia level 3 (CIN3) over 10 years in women infected with HPV 16 and/or HPV 18 [72]. Two of the currently available, FDA-approved HPV NATs have the ability to genotype

Table 51.12 Summary of selected NAT platforms for HPV testing

Manufacturer	Assay method	Sample preparation	Amplification strategy	Detection strategy	Contamination control	IC
Qiagen	Hybrid capture 2 technology	Crude cell lysate	DNA target-RNA probe hybridization with signal amplification	Chemiluminescent detection using AP-labeled antibody specific to RNA-DNA hybrids	Wear powder free gloves; do not contaminate Detection Reagent 2; avoid touching pipette tips on any work surfaces	No
Hologic Cervista	Isothermal	DNA extraction	Invader chemistry, Signal amplification	Cleavase based fluorescence	Recommend using ART, clean lab surfaces	Yes
Hologic Gen-Probe	Isothermal	Target capture via magnetic microparticles	Transcription mediated target amplification E6/E7 mRNA	HPA with DNA probes, DKA via chemiluminescence	Use of 2.5–3.5 % sodium hypochlorite to clean surfaces, racks and pipettes, avoid ribonuclease contamination; use good laboratory practices	Yes
Roche	Real-time PCR	DNA extraction via magnetic glass particles	Target amplification	Fluorescent oligonucleotide probes	Uracil-N-glycosylase and dUTP	Yes

AP alkaline phosphatase, *ART* aerosol-resistant pipette tips, *DKA* dual kinetic assay, *FRET* fluorescence resonance energy transfer, *HPA* hybridization protection assay, *IC* internal control, *HPV* human papillamavirus, *NAT* nucleic acid testing

Table 51.13 Roche Cobas HPV assay

Target	Portion of HPV L1 DNA
Specimens	Cervical specimens collected using an endocervical brush/spatula in PreservCyt solution
Specimen handling	Transport and storage at 20–30 °C for up to 6 months
Test interpretation	Positive-cutoff not given; performed by cobas 4800 software Negative-cutoff not given; performed by cobas 4800 software All HPV negative specimens must have a positive beta globin signal to be valid Invalid-cutoff not given; performed by cobas 4800 software Repeat testing necessary if invalid
High-Risk (HR) HPV types included	14 HR types Separate detection of 16 and 18 Combined detection of 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, and 68
Genotyping	Separate detection of HPV types 16 and 18
Workflow issues	33 min hands-on time, 94 tests completed in <300 min. HPV testing should be performed on PreservCyt specimens prior to automated cytology processing
Other features	No cross-reactivity with Low-Risk HPV types and no gray zone

HPV human papillamavirus

HPV 16/18. The Roche assay provides individual data on the presence of HPV 16 and HPV 18 genotypes, while the Cervista HPV assay provides pooled genotyping information for HPV 16/18. Genotyping recommendations have been intended for clinical management of women > 30 years of age who have HR HPV positive/cytology negative results [91, 92]. Genotyping is not meant for screening younger women. However, based on clinical trial data, several groups are now suggesting that HPV 16/18 genotyping could play an important role in women ≥21 years of age with ASCUS [93–95].

Historically, the Roche Linear Array (LA) HPV Genotyping test (Research Use Only) has been used frequently in studies to resolve discordant results from comparator nucleic acid-based HPV tests. This assay detects and differentiates a total of 37 HPV types; 14 HR HPV types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, and 68), and 23 low-risk HPV types (6, 11, 26, 40, 42, 53, 54, 55, 61, 62, 64, 67, 69, 70, 71, 72, 73, 81, 82, 83, 84, IS39, and CP6108). The Roche LA HPV Genotyping test incorporates the PGMY primers, which amplify a smaller region internal to the MY09/11 sequence of the HPV L1 gene for improved detection of HPV DNA in genital samples [96].

Table 51.14 Hologic Cervista HPV HR Test

Target	**DNA, HPV gene not specified**
Specimens	Cervical specimens collected using broom or brush/spatula device and placed in PreservCyt
Specimen handling	20–30 °C for up to 18 weeks
Test interpretation	Positive HR HPV Test FOZ ≥1.525 and HPV 16/18 Genotype FOZ >2.13 Negative FOZ <1.5 Invalid results if: (1) % CV >25 % (2) When all 3 FOZ values <0.7 (3) genomic DNA FOZ of a negative sample <1.5 Uses 3 separate HPV oligonucleotide mixtures, each containing different but related HPV types
High-Risk (HR) HPV types included	14 HR types Pooled 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, and 68
Genotyping	A separate genotyping assay is available for HR HPV 16/18
Workflow issues	129 min hands-on time, 48 test results in ~500 min. Each sample is tested in 3 reaction mixes.
Other features	No cross-reactivity with Low-Risk HPV types HPV HR test shows cross-reactivity with HPV 67 and 70 HPV 16/18 Genotyping test shows cross-reactivity with high levels of HPV 31

HPV human papillamavirus, *HR* high risk, *FOZ* fold over zero

Table 51.15 Hologic Gen-Probe Aptima HPV assay run on Tigris DTS system

Target	**HPV E6/E7 mRNA**	
Specimens	Cervical specimens collected with broom or cytobrush/spatula device and placed in PreservCyt solution	
Specimen handling	PreservCyt specimens should be transported at 2–30 °C, with *no more than* 30 days at temperatures above 8 °C; transfer into Aptima specimen transfer tubes can be stored at 2–30 °C ≤60 days	
Test interpretation	Positive:	Analyte S/CO ≥0.50, IC < 2,000,000 RLU and Analyte ≤ 13,000,000 RLU
	Negative:	Analyte S/CO < 0.50, IC ≥ IC cutoff and IC ≤ 2,000,000 RLU
	Invalid:	Analyte S/CO < 0.50 and IC < IC cutoff OR IC > 2,000,000 RLU OR Analyte > 13,000,000 RLU
HR HPV types Included	14 HR types; 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, and 68	
Genotyping	Not available	
Workflow issues	Automated using Tigris DTS system	
Other features	False-positive results may occur with this test from in vitro transcripts of LR HPV types 26, 67, 70, 82	

DTS direct tube sampling, *HPV* human papillamavirus, *IC* internal control, *RLU* relative light units, *S/CO* signal-to-cutoff

Table 51.16 Qiagen Digene hybrid capture 2 high-risk HPV DNA test

Target	**Whole HPV DNA genome**	
Specimens	Cervical specimens collected using hc2 DNA collection device with STM, or using a broom-type collection device and placed in PreservCyt solution.	
Specimen handling	Cervical brush and STM may be transported and held for up to 2 week at room temperature, with an additional week at 2–8 °C, or for 3 months at −20 °C. Cervical specimens in PreservCyt solution may be transported and stored at 2–30 °C for 3 months.	
Test interpretation	Positive:	RLU/CO ≥1.0
	Negative:	RLU/CO <1.0
	Invalid:	Mean value of the negative control must be <250 RLU with a %CV < 5 % for at least 2 of 3 values PreservCyt samples with RLU/CO value of ≥1.0 and <2.5
HR HPV types included	13 HR types; 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68[a]	
Genotyping	Not available	
Workflow issues	149 min hands-on time, 88 test results in <500 min	
Issues	Cross-reactivity occurs when high levels (≥4 ng/ml) of HPV 6 or 42 are present. False-positive results have been reported with HPV types 11, 40, 53, 54, 66, MM4, MM7, MM8, or MM9, as well as the plasmid pBR322. False-negative results can occur if no cell pellet is visible when processing PreservCyt solution. False-positive results can occur with inadequate denaturation, inadequate washing, or exogenous alkaline phosphatase	

[a]Detection of HPV types 39, 58, 59, and 68 has not been statistically confirmed due to low prevalence of these types in the general population
CO cutoff, *HPV* human papillamavirus, *HR* high risk, *RLU* relative light units, *STM* specimen transport medium

Interpreting the Roche Linear Array HPV Genotyping Test takes into account the PCR results of both the HPV and the internal control beta globin (BG) targets for each test strip being run. As a sensitivity control, the absence of one or both BG results in this assay indicates inadequate sample collection, failure to adequately extract DNA, or presence of inhibitors. A positive HPV result regardless of the BG results is interpreted as having detectable HPV DNA. A negative HPV result in the presence of positive results for both the BG low and high internal controls are interpreted as HPV DNA not detected. HPV test results are considered invalid if the HPV results are negative along with negative BG low and/or BG high results. Note that other HPV genotypes may be present in samples that were not detected because the type-specific primers were not included.

Future Directions

Much research is being conducted in the area of HPV and cancer and new diagnostic assay developments may arise from these findings. Research may lead to the development of newer technologies like quantum dots or superparamagnetic nanoparticle-based testing methods that may allow for easier and less expensive mass epidemiological screening for HR HPV. Because the vast majority of cervical cancers affect women in resource-limited settings, it is important to consider the impact that developing and implementing simple, affordable, and accurate testing for HR-HPV would have globally. Diagnostic tests such as point of care tests may be developed that allow for simple, affordable yet accurate screening of women who now have no access to cervical cancer screening.

Other assays may be developed to look at persistence and/or disease prognosis and may include those to detect HR HPV E6/E7 mRNA or protein expression. Determining the usefulness of measuring HPV viral load also may be considered as a means of predicting risk of disease progression. Further studies on the level of CpG methylation of HR-HPV DNA and/or the association of promoter methylation patterns of tumor suppressor genes linked to cervical cancers may develop into clinically useful tests. A research gap has been identified that could have important prognostic value which is the discovery and characterization of new biomarkers with strong association with cervical dysplasia and progression to cancer.

Evidence also links HR HPV with the development of non-cervical cancers. As such, it would be important to consider initiating studies to validate HR-HPV testing from other specimen types, including other female gynecologic cancers, anal or penile cancers, or oropharyngeal cancers. Lastly, with the increased adoption of HPV vaccination around the world post-vaccine studies will be important for tracking the prevalence of specific HR-HPV types associated with cervical cancer.

Respiratory Infections

52

Christine C. Ginocchio

Abstract

The majority of respiratory tract infections (RTIs) are community acquired and are the single most common cause of physician office visits and among the most common causes of hospitalizations. The morbidity and mortality associated with RTIs are significant and the financial and social burden high due to lost time at work and school. The scope of clinical symptoms can significantly overlap among the respiratory pathogens, and the severity of disease can vary depending on patient age, underlying disease, and immune status, thereby leading to inaccurate presumptions about disease etiology. The rapid and accurate diagnosis of the causative agent of RTIs improves patient care, reduces morbidity and mortality, promotes effective hospital bed utilization and antibiotic stewardship, and reduces length of stay. This chapter focuses on the clinical utility, advantages, and disadvantages of viral and bacterial tests cleared by the Food and Drug Administration (FDA), and new promising technologies for the detection of bacterial agents of pneumonia currently in development or in US FDA clinical trials are briefly reviewed.

Keywords

Respiratory infections • Viral respiratory pathogens • Bacterial respiratory pathogens • Lower respiratory tract infections • Upper respiratory tract infections • Community-acquired pneumonia • Hospital-acquired pneumonia • Molecular tests

Introduction

The majority of respiratory tract infections (RTIs) are community-acquired and are the single most common cause of physician office visits and among the most common causes of hospitalizations [10, 68, 146, 182, 194]. The morbidity and mortality associated with RTIs are significant and the financial and social burden high due to lost time at work and school. Viral infections cause between 65–80 % of respiratory tract diseases with mixed viral infections present in 5–20 % of viral RTIs in adults and as high as 62 % in studies of children ≥6 years of age [66, 80, 132, 172, 182, 194]. In Europe and in the USA the incidence of pneumonia due to a bacterial pathogen is 1–10 cases per 10,000 inhabitants, depending on various factors such as age. The differentiation of viral from bacterial RTIs can be assisted considering the rate of onset of illness, patient age, symptoms, radiographic changes, biomarkers, response to treatment, and the presence of documented viral epidemics in the community. However, the scope of clinical symptoms can significantly overlap among the respiratory pathogens, and the severity of disease can vary depending on patient age, underlying disease, and immune status, thereby leading to inaccurate presumptions about disease etiology.

Numerous studies have demonstrated that a rapid and accurate diagnosis of the causative agent of RTIs improves patient care, reduces morbidity and mortality, promotes effective hospital bed utilization and antibiotic stewardship, and reduces length of stay [9, 20, 22, 82, 92, 106, 115, 120, 121, 142, 160, 170, 191, 227, 229, 234]. Pathogen etiology may need to be considered in the clinical management of certain patients, such as immunocompromised patients or young infants, if there is a potential for the development of more severe disease [13, 65, 68, 80, 81, 86, 194]. In health care settings, the identification of a viral RTI prompts the initiation of appropriate infection control measures, thereby reducing morbidity and mortality associated with nosocomial transmission [19, 39, 40, 62, 126, 155, 217, 219].

Over the last several years great advances have been made in obtaining USA Food and Drug Administration (FDA) clearance for a variety of nucleic acid amplification tests (NAATS) that detect single or multiple viral respiratory pathogens and three bacterial pathogens (*Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*, *Bordetella pertussis*). This chapter focuses on the clinical utility, advantages, and disadvantages of these tests. Unfortunately, no FDA-cleared assays are available for the detection of the majority of bacterial and fungal pathogens associated with community-acquired pneumonia (CAP), hospital-associated pneumonia (HAP), and ventilator-associated pneumonia (VAP). New promising technologies for the detection of bacterial agents of pneumonia currently in development or US FDA clinical trials are briefly reviewed. Although sensitive, accurate fungal diagnostics is an area of importance, the development of new diagnostic assays has been significantly delayed. Hence, for the detection of the vast majority of the nonviral pathogens, laboratory developed tests (LDTs) are the mainstay of molecular testing and will not be discussed. The importance of new rapid diagnostics for CAP, VAP, and HAP has been highlighted by a workshop conducted in November 2009 by the Infectious Diseases Society of America (IDSA) in collaboration with the FDA, the proceedings of which have been published in a special supplement of Clinical Infectious Diseases [102]. The IDSA, in an executive summary of the workshop, states that there is "a need to develop and implement modern molecular technologies to advance microbiological diagnostic testing."

Epidemiology

The common viruses that cause both lower RTIs (LRTIs) and upper RTIs (URTIs) are listed in Table 52.1. Overall, viruses are the most common cause of URTIs and the second most common etiologic cause of CAP (behind *Streptococcus pneumoniae*), ranging from 13–50 % of diagnosed cases [10, 146, 132, 172, 182, 194]. CAP in children is predominately of viral etiology, with the majority of the infections caused by respiratory syncytial virus (RSV), human rhinovirus (HRV), human metapneumovirus (HMPV), and parainfluenza viruses 1, 2, 3, 4 (PIV) [99, 194]. Influenza A (FluA) and influenza B (FluB), adenovirus (ADV), and the coronaviruses (CoVs) are additional causes of CAP in children. RTIs in non-immune compromised hospitalized children (especially < 5 years of age), are mainly due to infection with one or multiple viruses without a secondary bacterial infection. Viral CAP decreases in frequency in healthy young and

Table 52.1 Common viral and bacterial respiratory pathogens

Virus: RTI and CAP	Bacteria: RTI and CAP	Bacteria: VAP and HAP

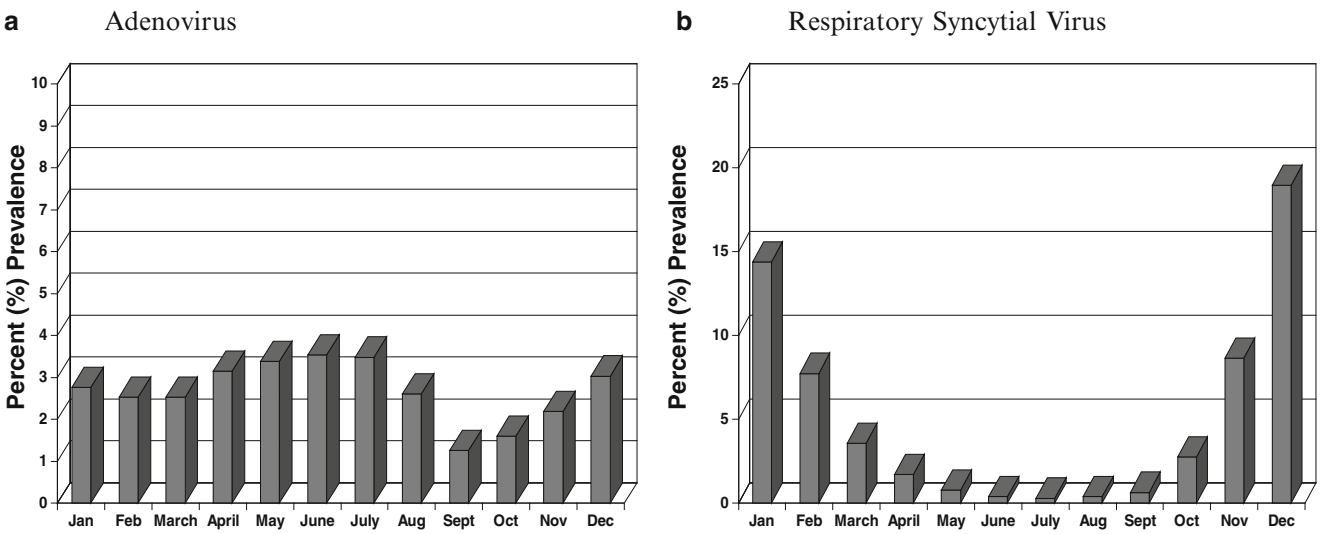

Figure 52.1 Mean prevalence of adenovirus (a) and respiratory syncytial virus (b) by month for the years 2000 through 2011. Adenovirus causes infections throughout the year, while respiratory syncytial virus infections are more seasonal

middle-aged adults to about one-third of the cases, with influenza, HRV, and CoV being the most common agents. Viral CAP rates substantially increase among the elderly, often complicated by secondary bacterial infection. The most common viral causes of CAP in the elderly are influenza and RSV; however, HMPV, PIVs, CoVs, and HRV cause both URTIs and LRTIs [66, 194].

Since 2008 several clusters of respiratory illness associated with human enterovirus 68 (HEV68) were reported in Asia, Europe, and the USA (MMWR [29]). HEV68, a unique enterovirus with similar biologic features to HRV, was associated with RTIs ranging from relatively mild illness to severe illness requiring intensive care and mechanical ventilation. Severe disease was particularly pronounced in children (MMWR [29]). Although human bocavirus (HBoV) has been implicated as a cause of RTI, in the majority of cases HBoV is detected in conjunction with other viral pathogens and the clinical significance of HBoV is still debated [105, 200]. HBoV is more commonly found in children; however, HBoV can affect persons of all ages. Underlying disease, such as cancer, is associated with severe infections requiring hospitalization.

Generally the CoVs (NL-63, OC43, HKU-1, 229E) cause mild, self-limiting URTIs such as the common cold. However, in the last decade, two CoVs—Severe Acute Respiratory Syndrome (SARS-CoV) and the Middle East Respiratory Syndrome (MERS-CoV) have emerged with a potential pandemic threat due to person-to-person communicability [33]. Both viruses can cause severe lower respiratory tract disease with extrapulmonary involvement and are associated with high case-fatality rates. Although SARS-CoV is currently not circulating, since 2012 MERS-CoV continues to cause outbreaks in the Middle East with secondary spread to Europe, Africa, Asia, and North America.

The prevalence of each viral pathogen can vary depending on environmental conditions (climate, season, geographic location). For example, in the New York City area, adenovirus (ADV) tends to circulate with the same prevalence year round (Fig. 52.1a), while RSV can be detected sporadically year round with the peak season in October through February (Fig. 52.1b) (unpublished data provided by author). The "classic" influenza season begins generally in late October and wanes during April. HMPV prevalence tends to rise as RSV season wanes in February and peaks in the spring, PIV-1 and PIV-4 are most prevalent in the summer through fall, while PIV-3 prevails in the spring and PIV-2 in the fall. Virus prevalence also can be patient population driven (e.g., pediatric, adult, geriatric, outpatient, or inpatient). For example, RSV and HMPV are primarily found in children <5 years of age, but can cause severe disease in all age groups [64, 65, 94, 97]. In the immunosuppressed population, other less common respiratory viral pathogens, such as herpes simplex virus (HSV) and cytomegalovirus (CMV), must be considered as a potential cause of RTIs.

The major bacterial pathogens responsible for CAP (Table 57.1) include *S. pneumoniae* (20–60 %), *Staphylococcus aureus* (methicillin-susceptible [MSSA] and methicillin-resistant [MRSA]) (3–5 %), *Haemophilus influenzae* (3–10 %), variable gram-negative rods (3–10 %), and rarely *Neisseria meningitidis* (<1 %) depending on the patient and underlying diseases such as chronic obstructive pulmonary disease (COPD) or asthma [10, 146]. *Moraxella cattharalis* is generally associated with otitis media in children and exacerbation of asthma and COPD in adults. The classic atypical pathogens that cause CAP include *C. pneumoniae*, *M. pneumoniae*, and *Legionella pneumophila*, which also can be nosocomially acquired in institutional settings [10, 17, 46, 67, 222].

The majority of RTIs (up to 70 %) caused by C. *pneumoniae* are asymptomatic or have minimal symptoms. *C. pneumoniae* accounts for 6–20 % of CAP and 5 % of cases of sinusitis, pharyngitis, tracheitis, bronchiolitis, bronchitis, and exacerbations of chronic bronchitis and asthma in both immunocompetent and immunosuppressed persons [17, 42]. *C. pneumoniae* can be present with other bacterial pathogens in up to 30 % of adult cases of CAP. *C. pneumoniae* infection can present with varied clinical courses from mild, self-limiting disease to severe forms of pneumonia, particularly in patients with cardiopulmonary disease and in the elderly [17]. All age groups are affected; however, *C. pneumoniae* infections are rarely found in young children < 5 years of age. However, by age 20, 50 % of persons have detectable antibody levels, with the elderly demonstrating a seropositivity rate between 70 – 80 % [221].

M. pneumoniae is estimated to cause 6–20 % of the cases of CAP [222]. Although most infections are asymptomatic, mild, and often self-limiting, approximately 1–5 % of infections may require hospitalization and can lead to serious extrapulmonary complications. LRTIs are more common in school age children and adolescents, with the prevalence in pediatric LRTI ranging from 10–40 %. *M. pneumoniae* infection can cause outbreaks in the community and institutions such as schools, prisons, and hospitals.

Legionella spp. causes two distinct clinical entities. Pontiac Fever is a self-limiting flu-like illness and Legionaire's disease is a severe multisystem disease involving pneumonia. Cases can be sporadic or part of outbreaks due to environmental exposure [51, 67]. *L. pneumophila* is responsible for 2–8 % of CAP and is responsible for 2–15 % of all CAP that require hospitalization. *L. pneumophila* (serogroup 1) is responsible for 90 % of the diagnosed disease, most probably because the major diagnostic tests are specific for this serogroup. Risk factors for contracting Legionellosis include smoking, immunosuppression, age ≥ 65, chronic lung disease such as emphysema, diabetes, kidney disease, cancer, or contact with environmental systems such as air conditioning cooling towers, evaporative condensers, whirlpools, and hot spring baths.

Coxiella burnetii, an obligate gram-negative intracellular bacterium has primary reservoirs in cattle, sheep, and goats. Transmission to humans occurs primarily through inhalation of aerosols from contaminated soil or animal waste. Most *C. burnetti* infections are manifested as Q Fever, a self-limited, influenza-like febrile illness (88–100 %) of abrupt onset, manifested by chills, headache, myalgia, fatigue, and sweats; ([150], CDC MMWR [30]). However, pneumonia is predominant in North America and usually mild in nature. Patients have dyspnea, pleuritic chest pain, and a dry, nonproductive cough. Rarely, *C. burnetti* infection occasionally can progress to acute respiratory distress syndrome (ARDS) ([150], CDC MMWR [30]).

B. pertussis is the cause of whooping cough [43, 119]. Pertussis-like illness can be attributed to *Bordetella parapertussis*, *Bordetella holmseii*, and rarely *Bordetella bronchioseptica* infections. Overall, *Bordetella* infections have increased dramatically over the last 10 years due to waning immunity, incomplete antibody response to vaccination with acellular vaccines, or lack of vaccination. Recent epidemics have occurred between 2010 and 2014. In 2010, more than 27,000 cases were reported, of which over 9,000 occurred in California. Nationwide by 2013 more than 28,000 cases were reported to the CDC (http://www.cdc.gov/pertussis/surv-reporting.html). The highest incidence was noted in infants < 1 year of age, but a significant amount of disease occurred among children aged 7–10 years. One large outbreak of pertussis-like illness in Ohio from 2010 to 2011 was attributed to both *B. pertussis* (68 % of the cases) and *B. holmseii* (29 % of the cases) [190]. Outbreaks of pertussis continue, highlighting the need for primary vaccination and the administration of "Tdap" booster immunizations.

HAP and VAP are more often associated with drug-resistant, multidrug-resistant, or pan-resistant bacteria, such as MRSA, extended-spectrum beta-lactamase (ESBL)-producing *Enterobacteriacae*, or carbapenemase-producing *Enterobacteriacae*, *Pseudomonas* spp., *Acinetobacter* spp., and *Stenotrophomonas maltophilia* [4]. For patients in the intensive care unit (ICU) or immunocompromised patients, other pathogens such as *Nocardia* spp, *Corynebacterium* spp., *Pneumocystis jiroveci*, *Fusarium* spp., *Aspergillus* spp, *Cryptococcus* spp., and the zygomycetes need to be considered in the differential diagnosis.

Clinical Utility

Limitations of Conventional Diagnostic Procedures

Conventional virus detection methods include rapid antigen detection tests (RADTs), direct fluorescent antibody tests (DFAs), rapid cell culture, and traditional tube culture [125]. Although these methods are acceptable diagnostic tools in certain clinical settings, they are often inferior in the breadth of pathogens identified, assay sensitivity, and result turnaround time, when compared to NAATs [18, 28, 39, 73, 74, 79, 125, 157]. The sensitivity and specificity of all the diagnostic tests, but in particular the conventional tests, are highly dependent on the viral target, age of the patient, duration of symptoms prior to sample collection, sample collection methods, and the transport and storage conditions [1, 39, 48, 49, 85, 95, 118, 127, 131, 164].

RADTs are generally the simplest tests to perform, many are waived tests under the Clinical Laboratory Improvement Amendments (CLIA), and results are generally available

within 15–30 min. Despite these benefits, RADTS have limited utility due to the narrow scope of pathogens detected (RSV, FluA, and FluB) [125], and modest to poor sensitivities [21, 39, 45, 61, 75, 79, 125, 199] which can range from 50–90 % for RSV [47] and 10–85 % for influenza viruses depending on the comparator method. Overall, the specificities of RADTs are good [21, 39, 45, 61, 75, 79, 125, 199]; however, the specificity for the detection of influenza A (H1N1) pdm09 was significantly lower than previously reported [197, 198]. RADTs generally perform better when testing pediatric samples since children shed higher titers of virus and for longer time periods than adults, especially the elderly [28, 85, 93].

DFAs detect a broader range of viruses (ADV, FluA, FluB, HMPV, PIV-1, PIV-2, PIV-3, and RSV) and can be performed in 30–60 min. The sensitivities of DFAs vary by virus, ranging from a high of approximately 60–85 % for RSV to a low of 50 % for ADV when compared to NAATs [116, 125]. DFAs are generally very specific, although specificity can be dependent on the level of technical expertise of the reader.

Rapid cell culture (Quidel/Diagnostic Hybrids, Athens, OH) can detect ADV, FluA, FluB, PIV-1, PIV-2, PIV-3, and RSV and has demonstrated sensitivities that range from a high of >80 % for some FluA strains to a low of 50 % for RSV [125, 130, 152] and excellent specificities of greater than 95 % when compared to NAATs. Rapid cell culture is generally positive within 48 h for >90 % of the seven viruses detected.

Depending on the cell lines used and antibodies available for confirmation, traditional tube culture can have a broader scope of pathogen detection when compared to RADTs, DFAs, and rapid cell culture [125]. Traditional culture will identify ADV, enterovirus (EV), HMPV, FluA, FluB, PIV-1, PIV-2, PIV-3, RSV, and HRV, plus additional viruses associated with lower RTIs in immunocompromised patients, including CMV, HSV-1, HSV-2, varicella zoster virus (VZV). Often laboratories do not specifically screen for HRV by culture, although HRV is the most common respiratory virus detected and has been shown to cause significant and serious disease in young, elderly, immunosuppressed patients, as well as patients with underlying chronic lung disease such as COPD and asthma [83]. In addition, many additional important viruses (229E-CoV, OC43-CoV, NL63-CoV, HKU-1-CoV, SARS-CoV, MERS-CoV), PIV-4, and potentially HBoV) that cause both URTIs and LRTIs are not routinely identified by traditional culture [83, 105, 200]. Finally, due to time-to-virus-detection by traditional culture (generally 3–7 days for most respiratory viruses and 3–4 weeks for slow-growing viruses such as CMV), results are usually not available within a time frame (48 h) that could affect patient management (i.e., initiate appropriate antiviral therapy and/or discontinue inappropriate antibiotic therapy). In summary, RADTs, DFAs, and rapid cell culture may provide results within a clinically relevant time frame but with limited pathogen scope and reduced sensitivity compared to NAATs. In addition, RADTs, DFAs, and rapid/traditional cell culture rarely detect more than one virus from a single sample.

The standard methods for the detection of bacterial pathogens causing pneumonia are gram stain in combination with microbiological culture of lower respiratory tract specimens and blood. Often culture of respiratory specimens is not ordered on hospitalized patients and rarely performed in the outpatient setting. A gram stain result can be available within a few hours but results do not always correlate with culture [10]. Culture and antibiotic susceptibility results are usually available in 2–5 days after sample collection, and detection rates for pathogens are relatively low. A meta-analysis that evaluated 122 reports on CAP for the time period of 1966–1995 showed that a bacterial pathogen was only identified in 18 % of the samples tested [68]. A urinary antigen test for *S. pneumoniae* offers a substantial improvement over culture, with a sensitivity of 82 % and a specificity of 97 % in bacteremic adults [209, 210]. However, in non-bacteremic adults and in children, both the sensitivity and specificity are lower [210]. False-positive *S. pneumoniae* antigen tests have been reported relating to antibiotic interference. *Legionella* spp. are identified by growth on buffered charcoal yeast extract agar [158]. The sensitivity of *Legionella* culture can vary significantly from <10–80 % and DFA sensitivity from 25–70 % [158]. A urinary antigen test for *L. pneumophila* improves detection but is suboptimal since detection is limited to serogroup 1. For *L. pneumophila* serogroup 1 the sensitivity of the test varies from 70–100 %. Most laboratories do not culture for *Mycoplasma* or *Chlamydophila* [140].

Traditionally, *B. pertussis* was identified using culture on Bordet–Gengou media and/or DFA. However, the sensitivity of culture ranges from 12–60 %, the sensitivity of DFA ranges from 11–68 % [119]. Additionally, culture can take many days. Therefore, NAATS have become the gold standard for the rapid and sensitive (70–99 %) identification of pertussis [119].

Serologic antibody testing is available for some of the respiratory pathogens and can provide supplemental information. However, due to a delay in the development of detectable IgM or IgG antibodies for certain pathogens (e.g., *L. pneumophila*, *C. pneumoniae*, *B. pertussis*), usefulness for diagnosis in a clinically relevant time frame is very limited [17, 151, 158, 221]. Shortcomings of serological testing include the timing of the serum samples, difficulty in obtaining appropriately paired serum samples, and the high background of IgG antibody prevalence in some adult populations [140]. Serologic diagnosis can be misinterpreted due to prior immunization or infections, such as in the case of influenza, and require demonstration of a significant rise in antibody titers from initial to convalescent samples.

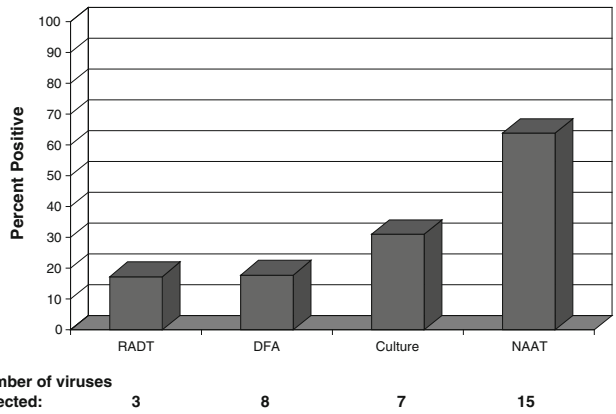

Figure 52.2 Comparison of viral test methods for identification of respiratory pathogens. Percentage of respiratory samples (n = 35,456) positive by each test methods: RADT (rapid antigen detection test) detects three viruses [influenza A (FluA), influenza B (FluB), and respiratory syncytial virus (RSV)]; DFA (direct fluorescent antibody assay) detects eight viruses [adenovirus (ADV), FluA, FluB, human metapneumovirus (HMPV), parainfluenza viruses (PIV) 1, 2, and 3, and RSV]; Culture (R-Mix rapid cell culture) detects seven viruses (ADV, FluA, FluB, PIV-1, PIV-2, PIV-3, and RSV); NAAT (nucleic acid amplification testing) detects 15 viruses (ADV, coronaviruses (CoV: OC43, NL63, HKU1, 229E), enterovirus/rhinovirus group (EV/HRV), FluA (A/H1, A/H3), FluB, HMPV, PIV (1–4), and RSV

Finally, persons with immune suppression may not develop antibodies or they may be of an insufficient level for detection, limiting the functionality of serology for monitoring vaccine response and for epidemiology studies to determine prevalence rates.

Application of Molecular Assays for the Detection of Respiratory Pathogens

Clinical Utility of NAAT for Respiratory Pathogens

Prior to the 2009 FluA(H1N1) pandemic, the infectious causes of CAP were mostly inferred based on clinical presentation which can be highly inaccurate since some bacteria, atypical pathogens, and many of the respiratory viruses cause illnesses with similar clinical symptoms [177, 194]. One study demonstrated that physicians recognized influenza in only 28 % of hospitalized children and 17 % of non-hospitalized children with laboratory-confirmed influenza when the diagnosis was based only on clinical symptoms [177]. Most diagnostic testing was limited to RADTs for FluA, FluB, and RSV as few hospitals offered comprehensive DFAs, viral culture, or laboratory-developed NAATs.

The superior ability of NAATs to rapidly and accurately detect both known and novel pathogens was best exemplified during the chaos of the 2009 FluA H1N1 pandemic [18, 39, 79, 197, 198]. Fortunately, at the start of the pandemic two NAATs were FDA-cleared for the detection of influenza viruses, the Prodesse PROFLU+ (Hologic, San Diego, CA) for the detection and differentiation of FluA and FluB ([124]; and one highly multiplexed NAAT: the Luminex xTAG RVP Respiratory Virus Panel (Luminex Molecular Diagnostics, Toronto, Canada) [113, 114, 143]. The xTAG assay enabled laboratories to detect FluA(H1N1)pdm09 and differentiate the seasonal FluA H1N1 (FluA-H1) and seasonal FluA H3N2 (FluA-H3), but also identify many other circulating viruses [79, 78]. As shown in Fig. 52.2, the number of samples positive for a respiratory virus increased dramatically with the use of the highly multiplexed xTAG RVP assay (64 %) compared to traditional test methods, including RADTS (17 %), DFA (18 %), and rapid cell culture (31 %) [79]. Interestingly, mixed viral infections containing up to four viral pathogens were identified in hospitalized patients [79]. Similarly, other studies have shown that when broad test panels are used more than one virus will be identified in 3–30 % of respiratory samples [8, 166]. Although the significance of mixed viral infections needs to be more clearly defined, the clinical impact needs to be considered as potentially severe in patients with comorbidities, immunosuppression, or other critical illnesses. During respiratory virus seasons with high influenza rates, patients with the same pathogen often are placed in hospital rooms together (cohorting) due to limited private rooms [19, 39, 40, 62, 126, 155, 165, 217, 219]. The consequences of a second viral infection in an already seriously ill hospitalized patient could be substantial, indicating that comprehensive test panels are essential in this setting.

Consequently, there has been a major shift in testing practices as numerous FDA-cleared single-and multi-analyte molecular tests for the detection of respiratory pathogens have become available (Table 52.2). Viral respiratory pathogens are particularly suited for detection using NAATs since the number of targets is relatively limited and the detection of a respiratory virus is generally considered diagnostic, although asymptomatic carriage of certain respiratory viruses has been reported in several studies [2, 14, 104, 181]. For the majority of viral and atypical bacterial respiratory pathogens, NAATs offer enhanced sensitivity over culture, RADTs and DFAs (see Tables 52.2 and 52.3 for references), and the specificity varies with the target and assay design but is generally very high. NAATs also are suited for detection of respiratory pathogens that are not routinely or easily cultured (e.g., *C. pneumoniae*, *M. pneumoniae*, HBoV, HMPV, and PIV-4), for pathogens dangerous to culture (e.g., SARS-CoV, MERS-CoV), and for pathogens where the time-to-detection by traditional testing is often too delayed to impact patient care (e.g., influenza and CMV by cell culture).

The expanded scope of pathogen detection from a previous low of three viral pathogens detected by RADTs to 17 viral and three bacterial pathogens detected by NAATs greatly enhances the clinical laboratory's diagnostic capabilities.

Table 52.2 FDA cleared tests for the detection of bacterial and viral respiratory pathogens[a,b]

Manufacturer/test[c]	Amplification and detection platform(s)[d]	Extraction Platforms	Targets[e]	Specimen types approved[f]	Method(s)[g]	References

The data derived from studies utilizing comprehensive viral and bacterial NAATs has and will continue to provide invaluable insights into the clinical manifestations of viral and bacterial infections, significance of mixed viral infections, and surprisingly the realization that viruses can colonize a host without overt disease.

Impact on Antimicrobial Selection and Stewardship

Aside from the use of RADTs during influenza season, RTI diagnostic testing including viral DFAs and culture, bacterial culture, NAATs, serologic testing for the atypical pathogens, and urinary antigen testing for *S. pneumoniae*

and *L. pneumophila* are still underutilized in the outpatient setting [10, 189]. Therefore, treatment of patients with CAP is generally empiric and based on guidelines by the American Thoracic Society and IDSA [146] rather than on a confirmed laboratory diagnosis. Antibiotic selection must cover both the most prevalent bacterial pathogens and the atypical pathogens.

Despite the high prevalence of viral infections, approximately 22.6 million (55 %) out of 41 million antibiotic prescriptions were prescribed for viral lower and upper RTIs, despite the fact that a bacterial etiology was highly unlikely [82]. Conversely the identification of the viral pathogen can lead to the administration of an appropriate antiviral. For example, during the early weeks of the 2009 influenza A H1N1 pandemic, four different influenza viruses were circulating with varying antiviral susceptibility patterns. According to surveillance data provided by the Center for Disease Control and Prevention (CDC, Atlanta, GA), FluA-H1 strains demonstrated >99 % resistance to the first line therapeutic oseltamivir, a neuraminidase inhibitor, and susceptibility to adamantine, FluA-H3 was oseltamivir-susceptible and >99 % adamantine-resistant, FluA(H1N1)pdm09 was oseltamivir-susceptible and >99 % adamantine-resistant; FluB was oseltamivir-susceptible and adamantine-resistant. Therefore, the identification of what specific strain of influenza virus was causing the infection of specific patients was essential to ensure proper drug selection, especially in high-risk or critically ill patients. Additionally, the more appropriate use of influenza antivirals can be achieved when an accurate, rapid diagnosis is made. Recent studies demonstrated that rapid testing permitted the timely administration of oseltamivir [229] and allowed for a more rapid discontinuation of treatment in persons without documented influenza [191]. Finally, new viral therapeutic agents for respiratory viruses other than influenza are in development and/or in clinical trials [171, 233]. Proper administration of these new agents will depend on the laboratory providing accurate tests that detect a broad range of viral pathogens [189].

For HAP and VAP, initial empiric therapy choices may be standardized and initiated based on patient clinical status, underlying disease, and/or risk for infection with a multidrug-resistant pathogen. Initial therapy often is inadequate, thereby extending the course of the disease and increasing morbidity, mortality, and hospital length of stay. The mortality rate in ICU pneumonia cases ranges from 20–30 % when initial therapy was adequate, to 50–80 % when initial therapy was inappropriate and changed after culture results were obtained [112]. Furthermore, inadequate and/or unnecessary broad spectrum antibiotic therapy can enhance the spread of drug-resistant pathogens within institutional settings and increase the risk of hospital-acquired infections such as *Clostridium difficile*, MRSA, and vancomycin-resistant enterococci.

Comprehensive NAATs provide key information not only for antiviral therapy selection but can also aid in restricting antibiotic use to those circumstances where antibiotic therapy is appropriate and in promoting switches to targeted specific therapies, thus reducing the use of broad spectrum antibiotics when not indicated [170, 142, 189]. This practice is in keeping with the goals of antibiotic stewardship, especially considering the steady and critical rise of antibiotic resistance and limited or no options available for the treatment of multidrug or pan-resistant bacterial infections.

Prevention of Nosocomial Infections

The burden of nosocomial infections can be significant, incurring additional costs for supplemental diagnostic tests, extended hospitalization, and increased morbidity and mortality [19, 40, 62, 126, 155, 217, 219]. Therefore, rapid diagnostic tests are needed to identify infected patients upon admission, thereby preventing nosocomial transmission by facilitating isolation and appropriate cohorting decisions [165, 206]. Studies have documented significant nosocomial transmission of ADV, influenza, RSV, HMPV, PIV, and HRV in hospital units, chronic care facilities, and pediatric units [19, 40, 62, 126, 155, 217, 219, 232]. During the height of RSV season, when prevalence can be >50 %, high numbers of hospital admissions often require the cohorting of RSV-positive children due to a lack of private rooms. However, limiting diagnostic testing to RSV alone in a cohorting scenario could put other seriously ill children at risk for acquisition of a second viral infection with other pathogens such as HMPV or HRV [80]. The rapid identification of health care facility-acquired *Legionella* infection is essential so that the environment source can be identified and eradicated, thus preventing further transmission. In addition, PCR techniques are used to proactively routinely screen potential environmental sources.

Epidemiologic Surveillance and Outbreak Investigation

The identification of a wide range of viral pathogens is essential for epidemiologic surveillance and establishes both seasonal and population patterns which can serve as excellent indicators for predicting immunization scheduling (e.g., influenza), or for administering preventive measures (e.g., RSV immune globulin). Previously, such surveillance was done by state Departments of Health or on a national level by the CDC. Comprehensive NAATs now enable local laboratories to monitor in real time viral prevalence and provide to their clinicians and health care facilities regular updates on circulating viruses. Testing decisions should use local data and additional resources and epidemiology information provided on the CDC web site (http://www.cdc.gov/flu/).

A study by S. Wong et al. demonstrated that the use of a multiplex NAAT (17 viruses) identified a virus in 59 % of the outbreaks and 29 % of the outbreak specimens that were negative using DFAs and a limited number of individual NAATs (ten viruses) [226]. Overall, the detection rate increased from 72–91 % for outbreaks and from 47–56 % for outbreak specimens. Comprehensive testing can identify reemerging or new emerging viral pathogens, as was the case during the influenza A H1N1 2009 pandemic.

Additionally, NAATs have been a key component in understanding both the epidemiology and features of large outbreaks of pertussis-like illness [190]. For example the large percentage of cases (29 %) of *B. holmseii* identified in an outbreak in Ohio in 2010–2011 was in contrast to some previous reports where the frequency of detection was very low [190]. The USA has seen peaks of pertussis activity every 3–5 years, with increasing cases since 1980. Accurate detection of pertussis is essential to better control the spread of disease from a public health standpoint through antimicrobial prophylaxis of asymptomatic household contacts, children less than 1 year of age, pregnant women in their third trimester, persons with preexisting conditions that are at risk for the development of severe respiratory failure, and all contacts in high-risk settings (http://www.cdc.gov/pertussis/outbreaks/pep.html).

Available Assays

Sample Types, Transport, and Storage

The recovery of respiratory pathogens is highly dependent on using the appropriate sample type and collection methods [139]. Laboratories using commercial FDA-cleared assays should refer to the manufacturer's package information to determine what sample types have been validated for use with the specific test (Table 52.2). The use of alternate samples types is permitted after the laboratory has performed their own validation studies that establish acceptable performance characteristics when testing the alternate sample type.

Applicable upper respiratory tract specimens for viral, *C. pneumoniae*, and *M. pneumoniae* testing include nasopharyngeal (NP) washes, NP aspirates, NP swabs, and midturbinate swabs placed in viral transport media [1, 48, 49, 95, 118, 131, 164, 223]. Oropharyngeal swab specimens are less sensitive (54 %) than either NP swabs (73 %) or NP wash specimens (85 %) due to the substantially lower levels of virus present in the oropharynx than the nasopharynx [131]. However, the combined use of nasal-oropharyngeal swabs can enhance the recovery of both avian influenza and SARS-CoV [49]. NP flocked synthetic swabs should be used in lieu of traditional synthetic NP swabs since flocked NP swabs yield a greater recovery of viral pathogens, with sensitivity comparable to NP wash specimens [1, 48, 95]. The rates of positivity for *B. pertussis* by real-time PCR were shown to be comparable when specimens were collected with either NP rayon swabs on aluminum shafts in Amies gel with charcoal or NP flocked swabs in universal transport media [6].

Lower respiratory tract (LRT) samples appropriate for viral pathogens, *C. pneumoniae*, *M. pneumoniae*, *L. pneumophila*, and bacterial pathogens include induced sputum, bronchial alveolar lavages, bronchial washings, protected brushes, and Combicath specimens. Studies that examined the detection of FluA(H1N1)pdm09 found that in seriously ill patients requiring intensive care, upper respiratory tract samples can be negative while LRT samples are positive [120, 123, 156, 230].

Additional factors that influence pathogen recovery include the time of sample collection after the onset of clinical symptoms and the age of the patient (children tend to shed higher titers of virus and for longer periods of time than adults). Therefore, for optimal detection, samples should be collected within 3 days for adults and within 5 days for children after the onset of symptoms [39, 85, 95, 120, 123]. Samples should be transported to the laboratory as soon as possible, preferentially on wet ice or refrigerated (2–8 °C) if testing will be performed within 48 h. If testing is delayed, the samples should be stored at −80 °C. Multiple freeze-thaws should be avoided as this process can decrease pathogen titers.

Nucleic Acid Extraction

Target lysis in a stabilizing matrix to prevent target degradation by deoxyribonucleases (DNases) and/or ribonucleases (RNases), followed by isolation and purification of the nucleic acids (NAs) are essential and critical steps of every NAAT. This is particularly important for respiratory samples that can be highly viscous and contain inhibitory substances and enzymes that destroy the target NAs. Some sample types may require a pretreatment with proteinase K or a similar enzyme. Highly efficient commercial NA extraction systems ensure sufficient NA recovery and the removal of inhibitory substances that could result in inefficient or no amplification of the target NAs. Presently, the majority of NA extraction systems use a chaotropic agent to lyse viral particles or bacterial cells, silica particles or a membrane to capture the released NAs, and a series of wash steps to remove inhibitory substances. NAs are generally eluted in either RNase/DNase free water or a stabilizing buffer such as EDTA-Tris. Although NA extraction can be performed manually using for example spin columns, the majority of laboratories currently

use automated platforms that can extract as few as one sample at a time or more than 96 samples in microwell plate formats. Many NAATs have been FDA-cleared with specific extraction platforms or methods and laboratories should be aware that the substitution of another extraction platform or method constitutes a major change in the assay protocol. From a regulatory perspective, if the extraction procedure is modified or changed then the entire test is now considered an LDT. Laboratories must be compliant with all applicable state and federal CLIA standards, and may choose to comply with the College of American Pathologists regulations to meet state or federal regulatory requirements.

Amplification and Detection of Nucleic Acids

Many amplification and detection methods are used in the current FDA-cleared assays (Table 52.2) and additional assays that are not FDA cleared but may be Conformité Européenne (CE) marked for use as an in vitro diagnostic device (IVD) in Europe (Table 52.3). Amplification methods include traditional reverse transcription polymerase chain reaction (RT-PCR), PCR, real-time RT-PCR and PCR, RT-PCR and primer extension, nested PCR, amplicon rescued multiplex PCR (ARM-PCR), and isothermal amplification such as nucleic acid sequence based amplification (NASBA), helicase-dependent amplification (HAD), nicking enzyme amplification reaction (NEAR), and loop mediated amplification (LAMP). Primers sets can be broad range (e.g., family), short range (e.g., genus), or pathogen-specific (e.g., genus and species). Targets may be single or multiple copy and include genomic RNA, or DNA, or messenger RNA. Detection technologies utilize fluorogenic intercalating dyes, fluorogenic probes (Taqman, fluorescence resonance energy transfer [FRET] hydridization, molecular beacons, scorpions, locked nucleic acid [LNA]), arrays (liquid bead, gold nanoparticles, or solid chip), electrochemical-based methods, melt curve analysis, lateral flow, or simple turbidity.

Tests vary considerably with the number of targets detected, ranging from one pathogen target plus an internal control (IC) to 20 targets plus an IC. They differ in which targets are detected (viral and/or bacterial) and if the tests are able to detect and differentiate various types within a virus family (e.g., PIV-1, -2, -3, and -4) (Tables 52.2 and 52.3). Platforms can be all inclusive with NA extraction, amplification, and detection performed in one cartridge (e.g., GeneXpert, Cepheid, Sunnyvale, CA; cobas Liat System, Roche Molecular Systems/Iquum, Marlborough, MA), in one pouch (Film Array, BioFire/bioMérieux, Salt Lake City, UT), or one chamber of a multi-test wheel cartridge (Simplexa Direct, Focus Diagnostics, Cypress, CA). Testing can be performed using modular systems that incorporate NA extraction with amplification but a separate unit for detection (e.g., Verigene, Nanosphere, Northbrook, IL), modular systems that separate isolation, from amplification combined with detection (Simplexa, Focus Diagnostics,; ProFlu+, Gen-Probe, San Diego, CA; Lyra, Quidel, San Diego, CA) and systems where isolation, amplification, and detection are all performed separately (xTag RVP, Luminex, Austin, TX; eSensor XT-8 System, GenMark Diagnostics, Carlsbad, CA; Infiniti RVP Plus, Autogenomics, Vista, CA; Resplex II, Qiagen, Valencia, CA).

Only a limited number of tests are FDA-cleared for the detection of bacterial pathogens. One highly multiplexed test, the FilmArray Respiratory Panel (BioFire/bioMérieux) tests for 17 viral pathogens and three bacterial pathogens, *C. pneumoniae*, *M. pneumoniae*, and *B. pertussis*. One additional assay is FDA-cleared for the detection of *M. pneumoniae*, the *illumi*gene Mycoplasma Assay (Meridian Biosciences, Inc, Cincinnati, OH). Two addition assays are FDA-cleared for the detection of *B. pertussis*, the *illumi*gene Pertussis assay (Meridian) and the Amplivue *Bordetella* assay (Quidel, San Diego, CA).

Time-to-results for the FDA-cleared assays ranges from 15 min to approximately 12 h depending on the platform, with the most rapid results (< 1.5 h) for the all-inclusive cartridge/pouch based tests. Technical hands-on time varies from < 2 min to approximately 3 h. Currently, most NAATs are rated as CLIA moderate to high complexity. In January 2015, the first waived NAAT under CLIA was cleared by the FDA, the Alere i Influenza A&B test (Alere Scarborough, Scarborough, ME). To perform the test, a sample receiver and test base are inserted into the Alere i instrument (Alere). After a 3 min heating step, the sample is eluted from the nasal collection swab directly into the sample receiver buffer. The transfer cartridge is used to transfer the sample to the test cartridge, where NEAR-amplification and detection occur in approximately 10 min [11, 12, 35, 162].

For comprehensive diagnosis of CAP and to rapidly identify pathogens associated with HAP and VAP, additional tests are needed that target the main bacterial pathogens [63]. The Research Use Only (RUO) Unyvero System (Curetis, Stutgart, GR) has an assay developed as an aid for the diagnosis of bacterial pneumonia. The specimen is preprocessed in Unyvero L4 Lysator, and then added to the assay-specific cartridge which is then inserted into the Unyvero A50 analyser. All steps are controlled by the Unyvero C8 Cockpit. The assay detects the major bacterial pathogens (*Acinetobacter baumanii*, *Enterobacter* spp. *Escherichia coli*, *Klebsiella oxytoca*, *Klebsiella pneumoniae*, *Haemophilus influenzae*, *Moraxella. catarrhalis*, *Morganella morganii*, *Proteus* spp., *S. aureus*, *Pseudomonas aeruginosa*, *Serratia marcescens*, *S. maltophilia*, *S. pneumoniae*), the atypical pathogens

(C. *pneumoniae*, *L. pneumophila*), and one fungal pathogen (*Pneumocystis jiroveci*) known to cause CAP, HAP, and VAP. In addition, the assay will detect 18 genes associated with the major categories of antibiotic resistance. Time-to-results is approximately 4–5 h. The assay serves as a preliminary screen to be followed by culture and traditional antimicrobial susceptibility testing. Preliminary studies demonstrated that the assay detected more pathogens than routine culture. The Unyvero system detected numerous resistance markers and allowed for a change in empiric antibiotic therapy within 5–6 h for 67 % of the patients tested [103, 201].

The RUO Abbott Plex-ID system (Abbott, Abbott Park, IL) is comprised of broad range PCR or RT-PCR and Electrospray Ionization Mass Spectrometry (PCR/ESI-MS) for pathogen detection [36, 37, 44, 55]. Following NA extraction, PCR and/or RT-PCR is performed in a microwell plate using multiple primer pairs, with one primer set per well. Following amplification, the automated platform performs post-PCR desalting, purification, and high-resolution mass spectrometry using ESI-MS. The raw spectra are analyzed and calibrated with an internal mass standard. Spectral analysis determines the nucleotide base composition of the single-stranded oligonucleotides complementary to the initial target. To evaluate the relative concentration of the target or targets present, a semiquantitative value can be obtained by comparing the peak heights with the internal PCR calibration internal mass standard present in every well. The initial Plex-ID (Ibis T5000) system has been replaced by the Abbott IRIDICA RUO system (Abbott) that is comprised of PLEX-ID SP (nucleic acid extraction platform), PLEX-ID FH (liquid handler for assay setup), and a new version of the PLEX-ID PCR/ESI-MS platform. Time-to-results is <8 h. PCR- or RT-PCR/ESI-MS has been used to detect and identify a variety of respiratory viruses, influenza subtypes, bacteria, and fungi associated with RTIs ([88, 159, 207, 214, 215]; Huttner et al. 2014).

NAAT Performance

Overall, NAATs for respiratory viral and the atypical bacterial pathogens are highly sensitive (85 – 100 %) and very specific (>95 %) when samples are collected shortly after the onset of clinical symptoms (see references in Tables 52.2 and 52.3). Assays can detect mixed infections [79] and a broad range of viral types within a family [34]. Performance results from clinical trials for FDA clearance and from investigator-initiated studies need to be reviewed carefully when evaluating an assay because many factors can affect the overall results, such as patient population and age, testing conditions, specimen collection factors, storage time from sample collection to testing, and comparator method used in the analysis. Similarly, results obtained in different studies can vary significantly for assays and targets, depending on the study design (see references in Tables 52.2 and 52.3). Numerous studies have demonstrated that not all targets within a particular assay are detected with the same sensitivity. NAATs also have certain limitations. Due to the complexity of primer and probe designs and interactions, highly multiplexed NAATs can sometimes be less sensitive than individual NAATs [70, 166, 167]. Reduced analytical sensitivity, however, does not always correlate with reduced clinical sensitivity since viral quantity in clinical samples, depending on the virus and timing of sample collection, are often much higher than the limit of detection of the assays. NAATs often are less sensitive for viruses with multiple serotypes, such as ADV [37, 74, 113, 133]. Decreased performance for the detection of ADV can be clinically significant, particularly when testing samples from immunosuppressed patients (e.g., transplant patients) for whom ADV infection has a high mortality rate if not treated. For high-risk patients, laboratories may elect to supplement testing with either a more sensitive, broadly reactive ADV-specific assay or with cell culture [25, 62, 148, 173]. Many of the assays cannot distinguish between HRV and EV due to the fact that the assays target the 5′ UTR which is genetically similar for the two viruses [113]. The performance of the assays, in particular for RNA viruses, also may be affected by sequence mutations that occur over time. These mutations can result in primer/probe mismatches that decrease assay sensitivity, result in a total lack of target amplification and detection, or result in cross reactivity [153]. Any modifications to the assays to accommodate such genetic changes would have to be cleared by the FDA. In highly multiplexed assays, revalidation can require extensive assessment of all target interactions, thus making changes extremely difficult.

The FDA-cleared assays for the detection of *B. pertussis* target the multicopy IS481 gene. This gene is found not only in *B. pertussis* (50–238 copies/cell) but also in *B. holmseii* (8-10 copies.cell) and in 1–5 % of the strains of *B. brochioseptica* [190]. Therefore, the assays are not specific for *B. pertussis* and alternative targets must be tested to differentiate the three species and also to detect *B. parapertussis* [89, 190, 216, 225]. Additionally, pseudo-outbreaks of pertussis have been described, indicating that great caution must be used not only in performing the NAAT but also in the collection of test samples, particularly in areas where vaccine is administered. Finally, due to the short time of localization of the atypical bacterial pathogens to the URT, the detection of these pathogens may require a combination of various sample types and various test methods, including NAATs, serology, and antigen testing, to provide the most sensitive results.

Interpretation of Test Results

The advantages of NAATs compared with traditional testing methods include improved sensitivity, not needing a viable organism for detection, broader scope of pathogens identified, and the ability to detect mixed infections. These same advantages can also raise issues with the interpretation of results. Until recently the detection of any respiratory virus had been considered significant. Several studies have shown that respiratory viruses can be detected in asymptomatic patients [2, 14, 104, 181]. One study found that NAATs identified a virus in 83 % of specimens from symptomatic children, but also detected a virus in 42 % of specimens from children without symptoms [2]. Another study demonstrated similar colonization with CoV (7.6 %) in symptomatic hospitalized children versus (7.1 %) in an asymptomatic outpatient control population. The overall prevalence of CoV or the types of CoV was not significantly higher among hospitalized children than controls. Respiratory viruses in NP swabs were identified from both asymptomatic and symptomatic solid organ transplant recipients early after transplantation [14]. The data suggest that due to the high prevalence of positive results in children and immunocompromised patients without symptoms, results should be interpreted cautiously, and in the context of clinical presentation, radiographic findings, and other laboratory tests. Additionally, clinicians must be aware that NAATs will detect nucleic acids lingering from a previous infection and that samples submitted for assessment of therapeutic response may remain positive for days to weeks after treatment due to the presence of nonviable organisms and not due to treatment failure. In these situations culture or quantitative NAATs (see Future Directions below) may provide the best option. With the increased use of highly multiplexed respiratory virus assays, a variety of mixed viral infections are detected and the clinical importance of each virus is not always evident. Nonviable virus from a previous infection may be detected, making it impossible to determine which or if all viruses contribute to the current illness. Test reports need to explain what viruses are included in the NAAT panel, sensitivity and specificity of the test, and that a negative result does not preclude infection with a specific pathogen due to many factors that can lead to decreased assay sensitivity.

Aside from the detection of the atypical pathogens and *Bordetella* spp. the detection of other bacterial pathogens, such as those included in the Unyvero test, directly from clinical samples raises several interesting questions that need to be addressed: (1) How do we differentiate between colonization and infection so as not to promote overuse of antibiotics? Are quantitative assays necessary or can assay cut off values be established at clinically relevant thresholds? (2) How many pathogens need to be included in a screening test? The detection of the broad scope of potential gram-positive and gram-negative bacterial pathogens is limited by multiplexing capabilities. Should these assays detect at a minimum those pathogens with the highest clinical impact or those difficult to treat? (3) How can we detect a broad range of resistance mechanisms, some of which do not have genetic markers (such as porin down-regulation in *Pseudomonas* spp.)? (4) Can we trust a positive result to direct antibiotic therapy? (5) Can we trust a negative result when there is the possibility of the presence of unknown resistance mechanisms? (6) Do we need to link a resistance marker to a specific bacterial target? For example, how do we interpret a result positive for a specific resistance gene when we do not detect the organism in which it would reside? (7) Will this type of testing provide actionable results, i.e., will this change clinical practice? The answers to these questions will only be resolved during clinical trials that compare NAAT results to classic microbiology testing, clinical practice, and patient outcomes. However, the future of testing may be a combination of multiplexed NAAT viral and bacterial screens.

Laboratory Issues

Laboratories must consider multiple factors in selecting the most appropriate NAAT or in developing testing algorithms (Table 52.4) [60]. Considerations include patient population(s), FDA status of the NAAT and the implications for regulatory issues, platform type, test complexity and technical expertise required, turnaround time, testing volumes, batch vs single unit testing, and the number and type of pathogens detected. The higher costs of NAATs can easily be offset by replacing the less sensitive test methods or by testing on site in lieu of referral to a reference laboratory [60, 144]. Additionally costs can be offset by other demonstrated benefits, such as improvements in patient care and financial outcomes, including 30 % reduction in antibiotic use, up to 20 % reduction in unnecessary diagnostic tests and procedures, and 50 % reduction in hospital days [9, 22, 82, 92, 115, 120, 123, 142, 170, 191, 227, 229]. To achieve these benefits NAATs should be performed within 24 h of sample collection so that results are available within a clinically relevant time frame. With the advent of single unit cartridge/pouch based tests that require minimal hands-on time and very minimal molecular technical expertise, all size laboratories can perform NAATs on all shifts. Considering the impact of global travel, comprehensive and highly specific NAATS should be performed year round and not limited to specific seasons. Although the positive predictive value of these tests remains high during times of low viral prevalence, laboratories should consider confirmatory testing when a virus is detected during an unusual time period. Some pathogens are more prevalent in specific groups

Table 52.4 Factors to consider in selecting an appropriate NAAT

Topic	Parameter	Factors to consider
Patient population	Age	Neonates, children, elderly
	Immune status	BMT, SOC, oncology, HIV
	Underlying disease	COPD, asthma, CHF, CF
	Health care inpatient setting	Risk of mixed infections, infection control
	Health care outpatient setting	Risk to family members
Regulatory issues	FDA status/CE marked	IVD, RUO, IUO, ASRs
	Regulatory requirements	CLIA, CAP, State, Federal
Laboratory issues	Test complexity	Technical expertise required, training
	Turnaround time	STAT (ED) versus routine, number of times tested per day
	Volume	Single unit cartridge versus larger batch testing
	Instrumentation/space	Complexity, cost, number of units
Assay performance	Appropriate sample types	Applicable for patient population(s)
	Sensitivity	Clinically relevant level (>90 %)
	Specificity	No cross reactivity (>95 %)
	Reactivity	Detect all subtypes (100 %)
	Consistent results	Reproducible, rare failures
Cost	Implementation	Assay validation or verification, training
	Instrumentation	Number of units
	Cost per test	Assessed by clinical benefit
	Quality	Quality control, proficiency testing

ASRs analyte specific reagents, *BMT* bone marrow transplant, *CAP* College of American Pathologists, CE cConformite Européenne, *CF* cystic fibrosis, *CHF* congestive heart failure, *CLIA* Clinical laboratory Improvement Act, *COPD* chronic obstructive pulmonary disease, asthma, *ED* emergency department, *HIV* human immunodeficiency virus, *IUO* investigational use only, *IVD* in vitro diagnostic, *NAAT* nucleic acid amplification test *RUO* research use only, *SOC* solid organ transplant,

(e.g., RSV and HMPV in children and the elderly), but limiting testing to specific age groups will miss clinically relevant disease in other patient populations [64, 83]. Infections with these pathogens can also sometimes have atypical presentations, such as pericarditis due to HMPV in an otherwise healthy adult [97]. Therefore, age may be useful in triaging initial testing but should not govern the final scope of what viruses are included in diagnostic testing. In addition, if step wise testing is considered based on risk factors such as age or immune status, coinfections that could lead to serious nosocomial transmission in health care settings should not be missed. Unexpected local, national, and international events, such as the H1N1-2009 pandemic can change our testing algorithms and laboratories must be prepared to adapt quickly to such events.

Quality Control

Kit positive and negative controls, ICs, and external controls should be used to verify the performance of the reagents and to ensure no inhibitory substances remain after extraction that could lead to poor amplification, reduced assay sensitivity, and false-negative results [77]. Controls should be tested in accordance with regulatory requirements as outlined by CLIA, CAP, and state or other federal regulatory agencies, and in accordance with the manufacturer's instructions. Ideally all controls should go through the same process as the patient sample. ICs are best added at the NA extraction step to ensure efficient recovery of NAs. ICs added after extraction will just confirm the amplification efficiency and an external extraction control must be used unless the extraction method has demonstrated negligible inhibition (generally <1 %) for the sample types tested. During amplification and detection, the IC is essential to demonstrate a lack of amplification failure or decreased efficiency. External positive and negative controls (not provided in the kit) must be used to verify each new lot and/or shipment of reagents. Each analyte of the multiplex must be verified individually in either a single reaction or as a component of a pooled control. Daily positive (individual or pooled) and negative controls must be run thereafter if batch testing is performed. Rotating controls after lot/shipment validation is acceptable. Tests using a single unit cartridge/pouch that contain a procedural control (IC or process control) do not require external controls to be run with each individual cartridge/pouch once the performance of the procedural control has been verified. External positive controls for each analyte and negative controls are only required for verification of each new lot/shipment or at a minimum once per month.

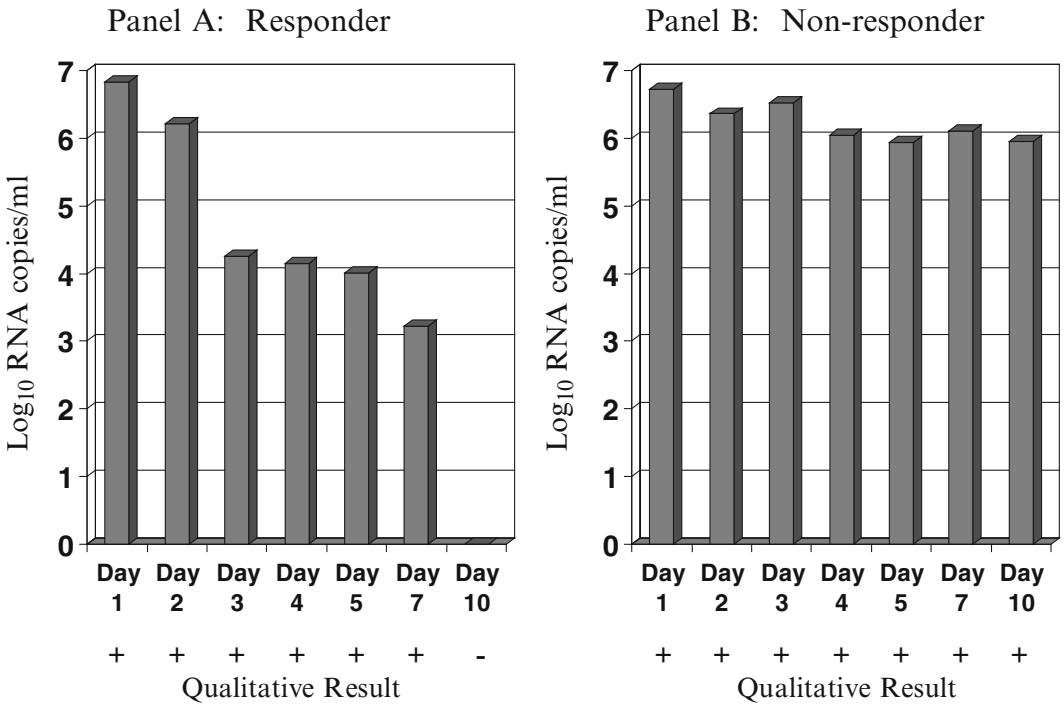

Figure 52.3 Quantitative versus qualitative testing for assessing antiviral response. Panel A: Influenza A viral load results over time in a patient with oseltamivir-susceptible influenza A virus. Panel B: Influenza A viral load results over time in a patient with oseltamivir-susceptible influenza A virus. +, positive for Influenza A detection; -, negative for influenza A detection

Laboratories must ensure proper procedures to prevent both sample and amplicon cross contamination that could cause false-positive results. Laboratories need to interpret negative results and IC values in the context of the presence or absence of potential nucleic acid degradation and amplification inhibition. Laboratories are responsible to continually assess the performance of their assays to ensure that over time, the performance has not declined due to factors such as genetic shifts in the target analytes. Finally, ongoing assessment of technical competency and participation in proficiency testing programs are essential to ensure high-quality performance and results.

Future Directions

Quantitative Viral Assays

Both virus type and the amount of virus present (viral load) can significantly impact the clinical characteristics and clinical course of RTIs. Quantitative detection of viral respiratory pathogens can help to assess the dynamics of viral proliferation, better understand viral pathogenesis, and permits a means to evaluate the significance of coinfections. Since NAATs detect both viable and nonviable virus, monitoring patients for treatment response with qualitative testing provides little information as tests may remain positive for days even with successful therapy. Quantitative tests that demonstrate a decline in viral load during therapy more accurately assess patient response (Fig. 52.3a) and the failure to see a decline (Fig. 52.3b) would potentially indicate earlier a need to consider alternative therapies. This information is especially important for critically ill patients and immunosuppressed patients. Finally, viral load assays provide important information in the assessment of new antiviral agents in FDA clinical trials. Future assay development should consider quantification of the viral targets.

Influenza Resistance Testing

Antiviral resistance to neuraminidase inhibitors can be assessed both phenotypically and genotypically [84, 161, 187]. Neuraminidase inhibition assays detect decreases in susceptibility by determining the 50 % inhibitory concentration (IC_{50}). However, these assays require growth of the virus and the presence of quasi-species can lead to unreliable results. Alternatively, genotypic assays are easier and identify known resistance mutations. However, newly identified mutations require phenotypic confirmation. Although no molecular assays are FDA-cleared for influenza resistance testing, several methods are used including traditional Sanger sequencing, pyrosequencing, PCR genotyping assays, and next-generation sequencing (NGS) [84, 161].

Pyrosequencing is currently the method of choice since the method is fast, has a high throughput, is sensitive (can detect a mutation if present in 10 % of the population), can assess multiple known mutations (e.g., H275Y mutation found in resistant H1N1-2009 strains) as well as unknown mutations and polymorphisms [52–54]. NGS has the added advantage of generating longer sequence lengths and has identified new genetic mutations associated with neuraminidase resistance. Laboratories should consider offering resistance testing in seasons where circulating strains may have varying resistance patterns (for example, H1N1 in 2007–2008 that demonstrated variable oseltamivir susceptibility), especially for patients at high risk to develop severe disease (e.g., pregnant or immunosuppressed) [38]. In addition, screening for resistance is indicated in seriously ill patients who continue to shed virus and are not clinically improving after prolonged antiviral therapy.

Next-Generation Sequencing

Over the last decade the development of NGS has transformed a labor-intensive slow process into a real-time method with applicability to respiratory diagnostics. The complexity of NGS is beyond the scope of this chapter but the use of NGS will continue to evolve in the clinical laboratory, particularly in light of easy-to-use bench top sequencers such as the Ion Torrent Personal Genome Machine (PGM) (Life Technologies, Carlsbad, CA) and the MiSeq (Illumina, San Diego, CA). Already NGS is used to detect and identify respiratory pathogens, resistance and pathogenicity markers, genetically characterize viruses, explore the respiratory microbiome, and understand the epidemiology of respiratory pathogens [169]. With new emerging technologies and simple methods to perform the required bioinformatics, this testing will increasingly become part of routine diagnostics.

Summary

The IDSA Diagnostics Task Force report: "Better Tests: Better Care: Improved Diagnostics for Infectious Diseases" highlighted the importance of diagnostic testing in the management of infectious diseases [27]. Likewise, the 2013 CDC [31] report "Antibiotic Resistance Threats in the US" states that both the development of new drugs and new diagnostics are essential to combat the threat of multiple-drug-resistant pathogens [30]. The incorporation of NAATs into routine practice for the diagnosis of infectious diseases will continue to grow, bringing new advanced technologies that allow the rapid and accurate detection of viral, bacterial, and fungal respiratory pathogens.

Mycobacterial Infections

53

Betty A. Forbes

Abstract

The genus *Mycobacterium* includes roughly 200 species. Some of these species are well recognized human and/or animal pathogens such as *Mycobacterium tuberculosis* complex. In addition, numerous other species of mycobacteria, referred to as nontuberculous mycobacteria (NTM), are present in the environment; certain NTMs possess moderate pathogenic potential and cause opportunistic infections in humans at a variety of body sites. Since all members of the genus *Mycobacterium*, by virtue of the high content of complex lipids in their cell wall, are acid-fast and are also slow growing compared to other bacteria, this group of organisms present significant challenges for timely and accurate laboratory diagnoses; in addition, chest X-ray and other clinical findings are nonspecific. In light of these challenges, molecular-based assays have been developed resulting in a dramatic improvement in the direct detection, identification, and susceptibility testing in particular for *M. tuberculosis*; however, numerous questions remain unanswered regarding the clinical utility of these various assays.

This chapter reviews current molecular-based assays for the direct detection of *M. tuberculosis* in respiratory and non-respiratory specimens as well as their use in identification of *M. tuberculosis* complex and NTMs. In addition, the use of various molecular methods to determine susceptibility of *M. tuberculosis* isolates to primary drugs used to treat tuberculosis and molecular epidemiology methods are discussed. Of significance, various laboratory issues associated with molecular-based assays are reviewed. And, finally, future directions and strategies for continued advances in nucleic acid testing technologies are reviewed.

Keywords

Mycobacterium tuberculosis • Mycobacteria • Nontuberculous mycobacteria • Nucleic acid amplification • Molecular-based assays • Direct detection

Introduction

The genus *Mycobacterium* includes roughly 200 species. Some of these species are well recognized human and/or animal pathogens such as *Mycobacterium tuberculosis* complex (*Mycobacterium tuberculosis*, *Mycobacterium bovis*, *Mycobacterium bovis* BCG, *Mycobacterium africanum*, *Mycobacterium caprae*, *Mycobacterium microti*,

Mycobacterium canetti, and *Mycobacterium pinnipedii*) and *Mycobacterium leprae*. In addition, numerous other species of mycobacteria, referred to as nontuberculous mycobacteria (NTM), are present in the environment. Certain NTMs possess moderate pathogenic potential and cause opportunistic infections in humans at a variety of body sites such as the respiratory tract, skin, lymph nodes, as well as bone and joint involvement; infections in humans caused by these organisms are increasing on a worldwide level [1]. Nevertheless, all members of the genus *Mycobacterium*, by virtue of the high content of complex lipids in their cell wall, are acid-fast and are also slow-growing compared to other bacteria.

Mycobacterium tuberculosis, transmitted via minute aerosol droplets that remain suspended in air for prolonged periods of time, is a significant human pathogen and public health problem. 2010 World Health Organization (WHO) estimates revealed 8.8 million incident cases of tuberculosis (TB), with about 13 % of these cases occurring among people infected with human immunodeficiency virus (HIV) [2]. Given the infectious nature of pulmonary TB, rapid and accurate diagnosis is a principal aim of TB control programs. Although worldwide TB incidence rates are estimated to have peaked in 2004, the overall worldwide burden continues to rise as a result of the rapid growth of the world population, the HIV epidemic, the growing challenge of drug resistance, and other epidemiological factors [3].

Clinical Utility

Despite the enormous global burden of TB and the overall low rates of case detection, conventional approaches to diagnosis continue to rely on tests that have major limitations: sputum smear microscopy is relatively insensitive, ranging from as low as 22–92 % [4–7]; culture is technically challenging and slow; determination of drug susceptibilities is even more technically challenging and slower yet; and chest X-ray and other clinical findings are nonspecific. In addition to further technological innovation, epidemiologic and operational research is needed to develop algorithms for optimal use of molecular-based assays for patient management, particularly in light of their expense. In developed countries, TB remains a low-prevalence disease, and the most rapid way to improve test performance is to select patients for testing in whom results will have the greatest predictive value. Towards this end, well-designed studies are needed to determine the clinical utility of nucleic amplification tests (NAATs). Numerous questions need to be answered regarding the effectiveness of NAATs for previously treated individuals, children, and other subpopulations, for detection of paucibacillary forms of TB, as well as how to assess the infectiousness of individual patients, when to isolate a patient, and when to begin contact investigations [8]. Nevertheless, a dramatic improvement in the direct detection, identification, and susceptibility testing of *M. tuberculosis* has been greatly facilitated in recent years using molecular techniques. Table 53.1 provides an overview of the commercial NAATs for *M. tuberculosis*.

Direct Detection

The limitations of routine acid-fast bacilli (AFB) smear and culture are well known. Although culture of sputum is positive in the majority of patients with pulmonary TB if multiple specimens are obtained, almost 30 % of patients reported to have TB, including 22 % of patients with pulmonary TB, are not culture-confirmed [2]. Similarly, childhood TB, drug-resistant TB, and smear-negative pulmonary and extrapulmonary TB in adults remain diagnostic challenges. Moreover, due to the slow growth rate of mycobacteria, cultures usually take at least a week, and in some instances, as long as 6–8 weeks to become positive.

Respiratory Specimens

While PCR is a common test method, alternative amplification techniques have been developed and patented by companies employing different enzymes and strategies, all based on reiterative reactions. The most commonly employed target amplified in *M. tuberculosis* is the IS*6110* insertion element, which is present in 10–16 copies in most clinical isolates. However, a number of other regions, either specific for *M. tuberculosis* or in conjunction with *M. tuberculosis*-specific probes, also are used as targets, such as the 16S rRNA gene, 65-kDa antigen, various regions of the β-subunit of the RNA polymerase (*rpoB* gene), and protein antigen b. Today, both commercial and laboratory-developed NAATs are available. Commercial direct amplification tests that are US Food and Drug Administration (FDA) approved include COBAS TaqMan *Mycobacterium tuberculosis* test (Roche Diagnostic Systems, Inc., Indianapolis, IN) based on PCR of 16S rRNA and the Amplified Mycobacterium Tuberculosis Direct (AMTD) Test (Hologic Gen-Probe, Inc., San Diego, CA) based on transcription-mediated amplification of rRNA. Both assays are US FDA-approved for direct detection of TB in AFB smear-positive sputum specimens from patients who have not received antituberculosis drugs for seven or more days, or have not been treated for TB within the last 12 months. However, only the Gen-Probe AMTD test is commercially available in the USA and is US FDA-approved for smear-negative specimens.

US FDA approved in 2013, the Xpert MTB/RIF test on the GeneXpert platform (Cepheid, Sunnyvale, CA) is an automated molecular-beacons test to diagnose *M. tuberculosis* and rifampin resistance. The Xpert MTB/RIF test is

Table 53.1 Commercially available, molecular-based amplification assays for the diagnosis and treatment of mycobacterial infections

Test (manufacturer)	Method	Applications/comments
Amplified *Mycobacterium tuberculosis* Direct Test (Gen Probe, Inc.)	TMA	US FDA-approved for testing smear-positive and smear-negative respiratory specimens. Target: rRNA. Direct detection of *M. tuberculosis* in broth cultures.
AMPLICOR *Mycobacterium tuberculosis* Test (Roche Diagnostics Systems, Inc.)	PCR	US FDA-approved for testing AFB smear-positive respiratory specimens only. Automated version: COBAS AMPLICOR MTB. Target: 16S rDNA. Direct detection of *M. tuberculosis* in broth cultures. No longer available in the USA
BDProbe Tec (Becton Dickinson Diagnostic Instrument Systems)	SDA	Fully automated. Targets: IS6110 and 16S rDNA.
INNO-LiPA Mycobacteria v2 (Innogenetics)	PCR with reverse hybridization	Identifies genus *Mycobacterium* and 16 mycobacterial species. Target: 16S-23S ribosomal spacer gene region.
INNO-LiPA Rif. TB (Innogenetics)	PCR with reverse hybridization	Detects *M. tuberculosis* complex plus rifampin resistance. Target: region of the *rpoB* gene.
GenoType Mycobacteria Direct (Hain Lifescience GmbH)	Nucleic acid sequenced-based amplification with reverse hybridization	Identifies 5 mycobacterial species. Target: 23S rRNA gene. Can be performed directly from decontaminated pulmonary and extrapulmonary specimens.
GenoType Mycobacterium CM/AS (Hain Lifescience GmbH)	Nucleic acid sequenced-based amplification with reverse hybridization	Identifies *M. tuberculosis* complex and 40 of the most common NTM species from culture and samples.
GenoType MTBDR *plus* (Hain Lifescience GmbH)	Nucleic acid sequenced-based amplification with reverse hybridization	Directly detects *M. tuberculosis* complex and 4 clinically important NTMs in smear-positive and smear-negative pulmonary and extrapulmonary TB or culture specimens. Detects isoniazid and rifampin resistance. Targets: region of the *rpoB* gene, *katG* gene and *inhA* gene.
GenoType MTBDR*sl* (Hain Lifescience GmbH)	Nucleic acid sequenced-based amplification with reverse hybridization	Identifies drug resistance of *M. tuberculosis* to second-line drugs (fluoroquinolone, amikacin-capreomycin and ethambutol).
Xpert MTB/RIF (Cepheid)	Semiquantitative, nested real-time PCR amplification	US FDA-approved for testing concentrated sediments from smear-positive and smear-negative induced and expectorated sputa for the presence of *M. tuberculosis* complex and detects genetic mutations associated with resistance to rifampin. Target: 81-base-pair region of the RNA polymerase (*rpoB*) Results are available in less than 2 h.

NTM nontuberculous mycobacteria
PCR polymerase chain reaction, *SDA* strand displacement amplification, *TMA* transcription-mediated amplification

approved for both AFB smear-positive and smear-negative induced or expectorated sputa obtained from untreated patients for whom there is clinical suspicion of TB. This commercial test integrates sample processing and PCR in a disposable plastic cartridge containing all reagents required for bacterial lysis, nucleic acid extraction, amplification, and amplicon detection; specimen processing is simplified to a non-precise step that both liquefies and inactivates sputum, which results in a reduction in viable tubercle bacilli of 6–8 logs and thereby eliminates the need for a biosafety cabinet. For culture-positive patients, a single direct Xpert MTB/RIF test identified 551 of 561 patients (98 %) with sputum smear-positive TB; sensitivities were 72.5 %, 85.1 %, and 90.2 % when processing one, two, or three AFB smear-negative specimens, respectively [9]. The Xpert MTB/RIF test also identified 98 % of organisms that were resistant to rifampin. This NAAT has been endorsed by the WHO for use as the initial diagnostic test for individuals suspected of having multidrug-resistant *M. tuberculosis* (MDR-TB) or HIV-associated TB (strong recommendation), and may also be considered as an add on test in settings where MDR-TB or HIV is of less concern, especially for further testing of smear-negative specimens (conditional recommendation acknowledging major resource limitations) [42]. Finally, the GeneXpert MTB/RIF detected *M. tuberculosis* in 521 non-respiratory specimens with a combined sensitivity and specificity of 77.3 % and 98.2 %, respectively [10].

Subsequent clinical trials following US FDA approval of the AMTD test on both AFB smear-positive and -negative specimens demonstrated the importance of using not only mycobacterial culture results but also multiple other parameters including clinical signs and symptoms, response to therapy, and other laboratory results to interpret the results of NAATs [11–13]. In one study [11], enrolling physicians were asked to quantify their degree of clinical suspicion for TB using a scale from 0–100 %; subjects were separated into three major groups (Table 53.2). In addition, a conservative consensus standard for the diagnosis of pulmonary TB was established and an independent expert panel reviewed all cases with a clinical suspicion < 80 % and only one culture or no cultures positive for *M. tuberculosis* (Table 53.2). Data from this and other studies support the use of the AMTD test as a rapid method for the diagnosis of pulmonary TB in patients for whom there is a moderate to high suspicion of TB, regardless of the AFB smear result.

Another commercially available NAAT is manufactured by Hain Lifescience Gmb (Nehren, Germany). This assay employs amplification followed by reverse hybridization of amplicon(s) to immobilized, membrane-bound probes, also referred to as a line probe assay (LPA). Hain Lifescience's first commercially available LPA, the GenoType Mycobacteria Direct assay, directly detects *M. tuberculosis* complex, *M. avium*, *M. malmoense*, *M. kansasii*, and *M. intracellulare* in clinical specimens [14].

More simplified versions of NAATs have been developed or are under development, particularly for peripheral laboratory facilities in resource-limited settings. A manual NAAT that uses loop-mediated, isothermal amplification (LAMP) with a simple visual colorimetric readout is being assessed in a joint development agreement between the Foundation for Innovative New Diagnostics and Eiken Chemical Company. The inherent properties of LAMP are particularly attractive for resource-poor settings, including the speed of reaction (40 min), lack of need for a thermal cycler, ease of use, and visual readout. A study in microscopy centers of developing countries using this assay to diagnose pulmonary TB demonstrated its operational feasibility [15]. In 2012, Fang et al. developed a portable integrated microchip of LAMP with sample-in/answer out capability [16]. This chip performed rapid DNA release, exponential signal amplification with a naked-eye result readout in single or multiplex format, and was able to detect 10–100 copies of *M. tuberculosis* and other bacteria. Noncommercial assays using LAMP have been reported for use with non-pulmonary specimens [17].

As more studies are published, optimal use of NAATs in conjunction with clinical information and other test methods will become manifest, allowing NAATs to be utilized in a cost-effective manner with positive impact on patient management. Clearly, based on recent studies, decisions about when and how to use NAATs for TB diagnosis should be individualized according to the clinical setting, and NAAT results interpreted within the context of the clinical suspicion for TB and on the basis of test performance. To help laboratories and clinicians in this regard, updated guidelines (Table 53.3) for the use of NAATs in the diagnosis of TB were set forth by the Centers for Disease Control and Prevention (CDC) in 2009 [18]. In 2013, the CDC published

Table 53.2 Evaluation of the enhanced AMTD test based on comprehensive clinical diagnosis [11]

Clinical suspicion of TB	AFB smear PPV and NPV (%)	AMTD test Sensitivity, specificity, PPV, NPV (%)
Low (<10 %)	36, 96	83, 97, 59, 99
Intermediate (10–80 %)	30, 71	75, 100, 100, 91
High (>80 %)	94, 37	87, 100, 100, 91

AFB acid-fast bacilli, *AMTD* Amplified Mycobacterium Tuberculosis Direct Test (Hologic Gen-Probe, Inc.), *NPV* negative predictive value, *PPV* positive predictive value, *TB* tuberculosis

Table 53.3 Guidelines for the use of nucleic acid amplification testing on respiratory specimens for TB

AFB smear	Specimen #	NAAT result	Action
Positive	1	Positive	Presumed to have TB and begin anti-TB treatment while awaiting culture results.
Positive	1	Negative	Test for inhibitors. If detected, NAAT is not informative. Clinician must rely on clinical judgment regarding the need for anti-TB therapy and further diagnostic workup while awaiting culture results. If inhibition not detected, repeat NAAT on an additional specimen.
	2	Negative	Presumed to have NTM if no inhibitors detected.
Negative	1	Positive	Use clinical judgment whether to begin anti-TB therapy while awaiting culture results and determine if additional diagnostic testing is needed. Consider testing an additional specimen using NAAT to confirm the NAAT result.
	2	Positive	Presumed to have TB pending culture results.
Negative	1	Negative	Clinician must rely on clinical judgment regarding the need for anti-TB therapy and further diagnostic workup while awaiting culture results.

Source: Data from [18]. *NAAT* nucleic acid amplification test, *TB* tuberculosis

considerations to use specifically with the Xpert MTB/RIF assay [19]. In this document, a decisional analysis of combinations of sputum AFB smear result(s) and NAAT test results was provided as well as interpretation and minimal laboratory reports for results from the Xpert MTB/RIF assay.

Non-respiratory Specimens

Both laboratory-developed and commercial NAATs have been used to test non-respiratory specimens, although no commercial assay is approved for this purpose. Because a clinical diagnosis of TB often is uncertain and AFB smear and culture lack sensitivity, NAATs are particularly attractive for suspected cases of extrapulmonary TB. In particular, NAATs have been evaluated in patients suspected of having tuberculous meningitis [20–22]. Signs and symptoms of this disease are nonspecific, and AFB smears in patients with TB meningitis are positive in only 10 % of cases. Isolation of *M. tuberculosis* is positive in only approximately 50 % of adults [23], and is insufficiently timely to aid treatment decisions. Although promising, results of these studies have varied with respect to sensitivity, while specificity was >98 % for most NAATs.

Similar results with other extrapulmonary specimens have been obtained. In many studies, the performance of NAATs with extrapulmonary specimens has been similar to their performance with respiratory specimens [12, 24, 25]; in other studies, the sensitivity was quite low for respiratory specimens [26]. Based on studies published to date, more studies are needed to establish optimal sample volume, nucleic acid extraction and amplification procedures, and uniform criteria for interpretation of results for each specimen type, including formalin-fixed, paraffin-embedded tissues. However, based on current data, a negative NAAT test result does not rule out extrapulmonary TB, particularly if the AFB smear for the specimen is negative.

NAATs are useful for early identification of *M. tuberculosis* complex for all specimen types grown in liquid cultures, except for blood [27]. Sensitivity and specificity of NAATs used to test positive broth cultures are both greater than 98 %. In addition, the INNO-LiPA Mycobacteria assay (Innogenetics NV, Ghent, Belgium) (Table 53.1) successfully identifies mycobacteria directly from aliquots of culture medium from the MB/BacT ALERT 3D System (MB/BacT) (Organon Teknika, Boxtel, The Netherlands) [28].

NAATs have also been evaluated for their usefulness in monitoring therapeutic efficacy. Although beneficial to initial diagnosis, most NAATs are unsuitable for monitoring treatment of TB patients since nucleic acid targets persist long after AFB smears and cultures become negative [29]. However, detection of *M. tuberculosis* mRNA may prove to be a potentially useful method for monitoring therapeutic efficacy [30, 31], although more studies are required to determine its clinical utility.

Identification

Mycobacterial isolates traditionally have been identified to the species level based on phenotypic and biochemical tests. These methods are slow and cumbersome and often fail to obtain an identification, with results varying among different isolates of the same species. Therefore, laboratories are increasingly using molecular methods for identification. Rapid identification of *M. tuberculosis* is of paramount importance for therapeutic and public health reasons. Rapid detection and identification of the approximately 200 species of NTM is becoming more important. Lung disease is caused by many NTM species with a range of clinical presentations and different treatment recommendations [32]. Importantly, since treatment differs among the various NTM species, including slowly and rapidly growing NTMs, and susceptibility testing results may not be available for up to 14 days, accurate species identification is a prerequisite for treatment [33, 34]. Towards this goal, numerous publications describe different molecular approaches to identify not only *M. tuberculosis* complex organisms, but NTM as well [35–38]). Finally, two commercially available systems have been used to identify mycobacteria by amplification of the spacer region of the 16S-23S rRNA genes or the 23S rRNA gene with subsequent hybridization to a membrane strip containing probes specific for the most commonly isolated mycobacterial species [39, 40].

Susceptibility Testing

To successfully control the spread of TB, cases must be detected and treated in a timely manner. At best, conventional susceptibility testing methods for *M. tuberculosis* are available within 7–14 days, after a culture result is positive, already 7–14 days from specimen collection. Thus, molecular methods that can rapidly detect drug resistance can improve the clinical timeliness of test results. Mutations responsible for resistance to the primary drugs used to treat TB have been delineated, including rifampin (RIF), isoniazid (INH), ethambutol (EMB), streptomycin (STR), pyrazinamide (PZA), fluoroquinolones, ethambutol, and amikacin-capreomycin. Because RIF resistance is an excellent marker for multidrug-resistant TB and 95 % of all RIF-resistant strains have mutations localized in an 81 bp region of the bacterial RNA polymerase gene, *rpoB*, which encodes the active site of the enzyme [41], numerous molecular strategies have been developed to detect RIF resistance. In contrast, more than a single gene mutation is frequently responsible for resistance to other drugs, such as INH, EMB, and STR. The complexity of the drug resistance mechanisms for other drugs combined with the complexity of the technology has hampered their broader acceptance of broader resis-

tance testing in the clinical laboratory setting. Nevertheless, relevant mutations for resistance to most of the primary and some secondary antituberculosis drugs have been described; most commonly, conventional or real-time polymerase chain reaction (PCR) in conjunction with analysis for specific mutations of the amplicon using a variety of methods are used to detect drug resistance mutations. Of note, to enhance the rapid diagnosis of MDR-TB, WHO in 2008 approved the use of LPAs for rapid molecular detection of drug resistance in smear-positive specimens or culture isolates [42]. Nevertheless, LPAs require routine specimen processing, DNA extraction, and conventional PCR analysis in a multiroom facility, and thus are limited to use in reference laboratories and not in resource-poor settings. Pyrosequencing also is used to detect resistance [43, 44]. More recently, a LPA has been used to detect resistance to second-line drugs and EMB in MDR-TB strains and clinical specimens [45, 46].

Epidemiology

Molecular epidemiology methods have made significant contributions to our understanding of the pathogenesis and transmission of TB within populations. For example, molecular fingerprinting techniques provided epidemiological evidence of exogenous reinfection as well as quantification of the level of infectiousness among AFB smear-negative patients [47]. Of great significance has been the use of DNA fingerprinting of *M. tuberculosis* isolates to determine the occurrence of laboratory cross contamination of cultures. Laboratory cross contamination represents a significant problem which can result in unnecessary treatment and drug toxicity for a patient. Molecular typing also provided insight as to the pathogenesis of cavitary and non-cavitary disease caused by NTM [32].

Available Tests

Hundreds of publications describe molecular methods, using a variety of formats, to directly detect mycobacteria in clinical specimens, identify mycobacteria, and detect drug resistance mutations in *M. tuberculosis*. Examples of NAATs used for mycobacteria are provided in Tables 53.1 and 53.4. The clinical use of many of these NAATs is described above in the "Clinical Utility" section.

Interpretation of Results

As with any laboratory test, prior to the interpretation of results of molecular assays on patient specimens or AFB clinical isolates, results of controls included with each run must first be interpreted. Selection and use of appropriate controls is an essential feature of any NAAT. Regardless of the format, positive and negative controls must be run in parallel with patient samples. If the assay is a laboratory-developed test (LDT) to directly detect *M. tuberculosis*, the concentration of the positive control should be near the lower limit of detection of the assay. If the run is large, multiple negative controls should be interspersed among the patient samples to monitor for cross contamination. If controls do not perform as expected, the run must be repeated. Optimally, an internal control with upstream and downstream primer recognition sequences the same as those used for detection of the organism should be added to each patient sample reaction to monitor for inhibition. If an internal control is not included (some commercial assays do not include an inhibition control, e.g., the AMTD test), a second reaction should be performed with addition and amplification of a known human target nucleic acid. If inhibition is detected, test results are reported as indeterminate or no amplification due to inhibition. For assays using gel or capillary electrophoresis, molecular weight markers are used.

Inherent problems and limitations associated with NAATs are false-positive results due to cross contamination, as well as false-negative results due to inhibition or inadequate sample collection, transport, and processing. In addition, sampling error due to low numbers of mycobacteria (paucibacillary) or inadequate sample volumes can lead to false-negative test results. Results should be interpreted in the context of the patient's history, physical examination, and clinical course. Thus, both clinicians as well as clinical microbiologists must have a thorough understanding of the advantages and limitations of the particular NAAT used for patient testing as well as the specific microbiology and pathogenesis of the identified mycobacteria.

Sequencing methods or PCR followed by restriction fragment length polymorphism (PCR-RFLP) analysis for identification of NTM provide a rapid tool for identification of this vast group of organisms. However, paradoxically, the identification of mycobacteria has become even more complex with the introduction of these techniques, since these methods have uncovered greater complexity of mycobacterial species. Further complicating the interpretation of molecular identification results were findings that specific species identification was not always successful by analysis of the 16S rRNA gene of patient strains [48]. Based on these results, identification of mycobacteria will mandate attention to quality control of available databases used for mycobacterial identification, coupled with the realization that the taxonomy of the genus *Mycobacterium* is far from elucidated. Thus, interpretation of identification results using molecular methods will require constant changes and updates to available databases [49].

In conclusion, molecular tests for mycobacteria should be interpreted within the context of clinical information and test

Table 53.4 Examples of laboratory-developed tests for mycobacterial infections

Application	Methods	Comments
Direct detection	PCR: single of multiplex Real-time PCR Peptide nucleic acids LAMP	Targets include *IS6110*, *MPB64* and protein antigen B.
Identification	PCR-RFLP with agarose gel or CE SSCP High-density DNA probe arrays Pyrosequencing	Targets include *hsp65*, 16S rDNA, *recA*, *rpoB*, *dnaJ*, and 32-kDa protein. Numerous techniques and targets for identification of *M. tuberculosis* complex.
Drug susceptibility	PCR-RFLP Heteroduplex analysis RT-PCR Real-time PCR Sequencing SSCP High-density DNA probe arrays Oligonucleotide arrays	To date, DNA sequencing is a more successful method for detecting RIF resistance.
Epidemiology	*IS6110* RFLP Secondary markers: Polymorphic guanine-cytosine-rich repetitive RFLP typing Spoligotyping (PCR-based) Mixed-linker PCR Variable number tandem repeat analysis Mycobacterial interspersed repetitive units analysis	*IS6110* RFLP has high discriminatory power. Spoligotyping is useful when discriminating isolates of *M. tuberculosis* with few *IS6110* bands, and is economical, easy to perform, and rapid.

CE capillary electrophoresis, *LAMP* loop-mediated isothermal amplification, *PCR* polymerase chain reaction, *PCR-RFLP* PCR restriction fragment length polymorphism, *RT-PCR* reverse transcription PCR, *SSCP* single strand conformation polymorphism

performance characteristics. Of great importance is strict adherence to guidelines for method validation that include the determination of clinical utility for accurate interpretation of results.

Laboratory Issues

Numerous laboratory issues pertain to the development, introduction, and performance of any clinical molecular test. To date, only guidelines, not universal standards, currently exist for the validation and subsequent quality control and assurance of commercial and/or laboratory-developed molecular tests; many of these guidelines are published by the Clinical Laboratory Standards Institute (Wayne, PA). For all NAATs, adequate and appropriately designed space, as well as other measures, is required to minimize cross contamination of samples [50]. This section will address those laboratory issues that are specific to the diagnosis of mycobacterial infections by molecular tests.

False-positive amplification results can occur from carryover of amplicon while setting up and performing the molecular assay, as well as from cross contamination of clinical specimens during processing for AFB smear and culture [51]. A review of 14 studies revealed a median false-positive rate of 3.1 % for AFB culture [52]. Of 236 patients reported with false-positive cultures, 67 % of patients were subsequently treated, and some had toxicity from therapy as well as unnecessary hospitalizations, tests, and contact investigations. Thus, performance of NAATs to directly detect and identify *M. tuberculosis*, with their inherent potential for false-positive results, underscores the critical need for adherence to strict laboratory technique, inclusion of appropriate negative controls, and careful interpretation of results within the context of the clinical presentation.

As is the case with other infectious agents, the lack of a perfect gold standard further complicates the interpretation of a positive amplification result with a negative culture for the same specimen or from different specimens from the same patient. Likewise, as previously discussed, false-negative amplification results can occur. The theoretical detection of one AFB has not been achieved in reality, which is a particular issue for the diagnosis of *M. tuberculosis* infection where there are often few organisms present in the

clinical sample. This low pathogen burden coupled with the tendency of mycobacteria to clump and thereby cause an uneven distribution of organisms in a sample can result in duplicate tests with discrepant results that are difficult to interpret.

Owing to the nature of NAATs, quality control is essential for these procedures. A quality control program should consist of an internal quality control program, as well as participation in an external proficiency testing program such as offered by the CDC. Although performance of NAATs for the detection of *M. tuberculosis* has improved over the years, a recent, multicenter quality control study demonstrated that a large number of procedures still lack sufficient sensitivity for application to AFB smear-negative samples [53].

Specific to molecular identification methods, laboratories performing these techniques must be aware of the multiple problems with present sequence repositories such as base errors, ambiguous base designations, and incomplete sequences [48]. Visual inspection of sequence results is becoming more cumbersome and challenging due to the growing number of *hsp65* alleles described in the literature [54]. Another issue slowly arising from PCR-RFLP analysis for identification is the lack of standardization for electrophoresis conditions, which makes comparison of data from different laboratories challenging. For example, difficulties in PCR-RFLP interpretation stemming from similarities in a number of band sizes needed to discriminate species via agarose gel electrophoresis could be alleviated using 10 % polyacrylamide gel electrophoresis [35].

As previously mentioned, the complexity of drug resistance in *M. tuberculosis* has hindered the utility of molecular assays. However, this limitation may be ultimately overcome by development of other molecular approaches (see Future Directions). Another caveat to testing is that the presence of a resistance gene does not always imply expression of that gene and phenotypic resistance.

Cost-effectiveness is another laboratory issue associated with the performance of NAATs for the diagnosis of TB and identification of mycobacteria. Since NAATs cannot currently replace conventional methods for the diagnosis and management of TB, a NAAT is an additional test with associated costs. Although cost savings may be realized because of possibly preventing more invasive and costly diagnostic procedures (e.g., bronchoalveolar lavage), limiting unnecessary or potentially toxic empiric antituberculous therapy, shortening hospital stays in costly isolation rooms, and limiting transmission, this type of outcomes research has yet to be systematically done. Our understanding of the natural history of infection caused by *M. tuberculosis* will continue to evolve as different applications are explored and evaluated in the clinical setting.

Many questions must be answered in order to fully exploit and utilize the potential of molecular tests for the diagnosis of mycobacterial infections. Towards this end, continued objective evaluation of the analytic and clinical performance of molecular tests, and the impact on patient outcomes, is imperative. However, published studies are often plagued by limitations such as bias in test evaluation due to inadequate blinding. Other errors in the design or reporting of TB diagnostic agent evaluations include failure to describe methods for selection and enrollment of patients, inadequate sample size, declaration of positive predictive values and negative predictive values even when the test population does not resemble the population for which the test was intended, use of inadequate gold standards for clinical case definition and microbiology, and failure to state a specific research question or test indication under study [55]. Also, a case–control study design often is used that tends to have higher bias risk than prospective, cohort-designed studies. Therefore, results from published studies evaluating the performance of NAATs are difficult to compare because of the different bias in study designs as well as in the analysis among the studies. Other contributing factors to this dilemma are failure to demonstrate statistical power, failure to appropriately evaluate and resolve indeterminate and/or discrepant results, and failure to show reproducibility of test results [55]. Another limitation of existing NAAT studies is lack of data on whether these assays have an impact on patient outcomes and how much value NAATs contribute over and above the information already obtained by conventional methods [56].

Systematic reviews of diagnostic test evaluations have been published regarding the ability of NAATs to directly detect *M. tuberculosis* complex in clinical specimens (e.g., [56–58]). The overwhelming majority of the individual studies included in the systematic reviews reported very high estimates of specificity of NAATs for pulmonary and extrapulmonary tuberculosis. However, the systematic reviews report sensitivities were generally lower and highly variable across most studies. Overall, the accuracy of NAATs for the direct detection of *M. tuberculosis* complex was far superior when applied to pulmonary samples as opposed to extrapulmonary specimens. In addition, the sensitivity of NAATs was optimal in smear-positive pulmonary tuberculosis. As proposed by Nahid et al. [59], a NAAT should not be performed if sputum smears are negative and the clinical suspicion is low; by the same token, a negative NAAT in a patient with a high index of clinical suspicion should not preclude continued investigation. Finally, meta-analyses have shown that LPAs are highly accurate, and the GenoType assay, in particular, performs well for rapid detection of RIF resistance in smear-positive specimens [60].

Future Directions

Continued advances in nucleic acid testing technologies will only serve to enhance capabilities for the diagnosis of mycobacterial infections. Efforts employing a variety of strategies already are underway.

Miscellaneous Methods

Different strategies and formats for easier and more rapid means to detect and identify mycobacteria are continually being published. To illustrate, DNAs extracted directly from slides of AFB smears (AFB smear-positive and -negative) made from specimens submitted for AFB smear and culture were tested for *M. tuberculosis* by PCR and sequence analysis for RIF resistance. This approach was 100 % sensitive and specific for the detection of *M. tuberculosis* and RIF resistance [61].

Another approach is the use of fluorescently labeled peptide nucleic acids (PNAs) to directly detect *M. tuberculosis* microscopically [62]. PNAs are DNA-like molecules in which the sugar phosphate backbone is replaced with a peptide-like structure that can hybridize to specific DNA sequences with specific base pairing. PNAs can be labeled with a fluorescent dye to allow for visualization of PNA binding to specific DNA sequences present on a slide. Of significance, the PNA can easily pass through an intact cell wall and bind specifically to intracellular nucleic acid sequences. This strategy for the direct microscopic identification of *M. tuberculosis* and NTM appears to hold some promise.

Finally, new rapid phenotypic methods employing reporter phages avoid some pitfalls associated with genotypic methods for detecting drug resistance in *M. tuberculosis* [63]. A high-intensity mycobacterium-specific fluorophage (NGFP10) was recently reported that allowed direct visualization of *M. tuberculosis* in clinical sputum samples that also detected drug resistance [64]. In addition, efforts are underway to expand the coverage of polymorphic alleles associated with drug-resistance in order to detect MDR-TB. New strategies will continue to be developed and evaluated in direct detection and identification of mycobacteria as well as drug susceptibility testing.

Automation and Miniaturization

The development of real-time PCR assays and other amplification methods in which single or multiple nucleic acid targets can be amplified and analyzed in a single closed tube in minutes rather than hours is particularly suited for subsequent automation. A new generation of mismatch-tolerant probes, referred to as sloppy molecular beacons, can identify mutations in *M. tuberculosis* in clinical samples that contain both drug-susceptible and drug-resistant nucleic acid [65]. This approach allows for homogeneous, closed systems which avoid carryover amplification contamination, are amenable to multiplexing, and are easily amenable to a high-throughput format. Instruments that automate the extraction of either RNA or DNA have been introduced allowing for the performance of a greater number of molecular tests while also providing a more consistent quality of nucleic acid for analysis.

In addition to automation of NAATs for the diagnosis of mycobacterial infections, miniaturization of analytical devices by micromachining technology will be developed to perform PCR in micro-reactors consisting of either silicon or silicon and glass microchips [16, 60, 66]. Although several new diagnostic tests recently have been endorsed by the WHO, a point-of-care (POC) testing device has remained elusive. Developing POC tests with sample-to-answer capability is much needed, particularly in those countries with the highest incidence of TB coupled with limited resources. Advances in this area will have a major impact on the ability to diagnose TB in the field and in poorly resourced regions.

Microarrays

High-density oligonucleotide arrays can rapidly examine large numbers of DNA sequences with a single hybridization step. DNA microarrays can be used in two modes: (1) DNA-based comparison of the genomic content of different strains, and (2) RNA-based monitoring of gene expression. Work has begun for species identification and drug resistance profiling, and strain genotyping of mycobacteria involved in human disease [66]. For example, a commercial, rapid microarray system for the identification of mycobacteria was reported to have correctly identified 100 % of *M. tuberculosis* complex and 98.4 % of NTM clinical isolates [67]. Moreover, an overall sensitivity of 52.5 % for direct detection and identification of mycobacteria in clinical specimens was achieved with 100 % detection and identification of mycobacteria from sputum specimens, albeit the sample size was small ($n=40$). A commercial oligonucleotide microarray to detect RIF resistance in *M. tuberculosis*, the TB-Biochip (Engelhardt Institute of Molecular Biology, Moscow, Russia), was evaluated in a small study in which results obtained with the TB-Chip were compared with conventional susceptibility testing results; the microarray had a diagnostic sensitivity of 80 % [68]. Of note, the spoligotyping assay format for *M. tuberculosis* was converted to a DNA microarray format [69]. As *M. tuberculosis* drug resistance determinants are gradually delineated, this type of platform could be expanded, even with the addition of epidemiological markers.

Forensic DNA Typing

54

Victor W. Weedn and David R. Foran

Abstract

Forensic DNA typing is generally dated to 1985 and has become the most commonly performed analysis in the modern forensic science laboratory. The technology and methods have evolved and continue to evolve. Analysis of Short Tandem Repeats (STRs) following polymerase chain reaction amplification is used routinely, but other genetic markers, such as Y chromosome STRs, single nucleotide polymorphisms, and mitochondrial DNA, are also tested. These technologies can be applied to a wide variety of evidentiary specimens and powerfully discriminate individuals. They are commonly introduced into court. In fact, forensic DNA is now considered the "gold standard" of forensic science technologies.

Keywords

Forensic DNA typing • Forensic molecular biology • Forensic genetics • STRs • Biological evidence

Introduction

The person on the street when asked about DNA testing will generally first envision a crime laboratory rather than a hospital laboratory. Still today, most criminal perpetrators are caught and prosecuted based upon eye witnesses or confessions, although increasingly scientific evidence comes into play. Forensic DNA typing has become the queen of the forensic sciences and is looked to as the most scientifically grounded of the forensic sciences [1]. The bulk of forensic evidence links an evidential item to the crime scene, but does not identify the perpetrator. Other than videocapture, only fingerprint friction ridge analysis and DNA typing identify the perpetrator per se. Fingerprints came into widespread use for forensic purposes in the late nineteenth century and were admitted into US courts as evidence in the 1930s. The Federal Bureau of Investigation (FBI) owes its origins to the need for a centralized database of fingerprints. Today, millions of fingerprints are filed for criminal and civil purposes. Likewise, millions of convicted offenders' DNA profiles, and in many states, arrestees', are also databased. Thus, DNA tests not only confirm a detective's hunch but, due to the DNA databases, also have become a powerful investigatory tool to identify otherwise unsuspected perpetrators [2].

Serology tests (blood group and type testing and then serum protein isoenzyme electrophoresis) were the forerunners to forensic DNA identity testing of biological materials. Unfortunately, these tests required specimens with a significant amount of high-quality blood serum and they did not have a very strong discriminatory power. Advantages of DNA typing over serologic methods include greater discriminatory power, species specificity, tissue independence, greater sensitivity, and less susceptibility to degradation [3].

The Bureau of Justice Statistics (BJS) first surveyed US crime laboratories in 1998, focusing exclusively on agencies

that performed DNA analysis, and found that there were 120 public forensic DNA laboratories, which had a median staff of 5 and faced substantial backlogs [4]. According to the 2005 *BJS Census of Publicly Funded Forensic Crime Laboratories*, about half the public crime laboratories were performing DNA testing [5]. Although there is no corresponding contemporary study, it seems clear that the size and number of forensic DNA laboratories have substantially increased, with most of the 450–500 public crime laboratories now performing DNA testing. The National Institute of Justice (NIJ), beginning with a 2003 *Advancing Justice Through DNA Technology* initiative, has spent hundreds of millions of dollars on forensic DNA capacity building [6].

Forensic Testing and Sample Considerations

Forensic v. Clinical Specimens and Tests

Forensic tests differ from clinical tests in several respects. First, whereas clinical samples can be standardized, forensic samples vary substantially. An analyst may routinely encounter cigarette butts as evidence, but then must be prepared to face a completely new challenge for the first time, such as a partially eaten piece of food. Second, clinical samples are relatively substantial, whereas forensic laboratories routinely receive trace evidence, permitting testing only once (although routine practice is to attempt to save a portion, if possible, for potential testing by the defense). Third, unlike clinical specimens, evidentiary materials are usually neither fresh nor pristine. For example, semen samples are generally admixed with vaginal cells and microbial flora in a rape swab (Fig. 54.1), spit on a sidewalk has been exposed to the sun and rain, and blood on the floor may have been there for months. Furthermore, forensic testing is performed with an eye to court challenges. Thus, the forensic scientist uses only well-validated protocols, documents all aspects of laboratory processing, and must be ready to defend the science, the procedures, and the testing against legal attack. Chain-of-custody must always be maintained in forensic laboratories. Moreover, clinical laboratory staff are generally not familiar with the regulations, standards, and quality assurance practices of forensic laboratories. Thus, clinical laboratories, though technically capable, are normally not prepared to conduct forensic identity testing. Nevertheless, since clinical laboratories use identity testing for other applications, an understanding of forensic identity testing is useful as an introduction to the methodology and for the historical background.

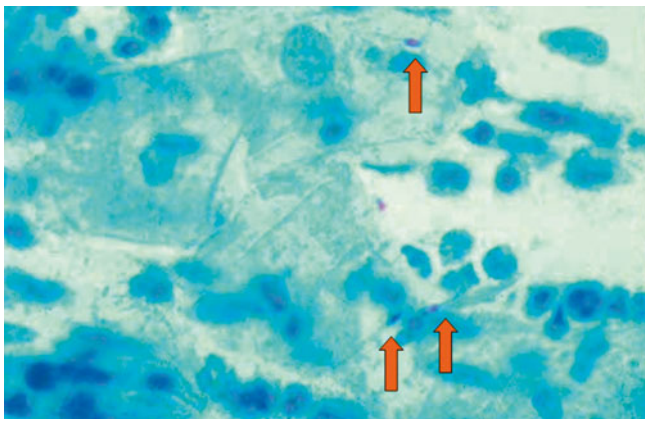

Figure 54.1 The most common DNA evidence in US crime laboratories is a vaginal swab from a rape kit. This photomicrograph is a stained vaginal smear from a rape kit. The *arrows* indicate spermatozoa. In addition to the DNA from the male contributor, there is DNA from the female epithelial squamous and white blood cells, as well as that of the microbial flora

Sexual Assaults (Swabs)

In the USA, rape kits have dominated the evidential submissions to forensic DNA laboratories (Fig. 54.1). Often, the demand for DNA testing on rape kits outstrips the ability of crime laboratories' testing capacity and large backlogs may exist despite substantial NIJ grant programs to reduce them [7]. Typical rape kits include vaginal, anal, and oral evidentiary swabs, buccal reference swabs, pubic combings, and exemplars of pubic and scalp hairs. If a condom was used by a rapist and later found, it may yield semen from the male perpetrator on the inside and vaginal epithelial cells from the female victim on the outside. Vaginal swab specimens are inherently mixed samples. Most commonly the DNA of the spermatozoa is partially purified by a differential extraction procedure in which the female fraction is released using a gentle lysis medium, after which male DNA is released from the sperm using a solution containing a strong reducing agent (dithiothreitol) to break the disulfide bonds in the capsules of the spermatozoan heads [8]. Laser capture of spermatozoa from microscopic slides has also been successfully used, while immunologic affinity methods have thus far been disappointing. Y-chromosome DNA markers (described below) are an alternative method of capturing male identity information.

Other Violent Crimes (Blood, Other Evidence)

Blood and similar specimens from homicides and other violent crimes are the next-most-common evidentiary materials submitted to forensic laboratories [9]. In an early study of biological evidence at crime scenes, blood was found to be present in 60 % of murders, assaults, and batteries [10]. The DNA can come from myriad items and materials. Saliva may

Figure 54.2 DNA testing identified a masked bandit when his peach strudel that was left at the scene of an armed robbery was used for DNA testing

Figure 54.3 This vacuum cleaner cord was used as a ligature for a strangulation murder. Swabbings of the cord along its length revealed the victim's DNA in the center and a mixture of victim and accused DNA on outer areas of the cord

be deposited on beverage containers, envelope seals, gum, cigarettes, or food (Fig. 54.2). Investigators have followed suspects to obtain "abandoned" specimens, such as facial tissues, cigarette butts, gum, or drinking glass. Cords used as a murder weapon for strangulation can yield both victim and perpetrator DNA (Fig. 54.3). Shed hairs, which contain little or no nuclear DNA (nDNA), still harbor mitochondrial DNA (mtDNA), which also can be used for identification purposes. Fingernail swabbing or scrapings occasionally yield foreign DNA if a victim struggled and scratched the perpetrator, and similarly bite marks can be swabbed for DNA. Reference samples may come from toothbrushes, razors, combs, clothing, and medical specimens. One of the authors (DF) has shown DNA to be useful to identify the bombmaker of deflagrated improvised explosive devices [11].

Property Crimes (Touch DNA)

Increasingly, jurisdictions are performing DNA testing in property crimes, including theft, burglary, robbery, and arson, among others. The vast majority of US crimes are property crimes: 9.3 million property crimes compared to 1.3 million violent crimes in 2009 [12]. The case closure (clearance) rate for property crimes is <20 % [13] and DNA testing for such crimes has been found to be cost-effective [14]. Furthermore, it is generally thought that some individuals progress from nonviolent to violent crimes; often from petty theft to burglary to rape, and thus interdiction of a criminal career progression may break the cycle and prevent major crimes [15, 16]. In general, DNA testing for property crimes involves "touch DNA" from handled objects. The possibility of testing such trace or "low copy number" (LCN) DNA was introduced in 1997 when Dr. van Oorschot reported that minute quantities of DNA can be recovered from fingerprints [17]. Conventional laboratory testing will successfully type DNA from approximately 100 cells (0.5–1 ng at 6.5 pg/diploid cell), although many forensic laboratories may be successful down to as few as 15–20 cells (approximately 100 pg). LCN DNA is generally defined as <100 pg, but 35 pg is often considered an analytical threshold. LCN DNA testing for property crimes was pioneered by Drs. Peter Gill and Dave Werrett at the Forensic Science Service (now disbanded) in the UK [18] and later in the USA by Dr. Mechthild Prinz and Theresa Caragine in the New York City Office of the Chief Medical Examiner's Department of Forensic Biology [19]. Such testing involves minimizing reaction volumes and increasing polymerase chain reaction (PCR) cycling (see below). However, only a portion of the specimens yield a useful profile (perhaps 10–20 %). LCN DNA testing is problematic due to detection of contamination from prior handling, in-laboratory contamination, and inconsistent results that stem from random sampling of one or both alleles when both exist at very small levels (so-called stochastic sampling effects). These difficulties are compounded by the destructive nature of DNA testing, which may negate the possibility of retesting. For these reasons, some have suggested that LCN analysis should only be used for investigative purposes, and not as probative evidence in court. No national standards are yet in place and the FBI has generally recommended against such testing [20]. Nonetheless, LCN testing is increasingly used. The object is swabbed and resultant DNA extracts may be amplified two or three times, wherein analysts hope to obtain pure (single) profile results that are assumed to be from the last person who pulled the trigger of a gun or handled a knife. Forensic laboratories performing this testing will generally simply disregard any results other than clear single profiles.

Other Forensic DNA Testing Applications

Forensic DNA identity testing also can be used in other forensic and non-forensic contexts. For example, urine samples from drug testing may be analyzed to confirm that the sample is truly from the person who allegedly generated it [21]. DNA testing is used for disaster victim identification [22]. In cases involving nonhuman DNA (discussed below), individual, group (clade), or species may be determined, linking items such as a plant leaf or animal hair to a criminal case, or proving illegal poaching activity [23]. "Microbial forensics" has been developed for source attribution of terrorist pathogens, such as the anthrax letter attacks [24, 25]. Genetic analyses can identify the type of body fluid or tissue (e.g., urine, semen, saliva) based on the RNAs expressed. DNA testing can be used for investigatory purposes by supplying information about the perpetrator using phenotypic markers (described below), as well as through partial ("low stringency") matches that may detect relatives who represent investigatory leads (described below). In non-criminalistic applications, the same tests used in forensic identity testing can be used for determinations of parentage and sample switch disputes [26].

Genetic Systems and Methods for DNA Typing

Genetic Variation

In everyday life, we easily recognize individuals through obvious biological variation among individuals. Positive identification or individualization is a statement of uniqueness, which is theoretically impossible to prove. However, forensic identity testing harnesses the extraordinary statistical discriminatory power of genetic variation to support a policy-based, administrative, or judicial determination of identity [27]. Indeed, forensic DNA testing often is thought of as tantamount to positive identification. Genetic variation occurs in a continuum of biological classification, from kingdom to genus, clades, and individuals. Specifically, forensic DNA identity testing is based on the detection and comparison of polymorphisms (poly—many; morphs—types) in the DNA among individuals. Statistically, there is variation at approximately one in every thousand base pairs (bp) between every two unrelated humans. However, this variation is not random; many protein-coding regions are highly conserved, as mutations in genes succumb to natural selection. Most polymorphisms occur in the noncoding DNA, which predominates in the human genome (>98 %) and is more tolerant of mutation than the protein-coding DNA regions. Differences between individuals can be due to single nucleotide polymorphisms (SNPs) or variations in length of a specific region or locus in the genome; that is, length polymorphisms. Such polymorphisms result in different forms, or alleles, of genetic markers. All individuals have two copies of each autosomal chromosome: one inherited maternally and the other paternally. Routine forensic DNA testing, using short tandem repeat (STR) typing, (described below) involves length polymorphisms in repetitive DNA from noncoding regions of the chromosomes, although it employs only a small fraction of the differences in the human genome among individuals.

Restriction Fragment Length Polymorphisms

Historical Context

In the mid-1980s, most DNA-based forensic analysis involved restriction fragment length polymorphism (RFLP) testing, first described by Dr. Edwin Southern in 1975 [28]. Such testing merely gave a binary result and was too little information for too much work. Drs. Wyman and White detailed a polymorphic RFLP marker in 1980, in which variation between human individuals was observed [29]. However, the beginning of the forensic DNA typing revolution began with the 1985 publication of a landmark article by Dr. Alec Jeffreys of Leicester, England, in which he coined the term "DNA fingerprint" and suggested the potential application of DNA fingerprinting in forensic investigations [30, 31]. His technique involved use of "minisatellites," which was a multilocus probe RFLP system that yielded a bar code pattern that seemed to be different for every person (Fig. 54.4). Jeffreys conducted the first DNA identity tests in 1986 in a disputed immigration case and a double rape-homicide, which resulted in the 1987 exoneration of Richard Bucklin and then the 1988 conviction of Colin Pitchfork [32, 33]. In the USA, single-locus probe RFLP analysis was pioneered by Dr. Arthur Eisenberg (then at Lifecodes Corporation), that was more robust and permitted statistical evaluation (Fig. 54.5). In 1986–1987, commercial laboratories, particularly involving Dr. Edward Blake of the Serologic Research Institute, Drs. Michael Baird and Arthur Eisenberg of Lifecodes Corporation, and Dr. Robin Cotton of Cellmark Diagnostics, undertook forensic DNA testing in the USA, and in 1987 Tommy Lee Andrews became the initial American to be convicted of a crime (rape) using DNA data [34]. The FBI, led by Dr. Bruce Budowle, began performing DNA typing casework in December 1988. A few months later, in March 1989, Virginia became the first state crime laboratory with an operational DNA unit, directed by Dr. Paul Ferrara. RFLP testing was the mainstay of most criminalistic DNA typing for a decade. At the same time, Dr. Henry Erlich and coworkers of Cetus Corporation, developed a faster PCR-based (see below) HLA DQ-alpha dot-blot system (and later the Polymarker system, Fig. 54.6), but

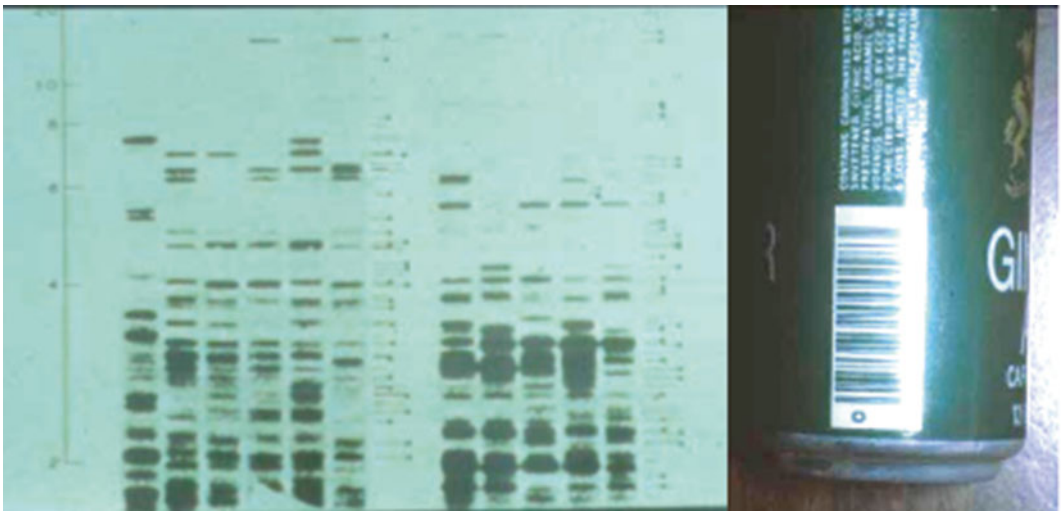

Figure 54.4 In 1985, Alec Jeffreys first described a DNA fingerprint. He used a multilocus minisatellite probe that resulted in a band pattern similar to a bar code, such as the one shown on the can to the *right*. The various lanes of the autoradiograph are from different individuals, demonstrating that each shows a unique pattern of bands. This multilocus probe method of DNA typing is no longer used in forensic identification

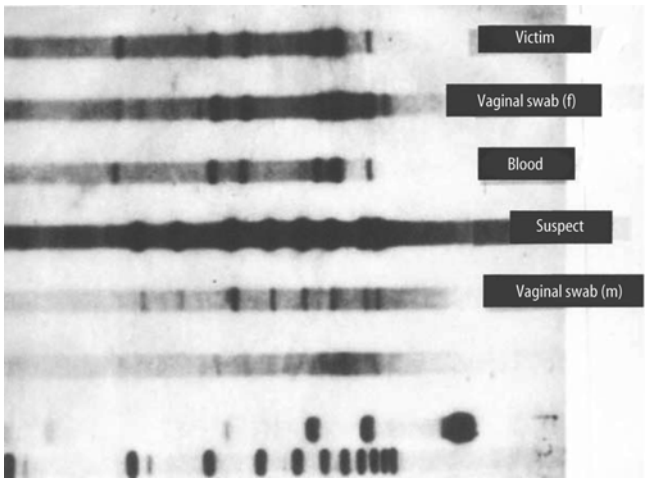

Figure 54.5 RFLP autoradiograph with five analytical lanes and three control lanes. The DNA profile of the reference sample from a female rape victim matches the DNA profile of blood found at the scene and that of the female fraction of a vaginal swab. The DNA profile of the suspect reference specimen matches the male fraction of a vaginal swab but does not match the DNA profile of the female victim

it did not have sufficient discriminatory power for widespread adoption by the forensic community. Nevertheless, the first use of DNA tests in litigation in the USA was in 1986, in the case of *Commonwealth v. Pestinikas*, using HLA DQ-alpha to show that organs had not been switched in an autopsy [35]. In the early 1990s, PCR-based STR systems (described below) were developed and eventually became the standard forensic DNA test worldwide. STR methods replaced RFLP systems due to robustness, sensitivity, statistically discrete systems, ease of automation, and economy. Other systems, such as Y-chromosome markers, mtDNA sequencing, and phenotypic markers also are sometimes used (described below) (see Table 54.1).

Early Cases Using DNA Testing

Queen v Pitchfork

The first criminal investigation using DNA typing was in a double rape-homicide (of Linda Mann in 1983 and of Dawn Ashworth in 1986) on a deserted footpath in the English countryside, known as the "Black Pad Murders." Richard Buckland, a person of low intelligence and sexual fetishes, became the focus of early suspicion and was charged but then exonerated by the new Jeffreys DNA tests. Males in the community between 13 and 30 years of age were asked to volunteer blood samples for DNA testing. There were no matches despite 4,500 "bloodings." However, police discovered that a man named Ian Kelly had substituted his blood for Colin Pitchfork's sample. Pitchfork was subsequently DNA matched and then convicted of both homicides.

Pennsylvania v Pestinikas

The first use of DNA typing in the USA was in a 1986 nursing home negligent homicide case. Forensic Science Associates performed DNA tests to prove that organs in the autopsy had not been switched as was alleged by one expert. The DNA in this case had become highly degraded, averaging fragments of approximately 100 bp.

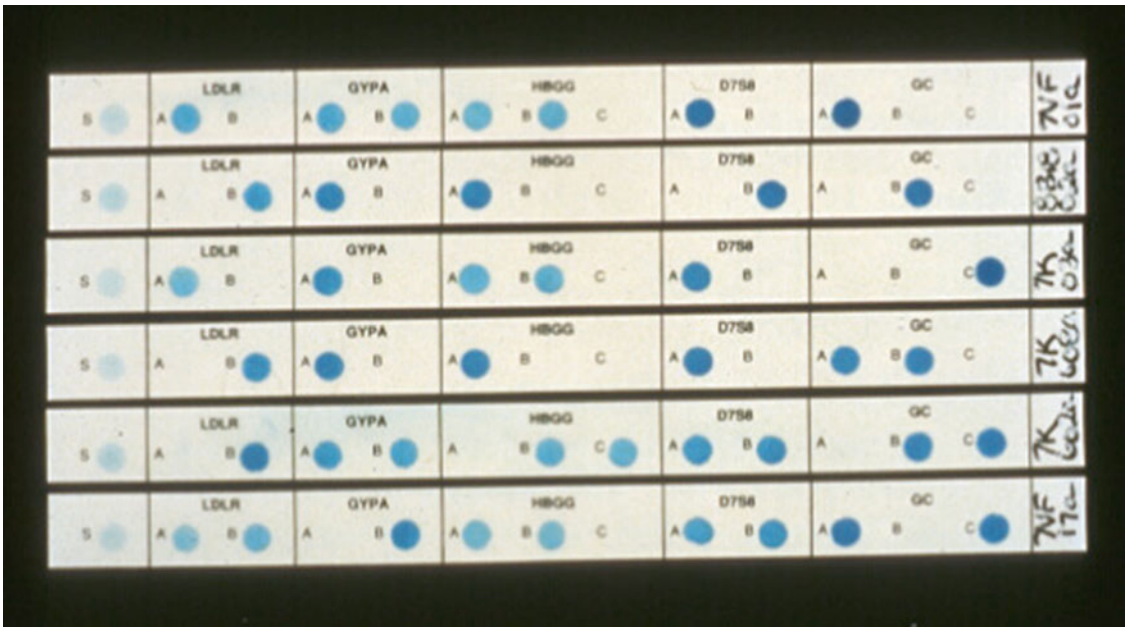

Figure 54.6 Polymarker strips from different individuals using five genetic systems detected by PCR amplification and reverse dot-blot hybridization probes. *GC* group-specific component, *GYPA* glycophorin A, *HBGG* hemoglobin gamma-globin chain, *LDLR* low-density lipoprotein receptor,

Table 54.1 Summary of DNA typing system usage in crime laboratories

Typing method	PCR-based	Late 1980s	1990s	2000s	Utility
RFLP	No	*Dominates*	*Dominates*	Abandoned	Routine casework
Dot blots	Yes	Used	Used	Abandoned	Routine casework
STRs	Yes	In research	Used	*Dominates*	Routine casework
mtDNA	Yes	In research	Used	Used	Hairs, degraded samples
Y-STRs	Yes		In research	Used	Vaginal swabs in rape cases
SNPs	Yes			In research	Very degraded samples

mtDNA mitochondrial DNA, *RFLP* restriction fragment length polymorphism, *SNPs* single nucleotide polymorphisms, *STRs* short tandem repeats, *Y-STRs* Y chromosome short tandem repeats

Florida v Andrews

The first US criminal conviction based on DNA typing was of a serial rapist, Tommy Lee Andrews (1987). A series of breaking and entering women's homes and rapes began in 1986 in Orlando, Florida. A stakeout resulted in an arrest, and Lifecodes Corporation matched the suspect's DNA to vaginal swabs of two of the rape victims.

PCR Amplification as Sample Preparation

Today, all major methods for routine forensic DNA testing begin with amplification of the DNA target by PCR. Dr. Kary Mullis shared the 1993 Nobel Prize in Chemistry for PCR development in 1983. Forensically valuable human leukocyte antigen (HLA) polymorphisms were among the earliest targets to be amplified by PCR in the laboratory [36]. PCR amplification is relatively easy to perform, inexpensive, quick, and amenable to automation. It also permits chemical labeling of the amplified fragments, as well as simultaneous amplification of several loci in a single reaction (multiplex). PCR amplification allows the routine testing of nanogram quantities of DNA, and can be optimized for testing of even picogram quantities, enabling the use of new classes of evidentiary specimens. However, such sensitivity requires extreme care to prevent contamination, including laboratory

facilities with separate pre- and post-amplification areas, unidirectional handling of evidence intake through final analysis, limited laboratory access by untrained personnel, and knowledge of each analyst's DNA profile to identify any contamination. Lastly, PCR can be successful on evidentiary material in which the DNA has become degraded and only a few fragments with the intact target sequence remain. Although amplification methods other than PCR exist, the conservative forensic community will not likely be quick to adopt an alternative to PCR unless there is a very good reason.

Short Tandem Repeats

STRs are repeat length polymorphisms that have become the mainstay of current forensic identity profiling around the world. Core repeat units in STR systems are tetranucleotide or pentanucleotide elements (i.e., have four or five nucleotides in each core repeat, respectively), with resulting amplicon sizes of approximately 100–450 bp (see Fig. 54.7). STR analysis is robust, amenable to automation, highly sensitive, relatively insensitive to degraded DNA, and yields discrete alleles. Multiplexed amplification of multiple STR loci achieves extraordinary discriminatory powers (typically $>10^{-12}$) (see Fig. 54.8). As a result, PCR-based STR testing has become dominant in forensic DNA laboratories (Table 54.1).

In the late 1980s, Dr. C. Thomas Caskey working with Holly Hammond, then at Baylor College of Medicine in Houston, Texas, was funded by NIJ to develop STR systems for forensic applications [37]. Subsequently, in 1991, STRs were first used in casework by one of the authors (VW) at the US Armed Forces DNA Identification Laboratory (AFDIL), through a subcontract with Cellmark Diagnostics, to identify service members who died in the first Persian Gulf War. However, it was Drs. Peter Gill and David Werrett at UK's Forensic Science Service who, in the mid-1990s, began applying STR analysis (using in-house systems) to routine criminal casework [38, 39].

Recognizing the importance of cross-jurisdictional matches, the FBI convened a panel of forensic scientists in 1998 to select a panel of STR loci for use in their National DNA Index System (NDIS). Thirteen loci, all containing tetranucleotide repeats, were chosen: D3S1358, D5S818, D7S820, D8S1179, D13S317, D16S539, D18S51, D21S11, CSF1PO, FGA, THO1, TPOX, and vWA (Table 54.2) [40, 41]. These 13 core loci have become standard for forensic casework in much of the world and are referred to as the "CODIS" loci, after the Combined DNA Index System (CODIS) software into which DNA profiles are entered [42]. Databases are maintained of the STR alleles of convicted felons, casework profiles, and missing persons, although exactly which profiles can or must be uploaded varies based on state requirements. The commonality of genetic systems (i.e., STR loci) used in forensic casework enables computer searches for matches across jurisdictions.

All CODIS STR loci are tetranucleotide repeats. In general, smaller fragments are preferred for amplification of potentially degraded samples. Additionally, preferential amplification, where smaller target DNA fragments are

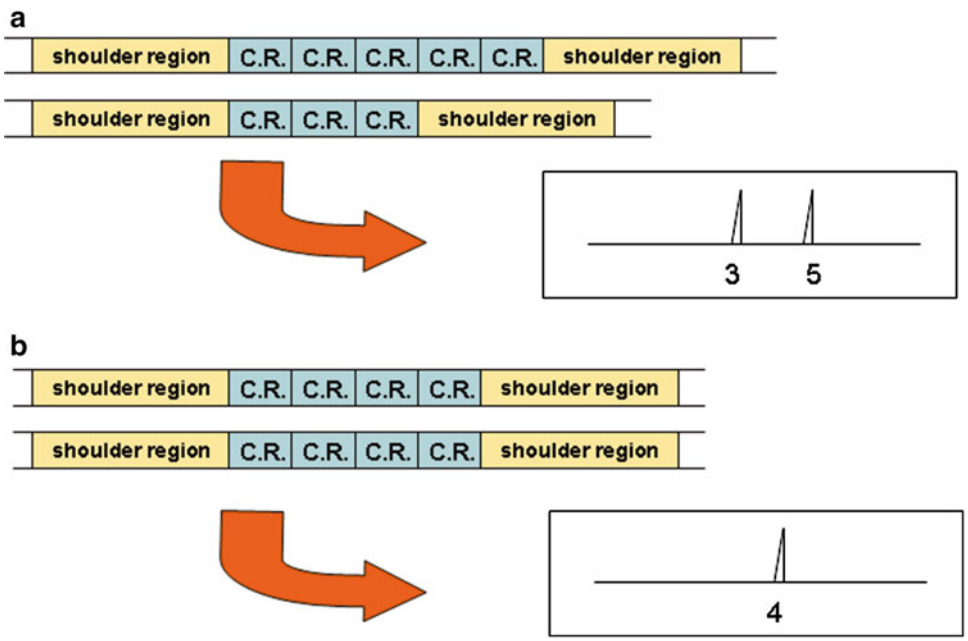

Figure 54.7 Diagram of short tandem repeat DNA segments composed of varying numbers of core repeats (C.R.) and accompanying electropherograms showing the corresponding allele peaks: (**a**) heterozygous pattern with alleles of 3 and 5 repeats, (**b**) homozygous pattern with allele of 4 repeats. The shoulder region is the flanking constant region to which PCR primers hybridize

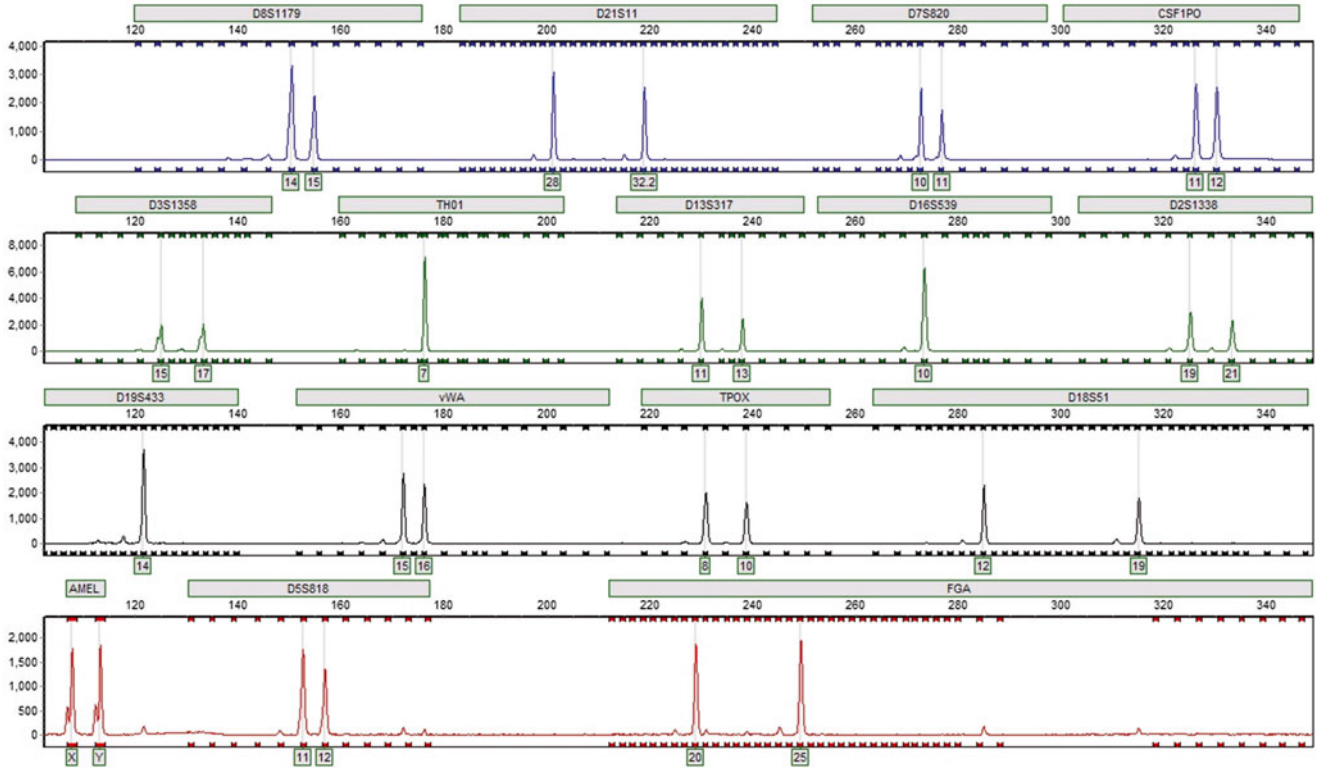

Figure 54.8 Electropherogram of multiplexed fluorescently labeled PCR amplicons of STR loci demonstrating the allelic determinations (*boxes*). The *X*-axis reflects time and the *Y*-axis reflects fluorescence intensity. Four fluorophore colors permit separate analysis of genetic loci with overlapping sizes. A fifth dye channel is used for a size standard that is not shown. This person is a 15,16 genotype at the vWA locus, a 7,7 genotype (7 phenotype) at the TH01 locus, has a 32.2 variant allele in the D21S11 locus, and is a male according to the amelogenin locus

The STR systems are named by their designated genetic locus. The physical location is their chromosomal site. The number of alleles is the observed number rather than the theoretical potential number of alleles. The range of repeats includes non-whole number integers which represent partial repeats. The heterozygosity (H) is the gene diversity (sometimes designated as D) calculated as 1 minus the sum of the population frequencies squared for each allele. The mutation rate (Mut %) is expressed as a percentage.

amplified preferentially over larger targets, becomes an issue with large core repeats as the size discrepancy between overall allele lengths increases substantially. However, "stutter" can become problematic if the core repeat size (for example, dinucleotide and trinucleotide repeats) is too small. Stutter peaks are produced when the DNA polymerase slips during amplification, resulting in PCR products that have fewer or more repeat units than the starting template, with the major stutter product generally one repeat unit less than the template. Dinucleotide and trinucleotide repeats have substantial stutter, while pentanucleotide or larger repeats have almost none.

Commercial kits for amplification of the CODIS core STR loci are available in various combinations of multiplex primer sets from two companies: Promega Corporation and Applied Biosystems Inc. (ABI, a subsidiary of Life Technologies, Cartsbad, CA). ABI sells the Identifiler series, which includes all 13 core loci as well as amelogenin (below), D2S1338, and D19S433 in a single reaction. Promega offers the PowerPlex series, such as PowerPlex 16 that includes the 13 core loci, plus amelogenin and two pentanucleotide repeat loci, Penta D and Penta E. These two companies regularly produce new products that add loci to the multiplex, increasing discriminatory power. Mini-STRs, such as Applied Biosystem's Minifiler, are traditional STRs with primers designed to reduce the flanking regions and thus the amplicon size, so that typing results can be obtained from more substantially degraded specimens.

The 13 CODIS core STR loci are being expanded to a likely set of 24 loci. The impetus for this expansion is to reduce the likelihood of adventitious matches in large databases, to increase the compatibility with international databases, and to increase the discrimination power for missing person cases [43]. The putative additional loci include loci from the European Standard Set (ESS). ABI has responded with the Global Filer kit and Promega with the Powerplex Fusion kit. These new kits have been engineered to be more sensitive as well as capable of more rapid amplification (see discussion below).

Amelogenin and Other Sex Markers

An amelogenin assay is included in current commercial STR amplification kits as a sex marker [44]. The amelogenin gene is present as homologs on both the X and Y chromosomes, but there are a number of sequence differences in the noncoding regions. The locus used in forensic testing involves a 6 bp deletion on the X chromosome; thus, the X marker is shorter than the Y marker and males manifest two peaks whereas females manifest a single peak of twice the intensity (Fig. 54.9). The amelogenin sex marker system is robust and reliable, although in very rare instances, sex-typing discrepancies have been noted [45]. Other sex markers have been described, including ones that exist at higher copy number and are thus more sensitive than the single copy amelogenin.

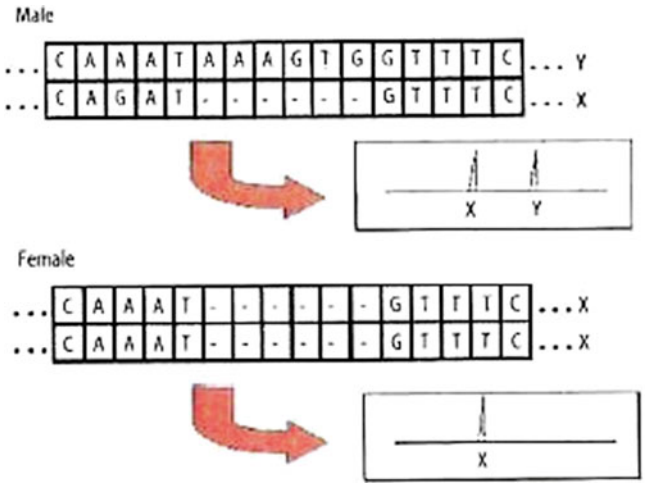

Figure 54.9 The amelogenin locus is 6 bp longer on the Y chromosome than on the X chromosome. Thus, a male will have two peaks and a female will have only one peak in the electropherogram

Male-Specific DNA Typing with Y-Chromosome Markers

Y-chromosome markers are not sex markers, but rather are male-specific identity systems that permit typing of the male DNA in mixed male/female specimens (e.g., vaginal swabs following rape or fingernail scrapings after assault). Y-chromosome markers are useful due to their strict paternal inheritance and can be helpful in lineage studies. The absence of recombination means that the exact same Y chromosome DNA alleles are present in distant paternal relatives of an individual. For example, Y-chromosome markers were used in determining the paternity of US President Thomas Jefferson among his distant descendants [46]. Y-chromosome markers are inherited together, and are reported together as a haplotype. Since they are not genetically independent, the population frequencies of each allele cannot be multiplied together; instead the counting method is used, where the number of times the haplotype is seen in a population database generates the frequency statistic. This means that the discriminatory power is much less than autosomal STRs and that a large number of loci is necessary to achieve substantial discrimination. Current commercial Y-chromosome markers are STRs that can be analyzed on the same equipment as standard STRs. More information on Y-STR haplotypes is available from various websites [47].

Single Nucleotide Polymorphisms

By far the most common polymorphisms in the human genome are SNPs [48–50]. It is estimated that there are approximately 15 million SNP sites out of the more than six billion bps of the diploid human genome. Very small DNA fragments can be interrogated for SNP alleles; thus, SNP genotyping can be applied for forensic identification despite extreme DNA degradation. The identification of human remains recovered from the World Trade Center disaster is one scenario in which SNPs showed an advantage over other DNA typing (Orchid-GeneScreen, now LabCorp, Burlington, NC), since the DNA was severely degraded in a large percentage of the specimens. Most SNPs are biallelic; that is, there are only two alleles, despite the fact that there are four possible nucleotide bases. Most SNPs are base substitutions; however, a smaller number are insertions or deletions ("indels"). Therefore, a large set of SNPs must be used to obtain decisive discriminatory values. In forensics, SNP analysis is not currently commercially available, but it is particularly amenable to automation and analysis with chip technologies. Indels are compatible with more standard fragment length technologies. SNPs may prove to be particularly valuable with Y chromosome or phenotypic markers (described below).

Mitochondrial DNA Sequencing

MtDNA is useful for forensic typing in tissues lacking a nucleus (e.g., shed [telogen] hairs), when specimens are greatly degraded (e.g., old skeletal remains), and in some cases of distant maternal relatives or to clarify kindred relations. Human mtDNA is a histone-free, circular, double-stranded DNA of approximately 16,569 bp (Fig. 54.10). MtDNA is useful for testing highly degraded specimens because it is present at a high copy number in each cell. Mitochondria are thought to be derived from ancient cellular symbionts, explaining the presence of their own DNA and modified genetic code. Each cell contains tens to thousands of mitochondria and each mitochondrion contains 1–10 copies of mtDNA; as a result there are a total of 500–2,000 copies per cell, compared to the single set of diploid nuclear chromosomes [51]. Furthermore, each mtDNA particle appears to be more resistant to degradation than nDNA [52], possibly because it is circular or because it is enveloped within the mitochondrion. The non-recombinant maternal inheritance pattern of mtDNA (Fig. 54.11) also can be of use in certain cases. Any paternal mtDNA that may pass into the fertilized egg from the sperm is thought to be destroyed by the ubiquitin pathway, leaving only the maternal egg-derived mtDNA intact. Thus, all mitochondria are derived from the mother's egg. MtDNA, unlike the paired nuclear DNA, does not undergo meiosis and does not participate in genetic recombination events, remaining unchanged through generations, until a mutational event occurs. In this regard, mtDNA analysis can be important when only a distant maternal relative is available as a reference specimen.

For identity testing, only nucleotide polymorphisms in mtDNA are of practical utility, since no STR-like repetitive DNA is present. The mtDNA sequence obtained from a sample is compared to the first complete human mtDNA

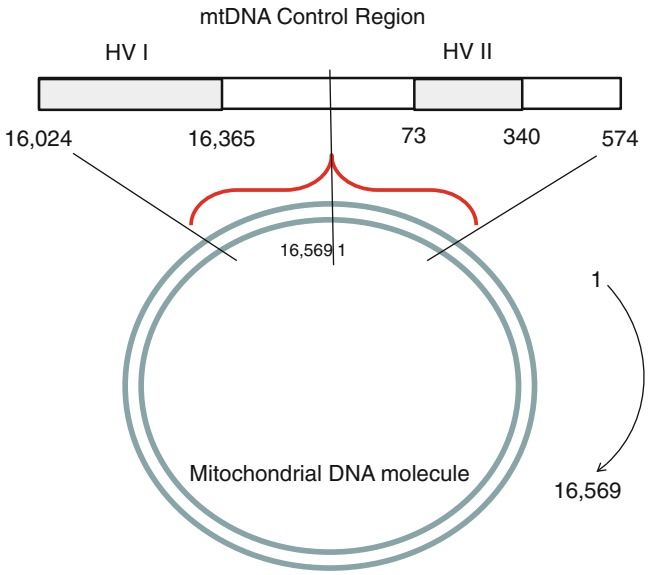

Figure 54.10 Mitochondrial DNA (mtDNA) is a circular DNA with 16,569 bp. The "control" region is a segment that encompasses the site used for the arbitrary numbering system and that contains two hypervariable regions (HVI and HVII) that are used for forensic purposes

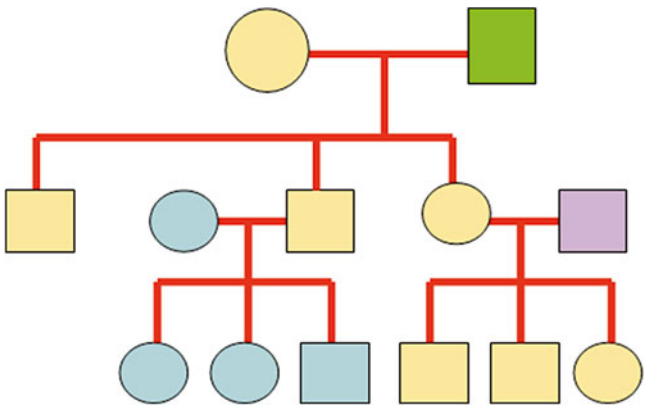

Figure 54.11 Mitochondrial DNA (mtDNA) is maternally inherited without recombination. The mtDNA sequence is exactly the same in all children of the grandmother and all children of her daughters. In contrast, grandchildren inherit only approximately 25 % of the nuclear DNA of their grandmother. The mtDNA sequence of the maternal grandmother (*top left*) represented by a tan color is transmitted to her male and female children (*middle row*) and her daughter's male and female children (*bottom row* on *right*)

sequence generated by Anderson et al. [53], or its Revised Cambridge Reference Sequence [54]. Using standard nomenclature, only the differences between the aligned sequence and the reference sequence are noted by the position and base (e.g., 16311C), with insertions designated by a period after the preceding base and the number of bases inserted (e.g., 16192.2T), deletions designated by D or minus sign (e.g., 249–), and ambiguous bases coded using an N. Human mtDNA is densely coding, specifically coding for 37 genes, and is thus generally highly conserved. The sequence polymorphisms are concentrated in two hypervariable regions that are located in the noncoding control region [55]. The control region is a 1.2 kb segment, which includes a cloning site that Anderson et al. arbitrarily set as base pair 1. Hypervariable region I (HVI) spans positions 16,024–16,365 and hypervariable region II (HVII) spans positions 73–340 (Fig. 54.10). Homopolymorphic C-stretch regions around positions 16,189 of HVI and 310 of HVII may complicate sequencing. MtDNA does not provide definitive identification due to maternal kindred sharing the same sequence and its relatively low discriminatory power. Common haplotypes exist (e.g., the 263G, 315.1C haplotype occurs in 7 % of Caucasians), but most haplotypes are rare. Polymorphisms in the rest of the molecule exist, but are too infrequent to be practically interrogated by traditional sequencing [56].

In the late 1970s, Dr. Wesley Brown brought mtDNA analysis techniques to Dr. Allan Wilson's molecular evolution laboratory at UC Berkeley, which eventuated in the beginnings of forensic mtDNA testing through Drs. Mary-Claire King, Mark Stoneking, and Svante Pääbo. In 1984, Dr. King began to use mtDNA for the "disappeared" in Argentina, which allowed lost children to be reunited with their grandparents [57]. Dr. Peter Gill at the Forensic Science Service (now disbanded) working with Erika Hagelberg of Cambridge University in the UK took the lead in mtDNA casework in 1992, and at about the same time AFDIL in the USA began to identify skeletal remains from the Vietnam War using this method [58, 59].

In crime laboratories, mtDNA is most commonly used to analyze shed hairs from pubic combings or those found at scenes, because such hairs lack roots and the hair shaft contains little or no nDNA. On average, an individual loses 200 hairs per day, and thus it is not surprising that shed hairs constitute an important trace evidential specimen. MtDNA may also be used on fingernails and keratotic skin, which also lack nDNA. The first recorded mtDNA case was in the successfully prosecuted 1996 case, *Tennessee v Ware*, involving a single hair found in the throat of a victim [60].

Occasionally, more than one mtDNA sequence exists in the same organism or tissue, a condition termed heteroplasmy. Although heteroplasmy was well known in plants and nonhuman animals, it was first seen in human mtDNA by Dr. Peter Gill of the Forensic Science Service [61] and

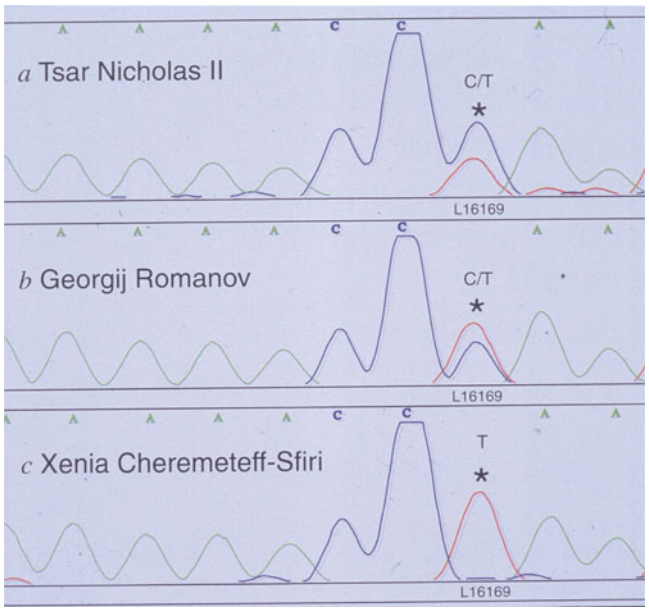

Figure 54.12 The first description of mtDNA heteroplasmy in humans was in the case of Czar Nicholas Romanov II, the last imperial Russian monarch. DNA sequence analysis shows that the czar (**a**) shares the heteroplasmy (C/T marked with an *asterisk*) at position 16,169 with his brother Georgij (**b**), but not with his distant relative Xenia Cheremeteff-Sfiri (**c**) (five generations removed) who has only the T nucleotide

then confirmed by one of the authors (VW) [62] during the identification of Czar Nicholas Romanov II (Fig. 54.12). Paternal leakage, recombination, and high mutation rates may contribute to heteroplasmy. The rate of mutations in noncoding mtDNA is 10–20 times greater than that in nuclear DNA, possibly due to the exposure of mtDNA to oxygen-free radicals or DNA polymerase with a higher error rate [63]. Thus single base differences between presumed maternal relatives must be viewed with caution. A low level of heteroplasmy may, in fact, be present in all individuals. To be detected using standard DNA sequencing, the level of heteroplasmy must be above approximately 30 % of the mtDNA sequence; otherwise, it is not distinguishable from background noise. Heteroplasmy is not uniform throughout the body and appears to be somewhat tissue specific. In addition, heteroplasmy may be rapidly lost (reversion to a homoplasmic state) in family lineages because of the bottleneck phenomenon that occurs during reproduction from a single egg. Heteroplasmy can complicate forensic analysis. For example, two hairs cannot be assumed to be from different individuals if they differ by a single nucleotide.

MtDNA testing is not performed by most forensic laboratories because the standard analytical method is DNA sequencing, which is expensive, labor-intensive, relatively slow, and, owing to how ubiquitous and prevalent the molecule is, may be susceptible to contamination. The exquisite sensitivity of the testing mandates special laboratory facili-

ties and procedures. Also, interpretation is less straightforward than for routine STR results [64]. In 2006, the FBI created four regional state mtDNA laboratories (Arizona, Connecticut, Minnesota, and New Jersey), expanding forensic mtDNA sequencing capacity beyond private and federal laboratories. The number of laboratories performing mtDNA sequencing has since increased.

Phenotypic Markers and Ancestry-Informative Markers

Most forensic DNA systems involve noncoding DNA loci and are not associated with phenotypic traits [65]. The amelogenin marker is a major exception in that it directly assesses the sex of an individual. Some of the loci, like vWA of the von Willebrand locus, have very weak associations with disease states or other phenotypic information; of course older serologic testing was phenotype-based.

In some instances use of descriptive traits of an individual may be desirable, particularly if no eye-witnesses exist. Phenotypic markers have been and continue to be developed for use in forensic investigations. Markers have been established for eye color and weaker ones exist for hair and skin pigmentation [66, 67]. DNA Print Genomics (which ceased operations in 2009) had claimed their RETINOME system could predict eye color with 96 % accuracy. Generally, such tests are SNP assays for a set of informative but widely disparate loci. A genetic version of "driver's license" data would be useful for investigations, even if it were not to be used as probative evidence in court. A danger of misdirection from an incorrect prediction would have to be considered, since the accuracy is less than perfect [68].

Ancestry-informative markers are used to suggest a geo-ethnic origin [69, 70]. DNA Print Genomics "DNA Witness" appeared to have used them successfully in some investigations, but the technique was controversial [71]. Other groups, most notably the National Geographic Genographic Project [72], with various sets of markers and analyses, claim to be able to make statements of various proportions regarding ancestry background. Of course, admixture and modern travel greatly limit the value of such efforts. Some would derisively characterize these trials as genetic profiling [73].

Species Identification

Animal, plant, and microbial identification is sometimes important in a forensic investigation and can be accomplished using DNA analysis [23]. Typical forensic specimens include animal hair and fly larvae. Animals are generally examined by forensic scientists using the cytochrome b [74], 12S ribosomal RNA [75], or other mtDNA loci [76], and plants through their chloroplast DNA [77, 78]. This interrogated sequence is then entered into the online bioinformatics program BLAST (*B*asic *L*ocal *A*lignment *S*earch *T*ool), hosted by the US National Institutes of Health. The utility of a BLAST search is that today almost all DNA sequences produced by scientists are entered into the database (often required for journal publication) meaning virtually every species ever studied at the molecular level is represented. BLAST undertakes a query of the questioned sequence and in a few seconds produces a list of the most similar sequences in the database (often 100 % matches), complete with sequence alignment and appropriate references. For instance, a questioned hair may have a 100 % match to dozens or hundreds of dog sequences, followed by 99 % matches to more dog sequences, and will then begin to be interspersed with wolf sequences, coyote, etc. Except for extremely closely related, or highly exotic and rare species, BLAST queries typically result in an exact match, and the questioned speciation is identified. However, there is often a need for further strain (clade) or individualizing analysis. For instance, strain testing is used to trace marijuana plant sources [79]. Source attribution at the specific individual level is accomplished by DNA methodologies similar to human identity testing.

Tissue Identification

Occasionally, determination of the tissue origin of a specimen is required. Since the DNA from an individual is the same in all tissues, forensic scientists assay either messenger RNA (mRNA), as certain genes are expressed in some tissues and not others, or using immunoassays of the protein products [80, 81]. Commercial human gene expression microarrays have been used to determine tissue origin, but this is not a capability of crime laboratories.

Instruments and Technologies for DNA Typing

Since STRs replaced manual RFLP slab gel methods in the 1990s, capillary electrophoresis (CE) of amplified DNA, pioneered by Drs. John Butler and Bruce McCord, then at the FBI, has become the mainstay of forensic DNA laboratory operations around the world. CE instruments have replaced slab gel electrophoresis systems because of automation, faster run times, smaller sample volumes, and greater resolution. Typical casework calls for on-demand instrumentation that can handle relatively few specimens but with fast run times. High-throughput CE instruments are used as batch

instruments for DNA data-banking operations. The ABI series of CE instruments (310, 3100, 3130 "Genetic Analyzers") from ABI are predominant and virtually exclusively used with the forensic community; the new ABI 3500 instrument is to supplant older models and features an ability to detect 6 dyes.

The forensic community is investigating other technologies for DNA analysis and NIJ has funded development [82]. Commercial "Rapid ID" DNA (rDNA) instruments (GE Healthcare Life Sciences [Pittsburgh, PA] and NetBio [Waltham, MD] ANDE; IntegenX [Pleasanton, CA] RapidHIT; and Lockheed Martin Corp [Bethseda, MA] and Zygem [Solana Beach, CA] RapiD; LGC [London, UK] RapiDNA) were introduced in 2012 to perform sample preparation, amplification, and electrophoresis to produce typing results within 2 h [83]. Their technology involves integrated microfluidic systems. Such systems are designed to be used at police booking stations to permit searches while persons of interest are in custody. These systems may also make crime-scene field-testing practical. Next-generation sequencers vary in their technologies, but also have microfluidics in common. They are designed for genomic/exomic applications for which they are incredibly rapid and relatively inexpensive for the amount of DNA sequenced. Analysis requires a specimen with a large quantity of DNA, relative to forensic evidentiary specimens, and is relatively expensive on a per run cost compared to current STR kits. However, if the next-generation sequencing assay is focused on targeted areas of interest, then less specimen DNA would be required and possibly multiple specimens could be processed in batch mode. In fact, the massively parallel sequence reads resulting from next-generation sequencing may be a benefit in analysis of degraded and low copy number DNA specimens.

Interpretation of Results

US crime laboratories will typically use the CODIS software ("popstats") to generate their statistics based on the FBI's allelic frequency data for Caucasian, African-American, and Hispanic racial groupings. STR systems are powerfully discriminating with an average random match probability of less than one in a trillion using the 13 core loci. "Discriminatory power" should not be confused with "accuracy" (e.g., ABO blood group typing is accurate but has low discriminatory power). The high discriminatory power of STRs is achieved because the statistic from each STR locus is multiplied together, the so-called "product rule" [84–88]. Current STR systems utilize genetically unlinked loci (STR loci are on different chromosomes, except CSF1PO and D5S818 which are sufficiently distant as to be genetically independent). Hardy-Weinberg disproportion, which may occur from population or racial grouping substructure (subgrouping), selection (non-random mating), inbreeding (mating within kindred), or linkage disequilibrium (from incomplete mixing of different ancestral populations), was cause for early court challenges to statistical interpretations of DNA results. Some of the early purported large deviations turned out to be an artifact of lower resolution RFLP tests where a single band was interpreted as a homozygote rather than two overlapping heterozygous bands [89, 90]. A National Research Council (NRC) report, NRC I [91], was issued in part to address these statistical concerns. The NRC I report itself proved controversial, which led to the NRC II report [92], that has, in fact, largely settled most statistical forensic identification issues.

In the USA, a Random Match Probability (RMP) is usually calculated as the chance of a random match in the population or racial grouping. Under conditions of Hardy-Weinberg proportions and linkage equilibria, the statistical calculation for the probability of an occurrence of a given genotype would be p^2 in the case of a homozygote or $2pq$ in the case of a heterozygote, where p is the frequency of observed occurrence for the p allele and q is the frequency of for the q allele. Instead, to account for population substructure, the NRC II recommended for calculation of homozygote frequencies from population allelic data: $p^2+p(1-p)\theta$, where θ is 0.01 for the US population as a whole and US racial groupings (empirically determined); but a more conservative value of 0.03 may be used in cases of smaller, isolated, and more inbred groups; and since heterozygote frequencies are overestimated in cases of disequilibria then $2pq$ can be used to calculate them (see Table 54.3 for an example RMP calculation).

In Europe, a Likelihood Ratio (LR) is usually used, wherein the hypothesis of the prosecution that the defendant is guilty and was the source of the DNA (assumed to be 100 % or 1) is divided by the hypothesis of the defense that the specimen is from someone else (some random individual) or p^2 or $2pq$ ($LR = 1/p^2$ or $1/2pq$) a result greater than one would support the prosecution and a result smaller than one would support the defense (see Table 54.3 for an example LR calculation).

MtDNA and Y-chromosome markers yield haplotype population frequency data that do not involve the product rule, and instead the frequency of the observed haplotype in a database is considered (the counting method). There has been some discussion as to whether these haplotype frequencies can be multiplied against each other as well as the STR statistic to achieve a summary discriminatory figure. Interpretation may be problematic when confronted with mixtures or from significant apparent imbalances or allelic drop-in and drop-out (Fig. 54.13) when testing highly degraded or trace DNA specimens.

Table 54.3 Example of random match probability and likelihood ratio calculations by ethnic group

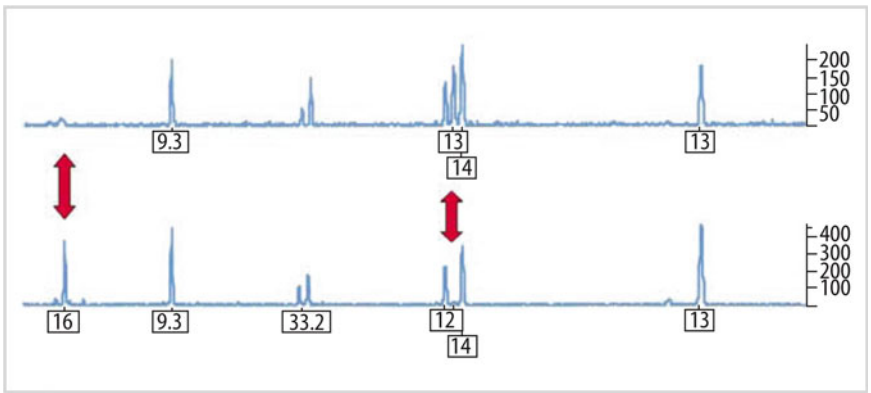

Figure 54.13 Allelic drop out from sample degradation or primer site polymorphism is one of the few interpretative pitfalls in the analysis of STRs. Allelic drop in can occur from contamination. This figure demonstrates a drop out of allele 16 and a drop in of allele 13 in the *upper* tracing compared to the *lower* tracing

Convicted Offender Databases

The DNA Identification Act of 1994 (US Public Law 103–322) authorized the creation of the FBI's National DNA Index System (NDIS). DNA profiles are uploaded using CODIS software, which may vary from state to state due to variations in state policy or statute [93]. Searches can be performed locally through a Local DNA Index System (LDIS) or State DNA Index System (SDIS), and across state lines through NDIS. Identifying information other than the DNA profile is not entered into the system. A match from an NDIS search results in the local crime laboratory of one state being put into contact with the local crime laboratory in another state to discuss case details. Uploading of DNA

profiles triggers federal regulatory requirements on the use of the DNA specimens and profiles. The federal government has its own database for federal crimes as well. The number of profiles in the DNA databases has increased dramatically as state laws have expanded the convicted offender requirements from selected offenses to all felons, a broad array of misdemeanor crimes, and even arrestees. In 2012, the US Supreme Court, in *MD v King*, upheld the routine search of DNA databases when DNA samples are collected upon arrest [94]. Today, approximately ten million convicted offender profiles exist in the database. In recent years, "low stringency matches" have enabled searches for family members to assist investigations when no DNA profile of the perpetrator is in the database [95, 96].

Quality Assurance and Laboratory Issues

The FBI formed the Technical Working Group on DNA Analysis Methods (TWGDAM) to allow analysts from different laboratories to share information on the new DNA technology. The DNA Identification Act of 1994 gave the FBI regulatory oversight of DNA profiles entered into the national database [97]. The legislation called for a DNA Advisory Board (DAB) that produced recommended standards, based largely on guidelines of the TWGDAM, which were adopted with little change by the FBI director [98]. DAB requirements include minimal educational credits and experience of the testing personnel, proficiency testing twice a year per analyst, annual audits, and technical and administrative reviews of all tests. TWGDAM has since been renamed the Scientific Working Group on DNA Analysis Methods (SWGDAM) [99] and continues to recommend new standards to the FBI Director. The FBI conducts audits of laboratories to verify and enforce compliance with the standards, at least with respect to profiles that are generated and uploaded into NDIS.

The FBI/DAB standards require accreditation. The American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB) and, more recently, the Forensic Quality Services (FQS) accredit laboratories. The accreditation requirements and audits are rigorous and are based on the International Organization for Standardization/International Electrotechnical Commission (ISO/IEC) Standard 17025. Standard reference materials from the National Institute of Standards and Technology (NIST) are available for autosomal STR analysis (SRM 2391b), Y-STRs (SRM 2395), mtDNA testing (SRM 2392), and DNA quantification (SRM 2372). Standards require annual comparisons with NIST-traceable standard materials [100]. In addition to these forensic science laboratory measures, judicial scrutiny provides further review of DNA findings in those cases that go to court.

Legal Issues

Shortly after forensic DNA tests were first introduced, defense attorneys attempted to directly attack this new scientific evidence. These early challenges are sometimes referred to as the "DNA wars" [101–104]. The first serious challenge to forensic DNA identity testing came in the 1989 case of *New York v Castro* [105] but legal admissibility of RFLP analysis was generally established in the 1991 case of *US v Yee* [106], and for PCR-based STR analysis in a series of cases in 2001 and again in 2005 [107–110]. Most prominent among the players were defense attorneys Peter Neufeld and Barry Scheck (subsequently part of the O.J. Simpson "dream team" and later founders of the Innocence Project), FBI lead scientist Dr. Bruce Budowle, and prosecutors Rockne Harmon and Woody Clark. The attacks were centered primarily on the issue of statistical interpretation. The early forensic DNA tests suffered from an inability to resolve discrete alleles. Moreover, the genetic independence of the loci was questioned based upon early Hardy–Weinberg disequilibrium calculations. Today, the "DNA wars" are largely over. The scientific basis of forensic DNA typing was never seriously questioned, but rather vitriolic challenges were launched at laboratory procedures and statistical interpretation. The admissibility of DNA evidence was not challenged in the 1995 O.J. Simpson trial despite the presence of a well-funded and experienced defense team; instead, the "weight" of the evidence was challenged, on the theory that police investigators had intentionally planted Mr. Simpson's blood. The most common challenges today are to sample collection, preservation of the evidence, chain of custody, documentation, and validation studies [111]. New genetic testing systems and technologies will undergo renewed judicial scrutiny and in particular, LCN DNA testing will generate anticipated challenges. While the challenges subside, the uses of DNA continue to grow. Police and prosecutors' office have created "cold case" units to try to close old cases with DNA evidence. Identification of the unidentified in medical examiner and coroner offices is also being pursued and is expected to close some old open cases as well. Indeed, the defense is now using forensic DNA identity tests after conviction to exonerate the previously convicted through the Innocence Project [112–114]. At the time of this writing there have been nearly 300 postconviction DNA exonerations.

Parentage and Relationship Testing

55

Robert W. Allen and Herbert F. Polesky*

Abstract

Parentage testing, also known as relatedness testing, is largely performed using polymerase chain reaction of short tandem repeats. The situations in which relatedness testing can be useful include parentage confirmation for legal cases, or for questions related to adoption, absent parents, or immigration. Sample collection methods depend on the purpose of the testing. Interpretation of the test results focus on exclusion or the likelihood of parentage when exclusion cannot be established, which requires use of standard probability calculations. Molecular testing of genetic systems can provide information to resolve questions of relatedness. Though these tests are powerful tools that can exclude almost all falsely accused parents, the tests alone do not prove absolutely that a relationship exists between two individuals.

Keywords

Identity testing • Parentage testing • Relatedness testing • Probability of parentage • Parentage index • Inclusion • Exclusion • Short tandem repeats

***In Memoriam: Herb Polesky**

Herb Polesky authored this chapter in the first edition of this book and is coauthor of the chapter in this edition. Herb Polesky died in December 2011 while travelling with his wife Susan in Chile. Herb became active in the field of parentage testing early on and had the good fortune to contribute significantly to the field of Identity Testing as a whole, but especially to the application of DNA-based technology for questioned parentage. Work published by Herb and his collaborators early in the history of DNA testing is classic and moved DNA extraction methods into an era of development, culminating with the fast and efficient methods most laboratories use today. Herb also was instrumental in developing standards of practice, proficiency testing, and accreditation programs for both the American Association of Blood Banks and the College of American Pathologists. Finally, Herb was a teacher. He valued education and was always watchful for opportunities to weave the education process into an activity he was engaged in. While serving on the Histocompatibility and Identity Testing Committee of the College of American Pathologists, Herb endorsed and helped develop a Paper Challenge program which is still submitted to subscribing laboratories as part of their proficiency testing process. Challenges typically represent unusual cases that a laboratory may see occasionally and provide the pathologists and staff with a learning and teaching opportunity. Such is the legacy Herb Polesky leaves behind for the relationship testing field and those in it who knew and worked with him. He will be missed.

Historical Overview

Questions of parentage and other family relationships between individuals are not new. An early reference is found in the Bible (Kings 3:16–27), in which Solomon uses the threat of dividing the child to determine maternity. The application of scientific methods to this identification problem followed the discovery of the ABO blood group. Laws recognizing the possible exclusion of parentage by blood group testing were enacted by some states as early as 1935. Between 1940 and 1960, as additional blood group systems were defined and shown to follow Mendelian inheritance, more tests to exclude paternity were introduced. When appropriate reagents and methods were used, these red blood

D.G.B. Leonard (ed.), *Molecular Pathology in Clinical Practice*, DOI 10.1007/978-3-319-19674-9_55

cell (RBC) group marker systems were reliable; however, the relatively small number of marker alleles and their distribution in most populations limited the chance that a falsely accused man could be excluded. Subsequently, in the 1960s and 1970s, the discovery of polymorphic protein and red cell enzyme systems resulted in new markers that increased the power of the testing. The introduction of human leukocyte antigen (HLA)-A,B typing further expanded the possibility of excluding most falsely accused men [1].

Prior to the 1970s, the information from genetic marker testing was largely limited to providing evidence that a relationship did not exist. As more test systems were used, when testing failed to exclude, the probability of the alleged relationship between the tested individuals could be reliably calculated from the genetic information obtained. An amendment to the US Social Security Law (title IV D) in 1974 required that women requesting financial aid for dependent children identify the father. This change in the law increased the importance of providing estimates that tested individuals could be related in an alleged way.

Reports suggesting the use of DNA markers based on restriction fragment length polymorphisms (RFLP) for the determination of parentage first appeared in 1986 [2]. Over the next decade most laboratories performing relatedness testing applied DNA-based methods. The development of polymerase chain reaction (PCR) methods, that easily allowed testing of a minimal sample, led to a shift from testing by the classic marker systems (RBC antigens, HLA, etc.) to testing by only DNA marker systems [3]. The evolution of testing methods used by laboratories subscribing to the College of American Pathologists (CAP) parentage proficiency testing program between 1993 and 2003 is shown in Fig. 55.1. The doubling of the number of laboratories performing parentage testing over this time period correlated with a sharp increase in PCR testing and a decrease in all other testing methods. Today, virtually all parentage testing laboratories rely on PCR-based genetic testing methods. In the most recent report from the CAP, 91 laboratories subscribed to the parentage proficiency testing program.

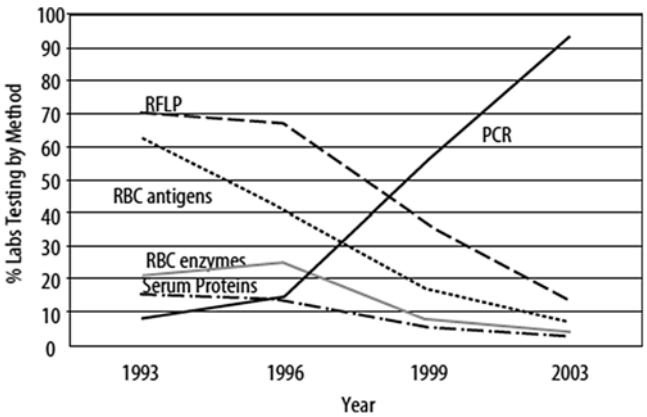

Figure 55.1 The evolution of testing methods offered by laboratories subscribing to the College of American Pathologists (CAP) parentage proficiency testing program between 1993 and 2003. There was a sharp increase in PCR testing with a concomitant drop in all other testing methods by 2003

Indications for Relatedness Testing

Parentage

Attempting to determine whether a man is or is not the biologic father of a child used to be the most frequent reason for performing relatedness testing. And although paternity testing may still represent the majority of tests performed, the expansion of testing into other biological relationships has occurred, largely due to the continued development of DNA markers with enhanced discriminatory power. As indicated above, child support programs are mandated to identify fathers of children born out of wedlock. In many situations the mother is unsure of who is the father. By establishing paternity, the mother is able to obtain financial support for the child from the father. Even when a child is born to a married couple, paternity is not a certainty. Family studies performed as part of medical trials have frequently reported that a small percentage of participants' children have extramarital genetic origins. Testing may be requested when a divorce is pending or when a father has doubts about his relationship to a child. Relatedness testing also is useful when it is suspected that babies have been mixed up in the nursery or to confirm the identity of a kidnapped child. Genetic marker tests can establish parentage of a child born to a surrogate mother or in some cases when assisted reproductive technologies, such as in vitro fertilization, are used.

Adoption and Absent Parents

A change in laws concerning availability of adoption records has increased requests for testing to identify biologic parents. Genetic evidence can confirm whether a relationship exists. Testing may be requested when individuals who were raised separately desire to establish whether they are siblings [4]. Similarly, testing may be useful to identify a person suspected of being an absent parent. In some cases, the establishment of parentage may be important with regard to resolution of inheritance claims. Proving membership in a Native American tribe is another reason for determining parentage.

Immigration

One rapidly expanding area for testing is in support of the immigration process in which claimed relationships to US residents must be proven genetically. The current US immigration quota system gives preference to relatives of US residents applying for immigrant status. Genetic testing evidence is considered in establishing the relationship between a US resident and a person desiring to immigrate to the USA. Often these cases involve putative children or parents with incomplete documentation of their relationship.

Forensic Parentage

The usual use of genetic testing in forensic cases is to compare DNA profile results generated from a reference sample from a suspect with the profile produced from a crime scene sample or a sample recovered from a victim. This testing generally involves determining whether the DNA profiles produced from the two samples match or not. In contrast, relatedness testing depends on the comparison of DNA profiles produced from samples from two or more individuals alleged to be related in some way and the goal of the testing is to assess whether or not alleles present in the tested individuals are identical by descent (i.e., inherited within a given family pedigree). Family relationship testing can be used to identify the perpetrator of a sexual assault resulting in conception, or for the identification of victims of naturally occurring or man-made disasters through establishing genetic relationships to surviving family members.

Sample Considerations

Samples

Relationship testing can be done using any sample from which DNA can be extracted and amplified. Most laboratories routinely use carefully collected buccal swabs. The advantages of buccal swabs include the ease of collection from infants, the ability to be collected by individuals with minimal training, and ease of sample shipping with a low risk for breakage or need of special shipping containers [3]. Additional sample types include whole blood, cord blood, tissue samples, and dried blood spotted on filter paper. Fetal DNA can be obtained from amniocytes, chorionic villus samples, and placental scrapings; however, it is important to rule out maternal contamination (see Chap. 57) when using these samples. The isolation of fetal cells from maternal peripheral blood samples also has been reported, but several laboratories using state-of-the-art single nucleotide polymorphism (SNP) testing platforms have reported successfully performing paternity testing with maternal blood during pregnancy, testing thousands of SNPs present in fetal DNA (inherited from the biological father and not present in the mother's DNA) [5].

Nuclear or mitochondrial DNA obtained from bones found at grave sites has been compared to samples from presumed relatives to identify individuals missing in action. Proof that the bones found in a mass grave site were those of Czar Nicholas II and his family was based on comparison with the mitochondrial DNA of living maternal relatives [6] (see Chap. 54).

Sample Collection

A testing facility must ensure that samples are identifiable and traceable from the time of collection through testing and reporting of results [7]. Samples need to be inspected and must meet acceptability criteria at all stages of testing. Collection of the samples must be done by individuals with no interest in the outcome of the testing, usually an employee or an agent of the laboratory; however, in some cases, submitted samples are collected "at home." Under these circumstances it is very important to have a second person witness and verify the collection procedure.

The American Association of Blood Banks (AABB) has developed very specific requirements for the information that must accompany samples used for parentage testing [8], including records of the name, alleged relationship, date of birth, and race or ethnic background of the individuals to be tested. Records must include information about the place, date, and person(s) collecting the sample. At the time of sample collection, the individual to be tested should be queried about a history of hematopoietic progenitor cell transplantation at any time in the past, as well as about transfusion in the past 3 months. If only DNA testing is to be done, it is unlikely that transfused donor DNA will be detected. In multiply transfused patients, DNA-based blood group testing is used to determine the blood group phenotype of the recipient when it is difficult to find compatible donor blood because of the presence of antibodies. For routine parentage testing, a photograph taken at the time of sample collection or a legible copy of a government photo ID, or both, should accompany the specimen.

Relationship Testing Methods

General Issues

RBC antigens, polymorphic red cell enzymes, serum proteins including Gm and Km, and serologic tests for HLA-A and HLA-B markers have been very useful systems for relatedness testing, although their use has all but disappeared in

favor of DNA-based identity testing [9] (Fig. 55.1). The molecular methods used for testing parentage samples are identical to the methods for forensic testing described in Chap. 54; therefore, this discussion is limited to method-specific requirements and quality control issues, some of which are particular to parentage testing. As is true for all molecular tests, the reliability, reproducibility, and accuracy of the method should be evaluated prior to use. Any new method or system used by a testing facility should be validated in several ways beginning with learning most of what can be known about the system or assay through performing a literature review, by using the method in parallel with existing laboratory methods, by sample exchange with another laboratory, or by a combination of these approaches [8]. In addition, for amplification-based methods, inclusion of negative controls to monitor for sample contamination is important. Regardless of the method used, appropriate documentation of all sample handling and testing steps is critical for parentage testing as mandated by AABB standards.

RFLP Analysis

While the use of RFLP analysis demonstrated the possibilities associated with the use of DNA-based methods for parentage testing, this methodology is seldom, if ever, used in family relatedness testing currently. The RFLP methodology was powerful but suffered several limitations including sample requirements for the DNA used, the largely manual processing required, and the inability to precisely identify all of the sometimes hundreds of alleles associated with a particular marker. With the introduction of PCR amplification of DNA markers consisting of short tandem repeats (STRs) in the mid-1990s, many of the RFLP limitations disappeared, causing a natural progression of parentage testing laboratories to adopt PCR-STR technology over RFLP analysis.

Short Tandem Repeat Typing

PCR amplification of STR markers is the method most frequently used for relationship testing. Several commercial test kits are available for multiplex amplification of many STR markers. These kits usually include the 13 CODIS loci that form the foundation of felon databases that are routinely searched by forensic DNA laboratories hoping to link evidentiary DNA profiles to incarcerated or even arrested individuals who may have committed the specific crime or additional crimes [10]. For parentage testing, unlike for stain analysis used when comparing evidentiary stains to possible sources, there is no specific recommended panel of loci. Although the CODIS loci can be used, alternative or additional loci, or both, can be selected at the discretion of each laboratory as long as the final results achieve or exceed statistical significance (see section on "Reporting of Test Results," below) in almost all cases.

Typical STR typing results in a case of disputed paternity are shown in Fig. 55.2. Visible in the electropherogram are peaks of fluorescence corresponding to the collection of STR alleles for the different loci produced from genomic DNA extracted from each of the tested individuals (only those alleles amplified from STR loci with primers coupled to the green fluorescent dye JOE are shown for discussion purposes). Each allele in the profile is labeled with a numerical designation (seen as "al" with a number) that corresponds to the number of repeats of the 4 base pair (bp) repeated element. In the child's profile, those alleles inherited from the father whose identity is in question are indicated with an arrowhead and are identified through comparison of the profiles from mother (M) and child (C) (understanding that the mother's relationship with the child is unquestioned). The alleged father (AF#1) lacks the obligate alleles for the THO1 and D16S539 loci so is excluded, but AF#2 is included as evidenced by his sharing of at least one obligate allele with the child at each locus.

Identification of alleles for STR loci relies upon accurate size estimates (within 1 bp) of alleles amplified from a genomic DNA template by PCR. Primers that direct the amplification of STR alleles are coupled to one of three or four different fluorescent dyes so the amplified alleles can be detected by fluorescence. The color of the emission coupled with the size determination of the DNA fragment allows a computer to designate a tentative repeat size for each amplified product that is confirmed by comparing the amplicon in a sample to the collection of known allele repeat sizes for each STR locus (i.e., the allelic ladder) that is included with each electrophoretic run. Ultimately, the STR profile obtained from a sample may consist of up to 30 identified alleles (or more depending upon the STR kit used) obtained from 15 independent STR loci (or more) plus two fragments from the amelogenin locus that identify the sex of the sample donor (see Chap. 54 for explanation). Determination of correct allele sizes in STR amplifications is of critical importance. For this reason, a human control of known genotype is subjected to parallel testing with unknowns in each analysis to ensure the accuracy and reproducibility of the test system. Allele assignments can be made using computer software; however, verification of allele assignments should include the visual inspection of peaks by a knowledgeable individual. Regardless of the reading method, AABB standards as of this writing require that PCR results be interpreted twice, independently [6].

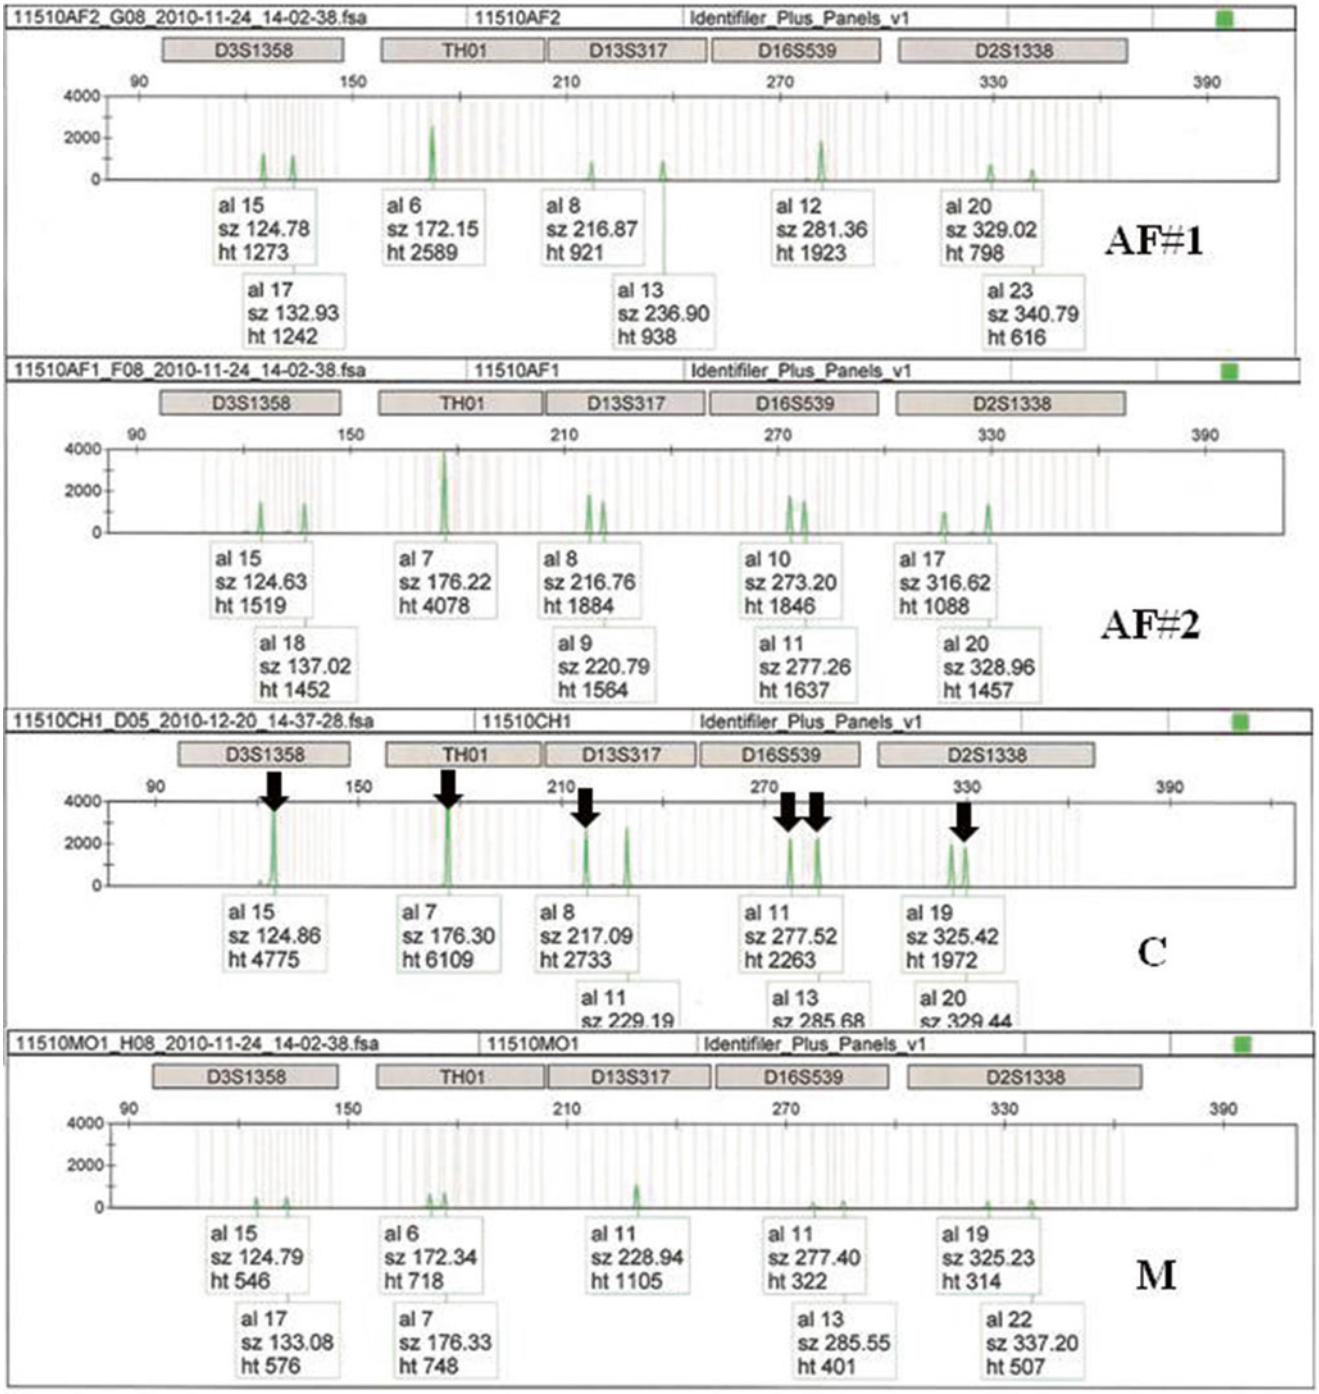

Figure 55.2 Typical STR typing results produced in a case of disputed parentage. DNA was extracted from a mother (M), a child (C), and two alleged fathers (AF#1 and AF#2) and amplified using the Identifiler® multiplex STR typing kit (Applied Biosystems, Inc., Foster City, CA). Amplified STR alleles were separated using capillary electrophoresis in an ABI 3130XL Genetic Analyzer and analyzed using GeneMapper software (Applied Biosystems). Only the results produced from the STR loci amplified from primers in the multiplex kit coupled to the green fluorescent dye JOE are shown in the figure and alleles are identified based upon the number of repeats in the tandem array. *Arrows* show the location of possible paternally inherited alleles in the child's sample. Alleged father 1 (AF#1) lacks obligate alleles for THO1 and D16S539 so is excluded, but alleged father #2 (AF#2) is included because he shares at least one obligate allele with the child at every locus shown

Nucleotide Sequence Determination

Nucleotide sequence determination can be used for relationship testing either by a traditional sequencing method or by a sequence-specific method, such as analysis of HLA alleles by sequence-specific oligonucleotide probes or sequence-specific primers [11, 12]. SNP analysis also can be applied using a variety of methods [13]. For all methods, inclusion of appropriate controls is important. Ideally, DNA sequencing should include analysis of both forward and reverse sequences. Comparison of results with a consensus sequence can be used for validation [8]. SSOP determination of HLA alleles should include a positive control probe that is complementary to a conserved sequence present in all alleles; likewise, the use of SSP requires that a positive internal amplification control of a nonpolymorphic sequence be included with each reaction. While SNP analysis can be highly automated, its use for relationship testing requires the analysis of a large number of loci to achieve statistical significance of the interpretation.

Next-generation DNA sequencing technology (NGS) has the potential to revolutionize the field of family relationship testing. Using NGS platforms, it is possible to determine the sequence of billions of nucleotides in a single sequencing run and, under the assumption that there is one SNP in every 1,000 bp of genomic DNA, there would be hundreds of thousands of SNPs in a single NGS test result. Among the SNPs detected, a significant proportion would differ between the mother and the child (i.e., those SNPs inherited from the father) and those remaining could be compared to an alleged father's reference sample to determine exclusion/inclusion in the case. The only question regarding the use of NGS technology is whether or not it can be priced competitively with classic STR testing performed by most laboratories.

Y Chromosomal and Mitochondrial DNA Markers

Polymorphisms residing on sex chromosomes are not routinely used for relatedness testing. However, the amelogenin locus is routinely amplified and is helpful to verify that male and female samples have not been switched. Mitochondrial DNA, which is maternally inherited, and Y chromosome markers (Y-STR) passed through the male lineage are useful for family and population reconstructions [14]. Sex-linked markers are especially useful when investigating questioned family relationships more distant than parent and child because of the conservation of haplotypes within the pedigree stemming from the lineage-specific inheritance pattern. For example, comparing the Y-chromosomal haplotypes of a male child and a male cousin of the untested alleged father who descended from a brother of the untested alleged father could establish with high certainty that the child whose paternity is in question does indeed belong to the male lineage within the pedigree. Autosomal STR markers would almost certainly fail to establish such a strong link. Sex-linked markers do have limitations, however. For example, in the scenario discussed above involving the Y-STR haplotypes, although the untested and deceased alleged father of the child could be the true father, his brother, or the cousin also possibly could be the father of the child. With sex-linked markers it is not possible to distinguish amongst all male or female members of the family. Some additional approach, such as those described below, must be taken with the sex-linked DNA results to make the distinction.

Interpretation of Parentage Results

Overview

Parentage testing seeks to determine whether a particular relationship exists between a set of individuals as evidenced by shared alleles inherited by the child from the parent (alleles designated as identical by descent). If the results of the testing provide sufficient evidence that the purported relationship does not exist, an exclusion is said to occur. When the results do not exclude a relationship, the situation is termed an inclusion, and a statistical analysis to calculate the probability or odds ratio that the relationship is true is performed using the test results. Several mathematical expressions are generally used to express the inclusionary results: paternity or parentage index (PI), combined paternity or parentage index (CPI), and the probability of paternity or parentage.

Exclusion

Test results from each of multiple independent systems are compared to establish whether the tested parties are related or unrelated. Table 55.1 shows examples of serological test results for several situations in which the test results indicate that a relationship does not exist. When an allele is found in a child that is not in the child's mother, it must have come from the biological father. Therefore, in a standard trio paternity case with a mother, father, and child, a direct exclusion for the system tested occurs when an alleged father does not have an allele that is found in the child but is not present in the child's mother (AF#1 in Fig. 55.2; Table 55.1). An indirect exclusion occurs when the exclusion is based on the observation that the child and the alleged father are homozygous for different alleles (Table 55.1). This type of exclusion is not conclusive, since it is possible that the child and alleged father actually share a null gene that is not detected.

Table 55.1 Examples of phenotypes that exclude parentage

Type of exclusion	Mother	Child	Tested man	Obligatory allele(s)
Direct	A	AB	C	b
	AB	AC	AD	c
Two-haplotype	A	A	BC	a
	AB	AB	CD	a or b
	AB	A	BC	a
	Unknown	AB	CD	a or b
Indirect[a]	A	A	B	a
	AB	B	A	b
	Unknown	B	A	b

The obligatory allele is based on the required paternal genetic contribution given the mother's and the child's phenotypes. If two alleles or two groups of linked markers are defined in one individual, but neither is present in the second tested person, the exclusion is defined as a "two-haplotype" exclusion

[a]Mutation must be considered if indirect exclusion is in a single system

Therefore, before an opinion of nonpaternity is rendered based on an indirect exclusion, a search is made for additional direct or indirect exclusions. Exclusions in two independent tests are sufficient to exclude an individual as the biological father of a child, as long as the chance of mutation has been considered.

Since mutations can occur, albeit rarely, in many of the DNA test systems, a single inconsistency in expected inheritance is also not adequate to reach a conclusion of nonparentage, particularly if the inconsistency is only one tandem repeat size different from the important allele in the alleged parent or child [7]. Mutation rates of commonly used loci are available, as well as statistical methods for incorporating the inconsistency into the final reported calculation [8]. To avoid misinterpretation, results should be reported as phenotype rather than as assumed genotype when a test indicates a single marker at a locus. In the parentage testing field, the term "phenotype" is used to represent the measurable genetic markers in a given individual at a specific locus. Although confusing to those more familiar with the term "genotype" in this setting, the terminology for parentage testing has its origins in RBC typing in which a person with type A blood is said to have the A phenotype but could have the AA or AO genotype. Therefore, to avoid the assumption of homozygosity, test results are reported as phenotypes, which may or may not reflect the genotype. While it is less common for a DNA-based genetic test result not to match the actual genotype, null alleles and primer-site polymorphisms have been reported. In addition to mutation, technical errors, sample mix ups, and reagent problems such as primer-binding site differences can lead to false exclusions. When an individual is excluded, his or her phenotype must be confirmed by repeating the test with an independent isolation of the DNA from the alleged parent and possibly also the child [7].

Maternity is presumed when samples are submitted for testing. However, occasionally a different child is substituted for the biologic child. When test results are completed on a trio (mother, child, and alleged father), the results on the mother and child should first be evaluated to determine that at each locus there is one common allele. This comparison is one of the ways that the laboratory can validate that the correct samples were tested. On rare occasions, inconsistencies between a mother and a child are observed. This finding can be due to a mutation and is not a maternal exclusion.

Inclusion

The most frequent use of relationship testing is to determine paternity. Each genetic system used in relationship testing should be well documented in the literature and must have been shown to follow Mendelian inheritance. Ideal genetic systems for relationship testing have multiple alleles, a low rate of mutation, and fairly uniform frequency distribution of alleles in the population [9]. The power of exclusion, which can be calculated for each locus based on the number of alleles in the population and their frequencies, represents the chance that an unrelated individual can be excluded by the locus. If a system has a few alleles that are common to most individuals, the chance that two unrelated individuals will share one or more alleles is high. If the system has multiple alleles, none of which occurs with a high frequency, then the power of exclusion is larger.

Based on Mendelian genetics, if a child has an allele that was not inherited from the mother, then it must have come from the biologic father. If the alleged father has that allele, then he is included among the group of men who could be the child's father (AF#2 in Fig. 55.2). The examination of alleles at multiple genetic loci is used to statistically reduce the number of men who could be the biologic father. AABB standards provide guidelines for the statistical significance that must be achieved to report the results, as described below.

Parentage Index

The PI expresses in mathematical terms how many times more likely it is that the tested individual is the biologic father of the child than a randomly selected man. Thus, the PI is an odds ratio comparing the probability that the child is the product of the mother and the alleged father vs the probability that the child is the product of the mother and a random man of the same racial background. At each of the multiple loci tested, the chance that the tested individual passed the obligatory allele is compared to the chance that the allele could have been contributed by a random individual [15]. A formula to calculate the PI can be derived using the laws of probability for each potential combination of

alleles for a mother, child, and alleged-father trio at each locus, based on allele frequencies (Table 55.2). A PI must be calculated separately for each locus tested.

Since the PI calculations require allele frequencies by racial group, for each locus the frequency of all the possible alleles must be determined from the phenotypes of at least 100 unrelated individuals from the same racial group. The larger the available database, the smaller the error of the estimate. The ideal population frequency is one calculated from testing done by the specific laboratory. These data should be evaluated by comparison with published frequencies. When a laboratory has accumulated additional test data or introduces a new method, new values should be calculated and compared with existing frequencies. This is helpful in monitoring changes in the laboratory. For STR systems with discrete alleles, it is fairly easy to establish frequency tables that can be validated and compared with those of other facilities. RFLP markers occur over a continuum and are influenced by measurement variables. Thus, determining the frequency of each band requires the use of the delta value for the test system [9]. Computer programs and manual calculations must be periodically reviewed and validated. Cases may involve individuals from racial or ethnic groups for which there is only a limited sample from the testing laboratory. In these cases, published tables may be used [16]. Table 55.3 shows the variation in PI values by racial group for several STR markers using published allele frequencies.

Table 55.2 Phenotype results and formulas used to calculate the parentage index by allele combination

Mother	Child	Tested man	PI
A or AB	A	A	1/a
A or AB	A	AB or AC	0.5/a
B	AB	A	1/a
B	AB	AC or AB	0.5/a
AB	AB	AB or A	1/(a+b)
AB	AB	AC	0.5/(a+b)
BC	AB	AB or AD or AC	0.5/a
BC	AB	A	1/a

A, B, C, and D represent different alleles. A is always used to represent an obligatory paternal allele; *a* and *b* are frequencies of alleles A and B, respectively, in the same racial group as the tested man (alleged father)

Combined Parentage Index

Assuming each locus tested is inherited independently, a CPI is calculated by multiplying the PI values of all the individual loci to obtain a combined odds ratio, as specified by the third law of probability for completely independent events. AABB standards require that multiple independent genetic systems be tested that will provide a CPI of at least 100, which indicates that it is 100 times more likely that "this man," rather than "some random man," is the father of this child [7]. Table 55.4 is an example of a case meeting this requirement for the three ethnic groups shown.

Residual Paternity Index

The residual paternity index is a calculation that is useful when there are inconsistencies in inheritance for some systems. This index is calculated by multiplying the PI for all systems that fail to exclude. A high residual PI suggests that the true parent could be a relative of the tested individual. Since a father and son share at least one marker at each locus, and brothers have more markers in common with each other than either would with a random man, if the true father is related to the tested individual, the alleged father is less likely to be excluded in most systems. An avuncular index is used to calculate whether there is biological relationship between the alleged father's child and aunts or uncles of the alleged father [17]. A high residual PI also may occur if the single inconsistency is due to a mutation or if there has been a laboratory error in testing or recording results of a single system. If the inconsistency is considered to be a mutation, the PI for the system can be calculated using a value for the mutation frequency, if known [18]. In these cases the CPI often exceeds 100 even though the PI for the system with the mutation is very small.

Probability of Parentage

If the individual in question is included as the parent by the genetic testing, this information is combined with the nongenetic evidence to calculate the probability of parentage (*W*, expressed as a percentage) using Bayes' theorem:

$$W = \frac{(p)(\mathrm{CPI})}{(p)(\mathrm{CPI})+(1-p)} \times 100$$

Table 55.3 Calculation of the percentage index (PI) using allele frequencies for different racial groups

					paternity indices (by ethnic background)		
	M	Child	Man	X/Y	Caucasian	African American	Native American
CSF1PO	9, 11	9, 11	11	1/(a+b)	2.98	4.10	3.29

vwa31/A	18, 19	18, 19	17, 19	18 = 0.23 19 = 0.08	0.5/(0.23 + 0.08)	1.61
Combined parentage index						11,444
Probability of paternity						99.99 %

OG(s), obligatory paternal allele(s). Frequency of OG(s) refers to the allele frequency of the given OG allele in the Caucasian population. *X*/*Y*, odds ratio of tested man vs a random man being the father of this child. Formula *X*/*Y* can be found in Table 55.2. Locus PI is calculated for each locus, and then the individual locus PIs are multiplied together to obtain the combined Parentage Index (PI). The probability of paternity is calculated using Bayes' theorem and a neutral prior probability of 0.5

where p is the prior probability of nongenetic events and CPI is the combined parentage index [19]. The nongenetic information is referred to as the prior probability and includes information about access at the appropriate time, fertility, and so on. Since the nongenetic information is unknown to the testing facility, it is general practice to assign a neutral value of 0.5 (50 %) to perform this calculation. Alternatively, the probability of parentage can be calculated with prior probabilities of 0.1, 0.5, and 0.9 to give a range of probabilities. The number calculated, referred to as the posterior probability, is expressed as a percentage. If the CPI is 100, then the probability of parentage is 99 % when using a 50 % prior. The higher the value of the CPI, the closer the probability of parentage is to 100 %; however, 100 % can never be reached. If the genetic evidence indicates that no relationship exists (multiple exclusions), then the probability of parentage is reported as zero.

Random Man Not Excluded

Random man not excluded (RMNE) is a calculation that estimates the fraction of the population that would not be excluded by a test system based on the phenotypes of the mother and child [20]. The results of the tested man are not considered in determining this value. The RMNE value for several systems used as a battery of tests gives a power of exclusion for a random man that is compared to the mother–child pair. RMNE adds little or no additional information to the PI and is not routinely reported by most testing facilities.

Reconstruction Cases

In many circumstances it is possible to estimate the likelihood of a relationship when only some of the persons in the family are available for testing.

Motherless Cases

If only the man and child are tested, a PI can be calculated using formulas that compare the chance that the tested man will transmit the shared allele(s) to the child through a mating with a "random mother" with the chance that the allele(s) are from two unknown and random parents [21] (Table 55.5).

Fatherless Cases

Formulas are available to calculate the possibility of parentage when the mother, child in question, and unquestioned relatives of the unavailable father are tested [22]. A common situation, shown in Fig. 55.3, is to test one or both parents of a deceased man (i.e., the presumed grandparents). If the

Table 55.5 Phenotype results and formulas used to calculate the PI by allele combination in motherless cases

b

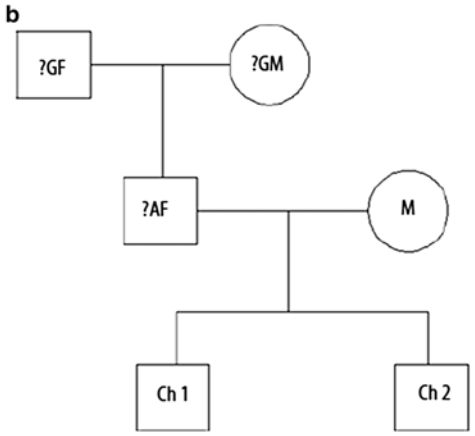

Figure 55.3 Reconstruction of a family with a deceased alleged father (?AF). (**a**) Phenotype results from two RFLP systems and three STR systems on members of the family shown in (**b**). (**b**) Pedigree of family relationships. The alleged father (?AF) is deceased. His presumed parents (?GF and ?GM) were tested, and the results are given in (**a**). Shown in *bold* are the obligatory paternal allele(s) (OG) that could be found in the alleged father if ?GF and ?GM are his parents. These results show that Child 1 (Ch 1) could be the product of a mating between the mother and the deceased man (?AF). Child 2 (Ch2) is excluded as being the child of ?AF and the mother in several systems (*shaded boxes*), since the OGs are not in the presumed parents of ?AF

obligatory paternal allele in the child is not present in either of the child's presumed grandparents, the man is excluded. If it is present, then the PI can be determined. It is also possible to use tests of other children of the deceased man with or without testing their mother(s), his siblings, or other related individuals. In doing these reconstructions, one assumes that the surrogate individuals are biologically related to the father.

Kinship Analysis

Estimation of whether two tested individuals are full siblings, are half-siblings, or have some other relationship is possible using appropriate kinship coefficients [4, 23]. Although full siblings will share one or both alleles by descent in most systems, 25 % of the time they will not share a common allele. Molecular genetic markers also are very useful in determination of the zygosity of twins. Table 55.6 shows the testing results for a mother and three children. From this data it is possible to determine whether the children have the same or different fathers and thus are full or half siblings. For the case shown in Table 55.6, the data indicate the existence of multiple fathers.

Table 55.6 Relationship testing to determine sibship

Sample/ system	Mother	Child 1	Child 2	Child 3	Inferred paternal alleles
D3S1358	16	16	16	16	16
D5S818	11, 12	10, 11	12, 13	11	**10**, **11**, **13**
D7S820	12	11, 12	8, 12	9, 12	**8**, **9**, **11**
D8S1179	13, 15	13, 14	14, 15	10, 13	10, 14

The paternal alleles can be inferred from each child. The existence of more than two obligatory paternal alleles in loci D5S818 and D7S820 indicates the existence of multiple fathers of these children

Reporting of Test Results

Many of the reports of relatedness testing may become part of legal proceedings. In some cases, one of the tested parties may challenge the results, and thus it is very important to have careful documentation of all steps from sample collection to reporting of results. AABB standards define the required information for a report of parentage testing [7, 8]. The date of collection of each sample, the name of each person tested, and his or her relationship to the child should be stated in the report. The phenotype observed for each

individual using standard nomenclature and the PI for each genetic system tested must be included. The report must explain whether a relationship can or cannot be excluded. The racial or ethnic background used for calculations, the combined parentage index, and the probability of parentage as a percentage must be stated. Any unusual findings such as mutations must be explained.

Conclusion

Testing of multiple genetic systems by validated molecular methods can provide information to resolve questions of relatedness. Though these tests are powerful tools that can exclude almost all falsely accused parents, they alone do not prove absolutely that a relationship exists between two individuals.

Chimerism Testing in Allogeneic Hematopoietic Stem Cell Transplantation

56

Vivianna M. Van Deerlin and Ran Reshef

Abstract

Allogeneic hematopoietic stem cell transplantation (HSCT) is a well-established treatment option for a variety of malignant and nonmalignant diseases. Each year, more than 28,000 patients undergo allogeneic HSCT worldwide. Molecular analysis of chimerism levels is used to monitor the proportions of donor and recipient hematopoietic cells in patients after HSCT. Chimerism studies can help identify the source of hematopoiesis after engraftment, identify graft rejection in patients with poor hematologic recovery, and assist in the diagnosis and prediction of relapse and clinical graft-vs-host disease (GVHD). The most commonly applied method is PCR amplification of short tandem repeats (STR), a type of genetic polymorphism. The interpretation of chimerism results depends on the context in which the testing was done, i.e., the type of transplant, conditioning intensity, timing of testing post-transplant and results of concurrent blood counts and bone marrow morphology. While the methodology is technically straightforward, the implementation, analysis, and interpretation of results can be complicated. The clinical importance of chimerism results warrants the effort required by the laboratory for validation and performance of the test. In this chapter we review the clinical utility of chimerism analysis and laboratory aspects of testing, including methods, reagents, approaches to pre- and post-transplant testing, analysis and interpretation, pitfalls and limitations, reporting, and data management.

Table 56.1 Terminology of post-transplant chimerism analysis

Term	Definition	Significance
Complete or full donor chimerism	Only donor detected	Suggests complete hematopoietic engraftment, but low levels of recipient cells may not be detected depending on the method used to assess
Mixed chimerism	Both donor and recipient detected	May indicate increased risk of relapse; dynamic change most important (increasing, decreasing, or stable); for RI-HSCT, mixed chimerism is expected initially
Subset chimerism	Mixed chimerism in a cellular subpopulation, e.g., T cells	Patterns of T cell and natural killer (NK) cell chimerism may be predictive of GVHD or graft loss in RI-HSCT recipients
Split chimerism	Recipient detectable only in some cell lineages	May indicate relapse or risk of relapse; important to correlate with clinical picture and original disease cell lineage
Microchimerism	<1 % recipient detected	Associated with solid organ transplantation; unclear significance in setting of allogeneic HSCT

RI-HSCT reduced intensity hematopoietic cell transplation

short tandem repeats (STR), a type of genetic polymorphism. The interpretation of chimerism results depends on the context in which the testing was done, i.e., the type of transplant, conditioning intensity, timing of testing post-transplant and results of concurrent blood counts and bone marrow morphology. In this chapter we review the clinical utility of chimerism analysis and laboratory aspects of testing including methods and analysis.

Terminology

A chimera is a mythological creature consisting of the head of a lion, the body of a goat, and the tail of a serpent. In medicine, a chimera is an individual whose cells derive from two or more genetically distinct individuals. While this can occur naturally by fetal-maternal transfer, in the context of HSCT, chimerism is the desired outcome, with the entire hematopoietic system genetically of donor origin. A variety of terms are used to describe post-transplant chimerism (Table 56.1). "Complete chimerism" (also referred to as "full donor chimerism") indicates that only donor hematopoietic cells are identified. In contrast, when both recipient and donor cells are present in a cellular subset, this is referred to as "mixed chimerism." The threshold that differentiates complete chimerism from mixed chimerism depends on the sensitivity of the assay used; that is, if the sensitivity of the assay is 5 %, then 95 % donor may not be a significantly different result from 100 % donor. Similarly, a technical result of complete chimerism does not indicate absolute absence of donor cells; only that it is below the limit of detection of the assay. Detection of < 1 % donor is sometimes referred to as "microchimerism," a term that arose from the solid organ transplant field, where passenger cells within the graft can persist in the recipient's blood.

Hematopoietic Stem Cell Transplantation

Each year, more than 28,000 patients undergo allogeneic HSCT worldwide. Allogeneic HSCT is accomplished by the infusion of either bone marrow or granulocyte colony stimulating factor (G-CSF)-mobilized peripheral blood stem cells from a related or unrelated donor. The stem cell infusion is preceded by the administration of a conditioning regimen (chemotherapy and/or radiotherapy), designed to eradicate residual malignant cells and induce sufficient immunosuppression to facilitate engraftment. Allogeneic HSCT permits the administration of myeloablative doses of chemotherapy and radiation, and offers important antitumor immunity through donor-derived T and NK cells. The genetic disparity between the donor and the recipient results in a therapeutic antitumor effect, often called the graft-vs-tumor (GVT) response, but also results in immune-mediated damage to normal recipient tissues, causing a clinical syndrome called GVHD. Reduced intensity HSCT (RI-HSCT) involves the administration of non-myeloablative doses of chemotherapy and radiation in order to reduce the toxicity associated with aggressive conditioning. The lower toxicity of RI-HSCT allows its use in patients deemed ineligible for myeloablative transplants due to age, comorbidities, or prior therapies. RI-HSCT eradicates malignant cells through a powerful GVT effect and not through chemotherapy or radiation.

Clinical Utility of Chimerism Analysis

Chimerism is a dynamic process following allogeneic HSCT, and its kinetics depend on the intensity of the conditioning regimen, sensitivity of different cell types to chemotherapy and radiation, the recipient's prior therapies, composition of

the graft, and other factors. Therefore, identification of longitudinal changes (increasing or decreasing mixed chimerism over time) is most useful clinically. The interpretation of chimerism testing depends on clinical context, type of transplant, and time after transplant. For example, the presence of "10 % residual recipient cells" may have completely different implications on day 21 vs day 100 after HSCT, or if the patient had a myeloablative or a reduced-intensity conditioning regimen prior to transplant. Similarly, the presence of "25 % donor cells" in a patient with aplastic appearing bone marrow is interpreted differently from a patient who has evidence for relapsed leukemia occupying the marrow. Here we describe the common clinical situations and various clinical outcomes that can be evaluated with chimerism testing.

Patterns of Engraftment

Recovery of normal hematopoiesis after HSCT occurs gradually after the stem cell infusion. In typical hematologic recovery, granulocytes recover first (within 10–24 days) and platelets and red blood cells ensue. Complete blood counts fail to reveal the origin of recovering hematopoiesis, which can be donor-or recipient-derived, and is very often mixed in the early phases after HSCT. Chimerism analysis is usually done in the first 100 days after the stem cell infusion to verify and document adequate engraftment of donor cells [1]. In myeloablative HSCT, if careful sequential studies are done, an early phase of mixed chimerism is usually observed, rapidly followed by conversion to complete donor chimerism (Fig. 56.1a). In cases of graft failure, transient mixed chimerism transitions back to predominantly recipient chimerism, followed by disappearance of donor cells (Fig. 56.1b). Therefore, chimerism studies are useful in the evaluation of poor hematological recovery, which may be the result of engraftment failure, infection, GVHD, or ABO incompatibility. In RI-HSCT, mixed chimerism may persist for long periods of time without indicating engraftment failure.

The kinetics of the transition from mixed to complete chimerism reflect the complexity of immune interactions between donor and recipient cells as well as differences in the HSCT process for different clinical situations. The major determinants of engraftment timing and levels of mixed chimerism include the type of conditioning regimen used (myeloablative vs reduced-intensity), graft type (bone marrow vs peripheral blood stem-cells vs umbilical cord blood [UCB]), graft source (related vs unrelated donor), human leukocyte antigen (HLA) compatibility, numbers of CD34+ and CD3+ cells in the graft, prior chemotherapy, degree of lymphodepletion prior to transplant, type of disease (acute myelogenous leukemia [AML], lymphoma, chronic myelogenous leukemia [CML], etc.), and the use of T cell depletion [2–11]. Acute GVHD is associated with accelerated engraftment, but the causal relationship is unclear. Faster engraftment may trigger GVHD by not allowing sufficient time for the immune system to develop tolerance [2, 3, 12, 13].

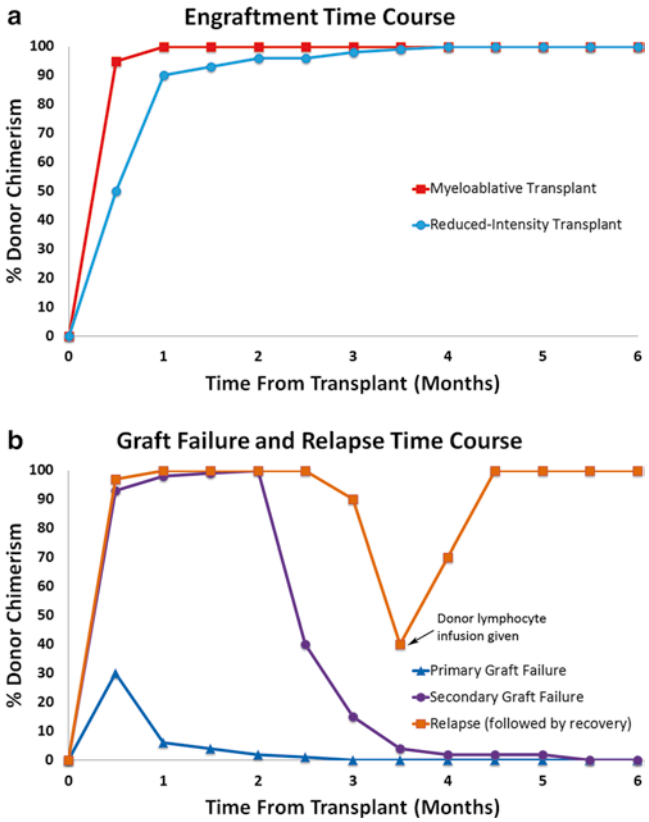

Figure 56.1 Comparisons of typical time courses of engraftment (**a**) and graft failure (**b**) after bone marrow transplant. The example of relapse (**b**) shows recovery of donor engraftment after infusion of donor lymphocytes

In RI-HSCT, higher levels of donor chimerism, and sometimes even early full chimerism, are more common in patients who had intensive chemotherapy prior to transplant, likely secondary to lymphodepletion, which leads to homeostatic expansion of donor cells and therefore faster engraftment [5, 14]. Strategies have been developed to intensify pre-transplant lymphodepletion in order to accelerate engraftment [11]. Chimerism analysis enables close monitoring in these cases.

In UCB transplants, slow engraftment and engraftment failure are common due to low numbers of CD34+ cells and HLA incompatibility. Chimerism is tested in these cases to monitor the engraftment process. Chimerism measurements as early as 14 days post-transplant can be helpful in predicting the risk for graft failure [15]. In order to overcome the barriers of slow engraftment and high incidence of graft failure after UCB transplants, a commonly used approach is the

concurrent transplantation of two different UCB units, which accelerates engraftment and reduces the risk for graft failure [16, 17]. After double cord transplant, chimerism analysis often detects DNA from both UCB units at the same time, with occasional residual recipient cells, especially after reduced-intensity conditioning. The usual course is that both units contribute to early hematopoiesis, but by 21–100 days post-transplant, one of the units predominates, and eventually the minor unit can no longer be detected [17, 18]. The factors determining which unit "wins" include the CD3+ and CD34+ cell doses, the order of infusion, and the degree of HLA match [16, 19, 20]. Interestingly, cases have been reported where reversal of dominance occurs a long time after the transplant, even after documentation of full chimerism with one of the donors [20, 21]. Evaluation of chimerism in the setting of two donors is more complicated than with a single donor.

Evaluation of Graft Failure

Graft failure presents as either failure to achieve adequate engraftment and recovery of blood counts (primary graft failure) or loss of normal blood counts after initial engraftment (secondary graft failure) (Fig. 56.1b). In the evaluation of graft failure, it is important to differentiate between graft rejection, defined as the absence of donor-derived hematopoiesis (usually < 5 % donor chimerism) in a patient with a hypocellular marrow, and poor graft function, where donor cells are present but production of blood elements is reduced. Poor graft function may result from a low dose of CD34+ cells in the graft, presence of recipient-derived anti-HLA antibodies against the donor cells, use of bone marrow or UCB as opposed to peripheral blood stem cells, infection, and factors in the bone marrow environment [22, 23]. A poorly functioning graft may respond to infusion of additional stem cells. Graft rejection is more likely to be the result of immunologic rejection of the graft, and can be treated with modulation of immunosuppressive therapies, donor lymphocyte infusions, or a second HSCT [24]. In all cases of graft failure, an evaluation of a bone marrow biopsy is mandatory to exclude a relapsed malignancy. The combination of bone marrow histology and chimerism levels in bone marrow and blood are useful to help interpret the clinical picture.

Mixed chimerism does not always predict graft failure, and is very common after RI-HSCT. However, it is known that predominant donor chimerism precedes hematologic recovery. A persistently low level of donor chimerism in whole blood, T cells, or NK cells after transplant is associated with subsequent graft failure [1, 5, 25, 26]. Serial monitoring every 1–4 weeks can identify a downward trend which predicts graft failure. Serial monitoring is also useful to measure responses to treatments of graft failure, such as withdrawal of immunosuppression, infusion of additional stem cells or additional lymphocytes, or a second transplant from a different donor.

Association with GVHD

In some studies, early conversion to full donor chimerism was associated with increased incidence of GVHD, while mixed chimerism seemed to be protective against acute and/or chronic GVHD [25, 27–29]. Mechanistically, co-existence of recipient and donor cells may facilitate peripheral tolerance induction, but mixed chimerism is not fully protective against GVHD, and conversion to full donor chimerism is not required for initiation of GVHD [5, 30–32]. Studies of T cell subset chimerism are potentially more informative than whole blood, and show that high donor T cell chimerism is associated with GVHD [5, 9].

Chimerism and Relapse in Myeloablative Transplants

The utility of chimerism testing for prediction of disease relapse depends on several factors. Attempts to associate mixed chimerism with relapse and survival outcomes resulted in conflicting results, possibly related to differences in diseases and conditioning regimens studied, and the use of T cell depletion strategies in some studies. In myeloablative HSCT for CML, the presence of mixed chimerism or mixed T-cell chimerism within 90 days after transplant correlates with disease relapse and a poor outcome, but this seems to depend on the conditioning regimen [33], and has questionable value in diseases other than CML [7]. The timing of testing is critical; studies in CML have shown that not only mixed chimerism but also residual copies of *BCR–ABL1* transcript are not predictive of relapse in the first 90 days after HSCT [34]. Therefore, in most clinical scenarios, early testing of mixed chimerism (day 30) should be reserved for evaluation of possible graft failure and not disease relapse [1].

Beyond the first 90 days post-transplant, many studies have demonstrated an association between persistence of recipient cells with relapse and worse survival [30, 35, 36]. More importantly, studies that looked at the dynamic changes in chimerism levels showed that a persistent or rapid trend of dropping chimerism levels often heralds relapse [31, 37–40], whereas stable mixed chimerism is not clearly associated with poor outcomes [27, 40–42]. One of the major limitations of these reports is that they included primarily patients with chronic phase CML, which rarely requires HSCT today [33, 36, 43–45]. In acute leukemias, trends seem to be more important than single measurements, and frequent monitoring

is more likely to predict relapse successfully than less frequent testing since the kinetics of chimerism prior to relapse can show an abrupt change [45–47].

Chimerism in RI-HSCT

In RI-HSCT, early evaluation of chimerism may have a more important role than for myeloablative HSCT. The low intensity conditioning regimen, combined with post-transplant immunosuppression, allows the establishment of mixed chimerism in most patients [48, 49]. With time, mixed chimerism may transition to complete chimerism, or remain stable and serve as a platform for subsequent immunotherapies such as donor lymphocyte infusions (DLI) [50]. After RI-HSCT, the initial recovery of neutrophil counts, traditionally named "engraftment," represents a mixed recovery of autologous hematopoiesis and engrafted donor cells, which quickly transition into complete myeloid chimerism (Fig. 56.1a) [5, 51]. Other lineages also recover gradually, but often remain in a mixed chimeric state for prolonged periods of time. Multiple factors determine the kinetics and the degree of donor chimerism achieved after RI-HSCT, and higher levels are achieved with a more intensive conditioning regimen, use of chemotherapy prior to transplant, use of G-CSF mobilized peripheral blood stem cells as opposed to bone marrow, and pre-transplant lymphopenia [5, 52]. The critical role of lymphodepletion prior to transplant in inducing full donor chimerism has led to the development of chemotherapy regimens that efficiently deplete recipient lymphocytes prior to RI-HSCT for lymphoma [11].

Is the degree of donor chimerism associated with outcomes of RI-HSCT? Early studies showed that full T cell chimerism precedes full myeloid chimerism and suggested that full chimerism precedes GVT and GVH responses [51, 53]. Other studies have found that low levels of T and NK cell chimerism predict graft rejection and lack of antitumor activity; high levels of T cell chimerism are associated with GVHD, while high levels of NK cell chimerism predict improved progression free survival [5, 26]. Some of these correlations might be specific to certain diseases and certain conditioning regimens [4, 6]. Recently, large retrospective studies have demonstrated the prognostic value of early (day 30 and day 100) measurement of donor chimerism in predicting relapse and survival after related or unrelated donor transplants, regardless of disease [52, 54]. Similarly, full donor T-cell chimerism on day 100 after double UCB transplants with reduced intensity conditioning seems to predict a lower incidence of relapse [55]. These studies strengthen the rationale for chimerism testing in the setting of RI-HSCT.

Failure to achieve full chimerism after both myeloablative and RI-HSCT can be overcome by DLI, which often successfully induces transformation from mixed to full chimerism and enhances the GVT response [56, 57]. Monitoring whole blood or T cell chimerism after HSCT has been used to guide and monitor preemptive DLI strategies in patients with mixed chimerism, considered to be at high risk for rejection and disease relapse [35, 46, 51, 53, 58–62]. Randomized studies have not been conducted to provide solid evidence for the benefit of this approach, but it is clear that DLI can induce favorable antitumor responses in several diseases [37, 58, 62]. Cytokine therapy also has been used to enhance engraftment and increase donor chimerism levels [63].

Chimerism vs Minimal Residual Disease

Minimal residual disease (MRD) detection can be performed by amplification of disease-specific markers such as *BCR–ABL1* transcripts. The analytic sensitivity of MRD analysis (generally between one cell in 1,000 and one cell in 1,000,000) is greater than that of standard methods for chimerism analysis (generally 1–5 %). In addition, MRD detection with a disease-specific marker detects only the malignant cells, while chimerism analysis detects all recipient cells without distinguishing between malignant and normal host cells. Chimerism testing is useful because it offers a universal way to detect residual recipient cells without the need to have a known disease-specific cytogenetic or molecular marker. A way to augment the sensitivity of chimerism analysis for early detection of relapse is by enriching the sample for cells that carry a phenotypic marker similar to the patient's malignancy, i.e., enriching for CD19+ cells in a patient who underwent HSCT for B-lymphoblastic leukemia [64, 65]. Cells also can be enriched for either an abnormal phenotype or CD34 positivity (a surface marker of immaturity, which is carried by most acute leukemias) [66, 67]. Potentially the best way to predict disease relapse is to combine chimerism testing with other MRD assays, if available, to increase the predictive value of both tests [37, 68, 69].

Guidelines for Chimerism Testing in HSCT

The American Society for Blood and Marrow Transplantation published a set of guidelines for the testing of chimerism after allogeneic HSCT (Table 56.2) [53]. These guidelines support the use of STR or variable number tandem repeat (VNTR) analysis of peripheral blood samples as the standard method to analyze chimerism and specify that lineage specific chimerism is useful following non-myeloablative and reduced-intensity conditioning.

Table 56.2 Comparison of chimerism analysis in myeloablative and RI-HSCT based on recommendations of the National Marrow Donor Program and the International Bone Marrow Transplant Registry 2001 Workshop

	Myeloablative HSCT	RI-HSCT (Non-myeloablative)
Recommended sample	Peripheral blood	Peripheral blood and cell lineage subpopulations
Frequency of analysis	3, 6, and 12 months after HSCT; after complete chimerism, based on change in clinical condition	Every 2–4 weeks
Significance	Mixed chimerism, particularly increasing mixed chimerism, may help predict relapse; significance depends on disease and cell lineage of chimerism	Early patterns of chimerism may predict either GVHD or graft loss
Method	Tandem repeat loci sensitive for detection of recipient allele(s)	Tandem repeat loci sensitive for detection of both recipient and donor allele(s)

GVHD graft-vs-host disease, *RI-HSCT* reduced intensity hematopoietic stem cell transplantation

Other Applications of Chimerism Analysis

HSCT for Nonmalignant Conditions

RI-HSCT is commonly used to treat nonmalignant conditions, where mixed chimerism is sufficient to reverse a clinical phenotype such as congenital immunodeficiency, enzyme deficiency, or hemoglobinopathy. In these situations chimerism studies are helpful in predicting the clinical benefit. For example, in HSCT for congenital immunodeficiency, the increase in T cell chimerism correlates with immune reconstitution [70], and in HSCT for hemoglobinopathies, establishment of 25 % donor chimerism is sufficient to reverse the clinical phenotype of sickle cell anemia and thalassemia, and usually correlates with transfusion independence [71, 72]. Factors that are associated with stable mixed chimerism include younger donor age, sibling donor, and the type of conditioning regimen used. Acute GVHD occurs more often in patients who achieve full donor chimerism [73].

Donor-Derived Clonal Disorders

Donor-derived malignancies are rare after HSCT and solid organ transplants [74]. These malignancies can easily be confused with relapsed disease in a patient after HSCT, and therefore chimerism testing is important to identify the origin of the malignant clone. When the donor is still alive, this may require advising the donor about appropriate screening procedures. Similarly, chimerism analysis allows determination of the origin of proliferating lymphocytes in post-transplant lymphoproliferative disorders.

Transfusion-Associated and Solid Organ Transplant-Associated GVHD

GVHD is rarely associated with the transfusion of cellular blood products containing viable passenger lymphocytes as well as solid organ transplants. In both cases, immunosuppressed individuals are unable to eradicate donor-derived competent T cells. The result is a severe form of GVHD that primarily attacks the bone marrow, leading to aplasia, which is frequently fatal if not identified early. In these cases of transfusion-associated GVHD, prior donor DNA is usually not available, but analysis of the recipient's blood will reveal foreign DNA [75]. Chimerism studies can show mixed chimerism in these patients, and cases of >50 % T cell donor chimerism have been described [76]. This topic is described further in Chap. 57.

Methods

Fluorescence In Situ Hybridization

Fluorescence in situ hybridization (FISH) analysis for the X and Y chromosomes (XY-FISH) can be used for chimerism analysis by hybridization of interphase preparations with two differentially labeled probes for sequences on the X and Y chromosomes, respectively [77]. Classic karyotyping methods could be used for detection of X and Y chromosomes but would be labor-intensive, slow, and limited by the number of cells able to be analyzed. For example, to attain a sensitivity of 1 %, more than 300 cells would need to be evaluated. FISH allows the rapid screening of a large number of cells. The method can yield quantitative results by rapidly counting between 500 and 1,000 cells. A sensitivity of approximately 0.1 % or lower can be achieved [59]. Standardization of XY-FISH has made it suitable for clinical use [78]. However, the major limitation of XY-FISH is the applicability only for sex-mismatched transplants.

Tandem Repeats

Tandem repeats are a class of polymorphism consisting of a variable number of tandemly repeated core sequences [79]. Tandem repeats are classified according to the number of

Table 56.3 Comparison of methods of chimerism analysis

Method	Sensitivity	Advantages	Disadvantages
Karyotyping	5–10 %	Monitors chromosomal abnormalities as well	Requires dividing cells; low sensitivity; high false-positive rate
RFLP	5–10 %	Highly informative	Requires Southern blot analysis; alleles not distinct
Red blood cell phenotyping	0.04–3 %	Simple	Not very informative; can be affected by transfusion; not useful for rapidly proliferating diseases
STR-PCR	1–5 %	Highly informative; quantitative	Only moderate sensitivity; multiplex amplification may decrease sensitivity
FISH for X and Y chromosomes	0.1–0.5 %	Sensitive; feasible to screen large numbers of cells for quantitative result	Only for sex-mismatched transplants
SNP Analysis	0.01–1 %	Highly sensitive; quantitative	Less quantitative with higher chimerism; need to evaluate many SNPs to find informative SNP
Y-chromosome PCR	0.001–0.1 %	Sensitive; highly informative in sex-mismatched transplants	Only for sex-mismatched transplants with male recipient and female donor
Cell sorting + STR-PCR	0.0001–0.1 %	Informative; sensitive; cell lineage information important	Requires large volume of blood; technically demanding

RFLP restriction fragment length polymorphisms, *SNP* single nucleotide polymorphism, *STR-PCR* short tandem repeat polymerase chain reaction, *XY-FISH* X and Y chromosome fluorescence in situ hybridization

nucleotides in each core sequence. Minisatellites have core sequences of approximately 8–80 base pairs (bp) and are also known as VNTR. In contrast, microsatellites, also known as STR loci, have core sequences of up to 7 bp [80]. Allelic variation at each VNTR and STR locus arises from the number of core repeats present. STR alleles have between 3 and 40 tandem core repeats; each STR locus typically has 10–20 different allelic variants. Variant alleles with imperfect repeats also occur [80].

STR loci and some VNTR loci are amenable to PCR amplification using primers that flank the repeating sequence. After amplification, the number of repeats is calculated from the size of the PCR product, or, more simply, the products are compared to an "allelic ladder" constructed to contain the majority of known repeat size alleles in the human population at a particular locus [80]. PCR amplification of tetranucleotide (four bp in each core repeat) and pentanucleotide (five bp in each core repeat) STR loci has become the predominant method for DNA-based human identification [81]. Comprehensive information about STR loci and their application in human identification is available from a Web site sponsored by the National Institute of Standards and Technology (http://www.cstl.nist.gov/div831/strbase, accessed 4/12/2015).

Amplification of STR loci has become the most frequently applied technology for the study of chimerism after HSCT for several reasons [82, 83]. By examining multiple STR loci, which is made easier by multiplex PCR, it is possible to find at least one STR locus for each donor–recipient pair that can be used to distinguish the donor from the recipient; thus, STR-PCR is essentially universally informative, except in identical twins. In addition, STR-PCR can be used to quantitatively discriminate mixtures of DNA based on relative amplification of alleles. The sensitivity of STR-PCR for chimerism analysis can achieve a limit of detection of about 1 % chimerism if performed following recommended guidelines [84]. STR alleles are relatively similar in size due to the small repeat unit; thus, compared with VNTR alleles, which have larger differences, STR-PCR theoretically is better for quantification because preferential amplification of smaller alleles is less likely to occur. The advent of capillary electrophoresis (CE) and automated fluorescent detection has made the analysis of PCR products technically straightforward. In addition, the availability of commercial reagents for STR-PCR simplifies assay development.

Y Chromosome Analysis

Amplification of Y chromosome-specific sequences can be used for assessment of chimerism in sex-mismatched HSCT involving a male patient and a female donor, which represents approximately 25 % of all HSCT cases. Because the targeted sequences are present only on the Y chromosome, the method is very sensitive. Sensitivities as high as 1 male in 100,000 female cells (<0.001 %) have been reported, although the clinical relevance of chimerism detection at

such high levels of sensitivity is not clear [45, 85]. Use of quantitative real-time PCR has the advantage of being not only sensitive but also quantitative for very low levels of mixed chimerism, useful for detecting an increasing or decreasing signal over time. Amplification of the amelogenin gene, which is present on both the X and Y chromosomes, but is 6 bp longer on the Y chromosome homolog, is used for sex typing in forensic analysis and also has utility for chimerism analysis [80]. The major disadvantage of all Y chromosome PCR methods is the limited application to only a subset of sex-mismatched transplants.

Single Nucleotide Polymorphism Analysis

Single nucleotide polymorphisms (SNPs) are primarily biallelic variants at a single nucleotide position. SNPs occur on average every 1.3 kilobases (kb) in the human genome. Since SNPs are sequence polymorphisms rather than length polymorphisms, their utility for chimerism analysis is based on the frequency of heterozygosity in the particular population under study. With only three potential genotypes for most SNP loci (AA, AB, BB), the chance of distinguishing two individuals is much lower than for STR loci, which have 10–20 alleles per locus. Consequently multiple SNPs must be analyzed to successfully distinguish all donors and recipients. One investigator statistically calculated the number of SNPs required to identify an informative locus in 96.5 % of cases to be 25 SNPs [86]. In one study using a panel of 51 SNPs, an informative locus was found in 100 % of cases; however, this study used a microarray-based system to enable high-throughput testing [87]. While the number of loci necessary is a disadvantage, an advantage of SNP detection over tandem repeat amplification is that SNPs are less susceptible to preferential amplification of alleles based on length, and stutter peaks (described later) are not a concern.

While there are many methods for analysis of SNPs, real-time PCR technology is commonly used for SNP-based chimerism analysis [82, 88]. Real-time PCR permits sensitive detection of mixed chimerism using SNPs at a level of approximately 0.1 %. Although real-time PCR is quantitative, the coefficient of variation (CV) at chimerism levels above 5 % is as high as 30–50 %, compared with a CV of about 5 % for STR-PCR methods [77]. Thus, while SNP real-time PCR is more sensitive and quantitative, particularly at low levels of mixed chimerism, the variability of the quantitation when the level of recipient is above 5 % does not permit accurate determination of dynamic change in mixed chimerism levels [82]. Real-time PCR SNP analysis of mixed chimerism is a promising method; yet, despite years of evaluation and new technologies for analysis, SNPs have not supplanted STRs for chimerism analysis [82].

Laboratory Testing

PCR amplification of STR loci is currently the most commonly accepted and most widely used method for assessment of mixed chimerism after HSCT [53, 84, 89]. Therefore, the remainder of this chapter details the use and interpretation of PCR testing of STR loci for analysis of mixed chimerism in a clinical laboratory.

STR Amplification Reagents

Chimerism analysis requires the identification of at least one informative STR locus that distinguishes recipient from donor cells prior to transplant, in order to be able to monitor recipient cells, donor cells, or both in the recipient after transplant. A variety of commercial reagents are available for amplification of STR loci. The majority of commercially available STR amplification reagents are designed for forensic analysis in which a maximum amount of information is desired from frequently limited samples. Multiplex PCR, in which multiple loci are amplified simultaneously by including more than one set of PCR primers in the reaction, is ideal for this purpose. The STR locus-specific PCR products from the multiplexed reactions are distinguished by the expected size range of the products for each locus (designed to be non-overlapping) and by the use of different fluorophores for each locus in a multiplexed set, allowing amplification of loci with overlapping product sizes. High-order multiplex primer sets have been designed that amplify 16 or more STR loci. The two major suppliers of forensic STR primer sets are Promega Corporation (Madison, WI) and Life Technologies (Foster City, CA), each with a variety of multiplex combinations, some designed for detection with specific methods or instruments. At the time of writing of this chapter, enforcement of a patent held by Promega currently prohibits the use of the Life Technologies STR reagents for chimerism analysis in the setting of HSCT and other clinical and research applications. Primer sequences are also available online and in publications for laboratories to develop and validate their own assays; however, the optimization of multiplex amplification is time-consuming and complex.

Selecting a STR Marker Panel

All STR loci are not created equal. Some are more informative than others based on allele frequencies and rates of heterozygosity. The possible constellations of alleles can be grouped into several categories [90, 91]. Some loci have a higher proportion of ideal allele constellations that improve the ability to detect low levels of recipient in a donor

background. The Penta E locus was found to have the highest percent of ideal allele constellations in a study that evaluated 27 loci in 203 recipient–donor pairs [90]. Interestingly, in our laboratory's experience using 15 STR loci for pre-transplant analysis and then selecting a single optimal locus, Penta E was the most commonly selected single locus. In contrast, CSF1PO was the least selected locus and it had the lowest frequency of ideal allele constellations in the study by Thiede et al. [90]. In Europe, the EuroChimerism consortium was established to facilitate harmonization of chimerism diagnostics between European centers because of their assertion that existing forensic commercial primer sets are not ideal for chimerism [92]. This group recommended an STR marker panel specifically for chimerism analysis to maximize informativity, reliability, and sensitivity. Nevertheless, in our experience over 15 years, 12–15 commercially available forensic loci have been used successfully in an active transplant program to perform chimerism analysis. Even though several loci have been informative more often than others, the less informative loci have all been used for some recipient–donor pairs, indicating that they all have potential value; this is especially true in a two-donor transplant case where several loci are usually needed to monitor chimerism.

Detection Method

Amplified STR products can be detected in numerous ways, as described for forensic analysis in Chap. 54. By far the most frequently used method in clinical laboratories for analysis of STR amplification products is fluorescent detection by CE, which has the advantage that a gel does not need to be poured and analysis of samples is rapid [80]. CE can be performed with a single capillary instrument or with a multi-capillary instrument; for example, with 16 or 24 capillaries. The advantage of multiple parallel capillary systems is that analysis can be performed more rapidly than with a single capillary instrument. Capillary arrays with 96 or more capillaries are available; however, their instrument and reagent costs are greater, and thus they are only cost-effective for very high-volume testing. CE instruments that can detect multiple fluorophores permit not only multiplex amplification of loci resulting in PCR products overlapping in size, but also inclusion of a size marker for accurate sizing of the fragments. Of note, not all fluorophores are detected by all CE instruments; therefore it is important to check for compatibility before selecting reagents.

Pre-transplant Testing

The goal of pre-transplant analysis is to identify the informative loci that can be used to monitor chimerism after HSCT. This is accomplished by determining the STR alleles of the recipient and the donor(s) at each STR locus in the marker panel used by the laboratory, and then selecting at least one locus with one or more different donor and/or recipient alleles in a constellation pattern conducive to sensitive and accurate monitoring of post-transplant chimerism.

Samples

Usually peripheral blood samples from the donor and recipient are used to extract DNA for pre-transplant analysis. Analysis of an additional buccal cell sample from the recipient not only serves as a quality control to confirm the identity of the recipient sample in the laboratory, but also as a control for balanced amplification of alleles in a non-hematopoietic lineage. If there is allelic imbalance in the blood sample at a particular locus, comparison with the buccal sample amplification pattern can help determine if the effect is constitutional, stochastic, or due to disease (Fig. 56.2). A locus with significant unbalanced amplification of alleles in either sample should be avoided.

On occasion, a recipient is transplanted prior to the STR evaluation of a pre-transplant sample. In this case, a post-transplant blood sample will not be useful for identification of the recipient's genotype. Buccal cells are the most commonly used source of recipient DNA if blood is not an option, although any other available historical tissue that is appropriately preserved can be used. While post-transplant buccal samples will be of mostly recipient genetic origin, they will frequently contain a minority of admixed donor DNA, thereby generating a mixed chimeric pattern [93]. Since the recipient's alleles usually predominate, they can be deduced if the donor alleles are known. A saliva or mouthwash sample is not equivalent to a buccal cell sample since saliva generally contains significantly more leukocytes. In one study, the median amount of donor DNA in the buccal swabs was 21 % whereas it was 74 % in the mouthwash samples [94]. If only donor alleles are detected in a buccal swab DNA sample (and the donor is not an identical twin sibling), complete "engraftment" of buccal epithelial cells should be considered. Several cases of buccal cell "engraftment" after HSCT have been reported [95].

Identification of Informative Loci

To identify ideal informative loci for each recipient–donor pair usually many loci must be examined. This is particularly true when the individuals are related and share many alleles by inheritance. Multiplex amplification increases the speed and decreases the labor associated with the analysis of multiple loci. Of the loci found to be informative, not all will be appropriate for chimerism analysis. This is because the goal is not to differentiate the individuals as in forensic identity testing but to detect small amounts of recipient or donor alleles in a mixed specimen [90].

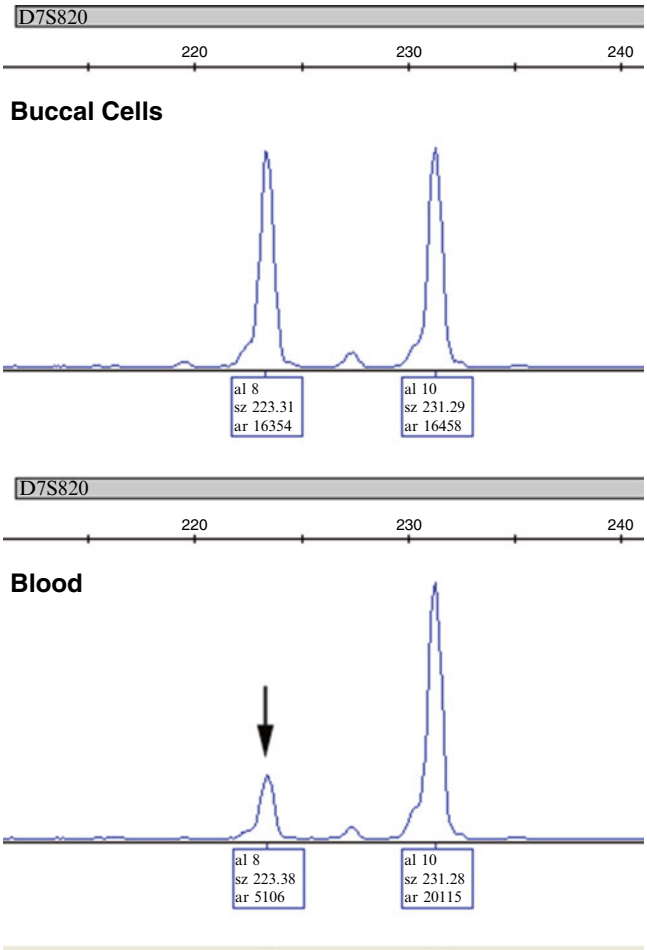

Figure 56.2 Amplification of the D7S820 locus in DNA obtained from buccal cells and blood in a patient with myelodysplastic syndrome. The blood, which contained disease, shows that one allele (8, *vertical arrow*) has only 25 % of the peak area of the other allele peak (10). The fact that the alleles are not imbalanced in the buccal cells suggests that this is due to a chromosomal abnormality related to the disease and not a constitutional polymorphism affecting amplification of allele 8. Thus, D7S820 should be excluded from calculations of chimerism due to underestimation of the % recipient if the disease relapses

The main factor limiting the utility of some informative alleles is the presence of a stutter peak which is one repeat smaller ($n-1$) and, to a much lesser extent, one repeat larger ($n+1$) or two repeats smaller ($n-2$) than each major allele peak [96]. When tandem repeats are amplified, stutter peaks are thought to result from slippage of the polymerase, causing mispairing of the template, which is shifted by one repeat unit, resulting in an additional PCR product predominantly one repeat smaller than the expected PCR product. The intensity of the $n-1$ stutter peak is usually approximately 2–11 % of the area of the corresponding STR allele [96]. The amount of stutter is influenced by the locus (some loci tend to have more stutter than others), the core repeat unit length (smaller core repeats have more stutter than larger repeats), and the allele size (larger repeat alleles have more stutter than smaller repeat alleles) [80].

For chimerism analysis, optimal informative loci have one or two recipient-specific allele(s) that do not co-localize with a donor allele or stutter peak (Fig. 56.3) [97]. Ideally, the recipient-specific allele should be at least two repeats larger or three repeats smaller than the donor allele(s) to avoid the stutter locations [89]. Having two unique recipient alleles that meet these criteria (recipient is heterozygous) may provide confirmation that a recipient DNA is present; however, at low levels of chimerism a heterozygous allele may be below the limit of detection compared to a homozygous peak. In addition, due to the theoretical possibility for preferential amplification of shorter fragments, the sensitivity for detection of a minor recipient-cell population may be greater if the informative recipient allele(s) have fewer repeats than the donor allele(s) [89]. Because of the many possible combinations of alleles between recipients and donors, each recipient–donor pair presents a unique situation, and each must be evaluated on a case-by-case basis to determine which loci can be used and which should be excluded due to artifacts (like stutter) that will reduce sensitivity and accuracy. These are only guidelines for the selection of informative loci; how useful or accurate a particular locus will be post-transplant ultimately is determined empirically by use in the post-transplant setting. In some instances, an optimal locus cannot be identified. In this case, post-transplant analysis still can be performed using a suboptimal locus with the caveat that the sensitivity of detection will be decreased because of co-localization of the recipient-specific allele with a stutter or other background peak. As described in the analysis section, chimerism calculations can be adjusted with caution to take stutter contributions into account.

Another factor to consider when selecting informative loci is whether there are specific alleles for both the recipient and the donor (Fig. 56.3). While this is not essential for myeloablative HSCT, for which the combined donor and recipient allele pattern of included loci must be optimized to enhance detection of a small percentage of recipient DNA in a donor background, it is very important for non-myeloablative HSCT, since any level of mixed chimerism (low donor or low recipient) may be seen. If no such locus can be found, then at least two loci should be selected, one optimized for detection of recipient allele(s) and the other for donor allele(s). As the level of mixed chimerism in the patient changes from low to high donor chimerism or vice versa in case of disease relapse, the loci used may need to be changed to optimize sensitivity (Fig. 56.4). The use of more than one informative locus to generate an average chimerism result will minimize the effect of artifacts and maximize analytic sensitivity. However, even if multiple loci are used the set of loci included in the average should be reevaluated if the percent of recipient DNA is very high.

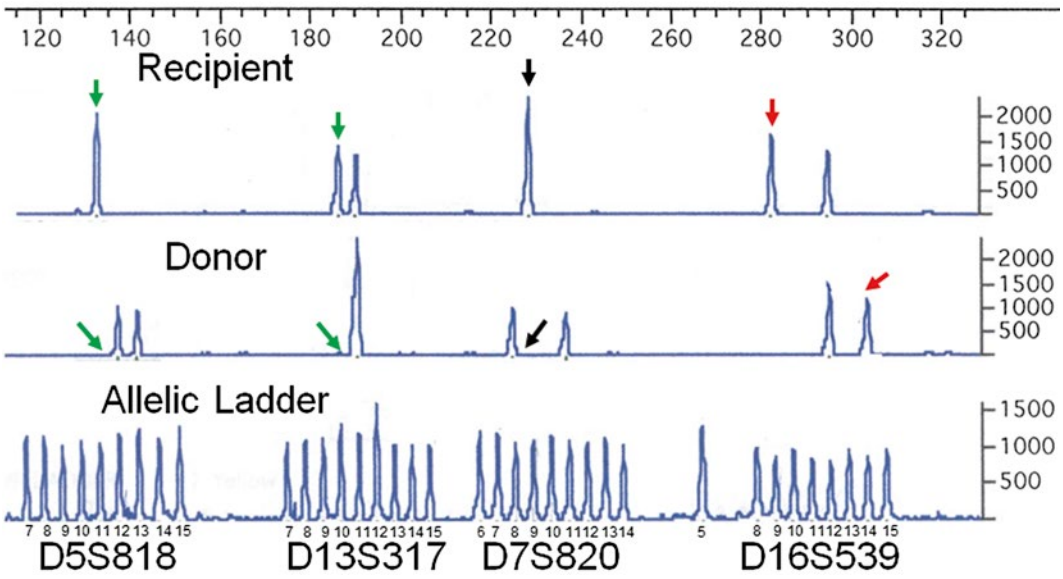

Figure 56.3 Identification of informative loci using PCR amplification of STR loci and CE analysis. The STR alleles at four loci (GammaSTR, Promega Corporation) are compared for a recipient–donor pair to identify the best informative locus. The number of repeats in each allele is determined by comparison to the allelic ladder for which the sizes are indicated. While all four loci are informative for distinguishing the recipient from the donor, the D16S539 locus is best because the recipient-specific allele (*red vertical arrow*) is separated from the nearest donor allele by at least two repeats. In contrast, for the D5S818 and D13S317 loci, the recipient-specific allele (*green vertical arrows*) co-localizes with a donor stutter peak, the location of which is indicated by the *diagonal green arrows*. The D7S820 recipient-specific allele (*black vertical arrow*) is acceptable, but, if present, an $n+1$ stutter (*black diagonal arrow*) from the smaller size donor allele may interfere with detection. The allele combination at the D16S539 locus also has the advantage of a unique donor allele (*red diagonal arrow*). *PCR* polymerase chain reaction, *STR* short tandem repeat, *CE* capillary electrophoresis

HSCT with Two Donors

A patient with a failed first transplant may undergo a second transplant with a new donor. The first donor may or may not be detectable in the recipient blood at the time of the second transplant. In addition, UCB transplants typically involve at least two donors. All these situations complicate the assessment of chimerism because all the individuals need to be able to be detected and distinguished. Generally one or more STR loci can be identified that have a unique allele for each individual. Prior to transplant an algorithm can be developed on a case-by-case basis to assess and calculate the percent of recipient, donor 1, and donor 2 [84, 98].

Post-transplant Testing

The goal of post-transplant analysis is to monitor chimerism after HSCT. This is accomplished by determining the percentage of recipient and the donor(s) alleles present in peripheral blood, lineage-specific cellular subsets, or bone marrow after HSCT.

Sample Types

Peripheral blood, lineage-specific cellular subsets, or bone marrow from the recipient after transplant can be analyzed for chimerism or to confirm engraftment. For RI-HSCT typically peripheral blood and a T-cell subset are evaluated in parallel at all time-points. CD3+ T-cells and other lineages such as myeloid and NK cells, can be obtained by manual or automated cell selection procedures [26, 99]. A commonly used procedure is the use of magnetic beads that bind to tetrameric antibody complexes recognizing CD3 or other lineage-specific markers (for example, StemCell Technologies, Vancouver, Canada). The unbound cells can be washed away and the cells of interest remain bound to the magnetic particles ready for DNA extraction. A purity of >99 % can be achieved for some subset types; however, the age of the sample is a critical preanalytic factor to control. Technical recommendations from the United Kingdom National External Quality Assessment Service for Leukocyte Immunophenotyping Chimerism Working Group (UK-CWG) suggest that lineage-specific cell separation should ideally be performed within 24 h of sample collection [84]. Additionally, each new lot of separation reagents should be assessed for production of high-purity subsets. This can be done using flow cytometry. Alternatively, commercial assays are available to assess purity of some cell subsets (for example PeloBiotech, Planegg, Germany or Accumol, Calgary, Canada). If using flow cytometry, it is important to be aware that certain individuals express one or more soluble serum factors that can cause cross-linking with the magnetic particles. This may result in visible aggregates in the enriched

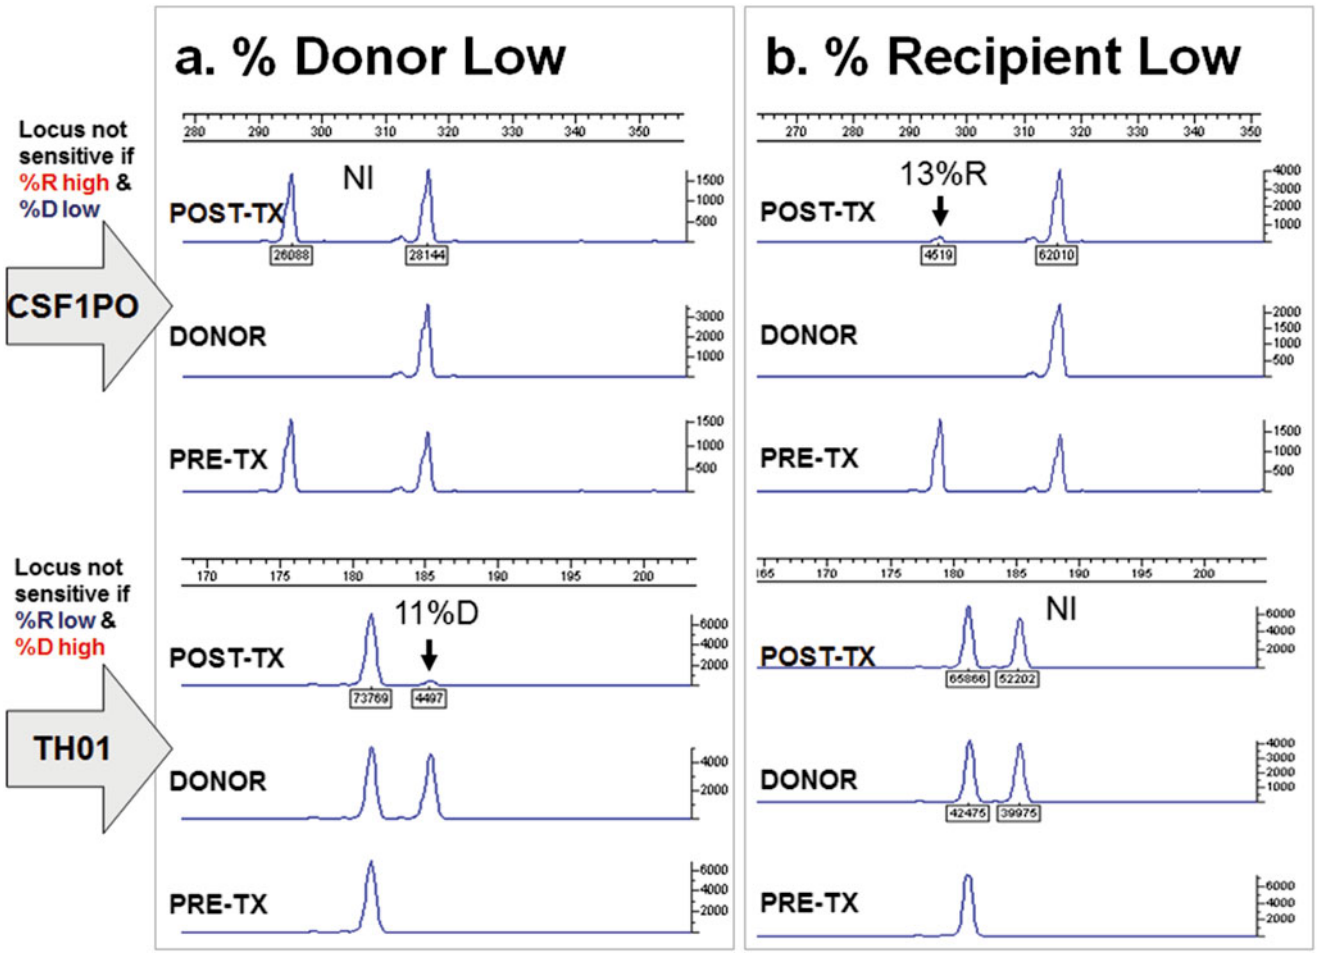

Figure 56.4 If the recipient or donor is homozygous and that allele is shared with the donor or recipient, respectively, this locus will not be equally informative at all levels of chimerism. Electropherograms at two loci (CSF1PO and TH01) are shown for two post-transplant time points (**a** and **b**) for a recipient–donor pair. For each time point, the donor and pre-transplant recipient (PRE-TX) alleles are shown as well as a post-transplant (POST-TX) sample showing mixed chimerism. For this recipient–donor pair, when the percentage of donor DNA is low (**a**), the CSF1PO locus is not informative (NI) for detection of donor because a small change in donor would be smaller than the measurement error of chimerism due to variable amplification of the two alleles. In contrast, the TH01 locus (*bottom* of panel **a**), which has a donor-specific allele is informative and sensitive for detection of donor (11 % donor). Similarly, when the percentage of donor DNA is increased (**b**), the situation is reversed. The CSF1PO locus is informative and sensitive for detection of low amounts of recipient (13 %R). On the other hand, the TH01 locus is not informative (NI) because, as with the CSF1PO locus when the donor was low, the potential variable amplification of the alleles (measurement error) could lead to a false-positive or a false-negative result. When the minor component (recipient or donor) is approximately 25 % or less, loci with this constellation of alleles should be excluded from use. In the ChimerMarker software (SoftGenetics). The use of loci with this constellation of alleles is called "deconvolution;" deconvolution should only be used when absolutely necessary if using this software because it does not distinguish between the two types of deconvolution

cell fraction following positive selection. These aggregates may appear as distinct, high side-scatter populations on forward-scatter vs side-scatter plots during flow cytometry analysis of the enriched fraction. This population consists solely of particles, with no cells or platelets present.

Approaches to Testing

In selecting the approach to use for post-transplant testing one must balance several factors: laboratory workflow, cost, accuracy, and analytic sensitivity. While sensitivity is theoretically optimized when a small number of loci are tested (single locus or low-number multiplex), laboratory workflow is more efficient with a high-order multiplex (fewer controls to run, less time determining which reagents to run for each patient, all reactions can be set up at the same time). Although cost of reagents is higher with high-order multiplex reactions, the improved efficiency of laboratory workflow may balance this factor, making it worthwhile to consider a reagent such as PowerPlex 16 (Promega Corp.) to simplify both pre- and post-transplant analysis.

A further advantage of using PowerPlex 16 for post-transplant testing is that accuracy may be theoretically improved if more than one locus is averaged (see section "Analysis and Interpretation" below). Indeed, the UK-CWG recommends reporting the mean of three or more markers where possible [84]. Changes made by the manufacturer in the conditions and reagents for PowerPlex 16 in recent years have improved the analytic sensitivity for detection of DNA mixtures of low percent (<5 %), making it amenable to use for post-transplant testing.

The alternative to using PowerPlex 16 is selecting from one of several lower-order multiplexes such as GammaSTR, CTTv, and CS7 (Promega Corp.). In this scenario, all loci are tested pre-transplant (PowerPlex 16 and CS7) [83]. One or more loci are selected and the primer set containing the locus/loci is selected for all post-transplant testing. Use of a primer set containing more than one optimal informative locus is preferable. This method has a lower reagent cost for the post-transplant analysis, but is more labor-intensive than using PowerPlex 16 for the technologists since they have to determine which primer set to use for each patient and set up the reactions separately.

Optimizing and Assessing Sensitivity

Irrespective of the primer set used, the sensitivity of chimerism analysis can be optimized. As mentioned earlier, the amount of DNA is important for sensitivity because it directly reflects the number of cells being analyzed. Since most commercial STR reagents are designed for forensic analysis of limited samples, the amount of input DNA indicated in the forensic protocols (usually <1 ng) may be less than optimal for chimerism analysis. Each laboratory should determine the maximum amount of DNA (usually 10–25 ng) that can be used without increasing the nonspecific background and spurious peaks that make interpretation difficult. The number of PCR cycles can be optimized to balance analytic sensitivity without exceeding the linear range of the detection method to ensure accurate quantification [84, 97]. The injection time for CE instruments, which is the time of applied voltage during which sample migrates into the capillary and is essentially equivalent to the amount of product loaded on a gel, also must be optimized (Fig. 56.5). Appropriate injection times are specific to each instrument. In some cases, very small recipient-specific peaks may be detected even though the predominant donor alleles are off-scale and not within

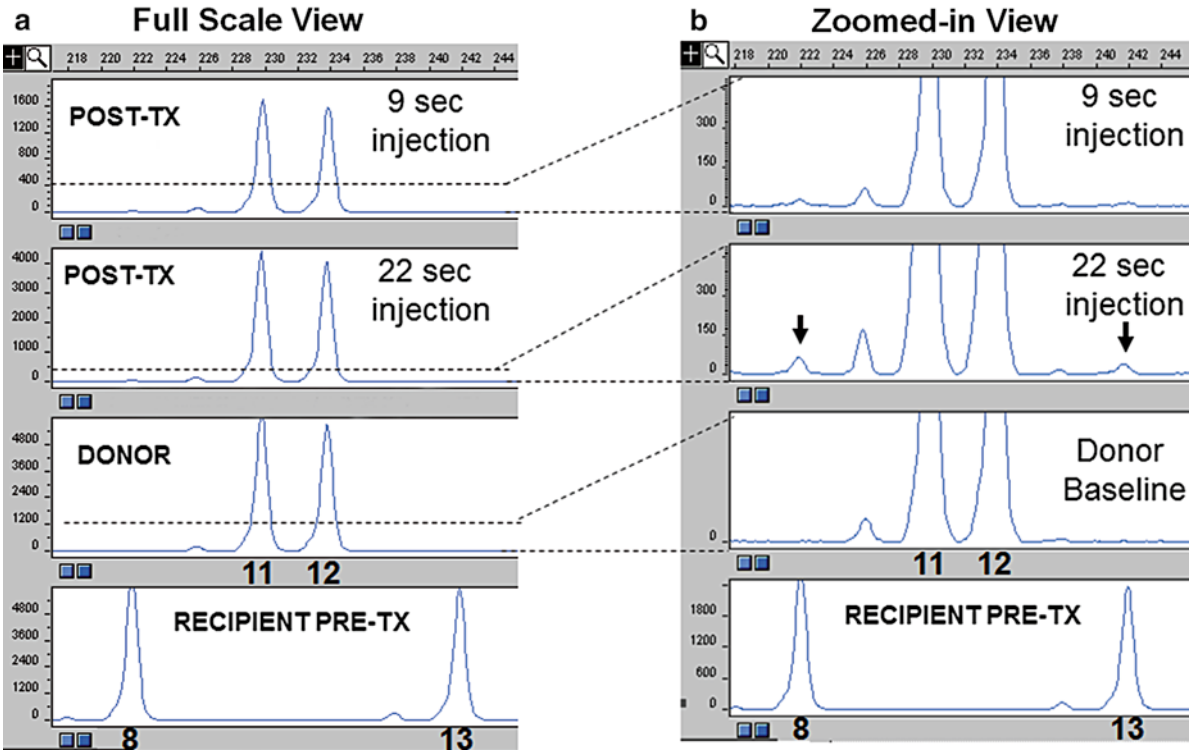

Figure 56.5 Optimizing sensitivity of PCR amplification of STR loci with CE analysis. The post-transplant (POST-TX) analysis of a recipient–donor pair at the D7S820 locus is shown at two injection times (9 and 22 s) on an ABI 3100 CE instrument (**a**). The donor and recipient pre-transplant (PRE-TX) alleles are shown. Because the recipient-specific peaks are small (*arrows*), the *y*-axis is expanded (zoomed-in view) to examine the baseline in greater detail (**b**). The zoomed-in view shows the presence of recipient-specific alleles in the 22-s injection, but they are not as clearly visible in the 9-s injection. To evaluate the post-transplant sample, a comparison is made to the donor baseline at the same *y*-axis scale, which in this case does not show a non-specific peak. *PCR* polymerase chain reaction, *STR* short tandem repeat, *CE* capillary electrophoresis

the linear range for quantification. The off-scale donor allele peak areas or heights would be under-representative of the actual amount of donor PCR product in the sample, but the percent recipient, if detected, can be reported as less than the limit of detection.

Unlike standard molecular pathology assays, assessment of the lower limit of detection (LOD) cannot be assessed for every possible sample, because each locus in each recipient–donor pair is a new situation. Mixing and artificial dilution experiments of a few sample pairs can be done to determine an average LOD (<1–10 % is typical), but the actual level of sensitivity may be higher or lower in different samples and even for different loci in the same sample. This variability may be explained not only by differences in methodology (number of loci co-amplified, input DNA, detection method) but also by differences in sensitivity for each recipient–donor pair based on each locus and its constellation of alleles [97]. Except in rare patient-specific scenarios, analytic sensitivities for chimerism analysis should generally be about 1 %. However, not all samples or loci will be equally analytically sensitive for the detection of low levels of mixed chimerism. If a locus is poorly amplified, then ability to detect low levels of donor or recipient will be compromised. If the yield of DNA is low due to low cellularity, this may affect the LOD for all loci tested. The total fluorescence at a locus should be high enough that a minor component of 1 % is detectable above background [92, 100]. The relevant peak areas or heights needed for 1 % sensitivity depend on whether the alleles are homozygous or heterozygous. In the simplest scenario where the recipient and donor are both homozygous for different alleles, if the detection threshold (the lowest peak that can accurately be distinguished from the baseline) using a specific instrument is 50 relative fluorescence units (RFU), then the sum of the unique donor allele peak areas must be 5,000 RFU in order to detect the recipient at 1 %. Any locus in a multiplex set for which the constellation of recipient and donor alleles does not achieve good sensitivity should be excluded from the average calculation, if more than one locus is averaged. If all loci tested have a compromised LOD, then a note stating this should be included in the report.

Analysis and Interpretation

CE results from post-transplant STR analysis are analyzed to determine whether recipient specific allele(s) are present, and if they are present, the percentage of recipient (%R) is calculated. Although analysis is focused on optimizing detection of the recipient component because it is usually the minor component, the percent donor (%D) or (100 − %R) is the value generally reported since clinicians base most patient management decisions on the level of donor in the patient. Absence of recipient-specific alleles or 100 % donor is consistent with complete engraftment at the level of sensitivity of the assay. Dynamic comparisons should be made only across the same type of sample, for example, peripheral blood, bone marrow, or cell lineage.

How Many Loci to Use?

The use of multiplex primer sets simplifies many aspects of chimerism testing as described above and enables the use of more than one locus to calculate chimerism. But is it necessary or advisable to use more than one locus? The use of a single locus or multiple loci each has advantages and disadvantages. An advantage of using a single locus is that manual calculation is relatively easy, so software to facilitate calculations is not needed. In contrast, since manual calculation of multiple loci is not time efficient, use of automated software for analysis is optimal. Commercial software packages are available (for example ChimerMarker, SoftGenetics, State College, PA) to simplify analysis of multiple loci. An advantage of using the mean of multiple loci is that the effect of any amplification artifact is minimized. In addition, this approach may prevent unrecognized chromosomal abnormalities such as loss of heterozygosity (Fig. 56.2) or extra copies of chromosomes from impacting the accuracy of chimerism results [82]. Furthermore, our experience indicates that using multiple loci increases the probability that low level recipient will be detected at one of the analyzed loci, whether it is stochastic or due to a locus-specific effect. These advantages would tend to greatly favor using multiple loci. For these reasons, as mentioned above, the UK-CWG recommends a minimum of three loci, if possible [84].

According to the Participant Summary Reports from the College of American Pathologists (CAP) Monitoring Engraftment (ME) proficiency testing survey, 75 % of participating laboratories use two or more loci to calculate chimerism; 10 % always use 14 or more loci. However, in one survey it was noted that 21 % of laboratories reported <100 % donor for a sample with a target value of 100 % donor. This may be due to reliance by some laboratories on automated software to average the results of multiple loci without regard to the appropriateness of each locus included. The more loci that are included without careful review of the contribution of background signals or artifacts in the calculation of chimerism, the less likely that a result of 100 % recipient or donor will be reported. Thus, the main drawback of using multiple loci in the chimerism calculation is the potential pitfall of automated analysis of data near 100 % recipient or donor. Near 100 % donor, the qualitative result of detected or not detected is more important than the quantitative value. Accuracy near 100 % ideally requires a manual review of the electropherograms with comparison to the donor baseline. Manual review of multiple loci for cases with >95 % donor

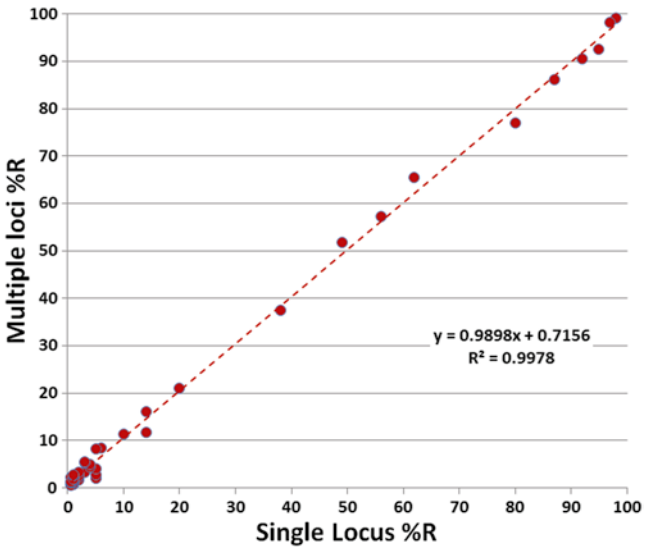

Figure 56.6 Comparison of the percent recipient (%R) result calculated using a single optimal locus to the mean result of all informative loci (mean 9, range 3–14, loci used) amplified with PowerPlex 16 reagents (Promega Corp.). Data are from 43 patients. The trend line (*red dashed line*) shows excellent correlation indicating that in most cases a single locus is approximately equivalent to the average of multiple loci. (Acknowledgement to Dr. Gregary Bocsi for assistance in data analysis.)

is possible, but could be cumbersome if the laboratory has a high volume of testing. Thus, automated analysis with chimerism software has many advantages, but must be done with careful attention to the interpretation. The ideal solution is to review all the loci at the time of the pre-transplant analysis to select the markers to include for post-transplant analysis using a pure donor sample and to analyze it as if it were a post-transplant sample. Any loci which do not yield a result of 0%R (100%D), as well as loci which are suboptimal due to co-localization of the recipient alleles in stutter locations, should be excluded from post-transplant analyses. A similar analysis can be performed with a pure recipient sample, if available, to select the markers best able to assess a result of 100%R (0%D).

Selecting a single optimal informative locus to calculate chimerism, on average, achieves an overall result essentially equivalent to the mean of multiple loci. We have demonstrated this in our laboratory experimentally (Fig. 56.6) and by review of data from the CAP ME proficiency survey for the last 2 years with over 70 participating laboratories. The key is the selection of an optimal locus using criteria described above to minimize the contribution of stutter peaks and other artifacts. That is not to say that a single locus will *always* perfectly match the mean of multiple loci, but on average, data suggest it will (Fig. 56.6). This is in part because the locus was selected to be optimal (including excluding chromosomal abnormalities at the locus in the diagnostic sample if possible) and because manual review enables identification and avoidance of artifacts. A single locus in a particular recipient–donor pair may have a significant bias compared to the true value at middle ranges (25–75 %) of chimerism due to a variety of factors; however, generally the locus will be consistently biased with each test for a specific recipient–donor pair. Thus, dynamic changes assessed over time will not be significantly affected by bias at a single locus used to follow the patient. In addition, a single locus, by virtue of the fact that it was selected to be optimal for the detection of low recipient, will generally provide a good assessment of complete engraftment (100 % donor) and low %R with manual review. Consequently, a single locus can achieve results similar to those of multiple loci, but has the advantage of being easier to analyze and more accurate qualitatively compared to an automated calculation of multiple loci without careful review of which loci to exclude. A schema for issuing a report on varying numbers of loci has been published taking into account variability between locus results [100].

In summary, both single and multiple loci are acceptable methods of calculating chimerism and both have some issues that must be evaluated before reporting results [82]. For multiple loci, the focus should be on the qualitative results near 100 % recipient or donor by careful selection of which loci to exclude. For a single locus, careful consideration of the patient's cytogenetic results to avoid loci on chromosomes affected by the malignancy and any artifacts that could affect the quantitative results is warranted. When a single locus is used, there is always the option, if a multiplex primer set was used, to review additional loci to confirm a questionable result before reporting.

Calculations

Single Donor

If both donor- and recipient-specific allele(s) are clearly identified in the post-transplant sample, then the percentage of recipient and donor DNA in the sample can be calculated [83, 92, 97]. For each allele peak, the intensity of the fluorescent signal, indicated by the peak area or height, is proportional to the amount of PCR product. CE instrument software can calculate the area or height of any peak recognized as an allele-specific signal. Either peak areas or heights can be used for chimerism analysis calculations as long as the same measure is used consistently and validated by the individual laboratory. In this chapter, peak area is used.

The percentage of recipient-specific DNA can be calculated as the quotient of the recipient specific peak area(s) to the sum of the recipient and donor specific peak areas, as shown in Fig. 56.7a, b. If the donor and recipient are both heterozygous and do not share any alleles, then the peak areas of both recipient alleles are added together for the numerator

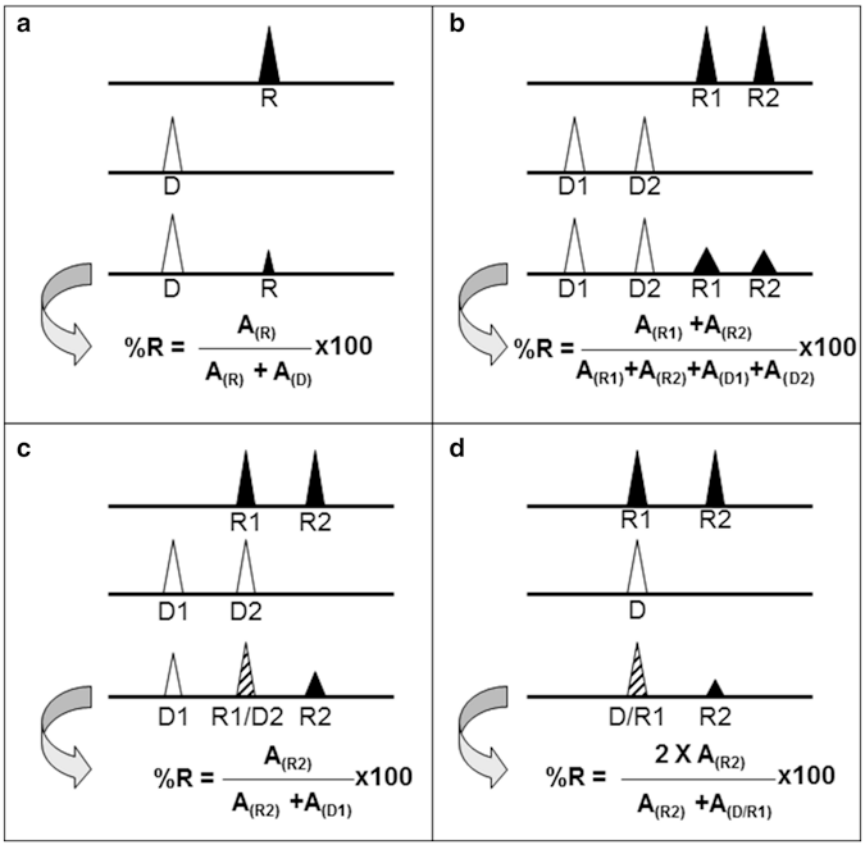

Figure 56.7 Formulas for calculation of percent recipient. Four representative scenarios (**a**–**d**) for combinations of informative recipient (R) and donor (D) alleles are shown. Recipient alleles are *black*, donor alleles are *white*, and shared peaks are striped. When heterozygous alleles are present, the numbers *1* and *2* indicate each allele. For each scenario, the third line in each box is a hypothetical post-transplant sample showing a mixed chimeric pattern. The calculation for the pattern shown in panel (**d**), also known as deconvolution, should only be used when the heterozygous individual (R in this example) is also the minor component. The formula that would be used to calculate the percent recipient is given, in which "A" represents the peak area of the appropriate peak designated by the *subscript*

and the areas of all four peaks (two donor and two recipient) are added for the denominator (Fig. 56.7b). When the recipient and donor share an allele, the %R is calculated based only on the unique alleles. The peak area of the shared allele does not enter into the calculation because it stays constant; that is, 100 % of the cells in the sample (donor and recipient) will have the shared allele (Fig. 56.7c). When the donor is homozygous for an allele and the recipient is heterozygous for the same donor allele and a second unique allele, as shown in Fig. 56.7d, the recipient area of the shared allele can be estimated by the area of the unique recipient allele. Thus, the %R is calculated as two times the unique recipient allele peak area divided by the sum of all peak areas (Fig. 56.7d). In this latter scenario, as the %R increases above 50–75 %, use of an alternate locus for the calculation should be considered because the constellation of alleles is not sensitive or accurate for detection of low %D (Fig. 56.4). In all cases, the fraction is converted to a percentage by multiplying by 100, and the %D is calculated as 100 minus the %R. Given that this method is inherently semiquantitative, rounding to the nearest percent to report the result is acceptable.

If recipient specific allele peak(s) are not visible initially, then close examination of the baseline in the region of the expected recipient-specific alleles is critical to identify small recipient peak(s) for each informative locus being analyzed. Depending on the analysis software being used, the scale of the *y*-axis can be adjusted to "zoom in" on the baseline (Fig. 56.5). Comparison of the post-transplant sample baseline at the location of the recipient alleles to the corresponding baseline of a donor sample is useful to assess for nonspecific peaks. Any peaks, including any bleed-through peaks from another fluorophore that happen to co-localize with the recipient alleles, that are present in the donor background in the location of a recipient-specific allele will not be mistaken for a recipient signal. When evaluating the donor baseline, the peak area(s) of the relevant donor-specific peaks should be compared to the peak area(s) in the post-transplant specimen. The peak area comparison is only valid if the areas of all the alleles are similar, because the level of background nonspecific signal is directly related to the adjacent peak areas. In cases of graft loss, comparison of the post-transplant sample baseline at the location of the donor alleles to the corresponding baseline of a pre-transplant recipient DNA sample can distinguish low levels of donor from nonspecific background signals in the recipient. For this reason, the use of recipient and donor DNA baseline controls is important. Historical recipient and donor baseline electropherogram traces are easy to use if a chimerism analysis software is used; however, it is important to make sure that the amplification levels of the donor baseline sample was optimal (not too high and not too low) so that it is representative of artifacts and stutter background. If using historical

recipient and donor baselines for comparison to post-transplant analyses, the pre-transplant samples should be retested if any significant reagent changes occur.

Two Donors

Calculation of chimerism is more complicated when two donors are involved since up to six alleles could theoretically be detected in one sample and many allelic configurations are possible [98]. There are three main questions to assess in a double-donor post-transplant analysis:

1. Is any recipient (R) DNA present?
2. Is any donor 1 (D1) present?
3. Is any donor 2 (D2) present?

Selection of informative loci before transplant is directed at finding alleles at one or more loci to answer these questions. While early in the transplant both donors may be detectable, usually one donor eventually predominates with loss of the other donor, so that only one donor is detectable after engraftment. If, for example, D1 DNA predominates, the questions being asked in post-transplant testing change to become more like a single donor case:

1. Is any R DNA detectable?
2. Is any D2 DNA detectable?

Even after D2 becomes undetectable, it can still reemerge, so it is important to check for the detection of D2 to ensure that the chimerism percentages are calculated correctly. The clinical significance of which donor is detected varies depending on the type of transplant and the clinical situation. The approach is to find at least one allele at one locus that can unequivocally identify the presence of R. If R is absent, then the same or another locus should be used to determine if any D2 (or D1 as appropriate) is detected (Fig. 56.8). A qualitative assessment of detected alleles is a helpful first step that will then define the next steps to calculate the %D1 and %D2. If only D1 allele(s) and no recipient allele(s) are detected, then this will be reported as 100 % D1 and 0 % D2.

If either the minor donor component and/or R are detected then a calculation must be done. The concept is the same as for single donors: 100 % = %R + %D1 + %D2. If no alleles are shared among the three individuals the calculation is straightforward:

$$\%\mathrm{R} = \left(\mathrm{Ra1} + \mathrm{Ra2}\right) / \left(\mathrm{Ra1} + \mathrm{Ra2} + \mathrm{D1a1} + \mathrm{D1a2} + \mathrm{D2a1} + \mathrm{D2a2}\right) \times 100$$

where a1 = allele 1 and a2 = allele 2 [98].

If Ra1 or Ra2 is shared with D1 or D2 the formula can be modified using 2 × Ra1 or 2 × Ra2 with the same denominator (using the shared peak area in place of the individual areas as shown in Fig. 56.8). Alternatively, when one or more allele(s) are shared it is sometimes easiest to do the calculation in a stepwise manner calculating each component separately using different loci. A detailed algorithm for calculating chimerism with shared alleles has been published [98]. In addition, ChimerMarker software (SoftGenetics) has an analysis mode for assessment of two donor chimerism (Fig. 56.8). From the pre-transplant evaluation, a case-specific analysis algorithm should be developed for which alleles and loci can be used to answer each of the questions above. The loci used can be subsequently refined and simplified after transplant as engraftment of one donor predominates.

Potential Pitfalls and Limitations

Assessment of Errors

There are several sources of error in the calculation of chimerism [101]. Measurement error estimates the relative deviation of DNA measurements from optimal at a single locus in a post-transplant sample. This is analogous to allelic imbalance which represents the ratio of heterozygous alleles at a single locus. Optimally, the measurement should be 1, indicating no imbalance between either donor–recipient allele pair. Percent measurement error (%ME) is only relevant for constellations of alleles in which the recipient and donor are both heterozygous.

$$\%\mathrm{ME} = \frac{A - B}{C} \times 100$$

%ME is calculated with A as the sum of the two smaller allele peak areas (A = R1 + D1) and B is the sum of the two larger allele peak areas (B = R2 + D2) and C = the larger of A or B.

A high %ME indicates a greater likelihood that the calculation at a particular locus will be inaccurate so the locus should either be excluded, or the data used with caution.

Locus error provides a measure of how the %D chimerism calculation (CHM) at a particular locus ($\mathrm{CHM_{locus}}$) is performing compared to the mean chimerism value using all loci ($\mathrm{CHM_{mean}}$). Suboptimal amplification of one or more alleles, stutter contributions which are not accounted for, and nonideal constellations of recipient and donor alleles are all potential sources of high percent locus error (%LE). Since the mean may be smaller or larger than the value at a particular locus, the absolute value of the difference is taken to calculate %LE as shown in the formula below. %LE is only relevant if more than a single locus is being used in the chimerism analysis.

$$\%\mathrm{LE} = \frac{\left|\mathrm{CHM_{mean}} - \mathrm{CHM_{locus}}\right|}{\mathrm{CHM_{mean}}} \times 100$$

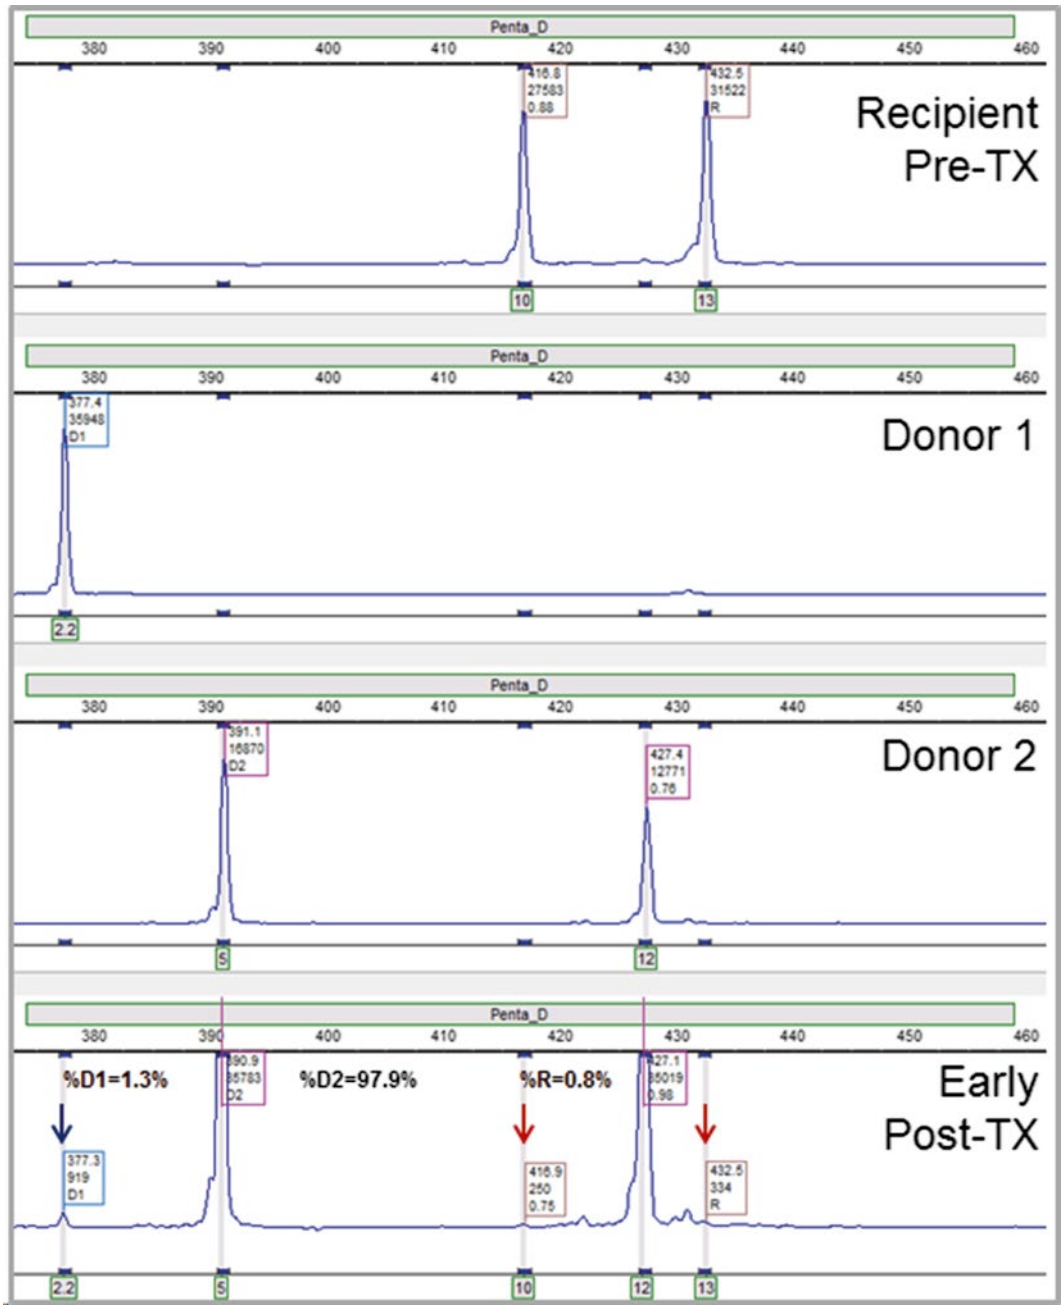

Figure 56.8 Two-donor chimerism analysis using ChimerMarker software (SoftGenetics). Electropherograms of a pre-transplant recipient (Pre-TX) and two donors (Donor 1 and 2) at the Penta D locus (CS7, Promega Corp.) from an ABI 3130 CE instrument (Life Technologies). ChimerMarker software labels each peak with a color-coded box with the peak size in base pairs, the peak area, and either the origin (R, D1, or D2) or the ratio of the sister peaks (to demonstrate how equally the two alleles amplified). An early post-transplant sample (Early Post-TX) within 30 days after transplant is shown in which predominantly Donor 2 has engrafted, but minor contributions of Donor 1 (*blue arrow*) and recipient (*red arrows*) are detected. Post-transplant chimerism was calculated using the following peak areas from the post-transplant sample: %R = (250 + 334)/(919 + 35,783 + 250 + 35,019 + 334) = 584/72,305 = 0.8 %, %D1 = 919/72,305 = 1.3 %, %D2 = 100.0 − 2.1 = 97.9 %. In a subsequent chimerism analysis only Donor 2 was detectable. *CE* capillary electrophoresis

Any locus with a %LE greater than 10 % should be evaluated to determine if there is an obvious cause for the variability, and therefore a reason for excluding the locus from the final calculation. In general, a higher %LE may be noted and tolerated at low levels of chimerism.

The coefficient of variation (CV) is another measure of the overall variability of the chimerism results. The %CV is calculated from the overall mean chimerism value and the standard deviation (σ) of all the included locus values.

$$\%CV = \frac{\sigma}{\text{mean}} \times 100$$

As with other error measurements, %CV is only a guide to flag potential problems and not as an absolute exclusionary criterion. For example, in Fig. 56.9 in the T cell subset, the %CV is low because the two included loci (Penta E and Penta D) have similar results; however, in the peripheral blood with a lower %R, the %CV is very high because one locus was not sensitive enough to detect the chimerism (Penta D), but 1.5 % chimerism was detected in the other (Penta E). Thus, in this case there is an explanation for the high percent CV which can be ignored.

The margin of error (MOE) is calculated using a T-table value obtained according to degree of freedom (Tscore) and the confidence interval (for example 90 %) multiplied by the standard error (SE) of the mean [102]. The standard error of the mean is calculated as $\sigma / \sqrt{N}$ where N = number of informative markers.

$$\text{MOE} = \text{SE} \times \text{Tscore}$$

A large MOE compared to the chimerism result is suggestive of greater variability in the data, in which case the results should be interpreted with caution.

If using chimerism software such as ChimerMarker (SoftGenetics), these error measurements are calculated and abnormal results are flagged automatically (Fig. 56.9). However, if the source of a high error measure is an artifact which could be manually corrected, the disadvantage of using analysis software is the relative inability to change the chimerism formula for specific analyses. In such cases, loci with artifacts can be excluded from the calculations, which is possible if a high-order multiplex with 16 loci is being used.

Stutter Adjustment

Loci for chimerism analysis should be selected to avoid recipient alleles that co-localize with a donor stutter peak ($n-1$ repeat, $n-2$ repeats, or $n+1$ repeat). If the recipient and donor are related, identification of ideal informative loci can be challenging. If using multiple loci, those loci in which a stutter peak would alter the calculation can be excluded. Comparison of the post-transplant recipient peak to the stutter peak in the donor baseline sample can help to determine whether the recipient signal is real if there is no unique recipient allele not affected by stutter. If for any reason it is necessary to use or include a locus in which a stutter peak would significantly alter the results, such as shown in Fig. 56.10a, several adjustment methods can be applied (see below), although the sensitivity for detection of low level recipient chimerism may be affected. The choice of adjustment method depends on the specific situation and the constellation of the donor and recipient alleles. In addition, these are only relevant for manual calculations, i.e., not if automated chimerism software is used.

Heterozygous Allele Estimate

When a heterozygous recipient has a unique informative allele and a second one that co-localizes with a donor stutter peak, the accuracy of quantification is affected rather than the sensitivity. The area of the peak co-localizing with the stutter is greater than the recipient contribution due to the additional stutter signal. To avoid an overestimate of the percent recipient, the peak area of the unique allele can be used as an estimate of the second recipient allele. Therefore, the area of the unique allele is multiplied by two (instead of including the area of the peak that co-localizes with the stutter peak) and used in the appropriate formula (Fig. 56.10b). This method also can be used to avoid other background artifacts affecting one recipient allele.

Donor Baseline Calculation

The donor baseline is a good control for the post-transplant sample if donor chimerism is high and if the levels of amplification (peak areas) are similar. While the peak areas cannot be directly compared between electropherograms, the percent contribution of the stutter peak to the chimerism result can be used. Thus, a calculation can be made for the donor stutter peak from the donor baseline sample analysis (using the same formula that would be used for the recipient if the stutter were not present), and this value can be subtracted from the chimerism result (Fig. 56.10c) [96]. Calculated differences of 1 % or less should not be used as the sole evidence for detected recipient; rather, if questionable, they can be reported as no recipient detected if they are below the LOD of the assay. Differences greater than 10 % clearly indicate presence of recipient DNA, because the contribution of recipient PCR product will be incremental and thereby additive to the stutter peak area. Differences between 1 and 10 % must be assessed on a case-by-case basis. To be clearly present, the recipient contribution must be greater than the standard deviation of the stutter percentage. In these cases, finding an alternate locus to use is the best option.

Stutter Percent Calculation

The stutter percentage (i.e., the percentage of the stutter peak relative to its main allele peak) is usually consistent within a narrow range for each locus, although it varies within a locus by allele size. An alternative method to perform stutter adjustment is to use the stutter percentage to calculate a correction for the area as shown in Fig. 56.10d [96]. The stutter percentage can either be determined on a case-by-case basis using the actual donor baseline sample or an average stutter percent can be determined for each locus using many samples and allele sizes. Once the stutter percentage is determined, the major allele peak area is multiplied by this value to determine what the expected area of the stutter peak would be. This calculated stutter value is then subtracted from the actual peak area in the stutter location. This adjusted peak area is used in the final chimerism calculation.

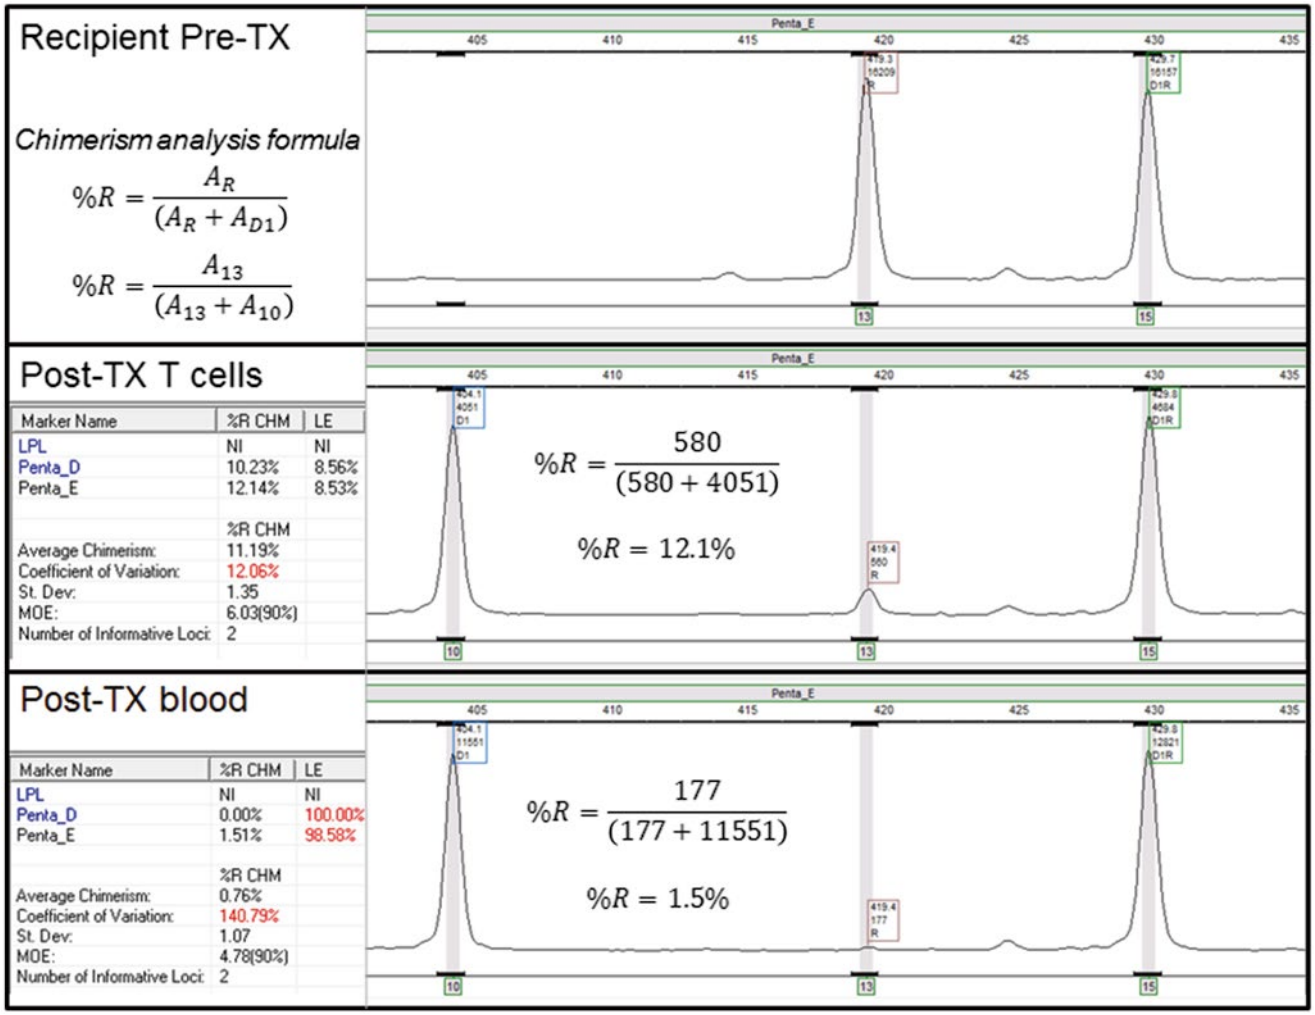

Figure 56.9 Single donor chimerism analysis in T cell subset and unfractionated peripheral blood using ChimerMarker software (SoftGenetics). Electropherograms (ABI 3130, Life Technologies) of recipient pre-transplant (Pre-TX) and two post-transplant (Post-TX) samples at the Penta E locus are shown. The recipient (R) is heterozygous for alleles 13 and 15 and the donor (D1 by convention of the software to designate the first donor) is heterozygous for alleles 10 and 15. Thus, allele 15 is shared between the recipient and donor (D1R). Each peak is labeled by the ChimerMarker software with a *color coded box* at the *top* with the peak size in base pairs, the peak area, and the source of the peak (R, D1, or D1R). The allele size in repeats is given at the *bottom* of each peak in a *green box*. The post-transplant samples are predominantly of donor origin with D1 and D1R peaks present. At the left of each post-transplant sample is a screen shot of the ChimerMarker single donor chimerism analysis results. Of the seven loci amplified (CS7, Promega Corp.), four were excluded before analysis for nonoptimal allele configurations, so the results of these loci are not shown. Of the remaining three shown, one (LPL) is not informative (NI). In addition to calculating the percent recipient chimerism (%R CHM) for each informative locus in each sample and the average chimerism (average of all informative loci), several measures of error are given: locus error (LE), coefficient of variation (CV), standard deviation (St. Dev), and margin of error at 90 % confidence interval (MOE). The formula for calculating the chimerism at the Penta E locus is given at the top left and the corresponding manual calculation with the actual areas in the electropherogram panels for both post-transplant samples. A similar calculation was done at the Penta D locus (electropherograms not shown) by the software, given in the result tables at left. For the T cell sample (*middle left panel*), the percent LE is low [1(average chimerism) − (locus % R chimerism)/average chimerism) × 100]. In contrast, in the post-transplant blood sample (*bottom left panel*) which has a much lower level of recipient chimerism, the recipient-specific allele is not detected at the Penta D locus, indicating that this locus is less sensitive than Penta E. Although the Penta E may be a false positive, this is unlikely because recipient is present in the T-cells which were originally isolated from the same blood sample. Therefore, the result of 0 % at the Penta D locus is indicative of lower analytic sensitivity at this locus. In this post-transplant blood sample, therefore, the LE and CV are very high, but these values are irrelevant because there is an explanation for the apparent variability. The average chimerism is reported, rounded to the nearest integer, as %D (or 100 - %R) which is 99 % for blood and 89 % for T cells

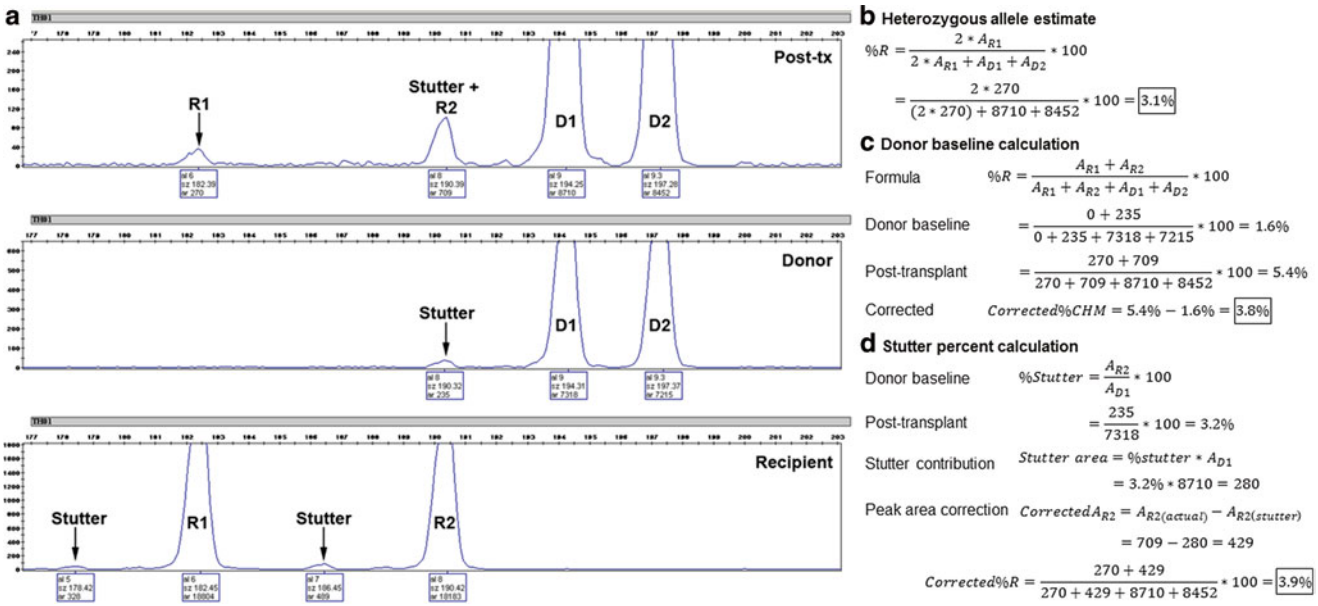

Figure 56.10 Example of chimerism analysis affected by a co-localized stutter peak. (**a**) Electropherograms of a recipient, donor, and post-transplant sample (post-tx) at the TH01 locus (CTTv, Promega Corp.) are shown. Below each peak the *box* indicates the repeat number (al), size in base pairs (sz), and area (ar). Stutter peaks ($n-1$) are indicated for the donor and recipient. In the post-transplant sample recipient allele 2 (R2) co-localizes with the stutter peak from donor allele 1 (Stutter + R2). Using all the peak areas in a standard chimerism formula would overestimate the percent recipient if an adjustment is not performed. Several adjustments to the chimerism calculation for stutter are shown in b, c, and d. For all three alternative methods, the final percent recipient (%R) result is given. (**b**) The heterozygous allele estimate method (b) assumes that the contribution of the R2 allele to the stutter + R2 peak area is similar to the area of R1. Thus, two times the area of R1 is used in the formula instead of the area of R1 plus the area of R2. (**c**) The donor baseline calculation method (c) uses the donor electropherogram to calculate the stutter contribution to the chimerism calculation by using the same chimerism formula used for post-transplant samples (formula). The corresponding peak areas from the donor baseline and the post-transplant electropherograms are used to calculate chimerism. The value from the donor baseline only represents the stutter contribution. Since this value is a percent and not an area it can be subtracted from the total post-transplant chimerism calculation to obtain the corrected chimerism (Corrected %CHM). (**d**) A stutter percent calculation is shown. In this example, the area of the stutter peak relative to the area of D1 is calculated as a percent (%Stutter). A standard average percent for the laboratory can be substituted if desired. Using the D1 peak area in the post-transplant sample, the %Stutter is used to calculate the contribution of stutter to the Stutter + R2 peak. The corrected area of R2 is used in the formula from (c) to calculate the final corrected percent chimerism. All three methods yield similar results for this case

Chromosomal Abnormalities

Chromosomal abnormalities are common in hematologic malignancies and may affect identity testing results if the locus used for chimerism analysis is present on the aberrant chromosome. Chromosomal abnormalities may be identified by cytogenetic analysis. If loci used for chimerism analysis are on the aberrant chromosome(s), the locus/loci should be avoided for chimerism analysis in the specific donor–recipient pair. On occasion unusual amplification patterns may provide evidence of abnormalities such as unequal amplification due to extra chromosomes or chromosomal deletions (Fig. 56.2). Chromosomal abnormalities also can arise after treatment. Such abnormalities have been reported and may produce unexpected or unusual post-transplant allele patterns and chimerism analysis results that are not consistent with the clinical status of the patient [103]. The use of multiple loci to calculate chimerism can minimize the potential impact of chromosomal abnormalities.

Doublet Peaks

Non-template addition of an extra nucleotide, usually an adenosine (A), at the 3′ end of PCR products is a known occurrence with DNA polymerases, particularly Taq [80]. This adenylation results in a PCR product that is 1 bp longer than the DNA template sequence. The degree of adenylation is dependent on the sequence of the template strand. Incomplete addition of A nucleotides can occur if too much DNA template is used. Addition of the A can be favored with a final incubation step at 60 °C at the end of the PCR reaction. If not all the PCR products have an extra A, this will lead to the appearance of split, or doublet, peaks. Usually this affects all the allele peaks at a particular locus. It is best to optimize reaction conditions to prevent incomplete adenylation, but if not possible and the peak areas of such doublet peaks are used to calculate the percent recipient, the areas of both parts of each peak should be summed and used for manual calculations (Fig. 56.11).

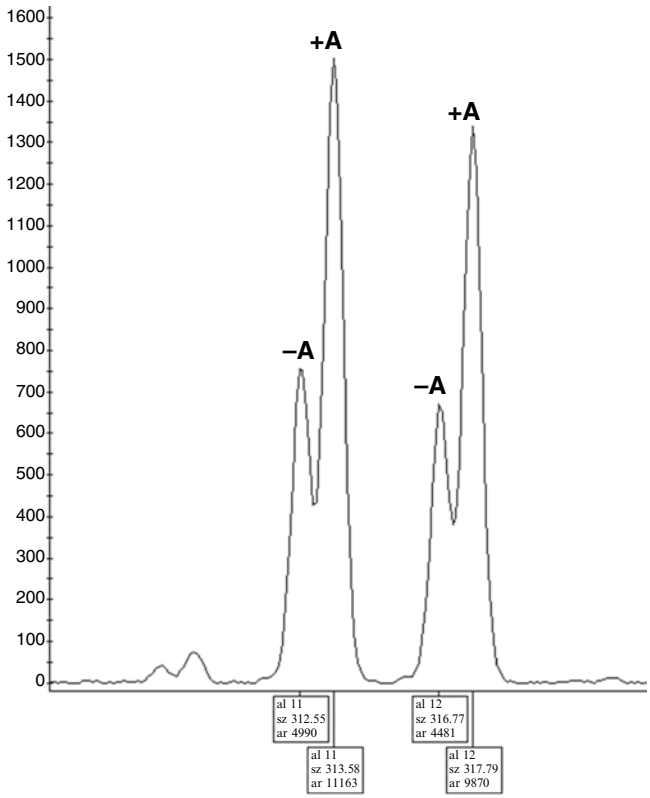

Figure 56.11 Non-template addition of an extra nucleotide, usually an adenosine (A), results in a PCR product that is 1 bp longer than the DNA template sequence. Heterozygous alleles of 11 and 12 repeats are shown, each with +A/−A doublet peaks

Reports

General molecular reporting guidelines should be followed for the reporting of chimerism results [104]. If pre-transplant testing is done, a report should be issued indicating that at least one informative locus that distinguishes recipient from donor DNA was identified. This pre-transplant report serves to inform the clinicians that the pre-transplant samples have been obtained and the pre-transplant analysis was successful. Post-transplant reports should report the %D rounded to the nearest integer for each specimen type tested; ideally peripheral blood and lineage-specific cellular subsets should be reported together in a single report to allow for easy visualization and longitudinal comparison by the clinicians. For two donor transplants the identification numbers for each donor should be provided along with the percent of each donor chimerism as well as the overall total percent donor chimerism. If the result of any sample or cellular subset had a compromised limit of detection, this should be noted in the report. The report is a method of communication between the laboratory and the clinicians; therefore, each laboratory should determine the information and format that are most valuable to their clinicians. In cases where mixed chimerism is detected or only donor (complete engraftment) is detected the report interpretation will reflect these results. However, there are a few possible results where a nonstandard interpretation is needed (see below).

Bone Marrow Specimens

When normocellular bone marrow is tested for chimerism, the finding of 1–3 % recipient DNA is very frequent. This is because there are non-hematopoietic cells, for example stromal cells, in the marrow. Thus, while mixed chimerism is commonly detected in bone marrow, low level chimerism is not likely to be clinically significant. Histologic and clinical correlation is always important. In particular, when the marrow is hypocellular the %R can be artificially elevated because the relative contribution of non-hematopoietic cells to the total DNA is high. In this situation an interpretive statement such as the following is recommended: "In the context of the concurrent bone marrow histologic evaluation demonstrating a hypocellular marrow, this chimerism result may not accurately reflect the percent of recipient hematopoietic cells due to the potential relative overrepresentation of non-hematopoietic elements in the bone marrow aspirate." This scenario should be considered whenever a bone marrow is tested and the donor chimerism is decreased (recipient increased) and there is no evidence of relapse.

Discordant Chimerism Result Between Blood and T-Cell Subset

When peripheral blood DNA is tested alongside a T cell subset, the detection of recipient DNA in T cells should by default imply that recipient DNA is present in whole blood. Occasionally recipient DNA is detected in T cells only and not in whole blood because T cells are only a subset of all nucleated blood cells so the overall level of chimerism in blood may be below the analytical sensitivity of the assay. This commonly occurs when the %R in the T cells is low and/or when the T cells represent a small proportion of all nucleated cells, which is a common scenario in the first few months after HSCT. The interpretation in the report should reflect this false-negative result rather than report complete donor engraftment. The opposite is not true. If recipient DNA is detected in the peripheral blood, but not the T cells then this simply means that the cells of recipient origin are not of T cell lineage. Interpretation of both "discordant" results should be made in the context of clinical and histologic correlation. For example, low levels of recipient T cells usually indicate incomplete donor engraftment, but persistence or reemergence of recipient T cells in

a patient with a T cell malignancy may indicate residual disease or relapse.

Data Management and Quality Control

Chimerism analysis poses several unique clerical and data management issues for the clinical laboratory. The laboratory must have a mechanism to match donor and recipient pre-transplant samples and track the results of pre-transplant testing for use in post-transplant testing. Subsequently, the results of repeated post-transplant testing for each patient needs to be easily accessible for review with each new sample and for longitudinal assessment of engraftment trends. Specimen and result tracking can be accomplished with a well-organized paper folder system or electronically using software such as ChimerMarker (SoftGenetics). Longitudinal assessment of a patient's chimerism results enables critical evaluation of the significance of changes over time for each sample type (blood, T-cells, bone marrow, etc.) [100].

Quality control is inherent to chimerism analysis because identity testing is performed on each sample. A pre-transplant buccal sample in addition to the recipient blood can confirm that the recipient and donor DNA samples are properly identified. Quality control at the DNA level for specimen switching is inherent for all post-transplant samples since the expected genotypes are known and the patients are repeatedly tested over time so that any unexpected result, such as different alleles, is immediately noted and investigated. If multiplex primer sets are used for post-transplant sample amplification, it is important to consider whether a small peak seen in one fluorophore is a true peak rather than a bleed-through from another fluorophore window. Proficiency testing for chimerism analysis is available from the CAP in the ME survey.

Conclusion

The monitoring of chimerism after HSCT has become routine to confirm engraftment and detect and monitor mixed chimerism. The use of chimerism analysis and its clinical utility are different for myeloablative and RI-HSCT. Chimerism analysis has clinical utility in guiding the use of therapeutic interventions such as DLI to treat or prevent relapse or graft loss. Although many methods have been applied, PCR amplification of STR loci is the method of choice because it is informative, quantitative, relatively rapid, and sensitive. While the methodology is technically straightforward, the implementation, analysis, and reporting of results are more complicated. The clinical importance of chimerism results warrants the effort required by the laboratory for validation and performance of the test.

Specimen Identification Through DNA Analysis

57

Gregary Bocsi, Andrew Ricci, Gregory J. Tsongalis, and Vivianna M. Van Deerlin

Abstract

Specimen identification through DNA analysis is an approach to solve several conundrums that may arise during the course of routine laboratory testing. In this chapter methods for specimen identification by DNA analysis are described, including specimen selection and specimen preparation, genotyping approaches, and result interpretation. Clinical applications for these methods are discussed, and example cases demonstrate how the methods can be applied to solve relevant problems such as identification of misidentified specimens, unexpected tissue in a specimen, maternal contamination of a prenatal diagnostic specimen, diagnosis of donor-associated malignancies, graft-vs-host disease, as well as gestational trophoblastic disease.

Keywords

Identity testing • Specimen identification • Specimen misidentification • Hydatidiform mole • Molar pregnancy • Gestational trophoblastic disease • Graft-vs-host disease • Donor-associated malignancy • Floater • Macrodissection • Microdissection

Introduction

In 1995, television viewers around the world followed a criminal trial, *People of the State of California v. Orenthal James Simpson*, which introduced many viewers to some of the nuances of DNA testing. More recently, the film and television industries have incorporated identity testing or DNA analysis in many productions, further familiarizing the lay public with the concept of "DNA testing" for identification purposes. In 1997, one of the first case reports on the use of forensic DNA analysis for specimen identification was published [1]. While analysis of identity through DNA typing has its origins in parentage testing and forensic identity testing, similar techniques have also found clinical utility in pathology laboratories for a variety of sample identification applications [2–5]. Such applications include identification of the origin of mislabeled specimens [2], exclusion of a potential source for a surreptitious histologic "floater" in an anatomic pathology specimen [2, 4, 6], diagnosis of hydatidiform moles [7, 8], detection of maternal

cell contamination in prenatal specimens [9, 10], identification of cell lines or research specimens [11], diagnosis of graft-vs-host disease (GVHD) [12], and identification of the origin of tumor cells in a transplant recipient [13].

Specimen misidentification is not a rare event in clinical practice. For prostate biopsies, the combined rate of type 1 (complete transposition between patients) and type 2 (contamination of a patient's tissue with that of other patients) errors has been estimated as 0.93 % or nearly 1 in 100 [14]. Recently, DNA testing helped to resolve biopsy misidentifications in a large multicenter clinical trial (The Reduction by Dutasteride of Prostate Cancer Events clinical trial) [15], and The Dark Report (http://www.darkreport.com/) has reported that a large Urology Group in New England approached a commercial laboratory to perform DNA testing on cheek swabs to confirm patient identity on *all* patients with a positive prostate biopsy [16]. On occasion a patient who questions a new cancer diagnosis requests DNA identification analysis of the tumor to confirm that the diagnostic specimen originated from the patient's body. A full description of the scientific principles and technologies for identity testing appears in Chap. 54. The practice of specimen identification through DNA analysis is well-established, but the cost-effectiveness of the use of these techniques must be determined on a case-by-case basis. This chapter focuses on identity testing issues and result interpretation specific to patient identification and related applications of identity testing in the clinical laboratory.

Methods for Specimen Identification

DNA typing exploits the polymorphic differences in DNA between individuals to resolve questions of identity. The first polymerase chain reaction (PCR) based DNA typing system to become commercially available was the AmpliType PM + DQA1 system from Applied Biosystems (formerly Perkin Elmer, Foster City, CA). This kit typed multiple loci simultaneously using a reverse dot blot procedure with an array of immobilized allele specific probes in a dot blot pattern on a strip of nylon membrane. The AmpliType PM+DQA1 amplification and typing kit was used routinely by many forensic laboratories, and it was applied to cases of clinical specimen identification as it could be used with many different specimen types [1, 17–19]. In recent decades, short tandem repeat (STR)-based methods have supplanted reverse dot blot methods, in part due to their greater discriminatory power. Single nucleotide polymorphism (SNP) analysis and mitochondrial DNA polymorphism analysis have some applications.

Short Tandem Repeat Analysis

Among methods of specimen identity testing, STR analysis has become the method of choice in most laboratories due to the convenience of several commercial assays, accessibility of equipment and genotyping software to assist with the analyses, and availability of technical resources and experience to facilitate the interpretation of results. The forensics community took the lead in defining panels of STRs (also known as microsatellites) leading to the development of the Combined DNA Index System (CODIS) loci originally selected by the US Federal Bureau of Investigation (FBI) for criminal identification investigations [20]. These loci have proven extremely useful because they exhibit not only polyallelism but also wide distribution of the different alleles across various racial and ethnic groups. Combined, these features allow STR-based testing to offer a great degree of discriminatory power for specimen identification.

For both forensic analysis and specimen identification, the ability to work with minute samples is important, as illustrated by the application of microdissection in resolution of tissue section "floater" cases (see below). STR-based methods employing PCR amplification of specific STR regions of the genome are applicable to small samples, permitting the interrogation of nucleic acids extracted even from samples with only a few cells as well as from partially degraded samples such as from formalin-fixed, paraffin-embedded (FFPE) tissue. Many STR polymorphisms are present in the human genome, and specific subsets are commercially available for identity testing purposes.

Multiplex primer sets are commercially available for amplification of STR loci (http://www.cstl.nist.gov/strbase/multiplx.htm) [20]. Such primers co-amplify multiple STR loci in a single reaction. Fluorescent labeling of the PCR primers at overlapping loci with different fluorophores allows multiplexing of STR loci which may have alleles that fall in the same size range. After amplification of the STR loci, fragment size analysis, usually by capillary electrophoresis, enables precise determination of the size of the polymorphisms at each locus for a specimen [2]. In general, two specimens are considered different when the alleles differ for at least one locus. The calculated probability that two individuals will share a set of STR alleles by chance depends upon the number of loci tested, as well as the ethnicity of the individual. Different alleles at as few as eight loci can quickly push the probability of two specimens matching by chance to less than 1 in 100,000,000, well below the number of patient specimens encountered in an entire year in a histology laboratory. Detailed information on STRs is available at http://www.cstl.nist.gov/strbase/.

Single Nucleotide Polymorphism Analysis

SNPs are the most common genetic variants in the human genome and occur approximately every 100–300 bases.

Each individual has an allelic profile at these sites. Several studies related to specimen identification have been published using SNP profiling by real-time PCR as an alternative to STR analysis [21, 22]. SNP analysis has advantages over STR analysis, including a lower cost per reaction, smaller target sequence which is more amenable to amplification in degraded specimens, and no requirement for capillary electrophoresis equipment. A disadvantage of SNP analysis is a lower power of discrimination for each marker thus requiring use of a larger number of markers. Which SNPs to detect and their population frequencies must be carefully considered. Currently, SNP analysis is not frequently used for specimen identification except in degraded specimens.

Mitochondrial DNA Polymorphism Analysis

Mitochondria contain a circular genome that is distinct from the nuclear genome. Within this genome are two noncoding regions, hypervariable regions I and II, which vary in their sequences and contain known polymorphisms. Indeed, for unrelated individuals, the mitochondrial DNA sequence will differ at multiple nucleotide positions. However, maternal relatives share mitochondrial sequences except for the presence of new mutations. Mitochondrial DNA polymorphism analysis therefore can be used both to exclude the possibility that an unknown sample matches a reference sample or that the sample is derived from a maternal relative of the reference sample. Because mitochondrial genomes are naturally amplified due to the presence of multiple mitochondria per cell and the circular DNA is more resistant to degradation, sequencing of mitochondrial DNA may prove useful as an alternative to STR typing of archival specimens with low DNA content and high DNA degradation [23, 24]. Mitochondrial DNA polymorphism analysis is not commonly used for clinical laboratory specimen identity analysis.

Clinical Applications

DNA analysis of polymorphic markers used in forensic identity and relationship testing can aid in the identification of specimens that are essential to proper management of a patient when the possibility of specimen misidentification has arisen. As the cost of STR-based identity testing decreases, it has been suggested that routine verification of the source of certain cancer-positive diagnostic specimens (e.g., prostate biopsies), may become a cost-effective approach for preventing medical errors resulting from a misidentified patient sample [25].

Specimen Identification

For patient safety and quality assurance purposes, clinical specimens are required to be labeled with two patient identifiers to assure the proper identification of the patient specimen and to associate each specimen with a correct patient. Examples of identifying information include patient name, date of birth, medical record number, demographic data, date/time of specimen collection, and laboratory identifiers such as a unique accession number. Despite written policies, training of personnel, and the careful attention of personnel collecting and handling specimens, sample mislabeling or switches occasionally occur. Tissue specimens may be mislabeled, co-mingled, or interchanged at the time of collection (i.e., multiple biopsies from the same or different patients) or during the various stages of tissue processing such as labeling of the blocks containing the tissue or the glass slides with sections of the tissue [1, 3, 15, 17, 26]. In a Q-probe study performed by the College of American Pathologists (CAP), mislabeling occurred in approximately 1 per 1,000 cases [26]. Sometimes, a patient will not believe a tissue diagnosis made on a sample submitted under the patient's name and will challenge a physician to prove that the tested and reported specimen was truly the patient's specimen.

Mislabeled or unlabeled clinical specimens remain familiar identification issues in clinical laboratories. According to regulatory standards, these improperly labeled or unlabeled specimens should not be tested by a clinical laboratory. The strict adherence to this standard varies by specific circumstances. On occasion, when the clinician can definitively document the identity of such a specimen and the specimen is irreplaceable, a laboratory makes an exception. Ideally, though, one rejects a mislabeled specimen in favor of a new, equivalent specimen. Unfortunately, some specimens are difficult or impossible to replace. For example, a replacement blood sample is rather easily obtained in most circumstances, unless the specimen was a timed or pretreatment specimen. On the other hand, in the anatomic pathology laboratory, tissue specimen recollection may be difficult or impossible and typically results in increased morbidity for a patient who must undergo a repeat procedure. Occasionally, the specimen itself may be so unique that it suggests its likely source. In the right circumstances, available DNA identity testing methods can confirm or exclude the source of a sample.

Histologic "Floaters"

Unfortunate occurrences that become critical challenges for the anatomic pathologist are tissue fragments referred to as "floaters." These tissue contaminants do not originate from

the patient's specimen but become intermingled with it at some point between specimen collection and pathologist interpretation. Indeed, these small fragments of loose tissue may be "carried over" from one case to another during various tissue handling or processing steps in the laboratory. During gross dissection, a tissue fragment from one dissecting field can be brought to another by a scalpel blade, forceps, or improper cleaning between grossing of specimens from different patients. Later, during histologic processing (i.e., fixation, dehydration, impregnation, sectioning, or staining), a tissue fragment may literally or figuratively float away from its source and become associated with another specimen. Such specimen contamination may occur despite rigorous quality control procedures. In one study, cross contamination to blank slides occurred in 8 % of cases (most commonly during the staining process) [27].

In many cases, during the course of careful histological examination of a slide, an anatomic pathologist is able to confidently identify when an unexpected fragment of tissue is present and dismiss it from diagnostic consideration. This is more easily accomplished when the "floater" does not resemble the histology of the remaining tissue, is positively recognized as coming from another case, is physically distinct from the main mass of tissue on the slide, or presents incongruous histology [2, 4]. However, when the "floater" is a type of cell or tissue compatible with the expected specimen or is closely intermingled with the expected cells or tissue, it is difficult to exclude the possibility that it is part of the sample originating from the patient. In addition, a "floater" may be a few cells or a cluster of cells that are difficult to evaluate and definitively classify. A common scenario is a tissue section that includes a small number of malignant cells suspected to be "floaters" by a pathologist. The pathologist cannot simply ignore such cells, but definitive interpretation and reporting of their significance is not straightforward. In the past, when diagnostic certainty could not be assured because of potential "floater" contamination, clinical recommendations were limited to a cautionary note such as "advise close follow-up and short term rebiopsy if possible" or a similar disclaimer. Using identity testing methods and processing techniques to carefully separate regions of tissue on a slide, the relevance of a potential "floater" to the diagnosis can be resolved.

Identifying Donor Cells in a Transplant Recipient

Chapter 56 details the utility of identity testing in the setting of hematopoietic stem cell transplantation (HSCT). Identifying cells of donor origin in a transplant recipient can be useful in additional settings, such as a new post-transplant neoplasm or suspected graft-vs-host disease in the recipient.

Donor-Transmitted Malignancies

Donor origin cancer, including malignancies transmitted with the graft as well as tumors that develop within a graft, have been estimated to occur in 0.02–0.06 % of recipients [28–30]. Donor-transmitted malignancies are more common in solid organ transplants than in HSCT [13]. When a transplant recipient develops a malignancy in the transplanted organ or in another location, identification of the origin of the tumor (recipient or donor) is important for patient management and for identification of other individuals who may be at risk because they received other tissues or organs from the same donor. Donors with a history of cancer are usually excluded; however, in some cases the cancer is remote or is not recognized at the time of tissue donation.

To assess the origin of a tumor sample one must have DNA from the recipient, the donor, and the tumor; the tumor being of "unknown" identity. The STR allele genotypes of these samples are compared. Usually the explanted paraffin-embedded tissue, if available, is a good source of recipient DNA; alternatively, recipient buccal cells may be used. Donor DNA or blood may be banked in an HLA laboratory or a donor tissue sample may be available (e.g., donor gallbladder is usually available in liver transplant cases). Alternatively, the transplanted organ can serve this function with the caveat that recipient white blood cells may be admixed, which can complicate the assignment of donor alleles. Assessment of the tumor specimen depends on whether the tumor is in the transplanted organ or in another location because this will determine the expected origin of the DNA of the adjacent normal tissue. The tumor specimen (either a biopsy or excision) should be evaluated as a paraffin-embedded tissue (unless it is a blood-based malignancy) in order to separate tumor from adjacent normal tissue, if possible. When the tumor is within the transplanted organ, the presence of recipient-origin white blood cells will complicate the interpretation. In such cases, a judgment must be made based on the relative abundance of donor and recipient DNA; therefore, it is preferable to isolate the tumor for DNA extraction by macrodissection or microdissection. A tumor that is not in the transplanted organ is easier to interpret as the presence of donor DNA is not expected, and the presence of a significant amount of donor DNA will indicate a tumor of donor origin. Assessment of recipient blood to rule out the presence of circulating donor DNA is a helpful control.

In a sex mismatched transplant, origin of a tumor can be inferred by traditional karyotyping when one has a viable tissue specimen with proliferating cells. Fluorescent in situ hybridization (FISH) can play a role in the evaluation of sex mismatched transplant recipients if the available sample is fresh frozen tissue, a cytologic preparation, or formalin-fixed paraffin-embedded tissue as the presence of two X chromosomes vs one X and one Y chromosome in the tumor cells can exclude a donor of the opposite sex as the source.

Limitations of FISH include nuclear truncation artifacts, hybridization failures, and a reliance on single regions of chromosomes that may be altered in a malignancy.

Graft-vs-Host Disease

Graft-vs-host disease (GVHD) results when donor T cells recognize alloantigens expressed on host antigen-presenting cells and initiate an attack on host epithelial cells, damaging host tissue in a variety of possible anatomic locations including the skin, mouth, eyes, gastrointestinal tract, or liver. As such, skin, gastrointestinal tract, or liver abnormalities in the setting of an organ transplant or even certain types of blood transfusion can point to the possible diagnosis of GVHD. A National Institutes of Health working group recognized two main categories of GVHD: acute and chronic [31]. Diagnostic manifestations in the skin, mouth, eyes, female genitalia, esophagus, lungs, and connective tissues exist for both categories. Although not always mandatory for the diagnosis of GVHD, a biopsy can confirm the diagnosis.

While the donor T cells are nonneoplastic, they may be abundant in GVHD. Although low levels of donor T cell chimerism may be observed in the peripheral blood of liver transplant recipients during the first month after transplantation [32], a study of liver transplant associated GVHD found T cell macrochimerism [33] of at least 4 % in the peripheral blood of patients with histologically diagnosed GVHD after transplant. Hence, DNA-based identity testing of a specimen with T cells can confirm donor origin and provide support for a diagnosis of GVHD.

Specimens for confirmation of GVHD are similar to specimens for assessment of a donor-associated malignancy, with selection of a recipient specimen, the "unknown" specimen suspected of containing the inflammatory cells of GVHD (usually blood or epithelium), and a donor specimen. Results supporting a diagnosis of GVHD would consist of the presence of donor DNA at a significant level in a specimen where only recipient DNA is expected, whereas detection of only recipient DNA indicates that GVHD is less likely. A negative result (no donor DNA detected) requires careful interpretation when only minimal inflammatory cells are present in the "unknown" specimen, as this can represent a false-negative result.

Maternal Cell Contamination of Prenatal Specimens

Clinical laboratories performing prenatal diagnostic testing of chorionic villus sampling (CVS) or amniocentesis specimens, or of products of conception face the risk of inaccurate prenatal diagnosis due to the presence of maternal cells in the specimen. If the specimen is mistakenly thought to contain only fetal cells, contaminating maternal cells may lead to a misdiagnosis even when the level of contamination is seemingly modest (1–2 %) [34]. Even with only approximately 10 % of fetal cell preparations complicated by maternal cell contamination, the problem is so well recognized that maternal cell contamination assessment has been recommended for all prenatal specimens [35, 36]. Despite the recommendation, all laboratories performing prenatal genetic testing do not exclude maternal cell contamination for every prenatal specimen [37].

Sometimes there is frank maternal blood in an amniotic fluid sample, but low levels of contamination usually go unnoticed. Interestingly, culture conditions favor growth of amniocytes over contaminating maternal cells, resulting in less maternal cell contamination of amniotic fluid cultures compared to direct amniotic fluid specimens [38]. CVS specimens present a higher risk of maternal cell contamination because completely separating the fetal cells from the maternal decidua is difficult to accomplish by gross dissection.

STR analysis can be used to test DNA isolated from a fetal specimen with comparison to maternal DNA tested in parallel to determine if maternal alleles are present and if so, to approximate the percentage of maternal DNA [9, 10]. The percent contaminating maternal DNA is significant depending on the prenatal testing method and its sensitivity. A relatively insensitive method may not be affected by 10 % or less maternal contamination; however a very sensitive method could result in an incorrect interpretation due to the unintended presence of maternal DNA. Therefore, the significance of the level of maternal contamination is assessed in the context of the intended use of the prenatal specimen. Recommendations by the American College of Medical Genetics, the Clinical Laboratory Standards Institute, and the Clinical Molecular Genetics Society confirm the importance of maternal cell contamination testing in prenatal diagnosis. Detailed preanalytical, technical, interpretive, and reporting guidelines for maternal cell contamination testing are available [36].

Evaluation of Hydatidiform Moles

Aberrant fertilization of a normal or abnormal egg by one or more sperm can lead to the formation of a hydatidiform mole. A hydatidiform mole can be classified as either complete or partial. Complete hydatidiform moles occur when one (90 %) or two (10 %) sperm fertilize an anucleate ovum, and the proliferating gestational tissue is entirely paternally derived (i.e., androgenetic diploidy). A complete hydatidiform mole can be either homozygous, when a single sperm fertilizes an empty ovum and that sperm's haploid genetic material is duplicated, or heterozygous when two sperm fertilize an empty ovum. Partial hydatidiform moles arise from the fertilization of a single egg by two sperm and are triploid with both

maternal and paternal genetic material (i.e., diandric triploid; usually 69XXX or 69XXY).

Differentiation of a hydatidiform mole from a non-molar specimen, as well as the type of hydatidiform mole, is important for clinical management of the patient because complete hydatidiform moles have a higher risk of developing into choriocarcinoma than do partial moles. Reliable diagnosis of hydatidiform moles based solely on morphology is challenging especially after early evacuation of a complete mole and in many instances of partial moles [39]. Ancillary techniques such as DNA ploidy analysis, immunohistochemistry, conventional karyotyping, and interphase FISH can inform the diagnosis, but have limitations [40]. Partial moles are triploid, so can be distinguished from a non-molar specimen by DNA ploidy analysis. In contrast, complete moles with a higher risk of choriocarcinoma are diploid and harder to distinguish from a non-molar specimen by DNA ploidy analysis. STR analysis definitively distinguishes complete moles, partial moles, and non-molar specimens.

As with other applications of identity testing in the clinical laboratory, STR analysis is the most commonly applied approach to compare the genotypes of the hydropic chorionic villi to those of the decidua (or maternal blood) to determine the genetic origin of the villi. For identity testing, chorionic villi are microdissected from maternal decidua. Significant contamination with decidua tissue will complicate analysis since a complete mole has no maternal DNA while a partial mole does. The maternal DNA for comparison can be obtained from maternal blood if available, or alternatively from microdissected decidua. Additional testing of paternal DNA, while not required, can help confirm the informative alleles in the molar tissue. Analysis of complete moles will identify only non-maternally derived homozygous or heterozygous alleles at multiple loci in the hydropic villi consistent with fertilization of an empty ovum [7, 8]. Analysis of partial moles will show three different alleles at multiple loci, one of maternal origin and two of paternal origin consistent with the fertilization of a normal egg by two sperm. Non-molar specimens are usually diploid with one maternal and one paternal allele (biparental diploidy). In many cases, if the maternal and molar tissue is adequately separated, visual inspection of the results of STR analysis can be diagnostic of a complete or partial hydatidiform mole.

Specimen Considerations

Specimen Selection and Documentation

The critical initial step in identity testing is selection of appropriate specimens to test, which are determined in consideration of the purpose for the testing and the questions needing to be answered. At a minimum there will be an unknown sample and a known sample. In some cases additional known samples for comparison from one or more individuals may be required (Table 57.1).

Table 57.1 Specimens frequently used for identity testing

Type of analysis	Typically tested specimens
Specimen identification	Unknown specimen
	Specimen confirmed to be from the known individual(s)
Histologic floater	Macrodissected floater tissue
	Main tissue on slide separated from floater tissue
	If available, additional specimen confirmed to have tissue from the known individual helps confirm the origin of the main tissue in the block
Pathogenic donor cells in a transplant recipient	Post-transplant tissue with suspected donor cells present
	Specimen with only recipient cells (e.g., pre-transplant blood, tissue, or buccal cells)
	Specimen with only donor cells
Maternal contamination of a prenatal diagnostic specimen	Prenatal specimen or products of conception
	Maternal specimen
Gestational trophoblastic disease	Gestational specimen with suspicious features, microdissected to enrich for gestational cells (villi)
	Maternal specimen (blood or carefully microdissected decidua)
	Paternal specimen (optional)

For specimen identification testing, the "unknown" DNA from the specimen is compared to "known" DNA from a specimen verified to be from the individual, such as a blood sample or a tissue block from a previous procedure. For mislabeled specimens, additional documentation of specimen handling and processing is useful. In contrast, for the identification of suspected floaters that are not consistent with the remainder of the specimen section, "unknown" DNA from microdissected floater tissue will be tested and compared to "known" DNA from an area of tissue containing tissue consistent with what is expected for the specimen. In this scenario it may also be prudent to analyze a verified alternative sample from the same individual as the current specimen in question as a further confirmation that the "known" DNA did, in fact, originate from the individual whose sample was contaminated by the floater. Confirmation of the actual source of the floater is unnecessary in most cases. In a case of two possibly switched samples, both are "unknown" and can be compared with two "known" samples from the two potential source individuals.

Analysis of maternal cell contamination of a fetal specimen requires a known maternal blood sample in addition to

the "unknown" fetal sample. Similarly, diagnosis of a hydatidiform mole requires analysis of both chorionic villi and a known maternal sample. In the typical post-transplant scenario, analysis of the "unknown" tumor specimen is compared with the analysis of "known" specimens from the donor and recipient.

These are only general examples, some of which are illustrated in the cases described later. In fact, identity testing for sample identification is useful in a host of situations, each requiring careful specimen selection on a case by case basis to ensure that the tested specimens reflect the best choices from the available specimens, and that the results of testing those specimens will enable resolution of the clinical question.

Tissue Processing

While specimen handling and processing are major issues for certain types of molecular genetic testing, the use of smaller polymorphic markers allows identity testing to be performed on specimens that would be less than ideal for other clinical molecular tests. Frequently, identity testing for sample identification involves the use of FFPE tissue specimens, which is the routine method for preserving tissue for histopathology in nearly all histology laboratories. Commercial reagents simplify extraction of adequate DNA for identity testing from FFPE tissue sections. However, not all fixatives or chemical treatments used in the histology laboratory are compatible with PCR amplification. Specimens exposed to fixatives containing heavy metals (for example B5 fixative) are not recommended due to inhibition of enzymatic reactions in PCR. Similarly, decalcification solutions are usually acidic as are some fixatives (e.g., Carnoy's, Zenker's, and Bouin's fixatives), which degrade the DNA and render the specimens unsuitable for PCR amplification. Therefore, it is very important to review the tissue processing during selection of tissue blocks for identity testing to avoid incompatible treatments. In extraordinary cases when the only specimen available is suboptimal but the testing will have a significant impact on patient management, testing of the compromised specimen can be considered. In such cases, if there is some amplification of the DNA, it may only be for loci with the smallest PCR target sizes. In some situations, sufficient information may be obtained to provide a limited interpretation, at the risk of over-interpreting potential artifacts that can occur at low DNA concentrations. If critical, testing using SNPs or mitochondrial DNA can be considered since those methods are more tolerant of degraded specimens.

Some staining methods may produce added damage to the nucleic acids. Most hematoxylin and eosin (H&E) stained tissue sections are acceptable [6, 41]. However, because reagents for histochemistry or immunohistochemistry may substantially degrade the nucleic acids or inhibit PCR and the effects of such potential interferences may not have been thoroughly examined during assay validation, due caution should accompany interpretation of STR analysis of previously stained material.

Selection of Tissue for Testing

Identity testing of tissue specimens begins with review of all available material by an anatomic pathologist. After assessing the quantity and distribution of the available material, the best method of isolating DNA from the submitted material is chosen. Available methods range from extraction of DNA from an entire tissue section to extracting DNA from small, isolated areas within a tissue section by macrodissection or microdissection. Regardless of the final method used, the goal of tissue selection is to obtain the appropriate specimens for comparison.

Testing All Tissue Within a Block

When the identity of all of the tissue in a block is in question, several (e.g., three) 10 μm thick section rolls from the FFPE tissue block can be cut and placed directly into microcentrifuge tubes for DNA extraction. This saves time and eliminates the effort of preparing a slide and then scraping the tissue off the slide for DNA extraction.

Testing Areas of Interest Within a Single Block

When different portions of tissue in the same block potentially originate from different sources, macrodissection or microdissection of the tissue from representative slides (see below) is appropriate to separate the tissues for subsequent comparison. Macrodissection after appropriate training and practice can be regularly employed using readily available tools [42]. Microdissection techniques permit more precise selection of cells for testing, but require more expertise and expensive equipment.

When the only slide containing the area of interest has been previously stained and coverslipped, xylenes can be used to remove the coverslip (with a risk of losing the desired cells) for DNA extraction from the stained tissue [6, 41]. Importantly, the scenario of tissue present on only a single level is suggestive of a true "floater" and may not merit further testing because tissue that is truly a part of the specimen is typically present on more than one level of a block.

Macrodissection

For macrodissection, an anatomic pathologist first identifies and outlines representative cellular, nucleated, non-necrotic areas of interest on a stained slide using a permanent marking pen (see Fig. 57.1a). Then, unstained

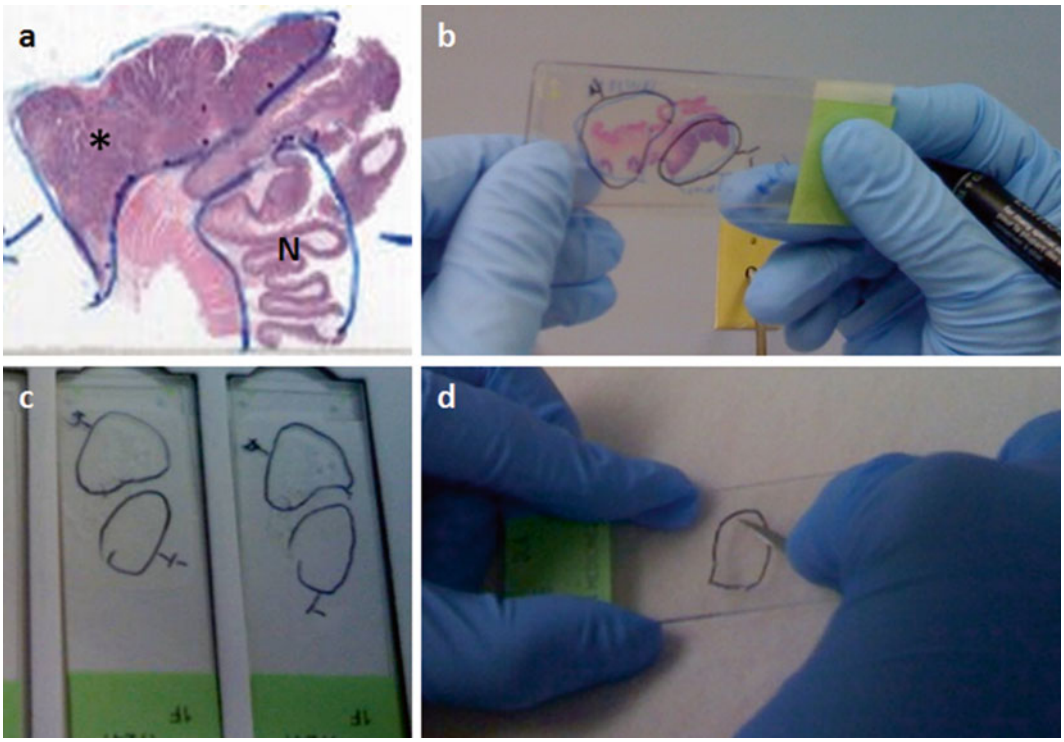

Figure 57.1 Macrodissection can be used to enrich for tumor and/or normal tissue from histologic tissue sections for identity testing, depending on the question being asked. Regions of interest on an H&E stained slide are indicated by an anatomic pathologist by circling the tissue areas of interest using a permanent marking pen, as shown in (**a**) (*, tumor; N, normal). This functions as a guide slide for marking regions of interest on unstained slides of sections adjacent to the tissue on the guide slide (**b**). A final H&E stained slide cut after the unstained sections is used to confirm that the tissue of interest is present on all the unstained slides. The marked tissue from the unstained slides (**c**) can then be individually scraped with a scalpel to isolate the tissue of interest (**d**)

4–10 μm sections are cut and placed onto glass slides (e.g., 5–15 slides are prepared). The first slide, "cut off the top," and the last slide "cut off the bottom" are stained with H&E to demonstrate the distribution of the areas of interest across the intervening unstained slides. Identifying the distinct areas of interest is necessary when the tissue on a slide is not homogenous. Regions representing "floaters," benign, malignant, or other relevant tissues and cells on a slide are delineated with a diamond etching pen (on the non-tissue-containing surface of the slide) or a permanent marking pen on a coverslipped slide (Fig. 57.1a, b). Alternatively, a permanent marking pen can be used to mark areas of interest directly on a faced FFPE block, and this marked area can be manually separated from the remainder of the block. The marked slides are used as guides for identifying and marking the areas of interest on the unstained slides that will be used for dissection and extraction of DNA (Fig. 57.1c). Macrodissection is done by eye or using a low power dissecting microscope and the equivalent circled tissue regions are scraped off the unstained slides (Fig. 57.1d).

Microdissection

Diamond etching pens and permanent marking pens are useful for delineating distinct areas on a slide, and in most cases of identity testing they are satisfactory for marking relevant areas to be collected for DNA extraction and comparison. When greater precision is required, microdissection techniques (i.e., use of a higher power microscope to assist dissection) may be used to isolate discrete cells or clusters of cells from a complex tissue section.

Laser Capture Microdissection

Laser capture microdissection (LCM) permits reliable procurement of pure cell populations from tissue sections. The principle advantage of LCM is the ability to isolate clusters of cells or even single cells of interest as a pure population free from contaminating stromal, inflammatory, and other surrounding cell types. Its precision can also complicate analysis by limiting the choice of analysis methods to those that are amplification-based because the amount of material isolated often is minute. Due to the increased expertise and cost associated with the LCM systems, many laboratories are unable to use LCM routinely for identity testing.

LCM systems such as the ArcturusXT™ LCM System (Life Technologies, Grand Island, NY), Leica LMD6500 and LMD7000 (Leica Microsystems Inc., Buffalo Grove, IL), or PALM MicroBeam (Carl Zeiss AG, Oberkochen, Germany) are available. Each system has unique technologies and techniques for separating the selected areas of interest from tissue sections. In general, the systems include an inverted microscope, an infrared laser, control systems for the laser and the microscope stage, and a digital imaging system to permit the user to view and capture images of the microdissected fragments [43]. The systems differ mostly in terms of the slides and other consumables they require to separate and collect the cells.

Chemical Microdissection

An alternative to LCM is The PinPoint Slide DNA Isolation System™ (Zymo Research, Orange, CA) [17]. With this system a solution is applied to the microscopic area of interest. The solution dries into a thin film that captures the underlying cells. The film is lifted with a scalpel and transferred into a tube for DNA extraction. This method is more time consuming than macrodissection of marked slides and requires a specific kit, but because the area of interest is precisely selected by an anatomic pathologist, the possibility that an incorrect area will be used for analysis is reduced.

Interpretation of Results

Specimen Identification

Sample identification determines whether two samples originated from the same or different individuals. Comparison of a tissue or other specimen with an identified specimen from the potential source patient, such as peripheral blood, can be used to verify the source of the specimen in question. Interpretation of the results involves comparison of the alleles (STR or sequence polymorphisms) between the samples. The identification of nonmatching alleles, preferably in two or more loci, provides evidence to exclude a potential individual as the source of the sample, or at least to conclude that both samples did not originate from the same individual. The possibility of microsatellite instability, loss of heterozygosity, or chromosomal abnormalities should be considered when malignant tissues are being compared to normal samples using STR analysis, as described further below. If an exact allele match is observed between two samples, then the likelihood that they are from the same person is high, and the matching probability can be determined from published data or manufacturer data for the loci used. The following case is an example of identity testing for sample identification.

Table 57.2 Case 1 genotypes confirming that specimens were switched

Locus	Alleles (repeats)			
	Confirmed A	Confirmed B	Unknown A	Unknown B
D3S1358	17,18	15,16	15,16	17,18
TH01	6,9.3	7,9	7,9	6,9.3
D21S11	28,30	30,32.2	30,32.2	28,30
D18S51	14,16	14,15	14,15	14,16
PentaE	7,11	11,16	11,16	7,11
D5S818	12,13	11,13	11,13	12,13
D13S317	9	10,11	10,11	9
D7S820	12,13	10,11	10,11	12,13
D16S539	11	9,10	9,10	11
CSF1PO	10,11	11	11	10,11
vWA	14,17	15,18	15,18	14,17
TPOX	8	8,11	8,11	8

Case 1

Two blocks of tissue (Unknown A and Unknown B) obtained from two different individuals were suspected of being switched and mislabeled. An alternate, confirmed sample from each individual (Confirmed A and Confirmed B) was available. DNA was extracted from all four specimens and each was amplified at 12 STR loci. Comparison of the genotypes indicated that the unknown samples had been switched (Table 57.2). Blocks Unknown A and Unknown B were relabeled to accurately reflect their true source, thereby avoiding the diagnoses of the two individuals being switched.

A "confirmed" specimen is partially a subjective designation due to the possibility of specimen misidentification. As such, in interpretive reports language such as "…block number 1 is identified as originating from patient '1' and block number 2 is identified as originating from patient '2'…" makes it clear that even for specimens with presumably confirmed identity there remains the possibility of preanalytical errors resulting in a specimen misidentification.

Analysis of Floaters

To assess the origin of an extraneous, frequently small, tissue fragment (floater) in a tissue section, the genotype of the majority of the tissue on the slide is compared with that of the floater. As with other forms of identity testing, differences in two or more markers should be identified in order to exclude the patient as the source of the floater. Generally it is not necessary or cost-effective to identify the source of the extraneous tissue; however, if desired, possible source cases with similar histology that were processed during the same time period can be tested. As always, histopathologic review of the case to verify the nature of the submitted material and to select the appropriate tissues for analysis is essential before initiating identity testing. The histopathologic review also informs the analysis, as macrodissection is frequently

Table 57.3 Case 2 genotypes confirming the presence of a floater

Locus	Alleles (repeats)		
	Suspected floater	Suspected source of floater	Benign block containing floater
vWA	11,18	11,18	16,17
TH01	10	10	6
TPOX	8,11	8,11	9,11
CSF1PO	11,12	11,12	10
LPL	11,12	11,12	10,12
F13B	6,10	6,10	9,10
FESFPS	10,12	10,12	11,12

D5S818	10,13	10,13	11
D13S317	9,10	9,10	9,10
D7S820	11,12	11,12	10
D16S539	10,12	10,12	12
Amelogenin	X,Y	X,Y	X,Y

imperfect and a minor component of the predominant tissue's genotype may be detected in what is intended to be only floater tissue. When mixed genotyping result are obtained, correlation with the histologic picture usually will show intermingled "known" and "floater" cells in the specimen with the mixed genotype result.

Case 2

An isolated fragment of adenocarcinoma was identified in a single block of prostate needle biopsies. The remaining five blocks were completely benign. A "floater" was suspected and the possible source was another prostate biopsy case processed immediately prior to the case with the suspected floater. The adenocarcinoma floater was macrodissected, as well as the majority tissue from the benign case with the floater and the prior case with adenocarcinoma. The three tissue DNAs were tested at 12 STR loci and the results confirmed that the tissue fragment was a "floater" (Table 57.3). As expected, testing of the amelogenin locus confirmed that both samples were from male patients.

Cells of Possible Donor Origin in Transplant Recipients

Case 3

GVHD was suspected in a patient who was critically ill and pancytopenic one month after an orthotopic liver transplant. A bone marrow biopsy showed that his bone marrow was aplastic. Identity testing was requested to determine whether donor cells were circulating in the recipient, which would support a diagnosis of GVHD [44]. Twenty STR loci were amplified using recipient DNA (FFPE tissue from the explanted native liver), donor DNA (FFPE tissue from the donor gallbladder that was removed and processed at the time of transplant), and three recipient-derived specimens: peripheral blood, CD3-positive cells (T cells) isolated from peripheral blood, and bone marrow. The results confirmed the presence of donor cells in each specimen. The relative amounts of recipient and donor DNA were calculated from the allele peak areas of four representative loci (Fig. 57.2), which demonstrated 62 % donor alleles in the recipient's bone marrow and supported the diagnosis of GVHD. GVHD after solid organ transplant has been reported, and in several cases macrochimerism (>1 % donor DNA) was observed. Thus, the finding of significant donor DNA in this case was consistent with the clinical impression of GVHD [45]. The percent of donor DNA in the blood may be tracked over time using this same method.

Case 4

Six months after receiving a double lung transplant, a patient was diagnosed with metastatic squamous cell carcinoma in a subcarinal lymph node. Identity testing was requested to ascertain whether the squamous cell carcinoma was of recipient or donor origin and to guide treatment of the patient and other potential recipients of organs from the same donor. Identity testing using 12 STR loci was performed using DNA from an FFPE cell block from an a fine needle aspiration (FNA) of the subcarinal lymph node with squamous cell carcinoma, an FFPE tissue section from the native right lung, and a stored peripheral blood specimen from the donor. Test results showed that the lymph node with the squamous cell carcinoma DNA had the same alleles as DNA extracted from the recipient's native lung specimen at 11 informative STR loci (Fig. 57.3 and Table 57.4). In interpretation of the test results, consideration was given to the surgical pathologist's note that the FNA only contained 5–10 % tumor cells. The relative amounts of neoplastic and nonneoplastic cells can help in interpretation of relative peak heights in an electropherogram and must be compared with an assay's ability to detect low levels of a minor DNA component. There was no evidence of donor allele peaks in the FNA specimen's electropherogram and the assay was validated to detect at least a 5 % component of DNA. In this context, the results were interpreted as consistent with a recipient origin of the squamous cell carcinoma cells in the lymph node.

Maternal Cell Contamination of a Prenatal Specimen

Case 5

A 37 year old pregnant woman underwent CVS. A limited amount of villi were collected, cultured, and karyotyped with a result of 46, XX. Identity testing was requested to determine whether the karyotype reflected only chromosomes

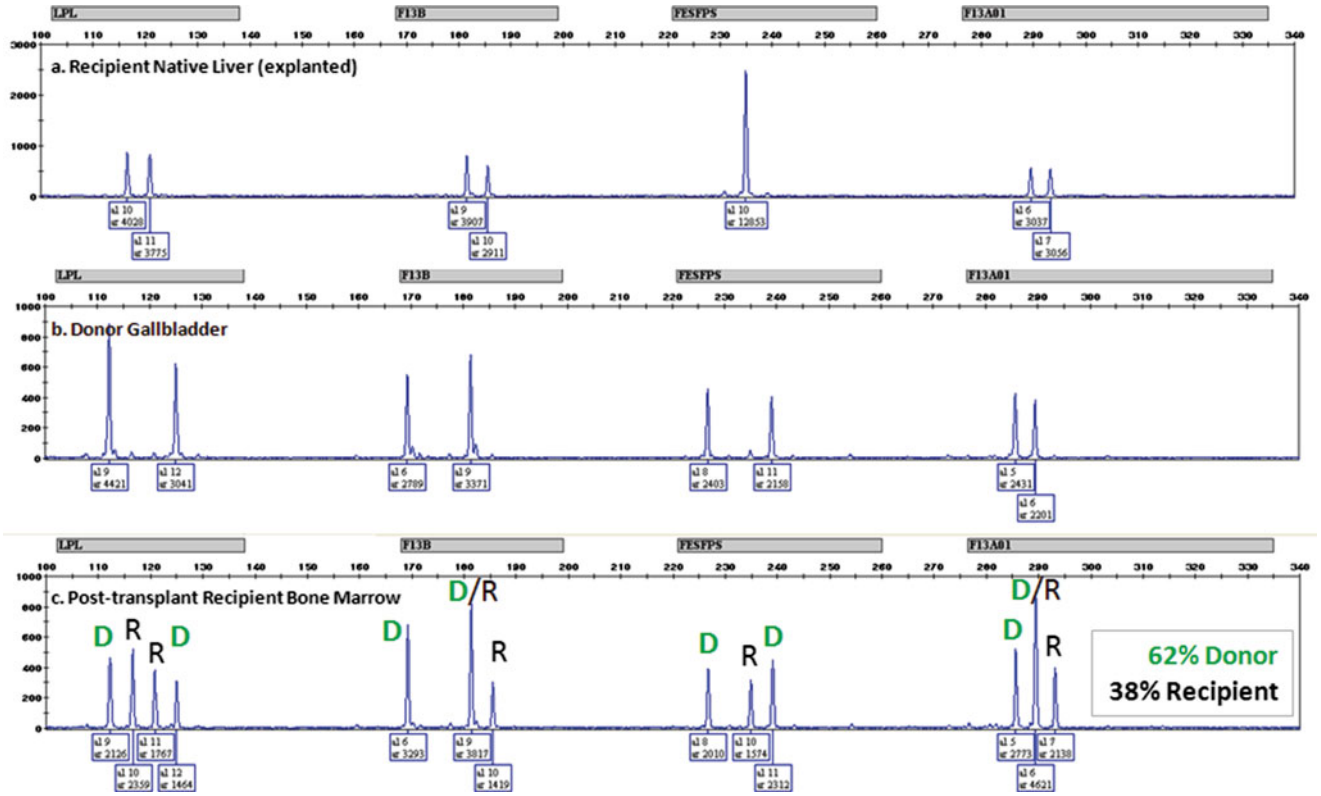

Figure 57.2 Electropherograms from Case 3. Amplification results for four STR loci are shown for DNA extracted from recipient native liver tissue (**a**), donor gallbladder tissue (**b**), and post-transplant recipient bone marrow (**c**). The bone marrow specimen shows the presence of both donor (green D) and recipient (R) alleles at all four loci. Alleles shared by the donor and recipient are indicated (D/R). The percent of donor DNA is calculated from the peak areas as described in Chap. 56. In this sample, the donor DNA was 62 %. This result was interpreted as macrochimerism supportive of a diagnosis of GVHD. *al* allele, *ar* area of peak, *GVHD* graft-vs-host disease, *STR* short tandem repeat

of the fetus or contaminating maternal cells. Identity testing using 12 STR loci and the amelogenin locus was performed using DNA from the cultured chorionic villus sample and DNA from a peripheral blood sample from the mother. The identity testing results demonstrate that the CVS contained fetal DNA with evidence of Mendelian inheritance, as well as low-level maternal contamination. The relative amounts of maternal and fetal DNA were calculated from the allele peak areas at informative loci with approximately 4 % maternal DNA present (Fig. 57.4).

Analysis of Hydatidiform Mole

Identity testing is used to characterize hydatidiform moles as complete or partial moles, as well as homozygous or heterozygous complete moles.

Case 6

A 25-year-old pregnant woman underwent a dilation and evacuation procedure after a missed abortion. The surgical pathologist who examined the specimen noted degenerated hydropic chorionic villi suggestive of a molar pregnancy. Tissue was submitted for cytogenetics and the resulting karyotype was 46, XX. Her physician was concerned about persistent trophoblastic disease or early choriocarcinoma based on serial measurements of human chorionic gonadotropin (hCG) in the patient's blood. Most cases of complete mole or choriocarcinoma have 46 chromosomes which are all of paternal origin. The genetic origin of the villi from the products of conception was questioned and DNA genotyping analysis was requested. Macrodissection was used to isolate the hydropic chorionic villi from the remaining tissue on the section (selected regions shown in Fig. 57.5).

Identity testing at 12 STR loci was performed on DNA from three specimens: macrodissected hydropic chorionic villi (Fig. 57.5) and maternal and paternal peripheral blood specimens. The chorionic villus genotype (Fig. 57.6 and Table 57.5) showed a mixed pattern attributable to incomplete separation of abnormal villus tissue from adjacent normal decidua by macrodissection, which is a common problem due to the difficulty in separating villus tissue from decidua using macrodissection rather than microdissection. Although the pattern appears triploid (three alleles

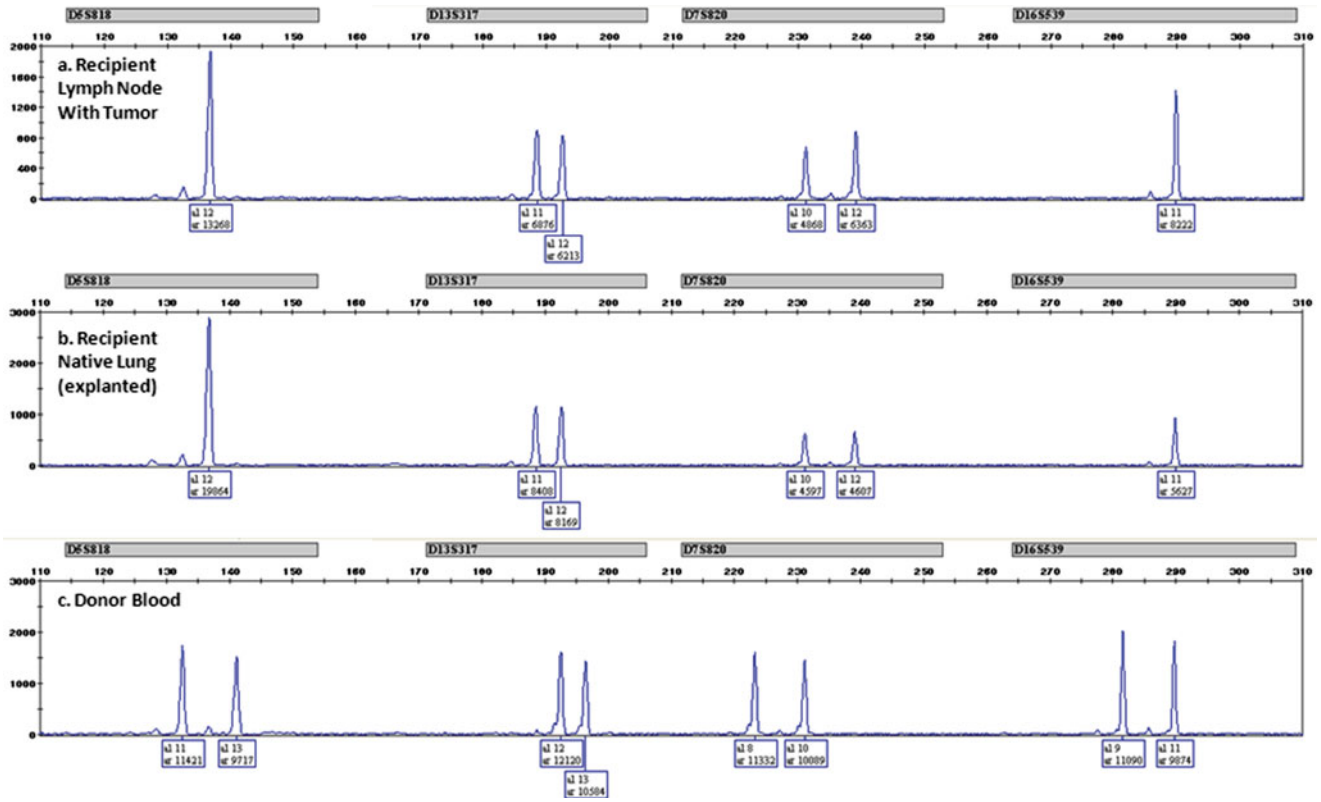

Figure 57.3 Electropherograms from Case 4. Amplification results for four STR loci are shown for DNA isolated from tumor-containing specimen (**a**), recipient native lung (**b**), and donor blood (**c**). Results indicate no evidence of donor-specific alleles in the tumor-containing specimen (**a**) at the level of sensitivity of the assay (5 %), supporting a recipient origin for the tumor. *al* allele, *ar* area of peak, *STR* short tandem repeat

at some loci), each locus has a predominant allele peak matching a single paternal allele and smaller adjacent peaks attributable to contaminating maternal alleles. This case demonstrates the importance of careful microdissection, as well as careful interpretation of the results in the context of the histology. A higher level of maternal contamination would be difficult to interpret. Based on a comparison with the paternal genotype, the dominant allelic pattern in the hydropic villi sample is most consistent with paternal isodisomy in which only a single paternally derived allele is present at each informative locus. The reported histologic features and identity testing interpretation support the diagnosis of a complete hydatidiform mole.

Identity Testing Results for Neoplastic Tissue with Mutations

The presence of a genotype mismatch at two or more loci is usually sufficient to conclude that two samples are from two different individuals. However, when one of the tissues is neoplastic, the differences at a single locus or few loci may be due to mutations in the tumor tissue. Nucleotide polymorphisms are often conserved between the normal and tumor tissue from the same patient, but microsatellite instability (MSI), loss of heterozygosity (LOH), and chromosomal alterations occur in tumors and should be considered

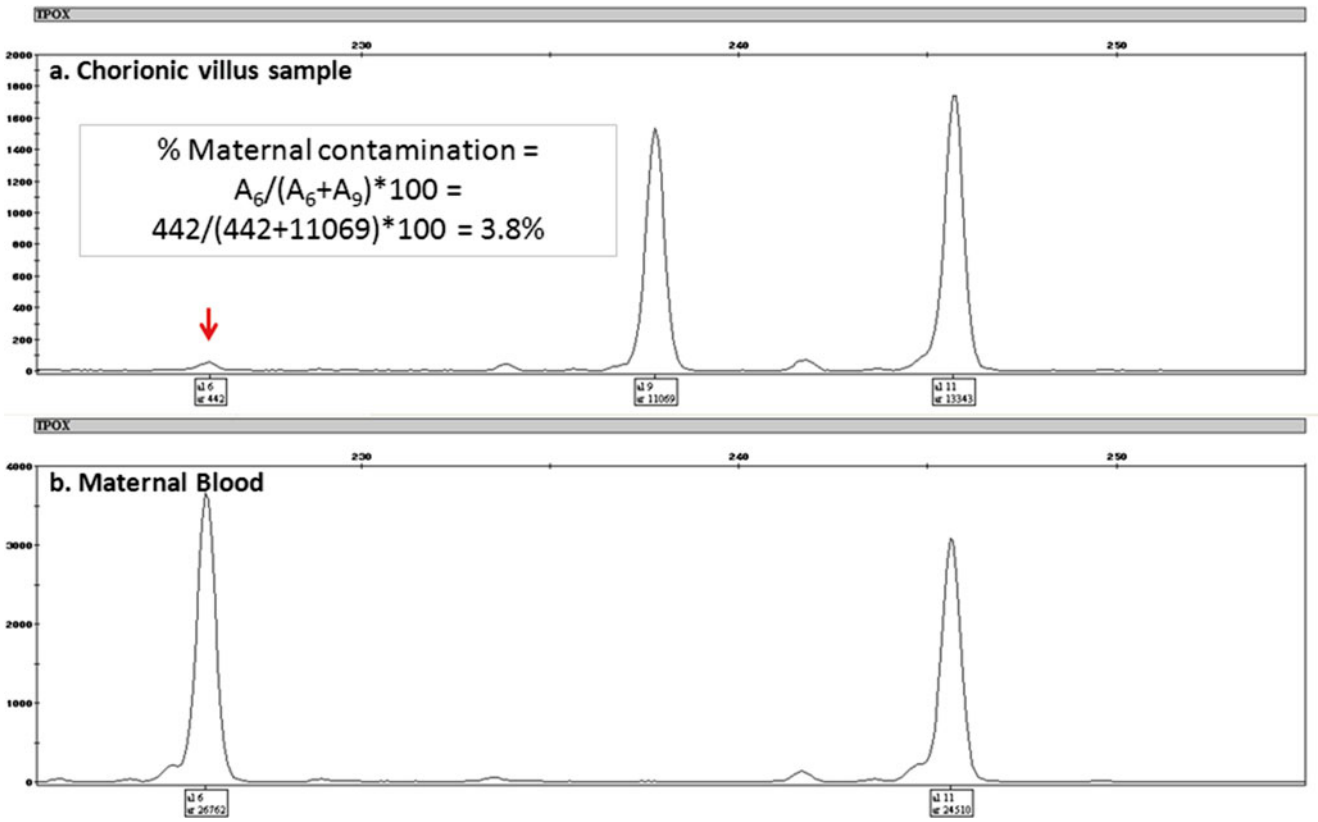

Figure 57.4 Electropherograms from Case 5. Amplification result for the TPOX locus is shown for DNA from chorionic villus sample (CVS) (**a**) and maternal blood (**b**). The CVS specimen shows a small amount (3.8 %) of maternal contamination indicated by the presence of the maternal allele of 6 repeats (*red arrow*). Mother and fetus share the 11 repeat allele. The percent of maternal contamination can be calculated using the peak areas as described in Chap. 56. *al* allele, *ar* area of peak

Figure 57.5 H&E-stained FFPE tissue section of a chorionic villus sample from a suspected molar pregnancy. Regions of hydropic villi were circled (*green circles*) with a marking pen to create a guide slide used as a reference for macrodissection of tissue on adjacent unstained slides. DNA was extracted from the macrodissected tissue for identity testing (fig. 57.6)

as a possible cause for allelic differences. MSI in a tumor results when errors in DNA replication of microsatellites (simple repetitive sequences) are unable to be repaired by DNA mismatch repair (MMR) proteins, either due to mismatch repair gene mutation or promoter hypermethylation. Since identity testing relies on polymorphic STR sequences, MSI at a locus being tested is a theoretical confounding factor in the interpretation of identity testing results. LOH at a tested locus is also possible. If a deletion or other mutational event involving a tested allele renders the tumor cells either hemizygous or homozygous at that allele compared to the heterozygous benign cells, then that discrepancy may mistakenly be interpreted as an indication that the tumor did not originate from the patient. Loci known to be frequently compromised by MSI, LOH, or chromosomal alterations and loci compromised in a specific tumor should not be utilized for an identity testing application. Therefore, when analyzing neoplastic tissue, examination of a number of loci rather than relying on the results at a single locus is necessary, and a cytogenetic karyotype, if available, can be used to assist with interpretation.

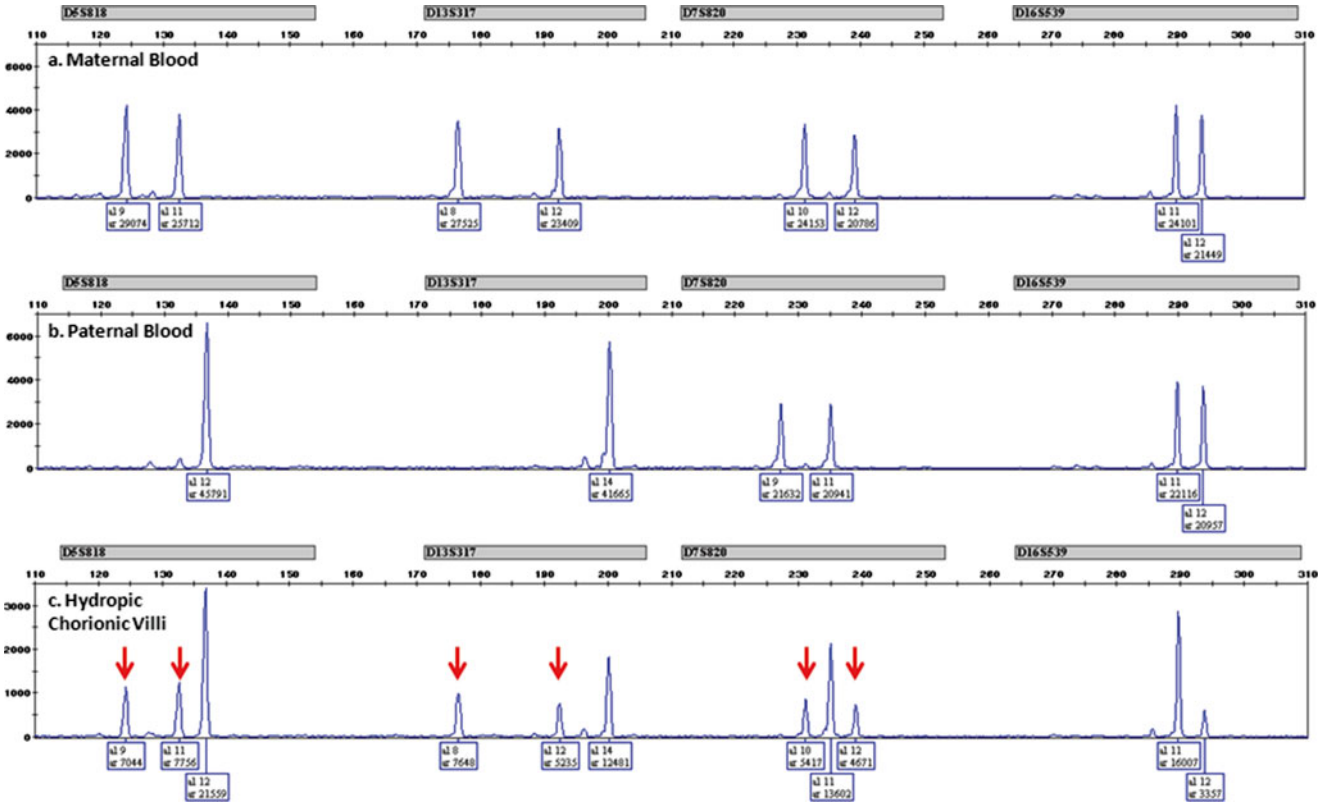

Figure 57.6 Electropherograms from Case 6. Amplification results for four STR loci are shown for DNA extracted from maternal blood (**a**), paternal blood (**b**), and macrodissected hydropic chorionic villi (**c**). The dominant alleles in the villus sample are composed of only a single paternal allele most consistent with paternal isodisomy. In addition, at all informative loci, both maternal alleles (*red arrows*) are present as a result of incomplete macrodissection with inclusion of maternal decidua. This result was interpreted as a complete hydatidiform mole. *al* allele, *ar* area of peak

Conclusion

Identity testing methods are well established for use in a variety of scenarios encountered in a clinical laboratory. Beyond the routine use for monitoring engraftment for HSCT, the applications described in this chapter demonstrate wide-ranging applicability of identity testing for clinical specimen identification. These applications include suspected specimen misidentifications, histologic floaters, or concern over the attribution of a diagnosis for a patient. Identity testing also has a demonstrable diagnostic role in the classification of hydatidiform moles, assessment of maternal cell contamination in prenatal specimens, determination of the origin of a tumor in a transplant recipient, and diagnosis of GVHD. In a vast majority of cases, polymorphic DNA marker analysis combined with clinical information and histologic correlation provides the answer to questions which are otherwise difficult to resolve.

Molecular HLA Typing

58

Malek Kamoun, Jill A. Hollenbach, Steven J. Mack, and Thomas M. Williams

Abstract

This chapter describes the molecular genetics of the HLA genes, which reside within a genetic complex referred to as the major histocompatibility complex (MHC). The MHC contains the most polymorphic coding sequences in the human genome. HLA molecules provide the molecular basis for immunologic self-recognition, and many HLA genes encode proteins that function within immune regulatory networks.

This chapter describes (1) methods used for population genetic analyses including estimation of allele and haplotype frequencies and disease association studies; (2) the clinical utility of HLA typing for solid organ and bone marrow/hematopoietic cell transplantation, autoimmune diseases, and other disorders; (3) available assays for HLA typing, definition of typing resolution, and interpretation and reporting of test results.

Keywords

HLA • Haplotype • Genetics • Genome • Histocompatibility • Linkage disequilibrium • MHC • Polymorphisms • Transplantation

Molecular Genetics of the Human Major Histocompatibility Complex

Histocompatibility antigens were first described by Snell, using inbred strains of mice. Later, Dausset, Payne, Van Rood, and others discovered that in humans antibodies to white blood cell antigens can be induced after pregnancy or transfusion. These antibodies provided the tools to define the human leukocyte antigens (HLA) ([1–3] and references therein). Recently, using molecular methods, researchers have defined thousands of different HLA alleles. The HLA genes reside within a genetic complex referred to as the major histocompatibility complex (MHC). The MHC comprises about 4 megabases (Mb) on the short arm of chromosome 6 (6p21.3). The MHC contains the most polymorphic coding sequences in the human genome. HLA genetic diversity accounts for more than 10 % of all genetic diversity observed in the human genome. HLA molecules provide the molecular basis for immunologic self-recognition, and many HLA genes encode proteins that function within immune regulatory networks.

A number of genes in the MHC, arranged in order from the telomeric to the centromeric end, are displayed in Table 58.1. The MHC can be divided into three major regions, each of which controls the production of molecules that have distinct biologic functions [4]. The class I region includes the HLA-A, HLA-B, HLA-C, and related loci; the

Table 58.1 Names for genes in the HLA class I and class II regions, ordered from telomeric to centromeric location on chromosome 6

Name	Molecular characteristics
HLA-F	Class I-like molecule
HLA-G	Class I-like molecule
HLA-H	Class I pseudogene
HLA-A	Class I α chain
HLA-J	Class I pseudogene
HLA-E	Class I-like molecule
HLA-C	Class I α chain
HLA-B	Class I α chain
MICA	MHC class I-like molecule
MICB	MHC class I-like molecule
HLA-DRA	DR α chain
HLA-DRB9	DRB pseudogene, isolated fragment
HLA-DRB3	DR β3 chain determining DR52 and Dw24, Dw25, Dw26 specificities
HLA-DRB2	Pseudogene with DR β-like sequences
HLA-DRB1	DR β 1 chain determining specificities DR1, DR2, DR3, DR4, DR5, etc.
HLA-DQA1	DQ α chain as expressed
HLA-DQB1	DQ β chain as expressed
HLA-DQB3	DQ β-chain-related sequence, not known to be expressed
HLA-DQA2	DQ α-chain-related sequence, not known to be expressed
HLA-DQB2	DQ β-chain-related sequence, not known to be expressed
HLA-DOB	DO β chain
TAP2	ABC (ATP-binding cassette) transporter (associated with antigen presentation)
LMP7	Proteosome-related sequence (role in loading class I molecules with peptides)
TAP1	ABC transporter (associated with antigen presentation)
LMP2	Proteosome-related sequence (role in loading class I molecules with peptides)
HLA-DMB	DM β chain (control peptide loading by class II molecules)
HLA-DMA	DM α chain (control peptide loading by class II molecules)
HLA-DPA1	DP α chain as expressed
HLA-DPB1	DP β chain as expressed
HLA-DPA2	DP α-chain-related pseudogene
HLA-DPB2	DP β-chain-related pseudogene

class II region includes the HLA-DR, HLA-DQ, and HLA-DP loci; and the class III region contains genes that encode a variety of proteins including molecules of the complement system (C2, C4, and Bf) and tumor necrosis factors (TNFs). Class I and class II loci encode two distinct classes of highly polymorphic cell surface molecules whose function is to capture and display various antigenic peptides to CD8+ and CD4+ T lymphocytes, respectively. The class II region also includes the genes for the TAP1 and TAP2 peptide transporter, the *LMP* genes that encode proteosome subunits, and the genes encoding the DMα and DMβ chains ([4] and references therein).

HLA Polymorphism

HLA genes are codominantly expressed, and most individuals are heterozygous at the classical (i.e., presenting peptides for inspection by T cells) HLA class I and class II loci. The nomenclature for the alleles of the HLA system is decided by an international nomenclature committee. Antigen names are composed of a letter designating the HLA protein encoded by a locus or loci and a number, for example, A2, B7, Cw4, DR17, and DQ3. Allele names are based on nucleotide sequence variation among alleles identified using DNA-based techniques (discussed below). The number of alleles at the HLA class I and class II loci and a listing of their serologically defined specificities and allele equivalents are available online at several Web sites (for instance, the Anthony Nolan Trust Web site at http://www.anthonynolan.org/clinicians-and-researchers/anthony-nolan-research-institute/hla-informatics-group and also at http://hla.alleles.org or the ImMunoGeneTics (IMGT)/HLA Database Web site at http://www.ebi.ac.uk/imgt/hla/).

Pattern of HLA Polymorphism

Most of the sequence diversity for the HLA class I loci is localized to the second and third exons and, for the class II loci, to the second exon of each gene. HLA diversity is generated through the selection of alleles with nonsynonymous substitutions encoding amino acid differences within the peptide-binding site. This contrasts with the bias against substitutions within the introns and other binding domains. Linear sequences identifying residues critical to the expression of allospecificities are found in the helices of the α1 and α2 domains as well as external portions of the β-pleated sheet. Other polymorphic amino acid residues that are important for peptide binding but not defined by alloantibodies are identified by DNA-based techniques [5–7].

The pattern of allelic sequence diversity for both the class I and class II loci is unusual; most alleles differ from their closest neighbor by multiple substitutions, with some alleles differing in the second and third exons by as much as 15 %. This pattern is suggestive of segmental exchange of nucleotide motifs between alleles of the same locus. There are also a few examples of interlocus gene conversion, and most are the result of HLA-B and HLA-C recombination. Thus, different HLA alleles of a locus are patchwork (i.e., mosaic) combinations of polymorphisms. The extensive allelic diversity at HLA loci is thought to have been generated by polymorphic

sequence motifs generated by gene duplication and recombinational mechanisms such as gene conversion-like events, which have shuffled these polymorphic sequence motifs. Point mutations also contribute to this allelic diversity [6, 7]. One consequence of this pattern of patchwork polymorphism is that the sharing of specific epitopes on the HLA molecules leads to antigenic cross-reactivity. Due to epitope sharing, HLA antigens may be arranged in cross-reactive groups or CREGs [2, 3]. CREGs are important in that they allow for greater latitude in donor–recipient HLA matching and at the same time may be used to predict potential problems with graft outcome. A problematic consequence of the combinatorial nature of HLA alleles is that a given pattern of sequence motifs may be consistent with more than a single genotype. This problem of ambiguity in DNA-based typing is discussed below.

HLA Haplotypes

The term "haplotype" applies to any set of genetic polymorphisms at contiguous loci. These neighboring polymorphisms are co-transmitted on a single parental chromosome in the absence of recombination. A haplotype can be defined at any level of polymorphism. Alleles at different HLA loci are often described as being transmitted as a multi-locus haplotype (e.g., the A1-B8-DR3 haplotype), but the sequence variants associated with specific HLA allele names are in fact haplotypes of individual polymorphisms at a given locus. An individual inherits one haplotype from each parent. In any family having more than one sibling, there is a 1 in 4 chance that the two siblings will be HLA identical and a 1 in 2 chance that they will share one haplotype. Given the number of existing alleles, the number of possible haplotypes is astronomical. However, due to linkage disequilibrium (LD), the number of haplotypes found in a population is more restricted [7, 8].

The organization of HLA-DQ and HLA-DP loci is conserved within humans and other primates, whereas the number of HLA-DR genes varies in different haplotypes. Within the HLA-DR region, the DRB1 gene encodes the DRβ1 chain, which determines the DR private specificities DR1, DR2, DR3,DR4, DR5, and so on. The DRB3, DRB4, and DRB5 genes encode the DRβ3, DRβ4, and DRβ5 chains, which determine the DR52, DR53, and DR51 specificities, respectively (Fig. 58.1).

Genetic recombination or crossing over in the HLA region is a relatively rare event, occurring for the most part no more than 1 % per meiosis between HLA-A and HLA-B and between HLA-B and HLA-DR. Recombination also can occur between HLA-A and HLA-C and between HLA-B and HLA-C (0.6 % and 0.2 %, respectively). Such recombination can have important clinical implications for transplantation.

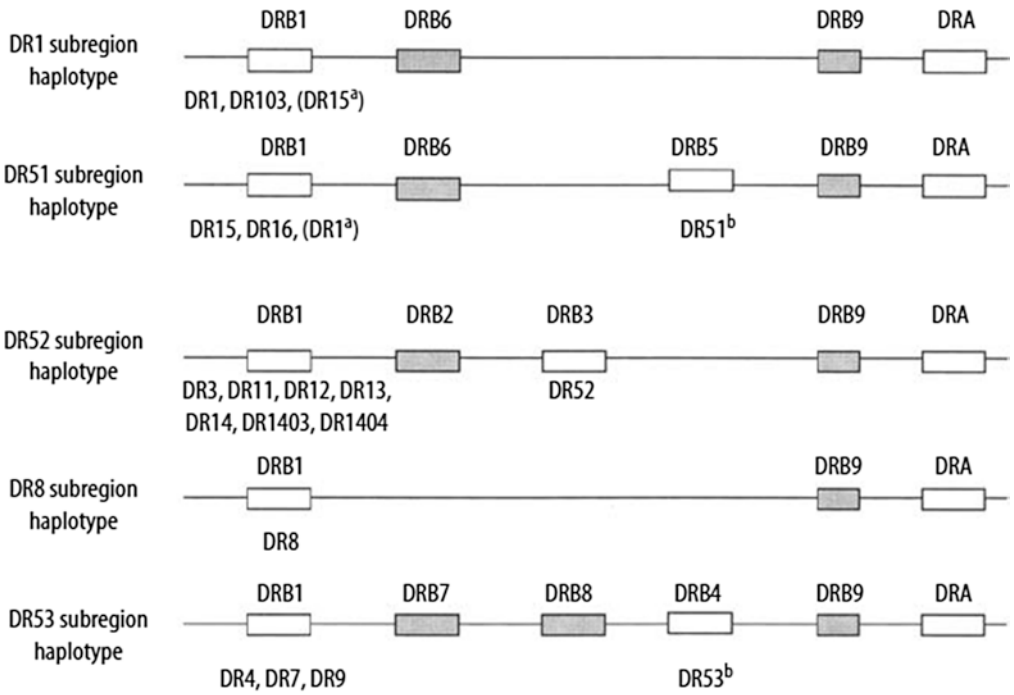

Figure 58.1 HLA-DR region and encoded allotypes. Pseudogenes are indicated by *shaded boxes*. Expressed genes are indicated by *open boxes*. The serologic specificity encoded by a gene is given underneath each expressed gene box. [a]Rarely observed haplotypes. [b]The DR51 and DR53 specificities may not be expressed on certain haplotypes (Adapted from Little AM, Parham P. Polymorphism and evolution of HLA class I and II genes and molecules. *Rev Immunogenet.* 1999;1:105–123)

Linkage Disequilibrium or Gametic Association

LD is an important feature of the HLA system. Gametic associations are regularly found between certain alleles of HLA-A and HLA-B, HLA-C and HLA-B, HLA-B and HLA-DR, and HLA-DR and HLA-DQ. In some so-called extended haplotypes, significant LD extends over 3 Mb from HLA-A at the telomeric end of the HLA region to HLA-DP at the centromeric end, including HLA class III genes ([8] and references therein). It is this LD that allows the identification of bone marrow or stem cell donors in population registries who are matched with a given patient at multiple loci (see "Histocompatibility Assessment in Unrelated Donors").

HLA Gene Frequencies in Human Populations

Although a very large number of alleles (e.g., >1,600 for HLA-B) can be found in the global population, a much smaller number (e.g., 30–50 for HLA-DRB1) is present in most individual populations. Importantly, different populations tend to have different frequency distributions of alleles and exhibit different patterns of LD. This variability exists among both racial and ethnic groups.

Clinical Utility of HLA Typing

Solid Organ Transplantation

Kidney and Pancreas

Over 570,000 patients had end-stage renal disease (ESRD) at the end of 2010. Treatment modalities include hemodialysis, peritoneal dialysis, and kidney transplantation. Kidney transplant is the most effective treatment for patients with ESRD. However, despite a waiting list of over 90,000 patients, only 10,622 deceased donor kidneys were transplanted in 2010. The median time a patient with blood type "O" listed in 2003 waited for a deceased donor graft was >5 years. Longer time on dialysis is one of the strongest risk factors for inferior transplant outcomes. The pursuit of kidney donation from living donors is essential to addressing the long and ever-growing waiting list (Scientific Registry of Transplant Recipients, 2011; http://www.srtr.org/).

Many transplant candidates have potential living donors, but approximately one-third of these potential donations do not lead to a transplant because of blood group type or crossmatch incompatibility. Kidney paired donation (KPD), also referred to as kidney exchange or live-donor paired exchange, provides an opportunity for donors to indirectly donate to their intended recipient, thereby ensuring living donor kidney transplantation without the barrier of incompatibility. Congress defined and supported KPD by passing the Charlie Norwood Living Organ Donation Act, signed in 2007. Support and interest in KPD has markedly grown in the last decade. However, KPD remains grossly underutilized. Nearly all the initial donor exchange transplants in the USA have been performed through independent, regional KPD registries. The logistics of maintaining a multicenter database, crossmatching potential pairs, and timing the transplants have become increasingly complex, raising concerns regarding programmatic efficiency and efficacy (reviewed in Ref. 9).

HLA Matching of Living Related Donors

Transplants are performed using donor–recipient pairs sharing HLA-A, HLA-B, and HLA-DR antigens from one or two haplotypes. The analysis of HLA matching for kidney graft survival over the period of 1985–1999 is based primarily on serologic typing data. The half-life survival for a graft from an HLA-identical sibling is 23 years, compared to a one-haplotype-related donor, which has a half-life of 12.8 years [6, 10].

HLA Matching of Cadaveric Donors

Data excerpted from the United Network for Organ Sharing (UNOS) transplant registry [9] indicate that HLA serologic matching appears to have an effect on long-term graft survival of kidneys from cadaveric donors. Although the 1-year graft survival is not very different in cases involving a complete match from those who are completely mismatched, after 5 years the gap in percent survival widens significantly, suggesting that the immunosuppressive drugs are potent in avoiding early graft loss due to acute rejections. However, as the drug dosages are tapered over time, the HLA-matching effect becomes significant. Patients receiving organs with zero mismatches for HLA-A, HLA-B, or HLA-DR antigens achieve a graft survival half-life of 11.3 years compared to a half-life of 6.3 years for grafts that were completely mismatched for these antigens. HLA matching is especially beneficial in second transplants and in patients with preformed antibodies. The effect of HLA-A, HLA-B, and HLA-DR matching remains significant even with the most recent forms of immunosuppression [10].

UNOS HLA-Matching Algorithm for Allocation of Cadaveric Kidneys and Pancreases

The selection of a recipient for any given random cadaveric donor is based on an HLA-matching algorithm defined by UNOS (http://www.unos.org). The current allocation policy considers the degree of HLA matching at HLA-A, HLA-B, and HLA-DR. The organs are distributed locally first, and if no match is found, they are offered regionally, and then nationally, until a recipient is found. Nationwide organ sharing is mandatory for pediatric and sensitized candidates with

zero HLA-A, HLA-B, and HLA-DR mismatches; local and regional organ sharing is based on one or two HLA-DR mismatches. All other match grades are allocated without regard to mismatching. The main purpose of this algorithm is to try to transplant more minority patients while at the same time not reducing overall graft outcome.

Transplantation of Other Solid Organs

HLA typing for heart and lung transplant patients and their potential donors is an important step for donor selection by virtual crossmatching. Virtual crossmatching is accomplished by avoiding HLA class I and class II antibody specificities identified by screening patients' sera prior to transplant. HLA typing in these patients usually includes low-resolution HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DRB3, HLA-DRB4, HLA-DRB5, and HLA-DQB for patients and their donors. In cases where anti-DQA, anti-DP, or allele-specific antibodies are present, HLA typing of donors and recipients also may include HLA-DQA, HLA-DP, or allele-level typing as needed.

The effect of HLA-A, HLA-B, and HLA-DR matching on the survival of heart and lung transplants is statistically significant. In addition, donor-specific antibodies to HLA antigens are associated with graft failure and poor survival. Antibody-mediated rejection appears in about 10–20 % of heart transplant patients, correlating with factors of poor outcome such as increased incidence for hemodynamic compromise rejection, greater development of cardiac allograft vasculopathy, and higher incidence of mortality. The effect of HLA matching for liver transplants is less clear.

Hematopoietic Cell Transplantation

HLA Typing Requirements

Typically, HLA typing for hematopoietic cell transplantation (HCT) initially would include low-resolution typing for HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DRB3, HLA-DRB4, HLA-DRB5, and HLA-DQB1 loci. Allele-level typing is subsequently performed in the final identification of suitable donors for HCT. Three different categories of donors usually are considered in the following order of preference: HLA genotypically identical siblings, HLA-mismatched relatives, and matched or mismatched unrelated donors.

Histocompatibility Assessment in HLA-Matched Relatives

The goal when screening for an HLA-matched sibling donor is to identify which of any siblings have inherited the same HLA haplotype from their parents. This requires typing all siblings and, if possible, both parents for HLA-A, HLA-B, HLA-DRB1, and HLA-DQB1. Given the current average family size in the USA of 2.7 siblings, the approximate probability that a patient will have an HLA match within the family is 30–35 %. For those patients who do not have an HLA-matched sibling within the family, an HLA-mismatched relative who shares one haplotype can be considered. However, the clinical data clearly indicate that with increasing disparity for HLA-A, HLA-B, HLA-DRB1, or HLA-DQB1 loci, there is increased risk of graft-vs-host disease (GVHD) following HCT.

Histocompatibility Assessment in Unrelated Donors

When a matched sibling donor does not exist for a patient requiring allogeneic HCT (70 % of cases), searching for extended family members or donors from unrelated bone marrow registries would be the next option. Registries of volunteer bone marrow donors as well as cord blood exist in most developed countries. The largest of these is the National Marrow Donor Program (NMDP) in the USA (http://www.marrow.org).

The probability of finding a matched donor at HLA-A, HLA-B, HLA-DRB1, and HLA-DQB1 depends on the ethnic origin of the patient and the composition and size of the donor registry being searched. Identifying a patient's haplotypes can help predict the probability of finding matched donors and assist in developing a search strategy, because some alleles and haplotypes are more common than others, and they are distributed at different frequencies in different racial and ethnic groups. When searching for a donor, for some alleles, an allele-level match is more likely to be found among persons of a particular ethnicity [11–14]. The NMDP matching algorithm HapLogic^{SM} is based on this principle: identifying the donors or cord blood units (CBUs) with the highest potential to match the patient. This allows transplant physicians searching the Be The Match Registry® (operated by the NMDP) to identify more quickly and efficiently the best immunogenetically matched donor or CBU for their patients. The transplant center is responsible for selecting an unrelated donor or CBU for a patient. The NMDP recommends that, when possible, patients and adult donors (marrow or peripheral blood stem cells) should be fully matched (8 of 8 loci) at high resolution for HLA-A, HLA-B, HLA-C, and HLA-DRB1. Matching for CBUs is less stringent, and the NMDP recommends fully matched (6 of 6) CBUs at HLA-A, HLA-B (antigen level), and HLA-DRB1 (allele level). This does not imply that availability of a partially matched donor or CBU is a contraindication to transplant. Instead, a less-than-optimal match is another risk factor to be considered in developing the patient's treatment plan.

Likelihood of Finding an Unrelated Donor or Cord Blood Unit

Today, patients are more likely to find an unrelated donor or CBU than previously possible. Through the NMDP, three potential hematopoietic cell options for patients in need of an unrelated donor can be available: marrow, peripheral

blood stem cells (PBSC), or umbilical cord blood. A patient's likelihood of finding a potential unrelated donor or CBU has increased with the continuing growth and increasing diversity of the Be The Match Registry. As of 2012, the registry includes nine million potential marrow or PBSC donors and nearly 145,000 CBUs. Through international connections, the NMDP searches more than 18.5 million potential donors as of 2012 and nearly 550,000 CBUs. Nearly all (>95 %) patients are able to find at least one potential 4 of 6 HLA-matched CBU on the Be The Match Registry, the largest in the USA, and the majority will find a potential 5 of 6 match. However, patients belonging to racial groups that are not well represented in the registries have a considerably decreased probability of matched donor identification [12].

Relative Impact of HLA Disparities

HLA compatibility affects not only the ability to achieve sustained engraftment following HCT but also the risk of developing acute and chronic GVHD [6, 13, 15]. Posttransplant risk of graft failure, GVHD, and mortality can be affected by quantitative and qualitative characteristics of donor and recipient HLA mismatching. Moreover, studies have reached different conclusions regarding the relative contributions of HLA class I and class II mismatching because of population-based differences in the specific HLA-mismatch combinations between patients and donors ([13] and references therein). In an analysis of HCT for chronic myelogenous leukemia (CML), the risk of graft failure is affected primarily by donor disparity for HLA class I including HLA-C. The incidence of rejection correlates with the number of donor-incompatible alleles. The incidence of graft rejection is 0.7 % for zero, 8 % for a single, and 19 % for multiple class I allele incompatibilities. Donor disparity for class II does not increase the risk of rejection [6, 13].

The level of matching is more critical for HCT than for solid organ transplantation because of the risk of GVHD. GVHD is a major cause of mortality in HCT and is more frequent than allograft rejection. Analysis of HLA and GVHD focuses on mismatches in the host recognized by donor T cells. Generally, host disparity for class II is thought to convey greater risk for GVHD than class I disparity. In an analysis of HCT for CML, patients with a single class II mismatch at HLA-DR or HLA-DQ have a hazard ratio of 1.8 compared to HLA matches. Single class I mismatches are well tolerated with respect to GVHD; however, combined mismatching at class I and class II confers a hazard ratio of 2.0. Allele mismatches for HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1 also are a significant factor for survival. Patients mismatched for more than one class I allele and those mismatched at both class I and class II alleles have a significantly lower survival than patients and donors fully matched for HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1. A single class I mismatch or single class II mismatch does not appear to affect survival [6, 13, 15]. It is likely that different modes of patients' immunosuppression after transplant would have an impact on the relative risk associated with various HLA loci. Criteria for "permissible" mismatching in HCT are center dependent. However, very few centers would perform HCT across more than one HLA mismatch at HLA-A, HLA-B, HLA-DR, or HLA-DQ. Interestingly, recent studies have shown that GVHD rates and survival outcomes in pediatric and adult patients receiving cord blood transplants with up to two HLA antigen mismatches (i.e., a 4 of 6 match) are similar to those for 6 of 6 HLA-matched unrelated donor marrow transplants, as long as the recipient received an optimal CD34 cell dose adjusted for the recipient's body weight [16–19].

HLA and Disease Association

Population Genetic Analyses

The extensive polymorphism observed for HLA loci requires a rigorous approach to data analysis [20]. The complex patterns of LD commonly observed for HLA data can make it difficult to identify specific causal genetic variants. Disease association studies of highly polymorphic HLA data may require the consideration of multiple units of analysis, including amino acid, allele, genotype, and haplotype levels, as well as consideration of gene–gene or gene–environment interactions. The selection of the appropriate statistical tests is critical and will be dependent on the nature of the data set as well as the specific research hypotheses being tested; there is no single analytical approach that can be applied to all data.

Population genetic analyses of gene (allele) frequencies, tests for fit Hardy–Weinberg equilibrium (HWE) expectations, and estimations of haplotype frequencies are the primary steps in analyzing immunogenetic data and provide additional means to assess underlying population substructure, as well as additional units of analysis on which association analyses will be performed. Basic methods for these analyses are described below.

Calculation of Gene (Allele) Frequencies

In the age of molecular typing techniques, HLA gene (allele) frequencies (GF) no longer need to be estimated from phenotype data. In most cases, GF for HLA data can be obtained via direct counting, where the number of observations for a given allele is divided by the number of chromosomes ($2n$, where n = sample size) under study.

Hardy–Weinberg Testing

The Hardy–Weinberg (HW) model is useful for primary quality control (QC) verification of the integrity of genotype data, as molecular genotyping errors can result in both

individual genotype deviations and overall (locus-level) deviations from HWE. In addition, HW testing also is useful for detecting sampling errors (see below) in population samples. Confidence in the accuracy of HW testing therefore is crucial for confidence in subsequent analyses, as many analytical methods (e.g., LD and haplotype estimation) are predicated on an assumption of HWE in the data set.

In a HW test, observed genotype counts are compared to those expected under HWE proportions (HWEP), as calculated from a table of all possible genotypes generated using an appropriate statistical method [21]. The relationship between the allele and genotype frequencies under HWEP is given as

$$f\left(A_iA_i\right) = p_i^2 \quad \text{and} \quad f\left(A_iA_j\right) = 2p_ip_j,$$

where *pi* is the allele frequency of allele *Ai* and *pj* is the allele frequency of allele *Aj*. Populations in HWE will not depart significantly from these allele and genotype frequencies.

Tests of overall locus-level HWEP compute a *p*-value to estimate the significance of observed deviations across all genotypes. Significant deviation of observed genotype counts from expected HWEP can result from factors that include sampling errors (the sampling of admixed, stratified, substructured, or some other form of blended populations), inbreeding or other nonrandom mating, natural selection, and genotyping errors. Tests for deviation from HWEP have low power, and significant deviation from HWEP is *not* common. Genotyping errors (e.g., failure to detect a specific allele, resulting in an excess of homozygotes) are the first consideration when significant deviations from HWEP are detected (especially when such deviations are detected only at a single locus in a multi-locus analysis), rather than the operation of selection, admixture, or nonrandom mating, unless the data are suspected to be from an unusual population.

Haplotype Estimation

Haplotype-level analyses are important to studies of the etiology of human disease, selective forces acting on populations, and optimal bone marrow donor registry (BMDR) size. Multi-locus analyses can be used to identify associations between markers and disease loci that are not evident with single-locus analyses. Haplotypes are used for disease association mapping, quantitative trait locus (QTL) mapping, and imputing underlying genetic markers.

Study design and subject recruitment depend on which of the alternative approaches of identifying haplotypes by segregation analysis in families or estimating haplotypes from population samples of phase-unknown unrelated individuals will be applied. Estimated haplotypes and haplotype frequencies (HFs) play a central role in most genetic studies [21].

It is important to understand that haplotype estimation always results in population-level frequency estimates, rather than haplotype assignments for individuals. Due to the limitations of current haplotype estimation methods, estimated haplotypes observed fewer than three times in a population should be considered unreliable.

Analysis in Disease Association Studies

The case–control study is the most common study design in HLA disease association studies. Case–control studies can be very sensitive to population stratification within sample cohorts. This issue is particularly important for HLA data, as HLA allele frequency distributions can vary considerably between human populations. If study subjects are not chosen with scrupulous attention to homogeneity of ancestral background, population-based genetic differences between cases and controls may be misinterpreted as disease associations.

The results of the basic population-level analyses outlined above can be used in case–control association analyses. Depending on the study hypothesis, the units of analysis may include gene, carrier, genotype, and/or haplotype frequencies in cases and controls. Assurance that the control population genotypic distributions conform to expected HWEP is critical.

Contingency Tables

A contingency table is used to test the independence of frequency distributions for categorical variables. Tests for heterogeneity between specific groups (e.g., cases and controls) for HLA data can be performed using contingency table testing and a standard Chi-square (χ^2) measure.

A contingency table always is constructed utilizing raw counts, rather than frequency data. The preferred approach in this type of analysis for highly polymorphic HLA data is to first examine heterogeneity in overall allele frequency distributions in cases vs controls for a particular locus, using a $2\times k$ row by column ($r\times c$) contingency table. If overall heterogeneity is detected at the locus level, the contributions of individual alleles to the overall deviation can be examined in a series of 2×2 tests.

When significance of the association of all individual alleles is assessed with the a priori knowledge of overall heterogeneity at the locus, it is not necessary to correct for multiple comparisons in subsequent 2×2 tests; however, if no overall heterogeneity has been detected, analysis of 2×2 tests requires corrections for multiple comparisons (usually via the Bonferroni method), with a correction factor minimally equivalent to the number of alleles tested.

Low-frequency alleles pose a particular challenge in traditional χ^2 association tests in disease studies. The χ^2 test can lead to false acceptance or rejection of the null hypothesis when the expected genotype counts in a contingency table are small. It is not unusual for 30 or more HLA alleles to be observed at a locus, with a wide range of frequencies, and the preferred approach is to combine low-frequency alleles into a single "binned" category, by combining alleles with an

expected value of less than five in cases or controls prior to calculation of the χ^2 statistic. The χ^2 statistic for a contingency table analysis of case–control data for a genetic association is calculated as

$$\chi^2 = \sum \frac{(O_i - E_i)^2}{E_i}$$

where

O_i = the observed count of allele i

E_i = the expected count of allele i

The expected count for each cell in the $r \times c$ table is calculated as

$$\frac{(\text{row total allele } i) \times (\text{column total})}{2n}$$

where

column total = sum of the counts in the column

row total = number of observations of allele i in all subjects

n = number of individuals (cases + controls)

$2n$ = number of chromosomes (cases + controls)

The degrees of freedom (df) for the χ^2 analysis are the number of alleles with expected values in cases and controls of five or greater, plus the combined category, minus 1 (i.e., $k-1$). A p-value is obtained by comparing the test statistic to the χ^2 distribution for the appropriate df.

Odds Ratio and Relative Risk

Odds ratios (ORs) are used in disease association studies to describe the strength of association between two variables and reflect the ratio of odds of an outcome (e.g., disease) in one group (e.g., individuals with a particular allele) to the odds of this outcome in another group (individuals without that allele). Relative risk (RR) is a different measure that describes the risk of having the outcome of interest relative to exposure (e.g., positive or negative for a particular allele). RR is more applicable to prospective studies, while OR is preferred for retrospective studies.

OR and RR values are only meaningful when presented with a corresponding confidence interval (CI). The standard probability level is generally 95 %, meaning that there is a 95 % chance that the OR or RR value of interest is in that range. Because the null hypothesis of both tests is that OR or RR = 1, a CI that includes 1 is not considered statistically significant.

Logistic Regression

Logistic regression (LR) analyses also can be used in case–control studies. LR is a form of generalized linear modeling for data with a binary outcome variable, such as case–control data. LR provides a means to develop association models that include the contribution of numerous covariables. LR is a critical tool in the analysis of complex multivariate data sets.

LR analysis always is performed using software, but extreme care must be taken in the coding of HLA data, as most LR software is not designed to handle high levels of polymorphism common in these data sets. A regression analysis produces a model that includes all of the variables that are useful in predicting the (binary) outcome variable. LR provides an OR for each variable involved in predicting outcome and can be particularly useful in HLA studies that must consider a large number of cofactors.

HLA Typing for Autoimmune Diseases and Other Disorders

Specific alleles of HLA molecules are associated with certain diseases. Associations have been shown to be of two types: those with disease association with class I antigens and those with strong associations with class II antigens (Table 58.2). Importantly, as shown in Table 58.2, the following HLA disease associations are of diagnostic importance. The best known is the association of HLA-B27 with ankylosing spondylitis (AS) and associated spondyloarthropathies (reviewed in Ref. 23). More than 90 % of AS patients are B*27, which is found in 5–10 % of the general population. An increased incidence of B*27 also is seen in patients with Rieter syndrome and anterior uveitis.

Celiac disease (CD) is caused by an immune response to gluten in genetically predisposed individuals. Although patients with CD may be asymptomatic, infants and young children commonly present with diarrhea, failure to thrive, and abdominal pain and distention. The prevalence of CD in the general population is estimated to be higher than 1 %. Approximately 95 % of patients with CD have the HLA-DQ2 heterodimer encoded by the DQA1*05 and DQB1*02 alleles, which are found in 20–30 % of the general population. Close to 5–10 % of CD patients have the DQ8 heterodimer encoded by the DQA1*03 and DQB1*0302 alleles, which are present in 10 % of the general population. High-risk HLA class II haplotypes include DR3/DR3. DR3/DR7, DR11/DR3, or DR11/DR7 carrying DQA and DQB susceptibility alleles in cis/trans associations [24–26]. Since 25–40 % of the general population has either DQ2 or DQ8, the presence of either heterodimer is not diagnostic of CD; the primary use of HLA-DQ typing is to rule out CD and genetic susceptibility for CD. Determining genetic susceptibility can avoid continual serologic testing and initiation of a gluten-free diet, especially in individuals in high-risk groups.

Narcolepsy is a chronic sleep disorder characterized by daytime sleepiness and dysosomnia. Narcolepsy is associated with DRB1*15 and DQB1*06:02. The DQB1*06:02 allele is found in over 90 % of patients with narcolepsy–cataplexy and is found in about 20 % of the general population [27–29].

Table 58.2 Examples of HLA testing for autoimmune diseases

Disease	HLA test	Comment
Ankylosing spondylitis (AS)	HLA-B*27	B27 is found in >95 % of patients with AS but also is found in 7 % of the white population. The presence of B27 is not diagnostic. The absence of B27 tends to exclude AS.
Celiac disease	HLA-DQ2 (DQA1*05/DQB1*02) and DQ8	More than 97 % of celiac patients carry either HLA-DQ2 (DQA1*05/DQB1*02) or HLA-DQ8 (DQA1*03/DQB1*0302) or both. However, 39 % of the general US population carry these HLA-DQ variants.
Narcolepsy	HLA-DR2, DQB1*06:02	DR2 (DRB1*1501-DQB1*0602) is present in nearly all patients with narcolepsy but also is found in ~20 % of the general population. The presence of DQB1*0602 is not diagnostic of narcolepsy, but the absence of DQB1*0602 tends to exclude narcolepsy.
Birdshot retinochoroidopathy	HLA-A*29	>95 % of patients carry HLA-A*29
Behcet's disease	HLA-B*51	50–80 % of patients carry HLA-B*51

Table 58.3 Examples of HLA testing for hypersensitivity reactions to drugs

Drug	Clinical indication	HLA specificity
Abacavir	Antiviral	B*57:01
Carbamazepine	Antiepileptic	B*15:02
Carbamazepine	Antiepileptic	A*31:01[a]
Allopurinol	Hyperuricemia	B*58:01

[a]Japanese population established by genome-wide association studies

Birdshot retinochoroidopathy (BSCR) is a rare disease, characterized by a posterior uveitis with multiple hypopigmented choroidal and retinal lesions. >95 % of patients carry A*29 [30, 31].

Behcet's disease is a chronic inflammatory autoimmune disease characterized by oral aphthous lesions, genital ulcers, and other symptoms and occurs more frequently in the Middle East and Asia. Behcet's is strongly associated with B*51 (50–80 % of patients carry B*51) [32, 33].

HLA Typing for Drug Hypersensitivity Reactions

Hypersensitivity reactions to drugs typically occur within the first few weeks after drug intake, but in the case of a reexposure, symptoms can be seen within hours, suggesting a delayed-type hypersensitivity reaction. Cutaneous adverse drug reactions include Stevens–Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and drug-induced hypersensitivity syndrome (DIHS). SJS is considered to be a minor form of TEN. These reactions usually are manifested by painful blistering skin rashes that may cause the skin to slough off. Lesions also may involve the mucous membranes. Complications may include internal organ lesions and sepsis and may cause death. The amount of skin sloughing determines morbidity. In either case, urgent medical care is necessary. SJS and TEN also can be caused by other factors such as infections or can be idiopathic.

Abacavir is a nucleoside analog reverse transcriptase inhibitor used to treat HIV patients. In Caucasians, B*57:01 is associated with hypersensitivity to abacavir [34, 35]. B*57:01 is found most frequently in Caucasians (4 %) and less frequently in African (1 %), Asian (0.9 %), or Hispanic (<0.1 %) populations.

Carbamazepine (CBZ) is an anticonvulsant known to be associated with cutaneous adverse drug reactions (cADRs), including SJS, TEN, and DIHS. B*15:02 is associated with these disorders in Asians [36–38]. Studies from Europe have shown that B*15:02 is not a universal marker for SJS/TEN. The prevalence of B*15:02 is high among Chinese (5–15 %), Malays (12–15 %), and Thais (8–27 %), but low among Japanese, Korean, Sri Lankan, and most ethnic groups in India. At the request of the US Food and Drug Administration (FDA), the makers of this drug have agreed to include the recommendation that all Asians be genotyped for this HLA allele before the drug is prescribed. In addition, a recent GWAS study showed that A*31:01 has 60.7 % sensitivity and 87.5 % specificity as a risk predictor for CBZ-induced cADRs. Although DIHS is clinically distinguished from SJS and TEN, these data indicate that they share a common genetic factor as well as a common pathophysiological mechanism [39].

Allopurinol is used to treat hyperuricemia. B*58:01 was found to be highly associated with hypersensitivity to allopurinol-induced SJS and TEN in Asian populations [40, 41]. It is not clear if similar association exists in Caucasians and Africans.

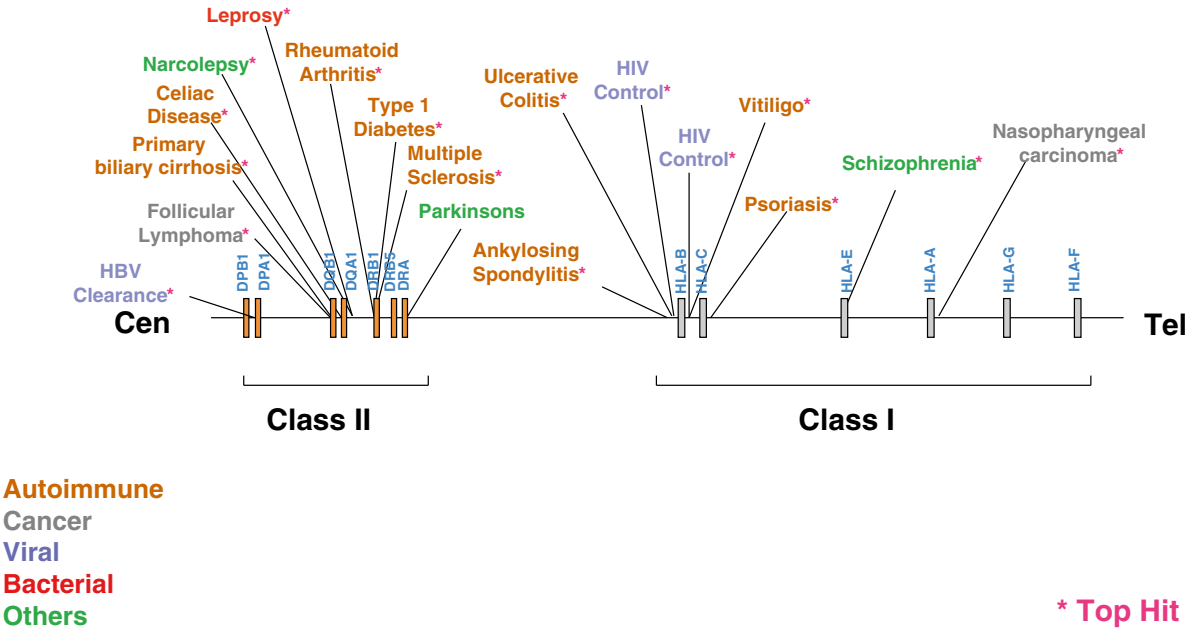

Figure 58.2 Genome-wide association studies within the MHC (This figure was kindly provided by Dr. Mary Carrington, National Institutes of Health, USA). *CEN* centromere, *TEL* telomere

Genome-Wide Association Studies Within the MHC

Genome-wide association studies have confirmed the preeminence of the human MHC in terms of the magnitude of the effect, statistical confidence, and the number of associations with autoimmune, infectious, inflammatory, and adverse drug effects (Fig. 58.2). Importantly, the MHC has the greatest genome-wide effect on control of human immunodeficiency virus (HIV) viral load; over 300 genome-wide significant single nucleotide polymorphism (SNPs) within the MHC were identified and none elsewhere. Stepwise regression analyses have narrowed these associations to four independent MHC SNP markers associated with host control of HIV viral load [42]. Specific amino acids in the HLA-B peptide-binding groove, which were previously described, as well as an independent HLA-C effect, explain the SNP associations and reconcile the previously reported protective and risk alleles.

Mechanisms for the Association of HLA Alleles with Autoimmune Diseases

The biological mechanisms underlying the associations between HLA antigens and various diseases remain mostly unknown. HLA-associated diseases are caused by interplay of multiple genes and environmental factors, in which HLA genes most often confer the strongest genetic predisposition. Based on results of a genome-wide search for susceptibility genes, HLA accounts for more than 50 % of the genetic risk in type 1 diabetes [23, 43]. Susceptibility to rheumatoid arthritis (RA) is strongly associated with the DRB1*04:01, *04:04, *04:05, and *04:08 alleles. On the other hand, DRB1*04:02, *04:03, and *04:07 are not associated with RA and may instead confer protection. A possible role of pocket 4 (residues 67, 70, 71, and 74) of the β chain of DR4 molecules has been suggested.

In type 1 diabetes, both susceptibility and protection are associated primarily with some class II HLA molecules. Association is strongest with heterozygosity for HLA-DR3- and HLA-DR4-bearing haplotypes. Data support that HLA-associated predisposition to type 1 diabetes is mainly determined by a complex multi-locus effect including HLA-DQ and HLA-DR alleles [22, 42]. This may explain differences among populations with respect to susceptibility associated with particular HLA-DQ or HLA-DR molecules. The HLA-DQ molecule associated with susceptibility often shares an amino acid other than aspartic acid at position 57 on the HLA-DQβ chain that is located in pocket 9 of the peptide-binding cleft. On the other hand, those HLA-DQ molecules associated with protection carry aspartic acid at this position (reviewed in Ref. 23).

Fine Mapping of Causal MHC Variants Associated with Complex Disease Traits

The mechanisms through which DNA sequence polymorphism operates remain unknown. The location of primary signal is confounded by multiplicity of DNA polymorphisms, frequencies in the population, and LD that may extend over several megabases in the MHC. Diseases often are found to be associated with common ancestral HLA haplotypes encompassing a very large number of MHC genes,

many of which are candidates for complex disease association. Disease susceptibility appears to result from complex multilocus effects spanning the entire HLA class I, class II, and class III regions with evidence of shared loci [44–46]. Recent studies showed that a 3′ untranslated region (UTR) HLA-C variant associates strongly with control of HIV [47], potentially adding to the effects of genetic variation encoding the peptide-binding region of the HLA class I loci and indicating that both structural and regulatory variants are important and may be operating in tandem. Narrowing the HLA associations and identifying the causal HLA genes would require deep sequencing of MHC haplotypes using new technologies applied to large disease cohorts in different populations of distinct ancestry.

Other Applications

HLA-matching algorithms have been used for patients receiving repeated infusions of platelet concentrate who become refractory due to the generation of antibodies to HLA class I antigens expressed on the surface of platelets. Other important applications include vaccine clinical trials for patients with melanoma and HIV infection, in which vaccines rely on defined HLA-restricted epitopes. Identification of the appropriate HLA type is an important step in identifying patients who could benefit from these therapies.

Available Assays

Virtually all methods used widely in clinical molecular laboratories have been applied to the problem of identifying HLA alleles (Ref. [6] and references therein). Strategies based on allele-specific DNA amplification, oligonucleotide probe hybridization, and DNA sequencing have become the most common methods. Each of these methods relies on isolation of genomic DNA from the tested individual with polymerase chain reaction (PCR) amplification of relevant regions of an HLA gene. Samples for testing are usually peripheral blood but may be any nucleated cell or tissue. Laboratories typically amplify at least exons 2 and 3 of class I genes and exon 2 of class II genes, but may prepare larger amplification products that include exons 4 and 5 of class I genes for DNA sequencing. Amplification primers may be located within exons or introns. Intronic primers allow complete analysis of exons and inspection of exon–intron junctions for splice-site mutations. Primers must be chosen with care to achieve locus-specific amplification since the HLA loci are the products of gene duplication and divergence and retain substantial homology. Further, many HLA loci have closely related pseudogenes that do not encode functional polypeptides but may result in nonspecific PCR products. Each of the methods discussed below generates a large amount of data for each patient that must be compared to extensive lists of potential alleles, hybridization probe "hit" patterns, or allele sequence libraries to assign an allele type. While this may be done manually, most laboratories use software packages that must be updated frequently to include newly recognized alleles.

Resolving Power of Methods

Laboratories tailor HLA-typing assays to the specific clinical applications discussed above. For example, assays helpful in evaluation of narcolepsy may test only for presence or absence of DQB1*06:02. Matching unrelated donors and recipients for HCT requires allele-level (high resolution) typing at several class I and II loci. Conversely, low-resolution typing at the allele-group or serologic-equivalent level is typically performed for renal transplantation. Choice of the methods discussed below depends on typing volume, turnaround time requirements, and the resolution needed.

Sequence-Specific Primer Polymerase Chain Reaction

The sequence-specific primer polymerase chain reaction (SSP-PCR) method employs pairs of PCR primers chosen so that their 3′-most nucleotide or nucleotides are complementary to a polymorphic position that distinguishes an allele or allele group from other alleles ([6] and references therein). If the individual possesses the allele(s) of interest, the PCR will lead to a product whose size and presence is typically identified by agarose gel electrophoresis or can be detected in real time [6, 47]. If one or both primers are not complementary to their targets at their 3′ ends, the reaction will fail. By choosing many pairs of primers in independent reactions to cover all allele groups, laboratories can perform allele typing. Laboratories include a second set of generic primers for a control gene in each reaction, as a DNA amplification control. Because of the large number of allele groups, about 100 PCRs are necessary to perform a low-resolution HLA-A, HLA-B, and HLA-DRB1 typing for a single patient. Additional reactions are required if allele-level typing is desired. Thus SSP-PCR typing requires considerable thermal cycler resources. SSP-PCR is suitable for low to moderate typing volumes in laboratories. Since it can be performed in a few hours, SSP-PCR can be used to identify HLA alleles in time-sensitive situations such as in deceased donors prior to renal transplantation.

Sequence-Specific Oligonucleotide Probe Hybridization

For sequence-specific oligonucleotide probe hybridization (SSO), PCR products amplified from the relevant regions of a particular HLA gene are hybridized to a large panel of

oligonucleotide probes that include the known polymorphisms ([6] and references therein). Hybridization and washing conditions of high stringency allow detection of single-nucleotide differences. Most laboratories detect bound probes colorimetrically or by chemiluminescence. The reactivity of the entire panel is analyzed against expected results for particular alleles or groups of alleles to assign an allele type. Forward SSO is useful for large-scale, batched testing, with the PCR products from many individuals immobilized on a membrane, with subsequent hybridization with a single probe. By preparing many membranes, the laboratory can test the entire panel of probes. Reverse SSO assays employ multiple probes immobilized on a membrane strip for hybridization to the PCR products from a single individual [6]. Whereas reverse dot-blot and SSO methods typically employ enzyme labels and colorimetric substrates that require subsequent development, other SSO methods employ microspheres. Up to 100 different populations of microspheres can be mixed together and distinguished by their unique fluorescence signatures when analyzed by a fluoroanalyzer. Thus, all variants in the PCR products are analyzed simultaneously, and the entire assay is carried out in a single vessel with the addition of a single reagent. Reverse SSO assays can be challenging to optimize since all probes must attain specificity under identical hybridization conditions. Reverse SSO reagents are available commercially. This type of method is very attractive for rapid, low- to mid-volume testing. SSO testing can yield low-resolution results or allele-level results using larger panels of probes.

DNA Sequencing

DNA sequencing of PCR products is a method increasingly attractive for allele-level typing because of the large numbers of alleles known to exist at several of the HLA loci. In theory, any known or new allele should be detected by this method if defined by polymorphisms within the nucleotide sequence amplified by the two PCR primers. Recombinant DNA polymerases for sequencing reactions, improved fluorescent dyes for dideoxynucleotides, powerful analysis software, and capillary electrophoresis instruments have made DNA sequencing technically easier and less labor-intensive for complex clinical molecular tests such as HLA typing [48]. Careful selection of PCR primers to ensure roughly equal amplification of the two alleles present in an individual is a crucial requirement for this method. Otherwise heterozygous peaks in the electropherograms will not be reliably identified and result in a false homozygous genotype. DNA sequencing requires less modification in response to new alleles than other methods and is a powerful and general way of performing allele-level typing.

The very large number of alleles and the patchwork patterns of polymorphisms clustered within a few exons make setting the phase of linked polymorphisms difficult and results in “ambiguous” typing results, i.e., data that are consistent with many different possible genotype assignments. Resolving these ambiguities with current techniques can be cumbersome, time-consuming, and expensive. One approach to reducing genotype ambiguity and achieving high-resolution HLA typing is to use the massively parallel clonal sequencing strategies of next-generation sequencing (NGS) systems. Current typing methods, including Sanger sequencing, yield ambiguous typing results because of incomplete genomic coverage and inability to set phase for HLA allele determination. When coupled with new softwares, NGS systems can provide very high-resolution HLA genotyping. High-throughput genotyping can be achieved by use of primers with multiplex identifier tags to allow pooling of the amplicons generated from different individuals prior to sequencing. NGS combines the advantage of long-range amplification and the power of high-throughput sequencing platforms. Overall, this technology has the capacity to deliver low-cost, high-throughput, and accurate HLA typing by multiplexing thousands of samples in a single sequencing run. Several strategies have been used; the first is an amplicon sequencing approach focused primarily on the exons of HLA class I and class II genes including HLA-A, HLA-B, HLA-C, DPB1, DQA1, DQB1, DRB1, DRB3, DRB4, and DRB5 (DRB3/4/5). Another strategy uses a long-range PCR of the entire HLA class I gene followed by fragmentation, shotgun sequencing, and assembly for a few samples on the first available NGS platform, the Roche GS 454 system (support for the GS 454 system is being phased out). Later, the Illumina (MiSeq) and Ion Torrent (PGM, Proton) platforms have been used for both of these approaches [49, 50]. A third strategy uses the Pacific Biosciences single-molecule real-time (SMRT) system to provide sequencing of entire long-range HLA PCR products, potentially generating complete allele-level genotypes for both HLA class I and class II genes [51].

In the targeted amplicon sequencing strategy, NGS permits phasing of polymorphisms within the amplicon but does not phase distinct amplicons. Genotyping ambiguity due to phasing can be eliminated using a bioinformatic approach wherein genotyping software considers all possible combinations of allelic amplicon sequences at various exons and compares these to the IMGT/HLA Database. However, this approach assumes that a potential genotype assignment with novel alleles that are absent from the database is extremely rare. Strategies that use a long-range PCR of the entire HLA gene can set phase for linked polymorphisms by shotgun assembly of overlapping short sequence reads and paired-end reads of fragments derived from the long-range amplicon. Phase can be set directly by long-read sequencing on the PacBio platform of the entire long-range HLA amplicon.

The use of clonal sequencing such as NGS has produced a large amount of novel HLA sequences including noncoding sequence. Polymorphisms located in these noncoding sequences (synonymous substitutions and intronic and flanking sequence) may have important biological function influencing gene expression. In addition, these polymorphisms can distinguish otherwise identical HLA haplotypes and contribute to disease association and population genetic analyses.

Other Methods

Nontargeted HLA typing: High-resolution HLA typing can be inferred from whole-genome sequences or whole-exome sequences using bioinformatics and software algorithms. Furthermore, the entire 4–5 Mb HLA region has been targeted by hybrid capture with probe panels. HLA types can also be imputed from SNP genotyping data. Typically, the HLA region SNPs used for HLA imputation are not in the HLA genes themselves. The imputation algorithms are based on LD between the SNPs and the sequence variants in the exons of HLA class I and class II genes. The accuracy of these imputation algorithms is highest when the training samples and the test samples come from similar ethnic populations. In general, the HLA typing performance of these imputation systems is high (>98 % concordance) at the single-field level and somewhat less accurate at the two-field level.

Early in the development of DNA-based HLA typing, restriction fragment length polymorphism (RFLP) analysis was employed. This approach declined in importance as laboratories realized that the complexity and number of HLA alleles outstripped the power of RFLP analysis. Reference strand conformation analysis is a method employing the analysis of heteroduplexes prepared by mixing PCR products from the tested individual with those prepared from a reference allele. The migration of the heteroduplexes is assessed on an acrylamide gel and compared to a library of migration profiles [6]. HLA alleles are likely to have unique migration patterns, especially when tested with several reference alleles. This is a fairly rapid method and is a simple and elegant way to assess whether a donor and a recipient are identical at a locus. Rare alleles not represented in the library with known migration patterns are difficult to identify.

Interpretation and Reporting of Test Results

HLA Nomenclature

HLA nomenclature and convention of HLA allele naming are shown in Table 58.4 and illustrated in Fig. 58.3. The alleles of each of the HLA genes are numbered based on the original serologic nomenclature. HLA alleles are designated by a superscripted asterisk after the locus of origin and a number corresponding to the particular allele (e.g., HLA-A*02:01). The parallel testing using serologic and DNA genotyping of HLA alleles has led to the use of one nomenclature for the description of low-resolution typing where the HLA assignment might include more than one possible related allele (e.g., HLA-A A2) and a nomenclature reflecting the high-resolution allelic typing. Thus, different HLA allele subtypes (e.g., for A2) can appear indistinguishable when tested by serology or with a limited panel of nucleic acid probes, so a generic or low-resolution typing is obtained. The naming of new HLA alleles is decided by an international nomenclature committee; however, the workshop prefix "w" and other designations often precede formal naming by the international nomenclature committee. As a result, the literature can be confusing for the uninitiated. Another feature of the nomenclature is the Bw4 and Bw6 specificities.

Table 58.4 Nomenclature of HLA alleles

Nomenclature	Indication
HLA	The HLA region and prefix for an HLA gene
HLA-DRB1	A particular HLA locus, i.e., DRB1
*HLA-DRB1*13*	A group of alleles that encode the DR13 antigen or sequence homology to other DRB1*13 alleles
*HLA-DRB1*13:01*	A specific HLA allele with a unique protein sequence
*HLA-DRB1*13:01:02*	An allele that differs by a synonymous mutation from DRB1*13:01:01
*HLA-DRB1*13:01:01:02*	An allele that contains a mutation outside the coding region from DRB1*13:01:01:01
*HLA-A*24:09N*	A "null" allele, an allele that is not expressed
*HLA-A*30:14L*	An allele encoding a protein with significantly reduced or "low" cell surface expression
*HLA-A*24:02:01:02L*	An allele encoding a protein with significantly reduced or "low" cell surface expression, where the mutation is found outside the coding region
*HLA-B*44:02:01:02S*	An allele encoding a protein that is expressed as a "secreted" molecule only
*HLA-A*32:11Q*	An allele that has a mutation that has previously been shown to have a significant effect on cell surface expression, but where this has not been confirmed and its expression remains "questionable"

Table adapted from a table kindly provided by Prof Steven Marsh, Anthony Nolan Research Institute, London, United Kingdom (www.hla.alleles.org)

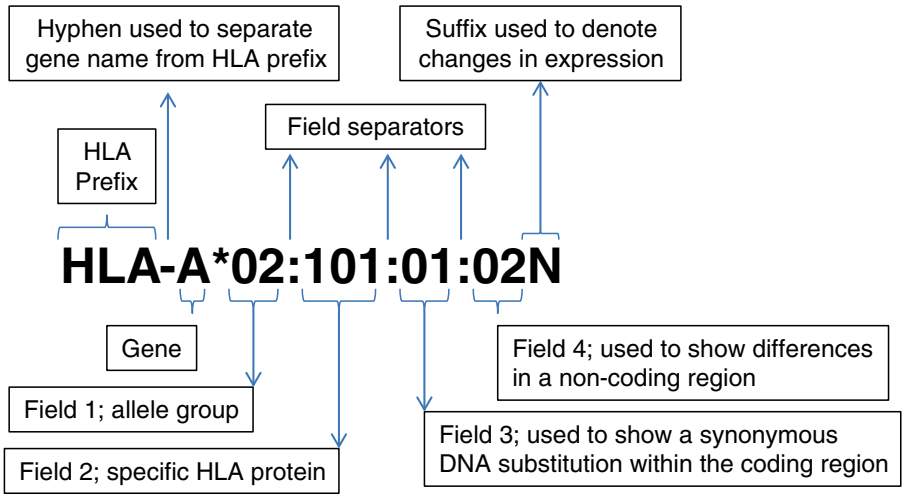

Figure 58.3 Convention for HLA allele naming (This figure was adapted from one kindly provided by Prof Steven Marsh, Anthony Nolan Research Institute, London, United Kingdom [www.hla.alleles.org])

All HLA-B alleles encode one of two possible epitopes located on the alpha 1 helix that were originally defined by serology as Bw4 and Bw6 specificities. The "w" prefix is retained in this case to distinguish them from true HLA alleles. Annual HLA nomenclature reports with frequent updates are available at several Web sites (HLA Informatics Group, http://www.anthonynolan.org/clinicians-and-researchers/anthony-nolan-research-institute/hla-informatics-group, or IMGT/HLA Database, http://www.ebi.ac.uk/imgt/hla/).

Due to the complexity of the HLA system, a common language for histocompatibility terms is used to avoid misunderstanding and for accurately reporting HLA typing results. In early 2010, representatives from clinical, registry, and histocompatibility organizations joined together as the Harmonization of Histocompatibility Typing Terms Working Group to define a consensual language for laboratories, physicians, and registries to communicate histocompatibility typing information. The Working Group defined terms for HLA typing resolution, HLA matching, and a format for reporting HLA assignments [52]. These recommendations are summarized below.

Definitions of Typing Resolution

The following definitions of typing resolution are currently recommended; however, the field of HLA biology continues to evolve; thus, changes in terminology are likely to occur in the future.

Allelic Resolution

The DNA-based typing result is consistent with a single allele as defined in a given version of the World Health Organization (WHO) HLA Nomenclature Report as described on the reference Web site (http://hla.alleles.org). An allele is defined as a unique nucleotide sequence for a gene as defined by the use of all of the fields in a current allele name. Examples include A*01:01:01:01 and A*02:07 (designations based on the international ImMunoGeneTics [IMGT]/HLA Database version 3.1.0, July 2010) (Fig. 58.3 and Table 58.4.).

High Resolution

A high-resolution typing result is defined as a set of alleles that encode the same protein sequence for the region of the HLA molecule called the antigen-binding site and that excludes alleles that are not expressed as cell surface proteins.

Low Resolution

A DNA-based typing result at the level of the digits comprising the first field in the DNA-based nomenclature. Examples include A*01 and A*02. If the resolution corresponds to a serologic equivalent, this typing result also should be called low resolution.

Other Levels of Resolution

If high resolution cannot be obtained, or if the laboratory's agreement with the entity requesting the testing limits the typing efforts to a subset of alleles, the laboratory may report its results at a level of resolution that falls between high resolution and low resolution. Examples include consideration of only those alleles that are expected to be found in the local population or that are designated as common and well defined. A third example is typing that assigns a G group code for reporting ambiguous allele typings. HLA alleles that have identical nucleotide sequences across the exons encoding the peptide-binding domains (exons 2 and 3 for HLA class I and exon 2 only for HLA class II alleles) are designated by an uppercase "G" which follows the first 3 fields of the allele designation of the lowest numbered

allele in the group. The group designation contains three fields (e.g., A*02:01:01G). A computer-readable file of these codes, hla_nom_g.txt, is available to download at http://hla.alleles.org/alleles/g_groups.html.

Replacement of the Term "Confirmatory Typing"

Verification Typing

Verification HLA typing is performed on an independent sample (or, for a CBU, from an attached segment or from the unit itself) with the purpose of verifying concordance of the typing assignment with the initial HLA typing assignment for that unit. Concordance does not require identical levels of resolution for the two sets of typing but requires the two assignments to be consistent with one another.

Extended Typing

Extended HLA typing is performed to add additional information to an existing HLA assignment. The purpose of this additional HLA typing (1) may include assignments at additional HLA loci (e.g., to type HLA-C for an HLA-A-, HLA-B-, HLA-DRB1-typed volunteer donor) and/or (2) may include increased resolution at any previously typed HLA locus (e.g., to type an individual with HLA-B serologic assignments to identify the HLA-B alleles). For some cases, extended typing will fulfill requirements for verification typing at a particular locus. In these cases, a combined term "verification/extended typing" can be used.

Format for Reporting HLA Assignments

HLA typing assignments must be clearly understood by the end user. HLA laboratories should have a written agreement with each transplantation entity requesting HLA typing regarding the specifications for the typing. The agreement should include the loci to be tested, the level of resolution of the typing, and the format in which typing results will be reported. The typing assignments must conform with WHO nomenclature for factors of the HLA system (http://www.hla.alleles.org) and comply with other applicable international conventions (e.g., multiple allele code definitions as designated by the NMDP).

Unresolved Alternative Assignments

Best practice for reporting is to include all uncertainty in the typing assignment relevant to the level of resolution. This means that genotypes and/or alleles that have not been excluded should be listed in the report as not having been excluded. If it is not possible to provide a list of all unresolved alternatives on the report, the laboratory should indicate that alternative assignments exist and provide a rationale for the HLA assignment that is selected for inclusion in the report.

Reporting a String of Alleles

Slashes should be used to separate a string of alternative alleles (e.g., A*02:01/02:02/02:07/02:20 to mean A*02:01 or A*02:02 or A*02:07 or A*02:20). Based on resolution requirements, allele names might be truncated from the right; for example, A*02:01 is understood to include all silent substitutions, differences outside the coding region, and expression codes that begin with the digits 02:01.

Matching

Directionality of Match

The laboratory may wish to refer to directionality of the mismatch in cases where the patient or a potential donor is homozygous at a locus or has a nonexpressed allele. If the patient is homozygous and one of the HLA assignments is identical to an assignment of the heterozygous donor (e.g., patient A*01:01:01:01, potential donor A*01:01:01:01, A*23:01), the mismatch may be referred to as a mismatch in the host-vs-graft vector direction. If the potential donor is homozygous and one of the HLA assignments is identical to an assignment of the heterozygous patient, the mismatch may be referred to as a mismatch in the graft-vs-host vector direction.

Matching Within a Family

HLA Haplotypes Identical by Descent

This phrase may be used when (1) parental HLA assignments are available, (2) all four haplotypes are unequivocally defined in the family, (3) the HLA assignments of the parents are clearly distinguishable from one another, and (4) the assignments include HLA class I and class II loci to the extent that potential recombinations have been ruled out. The patient and potential donor who share both haplotypes may be described as HLA identical by descent.

HLA Identical for All Loci Tested

This phrase may be used to refer to matching of related donors who appear to share the HLA loci tested with the patient based on segregation within the family. This phrase would refer to matching in which not all HLA loci are tested (e.g., HLA-A, HLA-B, HLA-C, DRB1 typed, but not DQB1 or DPB1), so the possibility of recombination is not excluded.

Families Where Segregation to Confirm Identity by Descent Is Not Possible

When it is not possible to unequivocally define haplotypes, the phrases used to describe matching should be those used for an unrelated donor.

Matching of Patient to Unrelated Donor or Matching Within a Family Where Identity by Descent Cannot Be Ascertained

The report should indicate the number of loci tested, the potential identity of the assignments (e.g., 8/8, 7/8, or 9/10), and the level of resolution used to determine the potential identity (e.g., high resolution or low resolution).

Correlation of Serologic and Nucleic Acid-Based HLA Typing

The HLA Dictionary provides a list of WHO-assigned serologic designations and the actual serology test results for many alleles. For most of these alleles, the serologic types are known to correspond to the first field of the molecular type. For those molecular types for which no WHO assignment or serologic typing results are available, use of the one-field low-resolution type for conversion is appropriate. Most of the time, molecular typing gives clear results that can readily be interpreted, even when serologic typing is ambiguous. However, for many new alleles, the serologic equivalents have yet to be defined.

Conversion of HLA Molecular Types for UNOS Matching and Data Entry into UNet

For cadaveric kidney transplantation, matching at the antigen level still is considered the standard method by which donor kidneys are allocated through UNOS. UNOS provides a list of antigens that may be entered through UNet; this list forms the basis of the HLA-matching algorithm for cadaveric kidney and pancreas allocation (http://www.unos.org/). The list of antigens and criteria are reviewed annually. While molecular class I typing is more robust and more accurate than serologic typing, a definition of equivalent "antigens" is needed for the purpose of proper organ allocation. When allelic nomenclature was initiated, it was intended to reflect the existing serological nomenclature. Thus, for most types, low-resolution (one-field) class I molecular typing provides the appropriate serologic equivalent. However, as new alleles were discovered, names of alleles were derived based on nucleotide sequence similarities that did not always result in similar serology. Thus, in many cases, derivation of a serologic designation based on an interpretation of a molecular HLA type is difficult. The low-resolution molecular types B*15 and B*40 represent complex examples. The use of the B15, B40, or other broad antigen designation can cause incorrect donor–recipient "matching" and can render molecular typing less specific and less accurate than serologic typing for the purpose of organ allocation. Because of these complexities, UNOS has developed guidelines for assigning antigen equivalents (http:/www. unos.org/). UNOS standards require laboratories to report the correct serologic equivalents for the UNOS application to ensure the most appropriate allocation and to allow screening for unacceptable antigens.

Another problematic issue involves the molecular detection of serologically null alleles (see next section). For instance, a patient with the null variant of A24 could make an antibody to A24. A donor with A24 should not be considered to be a zero mismatch for a recipient with an A24 null allele. Ideally, null alleles should be identified either by use of parallel serologic typing or by use of molecular kits that identify null alleles. All confirmed null alleles should be entered as blanks.

Null Alleles

Most HLA alleles are defined by polymorphisms that are essentially missense mutations leading to amino acid substitutions. Null alleles are variants that result in reduced or absent expression of mature class I and II proteins on the plasma membrane. Null alleles generally result from either alterations at exon–intron boundaries that cause aberrant RNA splicing or nonsense mutations that lead to truncated polypeptides. Most of the null alleles occur within the HLA-A and HLA-B loci; however, they are found at other class I and II loci as well. The nucleic acid sequences that characterize some of these null alleles may not be in the genetic region normally targeted by DNA typing; thus, without serologic information, these null alleles may go undetected. However, once a null allele is identified by serology and characterized by nucleic acid sequencing to identify the reason for the lack of expression, the null allele readily can be detected in subsequent individuals by DNA testing procedures alone. Testing strategies that do not distinguish between a null allele and its closely related expressed counterpart can lead to clinically significant errors. Fortunately, the allele frequencies of most null alleles appear to be less than 0.001. However, exceptions occur: DRB4*01:03:01:02N is relatively common and C*04:09N is associated with the HLA-B*44:03 carrying haplotype in some ethnic groups. Laboratories providing HLA typing for NMDP transplant programs must distinguish common null alleles according to the NMDP policy: http://bioinformatics.nmdp.org/Policies/Policies.aspx.

New Alleles

Laboratories performing clinical HLA typing will encounter patients and donors who appear to have heretofore unknown alleles. New alleles can be observed at relatively high rates, particularly in indigenous populations [7] that have previously been poorly characterized for HLA polymorphism. New alleles may be suspected when SSP-PCR assays result in unexpected negative or positive reactions or reactions with products of unexpected size. Similarly, unusual SSO patterns for the panel of oligonucleotide probes used may indicate that a new allele is present. DNA sequencing assay results will indicate the presence of a nucleotide or nucleotides that have not previously been observed at a particular position in a library of known alleles. Finally, typings that indicate that an individual is heterozygous for two alleles that are each uncommon are sometimes alternatively explained by the presence of a known common allele and a new allele whose sequence is not present in a laboratory's library of known sequences. Since typing strategies often rely on heterozygous PCR products, determining which of the two identified alleles is new may not be possible. Thus, a method of isolating suspected new alleles in a hemizygous form via traditional cloning techniques, allele-specific amplification, or single-allele amplification is necessary for unambiguous characterization. The sequences of potential new alleles should be communicated to GenBank to obtain accession numbers and then to the IMGT/HLA Database (http://www.ebi.ac.uk/imgt/hla/). The WHO HLA Nomenclature Committee will review the data submitted and assign the allele a unique number. The IMGT will display an authoritative sequence for the allele and information about the ethnicity and HLA alleles identified at other loci in the individual with the new allele. With the use of clonal sequencing such as NGS, the identification of allelic diversity is rapidly growing and the IMGT database is becoming populated with entire gene sequences. Consequently, the number of rare sequence variants and the proportion of non-"common and well-defined" alleles are expected to expand dramatically.

HLA Typing Problems

Ambiguities

Two major sources of ambiguity in HLA typing are polymorphisms outside the gene regions targeted by testing and the lack of information about phase in heterozygous individuals. Many laboratories choose tests designed to analyze exon 2 of class II genes and exons 2 and 3 of class I genes, since these regions include most of the known polymorphisms and encode domains that interact with bound peptides; however, polymorphisms occur in other exons as well. When a method does not test for a possible polymorphism, the typing is necessarily ambiguous. The laboratory should discuss with clients whether an ambiguity is likely to be clinically relevant, although the impact on transplant outcome of many known polymorphisms in other exons is unknown.

The second major reason for ambiguous typings derives from the fact that heterozygous typing data often is entirely consistent with two, three, or more possible pairs of alleles rather than just one allele pair. If the PCR products prepared include the sequences of both alleles in an individual and contain several heterozygous possibilities, identification of the cis/trans relationships of the heterozygosities may not be possible. These ambiguous heterozygous combinations can be solved in several ways. Allele-specific amplification leading to PCR products from one of the two alleles will resolve ambiguities. Family studies will resolve heterozygosity ambiguities, if appropriate relatives are available for testing. Traditional cloning techniques are a general solution but are time-consuming and labor-intensive. Single-allele amplification is a general and rapid, but expensive solution.

Recombination

The fact that recombination within the MHC sometimes occurs during meiosis is discussed above. When recombination appears to have occurred within a family, interpretation of results can be difficult. Before concluding that recombination explains the results seen, laboratories should consider the possibilities of typing error and false paternity as alternatives.

False Paternity

HLA typing is a form of identity testing and may reveal false paternity when members of a family are tested. Some transplantation clinicians do not want to disclose to families before testing that discovery of false paternity is possible. The ethical considerations associated with this issue are complex. When results are consistent with false paternity, the findings can be discussed with the ordering healthcare provider verbally and the conclusion of nonpaternity not stated explicitly in the report.

Laboratory Issues

Quality Control

Controls

Laboratories find assembling a comprehensive array of positive controls for over 3,000 known class I and II alleles difficult or impossible. Most laboratories acquire examples of the more common alleles for use in quality control over time in the course of clinical and research typing. The NMDP and the American Society for Histocompatibility and Immunogenetics (ASHI) maintain a cell repository of a

subset of known alleles (http://www.ashi-hla.org/). If controls for an allele cannot be obtained, alternative approaches include testing reagents such as SSO probes with related targets that have an identical sequence at a site of interest. Since HLA alleles in aggregate form a combinatorial array of possible sequences in the polymorphic regions, there are generally many opportunities to use surrogate alleles as positive controls.

Contamination

Potential contamination of pre-PCR work areas and reagents with extraneous genomic DNA or previously amplified PCR products is a problem clinical histocompatibility laboratories face in common with other clinical molecular laboratories. Appropriate measures to prevent contamination have been widely described (see Chapter 62; such information is available at the ASHI Web site [http://www.ashi-hla.org/]). Testing for contamination arising from PCR products prepared in SSP-PCR may be difficult. The products prepared in the many reactions necessary to type an individual vary in size and composition so that a general way to test for their presence may be difficult to devise.

Certifications of Laboratories and Professionals

Clinical histocompatibility laboratories are high-complexity laboratories that must be licensed under CLIA.

Laboratories may be inspected and accredited by the College of American Pathologists (CAP) or by the ASHI, UNOS, NMDP, and CLIA, all have designated ASHI with deemed status for purposes of accreditation of clinical histocompatibility laboratories. Laboratories are generally directed by individuals with Ph.D. or M.D. degrees or both. ASHI administers a program to assess the qualifications of doctoral-level individuals to direct ASHI-accredited laboratories. Directors can be certified by examination administered by the American Board for Histocompatibility and Immunogenetics (ABHI). The ABHI also certifies laboratory staff as histocompatibility technologists and specialists (http://www.ashi-hla.org/). The National Credentialing Agency and the American Society for Clinical Pathology have certification programs in molecular pathology for technologists.

Proficiency Testing

Three proficiency testing programs for HLA typing are available in the USA. The CAP, the ASHI, and the Southeastern Organ Procurement Foundation offer comprehensive programs to assess the ability of laboratories to correctly identify HLA alleles. Proficiency testing samples are typically peripheral blood samples for which laboratories can perform low-resolution or allele-level typing at one or several of the HLA class I and class II loci. These organizations also offer challenges for other histocompatibility laboratory tests such as crossmatching. Results from a number of years of DNA-based HLA allele identification proficiency testing challenges have demonstrated that participating laboratories generally achieve 90–100 % consensus. The University of California, Los Angeles (UCLA), has offered an international cell exchange program for many years. Laboratories are challenged to correctly type samples that often include unusual or recently described alleles. An important attribute of the UCLA cell exchange program is its ability to allow correlation of serologic and DNA-based results for a tested sample.

Abstract

High-throughput, massively parallel DNA sequencing, more commonly termed "next-generation sequencing," is an innovation in sequencing that emerged during the past decade. Next-generation sequencing (NGS) is not a single technology, but rather several different technologies that share a common feature of massively parallel sequencing of clonally amplified or single DNA molecules in a flow cell or chip. Inherent to NGS technologies are unique sequencing chemistries that differ from the Sanger dideoxynucleotide chain termination chemistry. NGS can generate, in a single instrument run, hundreds of millions to gigabases of nucleotide sequence data depending upon platform configuration, chemistry, and flow cell or chip capacity. This chapter describes principles of NGS and considerations for its application to clinical molecular tests. Although several NGS technologies have been commercialized, technologies finding greatest adoption into clinical laboratories are emphasized. Current clinical testing applications including multigene panels and exome and genome sequencing for candidate and causal gene identification are discussed. While the examples are primarily based on analyses for inherited disorders, the principles described are applicable to oncology and infectious diseases, with certain modifications mostly specific to the specimen characteristics and sensitivity requirements for these other applications.

Introduction

High-throughput, massively parallel DNA sequencing, more commonly termed "next-generation sequencing," is an innovation in sequencing that emerged during the past decade. Next-generation sequencing (NGS) is not a single technology, but rather several different technologies that share a common feature of massively parallel sequencing of clonally amplified or single DNA molecules in a flow cell or chip. Inherent to NGS technologies are unique sequencing chemistries that differ from the Sanger dideoxynucleotide chain termination chemistry. NGS can generate, in a single instrument run, hundreds of millions to gigabases of nucleotide sequence

data depending upon platform configuration, chemistry, and flow cell or chip capacity. This chapter describes principles of NGS and considerations for its application to clinical molecular tests. Although several NGS technologies have been commercialized, technologies finding greatest adoption into clinical laboratories are emphasized. Current clinical testing applications including multigene panels and exome and genome sequencing for candidate and causal gene identification are discussed. While the examples are primarily based on analyses for inherited disorders, the principles described are applicable to oncology and infectious diseases, with certain modifications mostly specific to the specimen characteristics and sensitivity requirements for these other applications. To address the space limitations of a chapter, the authors refer the reader to references and reviews that provide greater detail where appropriate.

Instrumentation

Conceptualization and instrument prototyping for the first NGS instruments began in the late 1990s and early 2000s. In 2005, the first commercial NGS platform, designated the GS-20, was launched by 454 Life Sciences, a company founded by Jonathan Rothberg. Shortly thereafter, the first NGS publication, authored by Margulies and colleagues, reported sequencing the entire 580,069 bp genome of *Mycoplasma genitalium* at 96 % coverage and 99.96 % accuracy in a single GS-20 run [1]. In 2007, Roche Applied Sciences acquired 454 Life Sciences and introduced the second version 454 instrument, the GS FLX. As the initial commercialized NGS technology, a review of 454 technical principles is historically important and illustrative as its workflow is relevant to other NGS technologies.

The first step for sequencing on the 454 is to generate a "library" of overlapping DNA fragments from genomic DNA. The most popular fragmentation method employs an acoustic wave-based technology commercialized by Covaris (Woburn, Massachusetts) in which a tube of genomic DNA in solution is placed in the Covaris water bath chamber and subjected to bursts of ultrasonic frequencies (>400 KHz) transmitted via very short wavelengths (~3 mm). Burst intensity and duration can be independently programmed resulting in a tunable fragment size distribution suitable for NGS (typically a few hundred base pairs (bp) in length depending on NGS platform requirements). After DNA fragmentation, fragment ends have overhangs which are enzymatically repaired to blunt ends prior to ligation to 454-specific adapter oligonucleotides required for downstream processes (see Fig. 59.1).

Once generated, the overlapping fragment library is subjected to a clonal amplification step using emulsion PCR (ePCR). Under limiting dilution concentrations, the library is denatured and hybridized to individual beads whose surfaces contain capture oligonucleotides with sequences complementary to the adapter oligonucleotides. The beads are then mixed with PCR buffer components and biotinylated primers in conjunction with oil and surfactant under limiting dilution conditions to create individual water-in-oil microvesicles containing single beads with hybridized library fragments. The emulsion is subjected to PCR during which clonal expansion of single DNA molecules bound to individual

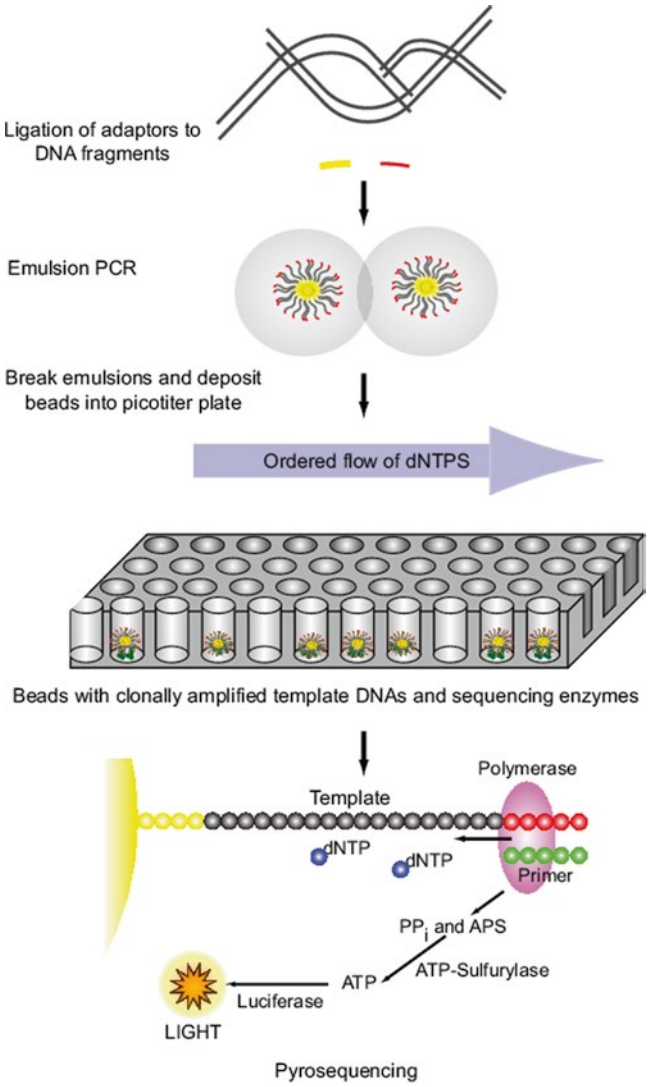

Figure 59.1 Roche 454 GS FLX sequencing. Template DNA is fragmented, end repaired, ligated to adapters, and clonally amplified by emulsion PCR. After amplification, the beads are deposited into picotiter-plate wells with sequencing enzymes. The picotiter plate functions as a flow cell where iterative pyrosequencing is performed. A nucleotide-incorporation event results in pyrophosphate (PPi) release and luminescence localized to the plate wells. *APS* adenosine 5′-phosphosulfate. From Karl V. Voelkerding, Shale A. Dames, and Jacob D. Durtschi. Next-Generation Sequencing: From Basic Research to Diagnostics. Clinical Chemistry 2009; v. 55, p. 641–658. beads occurs. After amplification, the emulsion is disrupted, and beads containing clonally amplified template DNA are enriched by a streptavidin hybridization step, removing the majority of beads without clonal amplicons.

The 454 technology introduced the concept of sequencing clonal amplicons in a flow cell. Specifically, the 454 flow cell is referred to as a "picotiter" plate and is made from a fused fiber-optic bundle into which millions of individual wells are etched into the surface. Beads containing clonal amplicons are deposited into individual picotiter wells that contain enzymatic components for pyrosequencing with luminescence signal generation. When loaded into the GS FLX instrument, the picotiter plate functions as a flow cell wherein iterative pyrosequencing is performed by successive microfluidic addition of polymerase and dNTPS (i.e., A followed by C, then G, then T, etc.). A nucleotide-incorporation event in a well containing a clonally amplified template results in pyrophosphate release, and the luminescence generated in the well is transmitted through the fiber-optic picotiter plate and recorded by a charge-coupled device (CCD) camera. With each dNTP reagent flow, wells are imaged and analyzed for signal-to-noise parameters. The collected data is algorithmically translated into a linear sequence output. One of the recognized strengths of the 454 technology is the progressive increase in sequencing read lengths that have been achieved, beginning with 100 base length reads on the GS-20 that have now been extended up to 1,000 bases.

In 2006, the second NGS technology, termed Solexa, was introduced onto the market. Review of this technology is essential as it is now the dominant NGS method [2]. In 1997, Shankar Balasubramanian and David Klenerman conceived of an approach to sequence single DNA molecules attached to microspheres, and in 1998 they founded Solexa. The goal of sequencing single DNA molecules was not achieved, and Solexa elected to pursue sequencing of clonally amplified templates. By 2006, the Solexa Genome Analyzer was commercialized and Illumina acquired Solexa.

The Genome Analyzer utilized a flow cell comprised of an optically transparent slide with eight individual microfluidic lanes on which oligonucleotide anchors are bound to the slide surface. As with the 454 method, genomic template DNA first is converted into a randomly overlapping fragment library using either Covaris fragmentation followed by enzymatic end repair and Illumina adapter ligation, or via Nextera transposition (described below). As shown in Fig. 59.2, the fragment library is denatured and, under limiting dilution conditions, is added to the flow cell and immobilized by hybridization to the oligonucleotide anchors. In contrast to ePCR, DNA templates are amplified by an isothermal "bridge" amplification method mediated by formamide denaturation that relies upon captured DNA strands "arching" over and hybridizing to an adjacent anchor oligonucleotide. Multiple amplification cycles result in conversion of single-molecule DNA templates to clonally amplified arching clusters with each cluster containing approximately 1,000 clonal DNA molecules. For sequencing, clusters are denatured, and then a chemical cleavage reaction and wash are conducted, leaving only forward strands for single end sequencing. Sequencing of the forward strands is initiated by hybridizing a primer complementary

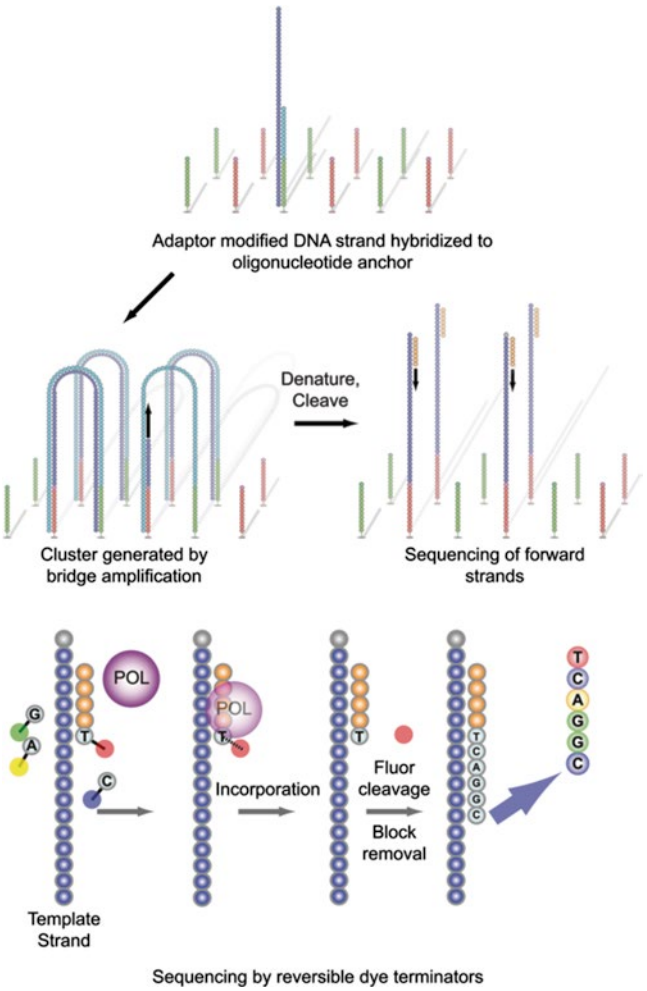

Figure 59.2 Cluster generation and sequencing on the Illumina platform. Denatured, adapter-modified DNA library fragments are hybridized, under limiting dilution concentrations, to complementary oligonucleotide anchors immobilized on the flow cell surface. Bridge amplification generates clonal clusters, which are subsequently cleaved to form single strands. Sequencing primer is annealed, and four uniquely fluorophore-labeled reversible dye terminators and polymerase (POL) are added during each sequencing cycle. Prior to initiation of the next sequencing cycle, the fluorescence signal of the incorporated base is optically recorded, and the fluorophore and termination block is cleaved and washed away. Sequencing is progressive and cyclical, and the read length is dependent on the number of sequencing cycles. From Karl V. Voelkerding, Shale A. Dames, and Jacob D. Durtschi. Next-Generation Sequencing: From Basic Research to Diagnostics. Clinical Chemistry 2009; v. 55, p. 641–658. Reproduced with permission from the American Association for Clinical Chemistry

to adapter sequences followed by addition of polymerase and a mixture of four uniquely labeled, fluorescent "reversible" chain terminating nucleotides. The dye-labeled nucleotides are incorporated according to sequence complementarity in each strand in a clonal cluster. After incorporation, excess reagents are washed away, the clusters are optically interrogated, and fluorescence is recorded. With subsequent chemical steps, the chain termination moiety and fluorescent labels are removed and washed away, allowing for a next sequencing cycle to be performed. Initial read lengths with Solexa/Illumina were 36 bases but are currently 300 bases. In addition, Illumina developed a "turnaround chemistry" that allows sequencing of clonal clusters in the opposite strand direction, resulting in bi-directional sequencing of templates.

Recently, Illumina acquired an alternative library preparation method termed Nextera (developed by Epicentre, Madison, Wisconsin) [3]. This approach fragments DNA and introduces adapter sequences in a process termed "tagmentation." A transposase enzyme is complexed with a transposon, which is modified to contain Illumina-specific adapter sequences. DNA is fragmented to a desired size distribution by optimization of the enzyme concentration and incubation time, and then adapter sequences are inserted at the cut site. The Illumina adapter-tagged fragments are then PCR amplified with tailed primers containing sequences for annealing on the Illumina flow cell, sequencing, and optional indexing (or barcoding) to uniquely label all fragments of each library. Indexing multiple libraries allows for pooling to leverage instrument capacity and reduce per sample costs. Most library preparation methods currently require an input of one to several micrograms of genomic DNA, whereas the Nextera technology requires only 50 nanograms of input genomic DNA, which is a sufficient quantity to assure adequate library complexity.

The introduction of the 454/Roche and Solexa/Illumina technologies began a paradigm shift in the biomedical research community. Many complex genomic studies that were previously either cost prohibitive or not technically feasible by the Sanger sequencing were now possible using NGS. Additional NGS technologies were subsequently commercialized including clonal amplicon-based sequencing by ligation (SOLiD/Life Technologies) and fluorescence-based single-molecule sequencing methods introduced by Helicos and Pacific Biosciences. As of this writing, several NGS technologies that were commercialized are either being phased out (454/Roche) or have been abandoned (SOLiD and Helicos), primarily due to insufficient market share. The research community has continued to use the Pacific Biosciences platform due to its ability to generate several thousand base length reads, a feature that has gained traction in the microbial genome sequencing community. However, a relatively high sequence read error rate (~10 %) and an approximate $750,000 platform cost have thus far precluded its entry into clinical use. In 2014, the first single-molecule sequencing technology utilizing engineered protein nanopores was introduced by Oxford Nanopore Technologies. The nanopores are embedded in a membrane in a buffer with an applied electrical field. As strands of DNA pass through the nanopore, they cause a nucleotide base-dependent change in current which is registered and algorithmically converted to sequence. In its first commercial iteration, the Oxford Nanopore platform is handheld in size (MinION), and its first applications have been focused on microbial genome sequencing. The sequence read lengths are on the order of several thousand bases; however, they display substantial error rates (>5 %). At present, considerable effort is ongoing to develop bioinformatic algorithms capable of processing and analyzing sequencing reads generated by the MinION. For more detail on Pacific Biosciences and Oxford Nanopore, the reader is referred to other reviews describing these methods [4–6].

The most recently commercialized and clinically adopted NGS technology, termed Ion Torrent Thermo Fisher Scientific (Waltham, MA) (launched in 2011), also was developed by Jonathan Rothberg (founder of 454) [7]. The sample preparative workflow is quite similar to the 454 technology in that template DNA is converted to an overlapping fragment library and clonally amplified on beads. The flow cell is a chip manufactured from semiconductor material with a high-density micron-scale well pattern etched into its surface. Underlying the well layer is a proprietary ion-sensing technology comprised of a sensing layer and a pattern of photolithographic generated transistors and circuits that can monitor ionic changes in individual wells. Sequencing of clonally amplified library fragments is conducted by an iterative, sequential flow introduction of the four natural nucleotides and polymerase. In contrast to measuring pyrophosphate release, hydrogen ion liberated during nucleotide incorporation and phosphodiester bond formation is registered by the ion sensing mechanism. If three identical adjacent bases on a template are being sequenced (e.g., a TTT homopolymer), the approximate tripling of hydrogen ion liberated generates an approximately tripled ion signal and is interpreted as a three-identical-base incorporation. Currently, the Ion Torrent technology is capable of generating 400 base length reads. In comparison to 454 and Illumina, sequencing speeds are significantly faster with Ion Torrent because there is no requirement for generating luminescence or monitoring fluorescence with subsequent chemical reversal of chain termination. Table 59.1 shows a comparison of 454, Illumina, and Ion Torrent platforms including chemistry, current read lengths, error propensity, and error rates. For additional comparative details, the reader is referred to recent reviews [5, 8–10]. Next discussed are fundamentals of NGS bioinformatics.

Table 59.1 NGS platforms and specifications

Platform	Template preparation	Chemistry	Read length[a]	Run time[b]	Throughput[c]	Primary errors	Error rates[d]
Roche 454							
GS Junior	ePCR	Pyrosequencing	400	10 h	35 Mb	Indel	~1
GS FLX+	ePCR	Pyrosequencing	700–1,000	23 h	700 Mb	Indel	~1
Illumina							
MiSeq	Bridge amplification	Reversible dye terminators	36–250	4–40 h	600 Mb–8 Gb	Substitution	~0.5–1
HiSeq 2000	Bridge amplification	Reversible dye terminators	100	11 days	600 Gb	Substitution	~0.5–1
HiSeq2500 Rapid Run Mode	Bridge amplification	Reversible dye terminators	150	27 h	120 Gb	Substitution	~0.5–1
Ion Torrent							
PGM	ePCR	Hydrogen ion sensing	100–200	2.5–4.5 h	500 Mb–1 Gb	Indel	~0.5–2
Proton	ePCR	Hydrogen ion sensing	200	~4+ h	Up to 10 Gb	Indel	~0.5–2

Bioinformatics and Data Analysis

Sequence Reads and Base Quality Scores

For the 454 and Illumina methods, NGS raw data is comprised of luminescent or fluorescent images, respectively, recorded after each iterative sequencing step. Each platform has its own algorithm for image processing, image compilation, signal-to-noise ratio assessment, and conversion into linear sequence. Nucleotide bases are assigned individual "quality" scores which share a conceptual analogy to Phred scores introduced in 1998 for estimating accuracy and quality of the Sanger sequence data [11, 12]. A Phred score provides quality values, q, using a mathematical scale converting the estimated probability of an incorrect call, e, to a log scale:

$$q = -10 \cdot \log_{10}(e)$$

Miscall probabilities of 0.1 (10 %), 0.01 (1 %), and 0.001 (0.1 %) yield increasing confidence Phred scores of 10, 20, and 30, respectively. Factors that contribute to lower quality bases in NGS include nonoptimal signal-to-background noise levels, cross talk between signals from adjacent beads or clusters, and a phenomenon termed dephasing due to unequal extension of individual reads in a clonal cluster or on a bead surface [13]. The signal output from Ion Torrent is a change in pH, and obtaining optimal signal-to-background pH ratios requires careful control of reagent pH. As with the 454 and Illumina methods, Ion Torrent signals are converted to linear sequence with quality scores assigned to individual bases. While each platform has a unique signal-to-sequence processing algorithm, instrument-specific sequence files are convertible to a common text-based file format termed FASTQ that contains sequence reads and individual base quality scores.

Sequence Mapping, Alignment, and Variant Calling

FASTQ-formatted sequence reads are used for two major computational purposes: assembly and alignment. Assemblies are performed when no reference genome exists for the sequenced DNA, an example being a previously uncharacterized pathogen. Assembly algorithms search for overlapping sections of sequence reads and join them together to generate longer length "contigs" that serve as a scaffold for genome assembly and subsequent alignments. To achieve more complete assemblies, longer sequence read lengths and sequencing from both ends of library fragments (termed paired-end read sequencing) are desirable. For most clinical applications, however, reference genomes exist (e.g., the human genome reference or a previously sequenced pathogen), and the primary computation is alignment of reads to the reference sequence. The unique features of NGS, notably shorter read lengths and massive read numbers, have spurred the development of many new alignment, variant calling, and annotation algorithms. While the reader is referred to a recent review on the topic of NGS bioinformatics [14] for greater details, major process steps are described next (shown in Fig. 59.3).

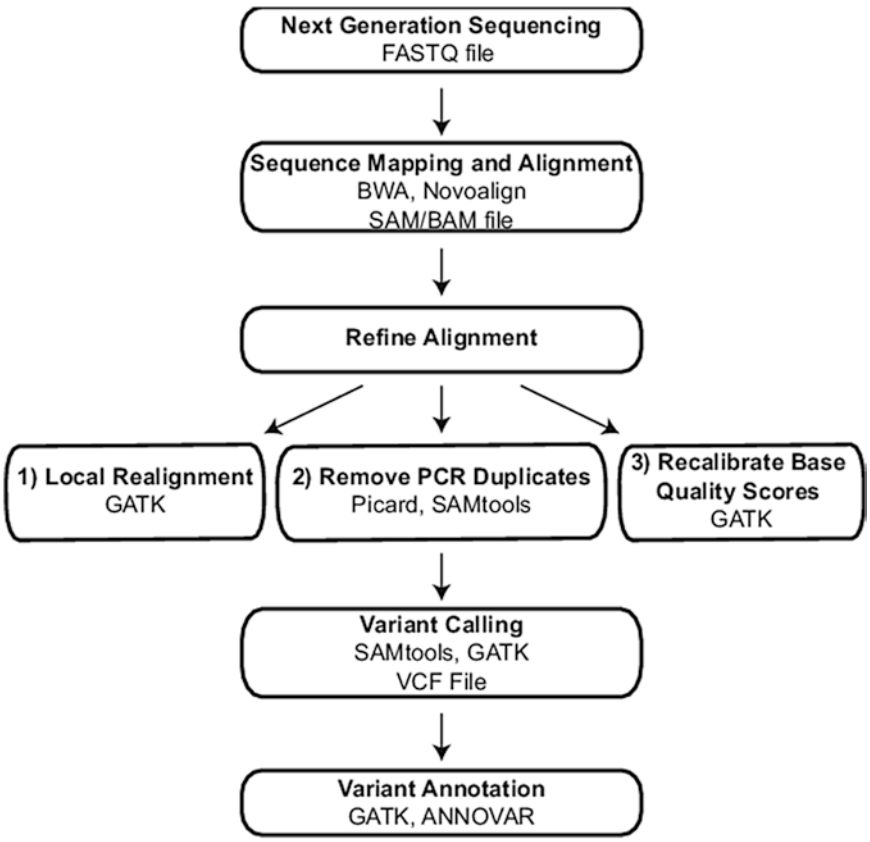

Figure 59.3 Exome and genome bioinformatic processing steps. Sequential steps required to generate an annotated variant list from exome and genome raw sequencing data are indicated in *bold*. For each step, programs used in the authors' laboratory are listed along with the file type that is generated, where applicable. *BWA* Burrows-Wheeler Aligner, *GATK* Genome Analysis Toolkit, *VCF* Variant Call Format. Alignment is the process of determining the best match between the sequencing reads and the reference sequence. Due to the large number of sequence reads that must be processed, NGS alignment algorithms typically employ one of two approaches to decrease computational time, and these include a data compression method referred to as a Burrows-Wheeler Transform (BWT) and a method based on the concept of a hash table. The BWT approach is integral to the popular open-source Burrows-Wheeler Aligner (BWA) algorithm that has become a standard for sequence alignment [15–17]. For hash table-based alignment, a first step is conversion of the reference sequence or the sequence reads into a population of shorter length sequences (termed an index), in which each sequence is given a read identifier that can be computationally tracked. By using indexes of shorter length (referred to as "seeds"), alignments proceed more rapidly [14]. An example of a popular aligner that utilizes a hash table function to create an index from the reference genome is NovoAlign (Novacraft, Selangor, Malaysia) [18]. For both BWT and hash table-based aligners, key criteria for initial mapping and alignment are established, including the number of nucleotide mismatches permitted across a given read or seed length and whether gaps in alignment are allowed to accommodate insertions and deletions (indels). With initial criteria applied, a first mapped and aligned read data set is generated. This data set is known to contain inaccuracies, and therefore additional algorithms are used to yield a more refined and accurate final set of alignments as described below.

Most alignment algorithms can provide results in a sequence alignment/map (SAM) file format, which contains information about read position and orientation in relationship to the reference sequence and confidence in the alignment. A binary version of SAM is the BAM format, and the SAM/BAM formats are the most commonly used file formats for storing and secondary manipulation of read alignments. After initial alignment, SAM/BAM files are used as inputs into secondary algorithms that refine and increase alignment accuracy prior to identifying differences between the sequencing reads and the reference sequence, a process referred to as variant calling. Popular open-source software for refining alignments and calling variants are the Genome Analysis Toolkit (GATK) [19] and SAMtools [20]. Algorithms within the GATK program are the most widely used for refining Illumina reads. Three major refinement steps are (1) marking and removal of reads with the same start and end points, referred to as PCR duplicates; (2) local realignment to improve accuracy in identifying indels; and (3) recalibration of base quality scores. PCR duplicates arise from sequencing identical fragments generated by PCR during library preparation. PCR nucleotide errors can be introduced

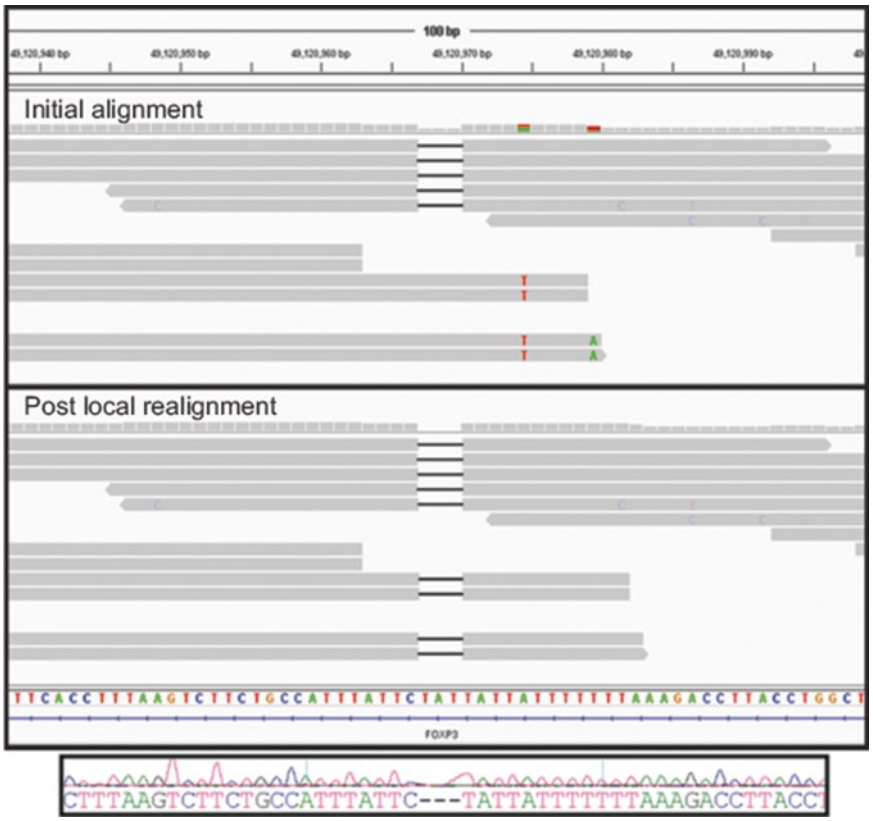

Figure 59.4 Generating refined alignments. Local realignment of an indel from a genome sequenced on the Illumina HiSeq 2000 and visualized in the Integrative Genomics Viewer is shown. The *upper panel* shows results from initial mapping and alignment of reads with an apparent 3 base pairs (bp) deletion in the *FOXP3* gene on the X chromosome of a male. In the *upper panel*, four reads contain the deletion (depicted by *black bars* within the read) and four reads do not contain the deletion. In the four reads that do not contain the deletion, six flanking single-nucleotide variants (SNVs) are present (T variant in *red* and A variant in *green*). The initial alignment suggests heterozygosity for the deletion on the X chromosome, but this is unlikely given that the sequence reads are derived from a male. The lower panel shows results after local realignment in which all reads contain the 3 bp deletion. In addition, flanking, false-positive SNVs are no longer present. The Sanger sequencing trace shown below confirms the deletion and zygosity of the g.49120967_49120971delTAT deletion. Reprinted from Coonrod EM et al. (2013). Developing Genome and Exome Sequencing for Candidate Gene Identification in Inherited Disorders. Arch Pathol Lab Med. Volume 137(3): 415–433 with permission from Archives of Pathology & Laboratory Medicine. Copyright 2013. College of American Pathologists

and propagated through unequal amplification of fragment library templates, and these errors can manifest as false-positive variants. During removal of PCR duplicates, only a single read with overall highest base qualities is retained for analysis. The purpose of recalibrating base quality scores is to compensate for the fact that the Phred-like quality scores generated by the Illumina platform have been demonstrated to deviate from the true error rate. Figure 59.4 shows an example of how local realignment improved the accuracy of detecting a 3 bp deletion in the *FOXP3* gene. The mapped and aligned reads are visualized in the open-source Integrative Genomics Viewer (IGV) [21, 22]. Subsequent to initial and refined alignment steps, variants are called and tabulated in the Variant Call Format (VCF) File that contains variant chromosomal position, reference base, and the alternate base(s) (e.g., single-nucleotide variant (SNV), indel).

Coverage and Variant Calling

By virtue of NGS libraries being comprised of randomly overlapping fragments, multiple reads align to the reference in a staggered fashion. This multiplicity provides quantitative information reflected in the number of reads aligned to the reference sequence at a given location and is designated as read coverage depth. Another feature of randomly fragmented libraries is that fragments are sequenced in both directions to yield forward and reverse strand sequences, and ideally their percentages should be approximately equal. If a variant is present, then the percentage of reads that contain the variant can be expressed as an "allelic read percentage," and the number of forward and reverse sequence strands containing the variant can be enumerated. Figure 59.5 shows a representative example of a heterozygous

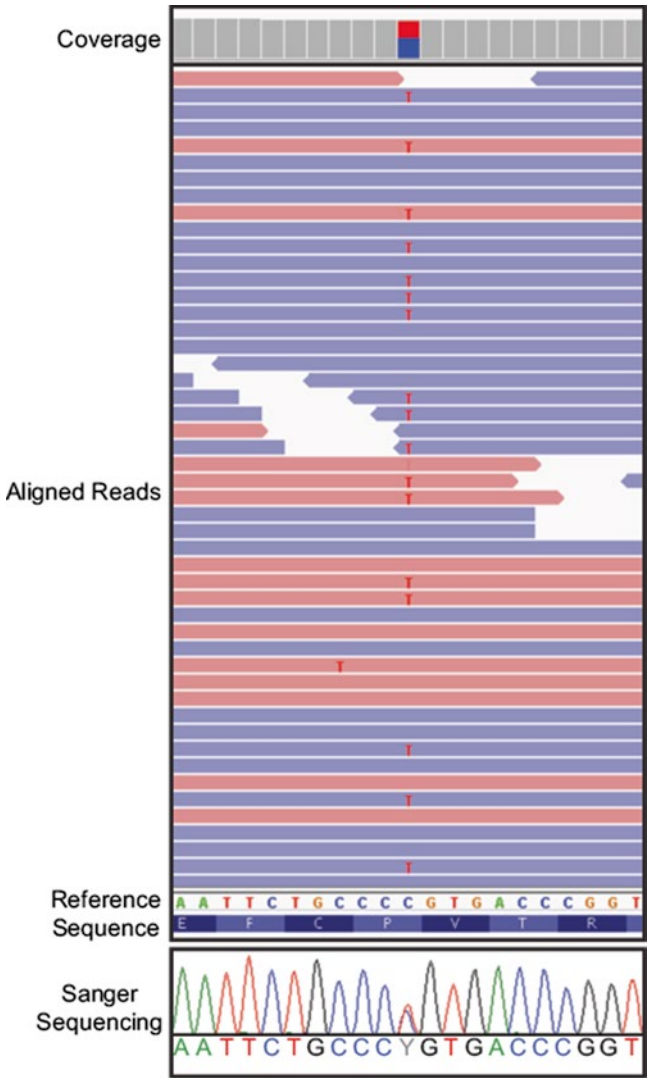

Figure 59.5 Example view of mapped and aligned Illumina reads in a genome browser. A screenshot of the *ZRSR2* gene from the Integrative Genomics Viewer is shown. Relative height of the gray boxes at the top indicates read coverage depth (Coverage). Mapped and aligned reads in the forward direction are shaded *red*, while reads aligning in the reverse direction are shaded blue (Aligned Reads). Variants from the reference are highlighted by a unique color. Forty-nine of 245 reads from exome sequence generated using the NimbleGen SeqCap in-solution exome capture and run on the Illumina HiSeq 2000 are shown. A cytosine to thymine (C>T) variant change is present with the T variant highlighted in *red* in the aligned reads. The heterozygous change also is indicated in the coverage portion of the viewer, and in this case because the variant is a heterozygote, the box is split into two colors, *red* for the variant nucleotide (T) and *blue* for the reference nucleotide (C). This T variant is present in 46 % of reads, while the other 54 % of reads contain a C at this position. The T variant is present in both forward and reverse reads. The reference nucleotide sequence (Reference Sequence) is shown below the aligned reads along with the amino acid translation of the sequence. This region was sequenced by the Sanger sequencing to confirm the heterozygous (C>T) variant. The trace from this sequence is shown at the bottom (Sanger Sequencing)

SNV and illustrates the concepts of coverage and allelic read percentage. Several points and caveats are important when considering coverage and variant calling. First, greater variant calling accuracy is achieved when there is a consensus among aligned reads that agrees with predictions for the variant. For example, a sample with a heterozygous SNV would ideally display a 50/50 ratio of reads containing variant and reference nucleotides, and forward and reverse strand reads would be equivalently represented in both variant- and reference-containing reads. By extension, a homozygous variant would be expected to be present in 100 % of aligned sequences with equal representation of forward and reverse strands. In practice, a wider range of allelic read percentages for true heterozygous and homozygous variants is observed. Further, forward and reverse strand read percentages divergent from expected are commonly seen (referred to as "read strand bias"). These read strand biases arise from technical and bioinformatic sources including differential PCR amplification of library fragments, sequencing errors in difficult-to-sequence regions, and misalignment of related sequences (e.g., pseudogenes or highly homologous genes).

Second, the minimum number of reads required to call a variant has not been standardized and varies depending on application needs and sequencing platform accuracy (i.e., lower sequencing error rates require fewer reads to accurately establish a variant call). In the 1000 Genomes Project [23], coverage as low as four- to six-fold has been used in a large-scale screening mode, whereas in other research studies 20- to 30-fold coverage has been empirically found to offer a balance between sensitivity, specificity, and sequencing costs for detection of constitutional variants [24–26]. By extension, clinical laboratories are typically requiring a minimum of 20- to 30-fold coverage for the detection of constitutional variants and are often designing diagnostic assays so that much higher coverages are routinely obtained in an effort to increase variant detection and improve variant call confidence.

Third, coverage depth across sequenced regions is variable, and factors that contribute to this are differential ligation of adapters to fragments during library preparation and differential amplification during clonal expansion [27]. NGS assays can be designed to achieve sufficient sequencing to meet clinically necessary minimum coverage for areas prone to lower coverage.

Fourth, whereas the above noted 50/50 and 100 % ratios are pertinent to identifying constitutional heterozygous and homozygous variants, respectively, they do not apply when identifying somatic variants in cancer samples comprised of a mixture of tumor and normal cell populations (where allelic read percentages for true somatic variants of interest can be

quite low), as well as for tumor heterogeneity in which not all tumor cells have acquired the same variants. To identify low allelic read percentage somatic variants, increased read coverage in the several hundred- up to thousand-fold range are being applied empirically for clinical testing [28, 29]. In sum, multiple variables ultimately need to be considered in variant calling, and more sophisticated algorithms are beginning to emerge for the detection of variants in both constitutional and somatic testing applications. For example, the open-source GATK program factors in coverage depth, read bias, recalibrated base quality scores, and variant prior and posterior probabilities based on comparison to control samples. In combination, these factors are used by GATK to generate statistical measures that predict variant accuracy and generate a "refined" VCF file.

Annotation

A final step is to input the VCF file information into an "annotation" program that ascribes additional features to variants. Open-source software that contain annotation functions are ANNOVAR [30, 31], GATK, and snpEff [32], among others. Annotation outputs can include many features, but those that are common are chromosomal location of base change from reference, whether the variant is in a gene and its respective location (e.g., exon, intron, splice site), the consequence of the change to a codon (e.g., synonymous vs nonsynonymous, missense vs frameshift), and zygosity (e.g., homozygous or heterozygous). Often incorporated into annotation software programs are algorithms that predict the functional impact of variants on proteins such as Sorting Intolerant from Tolerant (SIFT) [33, 34], PolyPhen-2 [35], and MutationTaster [36, 37].

Clinical Applications

The impact of NGS on biomedical research has been transformative. Similarly, the ongoing translation of NGS into the clinical laboratory represents a significant shift. In this section, two major clinical applications of NGS are discussed: (1) disorder- or disease-based multigene panel sequencing, and (2) exome and genome sequencing for candidate and causal gene identification.

Multigene Panel Sequencing via Targeted Enrichment

Investigations into the genetic basis of a growing number of inherited disorders have revealed that a clinical phenotype can be due to multiple causative genes with a broad mutational spectrum. Examples include X-linked mental retardation, mitochondrial disorders (secondary to mutations in both the mitochondrial genome and nuclear genes), congenital hearing loss, cardiomyopathies, and primary immune deficiencies [8, 10, 38–41]. A comprehensive diagnostic approach can require the analysis of a few dozen to over one hundred genes. Similarly, molecular analyses of hematopoietic and solid malignancies continue to identify a growing number of genes relevant to diagnostic stratification, prognosis, and therapeutic response [42–44]. The technical complexity of multiple gene analysis is very challenging with the Sanger sequencing, whereas it can be addressed by targeted enrichment of multiple genes followed by NGS.

In general, enrichment strategies can be categorized as either amplification-based or oligonucleotide-array-capture-based [45, 46]. For amplification-based enrichment, single locus or multiplex PCR remains a mainstay method. Resequencing of exons by targeted PCR enrichment has been demonstrated for a number of genes wherein amplicons are generated from a sample, pooled in equimolar ratios, then ligated to adapter oligonucleotides to generate an NGS library (without overlapping fragments). This approach integrates well with the longer read length technologies (e.g., Roche 454). Another strategy for target enrichment is to use overlapping long-range PCR with 5–10 kilobase amplicons, which are then pooled, fragmented, and converted into a library. Multiple samples can be sequenced together if index or barcode sequences are incorporated into adapter sequences. After sequencing, indexed reads are assigned to their respective sample of origin by bioinformatic algorithms, which is sometimes referred to as "deconvolution" [47–49]. To automate PCR amplification of many targets, a highly parallel PCR microdroplet technology has been commercialized by RainDance Technologies (Lexington, MA) [50, 51]. In this technology, individual primer pairs for targets are designed (for amplicon lengths of 200–600 bp), synthesized, and sequestered in individual, stable, emulsion microdroplets. Up to a few thousand primer pairs can constitute a microdroplet primer population. For targeted amplification, genomic DNA is first fragmented into a size range of 2,000–4,000 bp and then randomly distributed into a separate microdroplet population. On an automated microfluidic platform, individual primer pair and genomic DNA microdroplets are merged by exposure to a voltage potential so that one microdroplet containing fragmented genomic DNA is associated with one microdroplet containing an individual primer pair. The fused microdroplets are collected into a single microfuge tube and thermocycled to achieve highly parallel PCR amplification. After amplification, the droplets are disrupted and the pooled amplification products are converted into a library for NGS. An additional PCR-based enrichment approach, Fluidigm (South San Francisco, CA), commercialized their Access Array platform based on a

microfluidic chip that contains nanoliter-scale reaction chambers separated by valves. Forty-eight samples can be loaded onto the chip, and each sample can be distributed into 48 chambers with unique or multiplex primer pairs for subsequent PCR. After amplification, valves are reversed and samples are returned to their original wells and processed for NGS.

Oligonucleotide array capture methods constitute the second major enrichment strategy [52–59]. With array methods, genomic DNA, or genomic DNA converted into an NGS library, is hybridized to oligonucleotides complementary to target regions of interest. After hybridization, the enriched material is eluted from the array and processed for NGS. Originally, capture oligonucleotides were formatted on solid surface arrays, but this approach has been supplanted by in-solution formats offered by Roche NimbleGen (Madison, WI), Agilent (Santa Clara, CA), Illumina, and most recently Integrated DNA Technologies (IDT, Coralville, IA). In-solution oligonucleotide array capture procedures require several hours to days of hybridization depending on methodology, and an important array design consideration is the specificity of capture probes and the potential for co-capture and enrichment of nontarget sequences, notably from closely related genes and pseudogene analogs which can lead to false-positive variants in alignments. The inherent coverage variability in NGS libraries can be compounded by uneven and inadequate capture using in-solution probes, sometimes necessitating oligonucleotide array redesign.

A novel hybrid between capture and amplification approaches termed HaloPlex (Halo Genomics, Uppsala, Sweden and acquired by Agilent Technologies) is being adopted for clinical use. In this method, genomic DNA is digested with different combinations of restriction endonucleases and then hybridized to biotinylated oligonucleotide probes whose right and left sides are complementary to the fragment ends. The probes also contain a sequencing motif and index. Probe hybridization yields a genomic DNA circular structure that is isolated by incubation with magnetic streptavidin beads and then closed by ligation. Ligated circles are amplified by PCR yielding a library ready for sequencing.

Each enrichment method has advantages and disadvantages. For clinical applications, the choice of enrichment technology will depend on target size, content, and laboratory workflow preferences. Array capture is better suited for enrichment of larger target regions up to the scale of the human exome but is prone to co-capture of highly homologous sequences. Although amplification-based strategies are not as scalable, their increased target enrichment specificity may be preferable or required depending on target content. As an example of in-solution array capture data, Fig. 59.6 shows two genes, *FOXP3* and *HLA–DOB*, and their respective

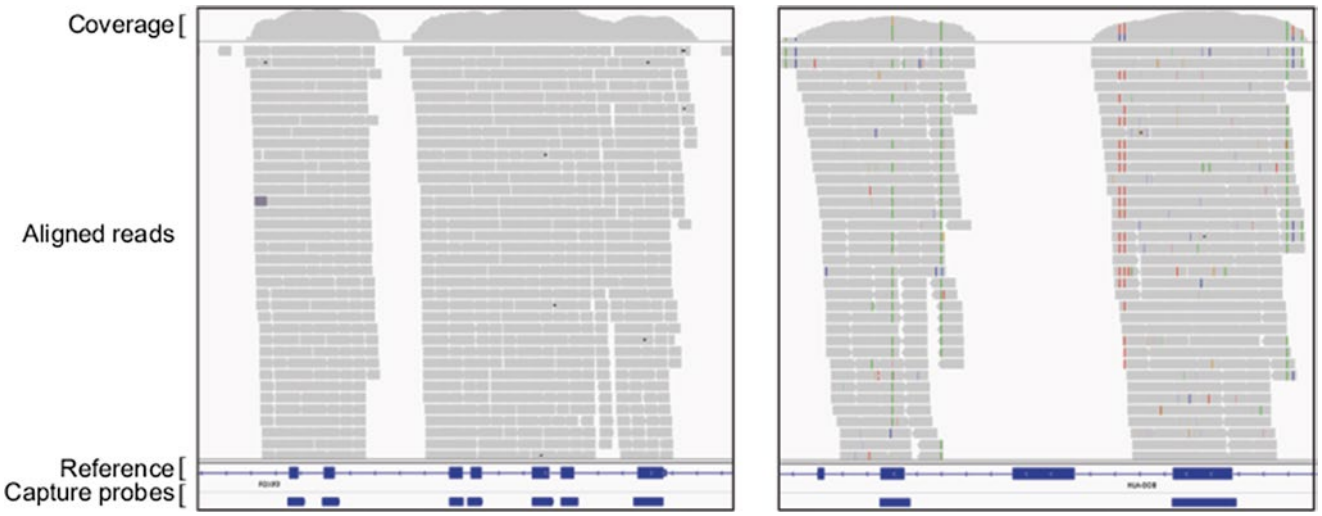

Figure 59.6 Exome read coverage and targeted regions. Paired-end exome sequencing reads are shown for two example genomic loci in the Integrated Genomics Viewer. *Boxes* along the bottom show the positions of the capture probes for the NimbleGen SeqCap in-solution capture design (Capture Probes). The reference sequence is shown above the capture probes, and exons are represented by *blue boxes* (Reference). Changes to the reference sequence are shown by vertical multicolored hatch marks throughout the coverage and aligned read regions (Aligned Reads). *Left panel* shows capture probes and coverage of seven exons from the *FOXP3* gene located on the X chromosome. *Right panel* shows capture probes and coverage of two of four exons from the *HLA–DOB* gene located on chromosome 6. *HLA–DOB* belongs to a larger gene family with highly homologous sequences, making the design of unique capture probes difficult. As a result, only two exons shown here contain unique probes, are captured efficiently, and can be aligned to the reference sequence, thus highlighting that problematic genomic regions are not included in capture probe design. Volume 137(3): 415–433 with permission from Archives of Pathology & Laboratory Medicine. Copyright 2013. College of American Pathologists

capture results. The left panel shows capture probes and coverage of seven exons from the *FOXP3* gene located on the X chromosome. The right panel shows capture probes and coverage of two of four exons from the *HLA–DOB* gene located on chromosome 6. *HLA–DOB* belongs to a large gene family with highly homologous sequences, making the design of unique capture probes difficult for all exons.

Currently, the majority of clinical NGS testing is comprised of multigene panels for inherited disorders and oncology applications (discussed further in the Considerations for Clinical Implementation of NGS). The adoption of multigene panels has been greatly facilitated by lower cost platforms, notably the Illumina MiSeq and the Ion Torrent PGM. In parallel, exome sequencing (and to a lesser degree genome sequencing) is being increasingly applied to identify causal and candidate genes in patients with disorders suggestive of a genetic etiology. We next discuss exome and genome sequencing, and the Illumina technology is highlighted as it has been used in the majority of clinical exome and genome publications.

Exome and Genome Sequencing for Candidate and Causal Gene Identification

In the scenario of a suspected inherited disorder, the overarching goal of exome or genome sequencing is to generate a list of variants from which a presumptively rare and pathogenic variant (or variants depending on mode of inheritance) can be identified. The complexity of this goal is reduced if a family with more than one affected member or even a trio of both parents and the affected child can be tested, as this allows segregation analyses of putative pathologic variants to be performed. While complex, the reported success of exome and genome sequencing for identifying candidate and causal genes in patients and families whose disorders strongly suggest a genetic etiology is 25–40 % [60–63]. Technical and bioinformatic considerations are presented before describing how to "search" for candidate genes.

As shown in Fig. 59.7, initial preparatory steps are the same for exome and genome libraries and include genomic DNA fragmentation and conversion of fragments into an oligonucleotide adapter-tagged library. For exome sequencing, in-solution capture with probes complementary to coding regions is performed as described above to yield an exome-enriched library. Several commercial vendors offer in-solution exome capture probe reagents including Agilent which uses RNA probes and Roche NimbleGen and Illumina which use single-stranded DNA oligonucleotide probes. While there is considerable overlap in the performance characteristics of these three approaches, each differs in targeted capture areas and capture probe sequence composition [64–66].

Prior to Illumina sequencing, the genome or exome library concentration needs to be determined to guide the preparation of an appropriate dilution for loading onto the flow cell. Quantitative PCR (qPCR) is performed on the library using amplification primers complementary to the adapter oligonucleotide sequences that bind to the flow cell surface capture oligonucleotides. A qPCR standard curve is generated using artificial templates of known concentrations that also contain the same primer target sequences complementary to the flow cell surface capture oligonucleotides. The library concentration is determined by comparing the PCR crossing threshold of the library to those of the standard curve templates. The use of PCR primers complementary to adapter sequences that bind to flow cell surface oligonucleotides specifically assesses the number of library molecules that should form clusters. Based on the library concentration determined by qPCR, a dilution is prepared with the goal of achieving optimal cluster density formation.

The bioinformatic steps for generating annotated variants from Illumina exome or genome sequencing data are similar to those described above. After sequencing, FASTQ read files are aligned to the human genome reference sequence using BWA followed by refined alignment and variant calling with GATK. Annotation is performed with either GATK or ANNOVAR. The process of alignment and variant calling generates, for a genome, approximately 3–3.5 million positions that differ from the human reference sequence. In comparison, approximately 15,000–30,000 differences from the reference will be observed in the coding regions in a genome or exome data set depending on bioinformatic filtering parameters. Within these ranges, the greatest number of variants from the human genome reference is observed in individuals of African and African-American descent, an intermediate number are observed in individuals of Asian descent, and the fewest variants are observed in Caucasians of European descent. At this time, genome sequencing costs approximately three times more than exome sequencing. Operationally, analyses of either genome or exome data typically focus on coding region variants and variants in close proximity to coding regions because this currently is the most "interpretable" portion of the genome. In considering the use of exome vs genome sequencing, exome sequencing does not provide as comprehensive an analysis of coding regions as genome sequencing. This reflects the difficulty of designing specific capture probes for all coding regions due to the variability of capture efficiency and the presence of cross homologous sequences. Figure 59.8a shows a comparative example of these differences for the *RET* gene in exome and genome data sets. The genome data shows comprehensive coverage across the gene region, whereas the exome data has sequencing reads only in locations enriched by capture probes. Figure 59.8b illustrates in exome sequencing of the *ABCF1* gene that some exon regions do not have

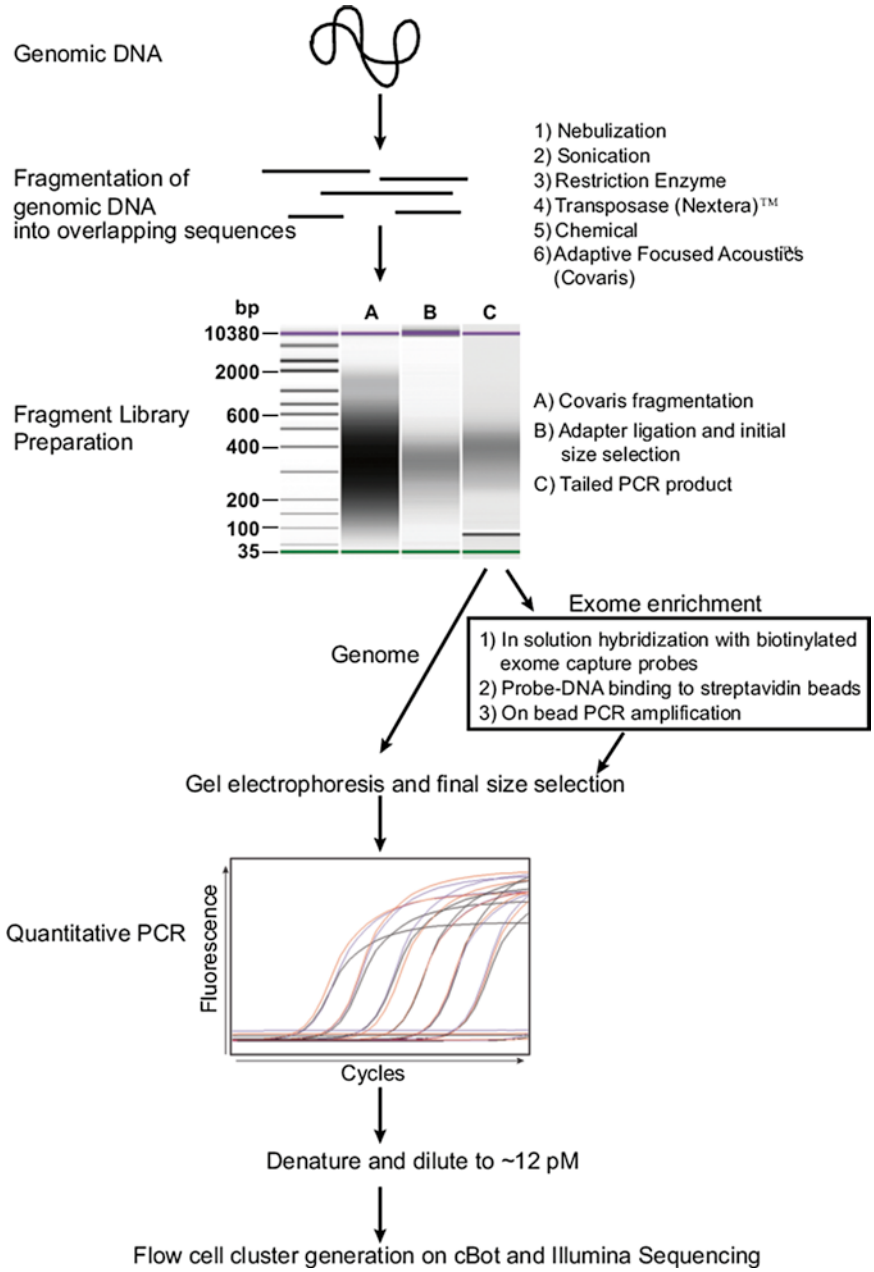

Figure 59.7 Sample preparation for genome and exome sequencing. Workflow diagram for converting genomic DNA into a genome or exome library for sequencing using the Illumina platform is shown. Options (*1–6*) for fragmenting DNA are shown at *top right*. Library preparative steps (*A–C*) as assessed on the Agilent BioAnalyzer are indicated. Steps for exome enrichment after polymerase chain reaction (PCR) amplification of adapter ligated library fragments are *boxed*. Example quantitative PCR traces are shown. Reprinted from Coonrod EM et al. (2013). Developing Genome and Exome Sequencing for Candidate Gene Identification in Inherited Disorders. Arch Pathol Lab Med. probes and therefore are not covered (Fig. 59.8b), while the genome sequencing data is complete across this region. Another technical consideration of exome sequencing that impacts data analysis is that coding regions with high or low GC content are captured less efficiently under single temperature hybridization conditions. This variability of capture was described by Clark et al. [65] and is inherent to all three commercially available exome capture reagents. The effect of GC content is particularly pronounced for the first exon of human genes, which on average have higher GC content. This can lead to reduced coverage of first exons in exome data sets as illustrated for the *MAZ* gene in Fig. 59.9 where read coverage for exon 1 is greatly reduced compared to other exons although a capture probe is included for this exon. While these limitations exist, exome sequencing is routinely performed at higher coverage depths compared to genome sequencing (due to cost considerations). The increased coverage depth can allow for identification of coding region variants missed in lower coverage genome sequencing data [26, 65].

The operational premise used in most candidate gene discovery analyses is that one is looking for a rare variant(s) that encodes a pathologic change (with high phenotypic penetrance) in the form of a missense, nonsense, frameshift, or splicing mutation. Depending on the presumed inheritance pattern, either single variants (e.g., dominant, X-linked, or a

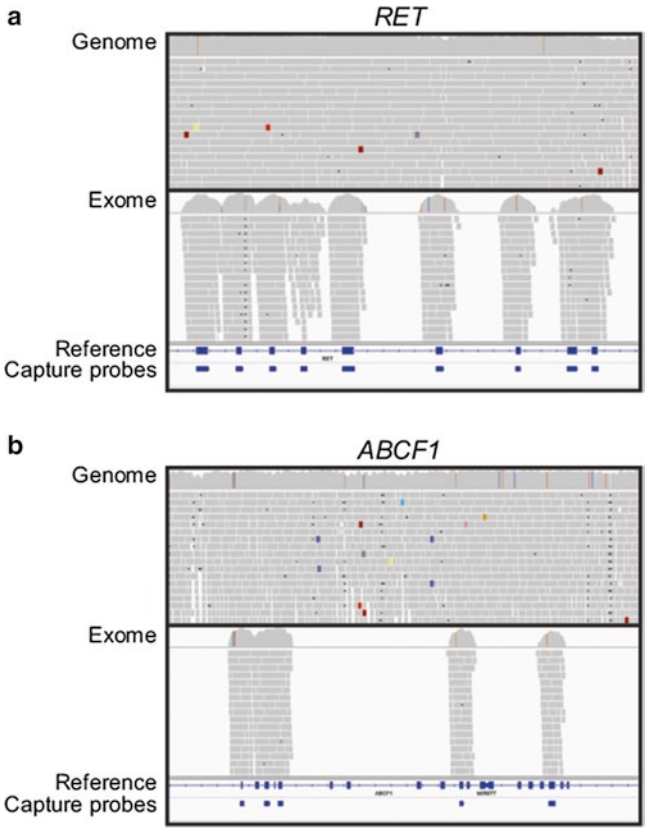

Figure 59.8 Comparison of genome and exome data. Screenshots of *RET* (**a**) and *ABCF1* (**b**) sequence alignments in the Integrative Genomics Viewer. In both **a** and **b**, *top panels* show genome read coverage and aligned reads (Genome), and *bottom panels* show exome read coverage and aligned reads (Exome). Reference exon positions and locations of corresponding NimbleGen capture probes are depicted as *dark blue boxes* (labeled Reference and Capture Probes, respectively). NimbleGen SeqCap EZ Human Exome Library version 2.0 reagents were used for exome enrichment, and the genome and exome samples were sequenced on the Illumina HiSeq 2000. These comparative results highlight the increased amount of sequencing information generated by genome sequencing (i.e., noncoding in addition to coding sequences) compared to exome sequencing. In addition, shown are differences between the well-captured gene, *RET*, and the suboptimally captured gene, *ABCF1*, using the exome sequencing approach. In this example, all exons in *RET* have exon capture probes and sequence information, whereas several exons in the *ABCF1* gene do not have exon capture probes. In contrast, all exons in both genes are sequenced with the genome sequencing approach. Reprinted from Coonrod EM et al. (2013). Developing Genome and Exome Sequencing for Candidate Gene Identification in Inherited Disorders. Arch Pathol Lab Med. Figure 59.9 Effect of GC content on exome capture. Integrative Genomics Viewer screenshot of exome sequencing results for the *MAZ* gene using NimbleGen SeqCap EZ Human Exome Library version 2.0 capture probe enrichment and Illumina HiSeq 2000 sequencing. Read coverage (Coverage) and aligned reads (Aligned Reads) are shown with reference exon positions and locations of corresponding NimbleGen capture probes depicted as *dark blue boxes* and labeled Reference and Capture Probes, respectively. The capture probe track shows that a probe has been generated to capture exon 1, but the read viewer shows only nine reads aligned to exon 1 compared to the greater read depth observed for the other *MAZ* exons. This indicates suboptimal capture during probe hybridization. Reprinted from Coonrod EM et al. (2013). Developing Genome and Exome Sequencing for Candidate Gene Identification in Inherited Disorders. Arch Pathol Lab Med. Volume 137(3): 415–433 with permission from Archives of Pathology & Laboratory Medicine. Copyright 2013. College of American Pathologists

new `e novo] mutation) or combinations of variants (e.g., recessive homozygous or compound heterozygous) are being sought in the form of SNVs or indels. Copy-number variations or other structural changes may be disease causing, and improving their identification in exome and genome data is an active area of investigation. Prior to searching for causative variants, other data such as linkage or identity by descent in families may have identified areas of the genome for focused analysis. Due to the enormity of either exome or genome data sets, bioinformatic tools are required to narrow down variant lists to a smaller subset of variants in candidate genes. In this evolving area, two main categories of bioinformatic approaches are used: heuristic filtering methods and statistical prediction algorithms or a combination thereof. A schematic of these two approaches is shown in Fig. 59.10.

A heuristic is a series of logic steps applied to arrive at a solution. In the context of candidate gene identification, the heuristic is typically guided by the premise of a rare variant that co-segregates with disease; therefore, one first assumption is that the causative variant is not represented in databases of "control" genomes, such as dbSNP [67], the 1000 Genomes Project, or in-house control databases. When applied as a filter, variants present in these databases are removed and typically reduce an exome variant list by about 95 % from 15,000 to 20,000 variants to approximately 1,000 variants. Caveats with this filter are that some known rare pathogenic variants and more common variants linked to disease by genome-wide association studies are present in dbSNP and a subset of the 1000 Genomes Project subjects are likely carriers for a genetic disease or may have late-onset

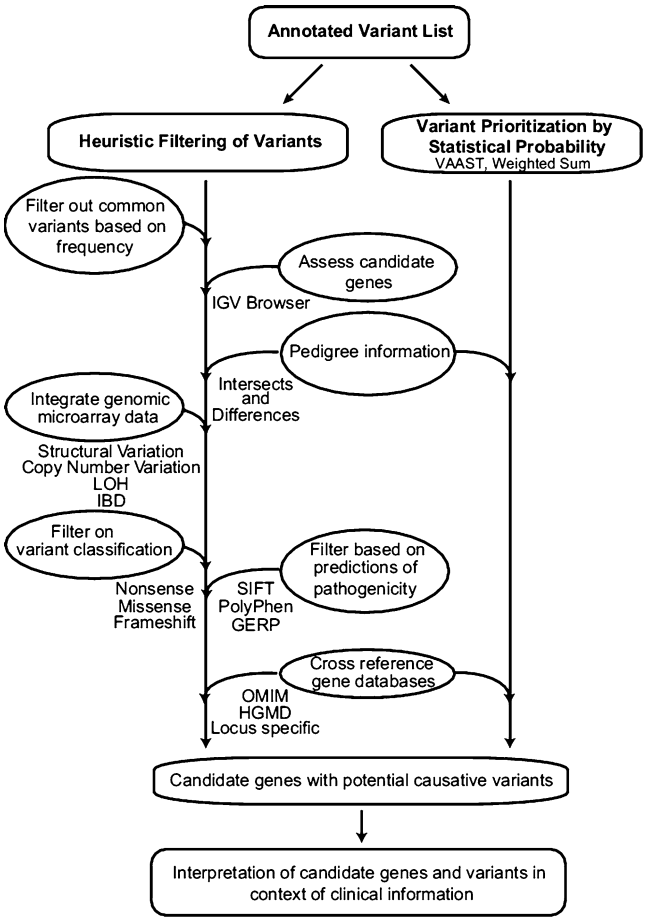

Figure 59.10 Heuristic and statistical probability approaches for candidate gene discovery. Shown is a schematic of sequential bioinformatic steps used by the authors for candidate gene discovery from exome and genome sequencing data. Annotated variant lists from genome or exome sequencing can be analyzed with heuristic filtering approaches, statistical probability approaches, or a combination of both to generate candidate gene lists. Multiple process steps are involved in heuristic filtering, as depicted. The process steps that incorporate pedigree information and cross-referencing of gene databases are critical components of both heuristic and statistical probability approaches. The additional steps involved in heuristic filtering are described in the text. *GERP* Genomic Evolutionary Rate Profiling, *HGMID* Human Gene Mutation Database, *IBD* identity by descent, *IGV* Integrative Genomics Viewer, *LOH* loss of heterozygosity, *OMIM* Online Mendelian Inheritance in Man, *PolyPhen* Polymorphism Phenotyping, *SIFT* Sorting Intolerant from Tolerant, *VAAST* Variant Annotation, Analysis, and Selection Tool. genetic diseases. Variants can alternatively be filtered into frequency bins such as 0–1 % and 1–5 % based on minor allele frequency (MAF) within the context of dbSNP, the 1000 Genomes Project, or in-house control databases. This approach assumes that variants with higher MAF values are less likely to be pathogenic but could lead to missing a deleterious compound heterozygous set of variants with different MAF values. Although most known highly penetrant, disease-causing variants are present at a frequency of <1 % in the population, deleterious variants can be present at higher frequencies [68].

The goal of the following filtering steps is to further reduce the list of potential candidate genes and their associated variants (Fig. 59.10). There are several options for filtering depending on the scenario, including (1) examining only genes previously implicated in the patient's disease phenotype, (2) identifying intersects (i.e., shared variants) and differences between affected and unaffected individuals based on pedigree information, (3) incorporating linkage or identity by descent (IBD) information from genomic microarray analyses, and (4) applying filters based on assumptions about the candidate gene and variant (e.g., zygosity, variant classification, or predictions of pathogenicity) (Fig. 59.10). To predict the functional effect of a DNA variant on the encoded protein, programs such as SIFT, Genomic Evolutionary Rate Profiling (GERP) [69, 70], and PolyPhen are often used and the results incorporated into the filtering and/or prioritization process. Once a candidate gene has been identified, cross-referencing the literature and consulting databases including the Human Gene Mutation Database (HGMD) [71], Online Mendelian Inheritance in Man (OMIM) [72], and locus-specific databases (e.g., http://www.arup.utah.edu/database/) may identify a previously described genotype-phenotype correlation for the specific variant or loss of gene function.

Heuristic filtering methods have proven successful in identifying the majority of reported candidate and causative genes. They do not, however, provide any measure of statistical uncertainty for a specific variant or candidate gene. Recently, a probabilistic candidate gene algorithm termed the Variant Annotation, Analysis, and Selection Tool (VAAST) has been described [73]. Using a multiparameter likelihood equation, VAAST compares allele frequencies between cases, controls, and background data sets in conjunction with modeling variant severity by amino acid substitution analysis to provide a list of variants, each associated with a VAAST ranking score and a p-value. The p-value is a measure of the probability that a variant is statistically significant in a case as compared to the control data set. Successful application of VAAST was recently reported in the discovery of a causative variant in a previously uncharacterized, rare, dominant, X-linked Mendelian disorder causing infant boys to have an "aged appearance" and cessation of growth after birth called Ogden syndrome (OMIM# 300855) [74]. In the future, additional algorithmic approaches for candidate gene identification are expected to emerge and will likely increasingly incorporate stratification based on population genetics data and cross correlation with evolving genotype-phenotype databases.

Follow-up medical, genetic, and/or functional studies are important to establish causality of a candidate gene with predicted deleterious variants. Correlation of known effects of gene function or loss with clinical symptoms and phenotype in the medical record can support the causality of the variant; however, correlation often requires discussion with the ordering physician(s), the patient, or their family regarding specific symptoms not described in the clinical record but known to result from the functional gene loss. In some cases, additional laboratory testing of the patient informed by the candidate gene can support causality. There are several different categories of variants that may be uncovered during a search for candidate genes. First, the gene and variant may have been previously associated with the patient phenotype. Second, the gene may have been previously implicated in the disease phenotype while the variant is novel. Screening for this variant in patients with similar signs and symptoms along with unaffected controls can be powerful for establishing causality. Third, the gene may not have been previously implicated in the patient phenotype but is supported by its known biological function. Here it is essential to understand the frequency of the variant in an ethnically matched data set and to screen for variants in the gene in unaffected individuals and patients with similar signs and symptoms.

Considerations for Clinical Implementation of NGS

A growing number of clinical laboratories are performing or developing clinical NGS-based tests. Multigene panels are driving this translation, and a literature base describing the development, validation, and implementation of NGS multigene panels is emerging. Overall, these reports describe encouraging performance characteristics for different multigene targets (e.g., retinal disorders, Lynch syndrome, *BRCA1* and *BRCA2*, and congenital hearing loss) using different enrichment approaches and sequencing platforms while also highlighting test limitations [38, 75–81]. Based on these initial reports and expected improvements in sequencing chemistries and options for data analysis, NGS is becoming a routine method in the clinical molecular laboratory. In this final section, we present several additional considerations based on our observations and those reported in the literature.

Clinical molecular tests based on NGS technologies should incorporate core principles shared with other clinical laboratory tests. Assay design, development, and optimization, followed by validation and subsequent quality control and assurance monitoring, are cornerstones. For multigene panel tests, panel content, choice of enrichment method, and platform compatibility are initial considerations. One continual challenging aspect is the rapidly growing knowledge base of genes involved in a particular phenotype posing the proverbial "moving target" problem to gene panel design. One approach is the design of panels to include only genes for which there is substantial evidence for their causal association with the disease phenotype. Alternatively, the panel can be expanded to include genes whose role in a given disease is biologically plausible but currently not proven. In this approach, only genes with the highest evidence for phenotypic association are reported clinically, while information is collected on less well-established gene-disease relationships for future use.

Major vendors offer free target enrichment design using chromosomal coordinates for the genes of interest, the sequencing platform, and the read length information to generate an in silico design report. The designs contain lists of primers and/or probes for the genes of interest and a bioinformatic projection of how comprehensively the targets will be enriched. Design success can vary significantly between target genes and enrichment methods. Critical to the success of these designs is the vendors' reporting on the potential for co-amplification or co-capture of nontarget, highly homologous sequences such as pseudogenes. In conjunction, the laboratory should independently determine if target genes have homologs or pseudogenes using homology search tools such as BLAST. While the presence of a highly homologous gene or pseudogene is not an absolute contraindication for inclusion in a multigene panel test, the laboratory needs to be aware that bioinformatic analysis of the corresponding functional target gene may be confounded by the pseudogene or homolog, especially when using an in-solution oligonucleotide capture method.

The next step is to assess the performance of the enrichment method in the laboratory. Pilot testing will define metrics such as actual target coverage in comparison to in silico predictions. Gene regions with inadequate coverage may be addressed by deeper sequencing or by redesign of the enrichment method. For regions that are recalcitrant to sequencing by NGS, the laboratory can develop an alternative analytical approach, such as targeted Sanger sequencing. In addition to determining coverage adequacy, assessment of sequence read qualities and allelic read percentage ranges provides method performance assessments. Plotting allelic read percentages for variants and performing confirmatory Sanger sequencing on a subset provide an evidence base by which the laboratory can establish allelic read percentage ranges for heterozygous and homozygous variant calls. The presence of co-captured homologs or pseudogenes can manifest as regions of poor sequence mapping and alignment or as variants with lower allelic read percentages. Interference by homologs and pseudogenes needs to be empirically determined because they can contribute to assay background noise. The range of allelic read percentages tends to be broader for in-solution capture-based enrichment methods compared to those that are amplification based.

Feedback from variant confirmation methods can guide the adjustment of technical wet bench approaches and bioinformatic parameters. For example, false-positive results may be due to co-capture of highly homologous sequences, sequencing errors, or alignment and variant calling errors. False-negative results may arise from inadequate coverage or alignment and variant calling errors. Therefore, confirmatory studies must be sufficiently comprehensive to define the sensitivity and specificity of the test, which is a significant but essential undertaking. If false-positive results are due to bioinformatic parameters, then these may be reduced by increasing the stringency of alignment and variant calling or utilizing different algorithms. The Sanger sequencing for confirmation of specific variants may reveal variants (NGS false negatives) in flanking regions not detected by NGS due to inadequate coverage or less permissive alignment and variant calling parameters.

Once basic technical performance characteristics of a targeted enrichment panel have been established, validation is undertaken using a series of samples. This is optimally done with the same reagent lots for sequencing, and the bioinformatic analysis parameters should be consistent. Traditionally, laboratories validating single-gene Sanger sequencing assays have tested samples with pathologic mutations present in the gene of interest. However, even at the single-gene level, obtaining samples with mutations for rare disorders can be challenging. This challenge is magnified when validating a multigene panel; therefore, a more practical approach to validating NGS-based tests is to perform a methods-based validation to determine the ability to accurately detect the types of variants for which the assay is designed (e.g., SNVs and indels). The combination of multiple gene targets and multiple samples typically yields a diversity of variants in most targeted genes with the caveat that some genes or gene regions are highly conserved and have fewer variants.

An open question is what constitutes an adequate validation for an NGS-based clinical test, and an important practical limitation for laboratories is the current significant cost of enrichment and sequencing reagents. In this context, reports describing the development and performance of NGS multigene panels have used sample numbers ranging from a dozen to over 80 with a mix of normal and variant-containing samples. One approach to reduce validation costs is the use of barcoding or indexing of samples, followed by pooling and data deconvolution. While a conceptually attractive approach from an operational and cost perspective, key caveats require attention. The use of sufficiently distinct combinations of indexes is critical to allow for unambiguous bioinformatic deconvolution and original sample assignment. Nucleotide errors can be introduced into indexes by PCR amplification during library or enrichment protocols, and these can lead to misassignment of sequence reads during deconvolution, which would manifest as variants with lower allelic read percentages than expected. Thus, pilot studies with confirmatory analyses should be performed to determine if the pooling and deconvolution approach yields equivalent results to those observed with single sample sequencing.

Following validation and implementation, ongoing monitoring of the assay performance through an ongoing quality assurance program is essential. Important metrics to accrue are false-positive and false-negative rates, which are determined through continuous or periodic confirmatory studies. An ongoing operational and cost challenge for laboratories is the evolution of NGS reagents and platform hardware and software that necessitate revalidation. This is anticipated to be a continual feature of NGS for some time.

While multigene panels are more common, several clinical laboratories now offer diagnostic exome and genome sequencing. In essence, exome sequencing is a large-scale multigene panel, and the considerations and caveats described above are directly applicable. Commercial exome enrichment reagents contain largely overlapping capture probe content. An important caveat is that current capture probe sets do not target the entire human coding region and in practice approximately 85 % of the coding region is enriched. During pilot experiments, the laboratory needs to define the coding regions that are adequately captured and sequenced. Conversely, the laboratory should define coding regions that are not represented or consistently display low coverage and those which are challenging or not feasible to interpret due to various factors including co-capture and alignment of highly homologous sequences or genome regions otherwise prone to sequencing errors. It is attractive to consider using exome sequencing as an "all-purpose" enrichment method followed by selective analysis of genes guided by phenotype. However, due to the incomplete coverage of the exome, this is feasible for some, but not all, sets of genes [80].

In contrast to exome sequencing, genome sequencing improves coding region coverage and approximately 95 % of coding regions are sequenced. Although co-enrichment of highly homologous regions is not inherent to genome sequencing, these regions and low-complexity intronic and intergenic regions pose the same bioinformatic challenges noted for multigene panels and exomes. As the cost of genome sequencing declines, genome sequencing may become the method of choice and thereby supplant panels and exome sequencing. From a practical standpoint, the actual preparation of a genome library is technically more straightforward than multigene panel and exome sequencing. Computationally, analysis of genome-scale data requires a much greater computational hardware infrastructure for expeditious alignment and variant calling and for data storage. In practice, most groups (including ours) that perform genome sequencing for candidate gene discovery efforts focus their analyses on coding regions. As our understanding of the contribution of

noncoding variants to human disease increases, the ability to expand analyses into noncoding regions afforded by genome sequencing will be advantageous. For further details on the use of NGS in the clinical molecular laboratory, the reader is referred to several reviews [64, 82–84]. These reviews describe the successful application of NGS approaches to clarifying diagnoses, adjusting patient treatment based on the patient's genotype, and identifying novel causative variants associated with a variety of diseases.

Results Reporting and Informed Consent

The implementation of NGS into clinical practice has posed new questions with respect to appropriate test utilization, informed consent, and the reporting of genetic testing results [85–87]. While the conceptual framework for pretesting consent and genetic counseling and posttesting reporting and counseling has been in place and practiced for many years, studies have determined that patients and family members struggle with fully understanding the meaning of genetic testing results, even for single-gene tests [88, 89]. In this context, active discussions are ongoing within professional societies involved in genetic testing to address the question of how to assure the adequacy of the consent process and how and what results to deliver from multigene panel and exome and genome sequencing [90]. As multigene panel testing is largely performed for the purpose of determining if a mutation(s) is present in a gene previously associated with a disease, it is qualitatively similar to single-gene testing. However, multigene panel testing is inherently accompanied by an increase in the number of variants requiring classification and potentially reported, all of which adds substantially to the interpretive load in the clinical laboratory setting. As described earlier, clinical exome and genome sequencing are being applied primarily to elucidate genetic causes in the setting of enigmatic diagnostic scenarios, and the reader is referred to a policy statement on the clinical use of exome and genome sequencing published by the American College of Medical Genetics and Genomics (ACMG) [91]. The policy statement provides guidance on indications for diagnostic testing, reporting, and pre- and posttesting considerations including informed consent and counseling. When exome and genome sequencing are applied in a phenotype or symptom-guided approach, bioinformatic analyses are focused to yield a list of candidate genes and associated variants which, in some cases, contain the causal diagnostic variant(s). When applied in this manner, noncandidate genes throughout the genome that do not appear in the candidate gene list are typically not evaluated. However, the total variant file from exome or genome sequencing for each individual contains multiple variants in genes that are predicted to result in loss of gene function or otherwise affect gene function [92, 93].

A subset of functional variants may not be directly pertinent to patient management, and these are termed "secondary" or "incidental" variant findings [94]. An ongoing area of research and discussion is whether or not to evaluate for and disclose all or some subset of secondary deleterious variants [95, 96]. Strategies have been proposed to categorize secondary findings, and example categories include variants that are associated with (1) cancer predisposition, (2) non-oncologic early- or late-onset disease, (3) recessive disease (in the setting of reproductive decisions), and (4) drug metabolism [97]. Opinions regarding the reporting of secondary findings vary among authors, and the reader is referred to the ACMG [91] recommendations on the return of results from genome-scale sequencing which includes a list of genes for which the return of incidental findings are recommended. The most recent revision includes the recommendation that patients should have the option to opt out of receiving incidental findings.

Indeed, the complexity of primary and secondary findings that exome and genome sequencing generate necessitates and highlights the importance and challenge of informed consent in the genomics era. A tiered consent process can be envisioned in which patients will be informed of the types of information generated by exome and genome sequencing. Patients may elect to receive only information pertinent to their presenting symptoms, or they also may request to receive all or some portion of their secondary findings. Another scenario would allow for patients to request secondary findings at a later date. In the pediatric setting, consent scenarios also would need to account for primary and secondary findings in children that are relevant to siblings and biological parents. The consequence of this complexity is that the field of molecular pathology is entering into an unprecedented era of result reporting that will encompass not only diagnostic findings but risk prediction for patients and family members. While not a new concept in genetic testing, the magnitude of this endeavor will strain current healthcare delivery models. Going forward, the successful broader implementation of genome-scale testing therefore will require sophisticated consent and reporting approaches that accommodate individual patient wishes and provide genome-scale information to patients in accessible and understandable formats.

Conclusions

Next-generation sequencing has entered the clinical laboratory and in the years ahead will transform many areas of clinical molecular pathology. In the span of a single chapter, it has not been possible to describe all aspects and applications of NGS. In response to the growing adoption of NGS, professional societies and organizations have begun to develop guidelines and standards for the clinical use of NGS.

Recently, the College of American Pathologists (CAP) published NGS-specific laboratory accreditation requirements for clinical molecular laboratories [98]. As noted above, the ACMG has published a policy statement addressing the clinical use of genome sequencing. It is anticipated that additional guidelines will be developed for multiple areas of clinical applications of NGS and the CAP is actively developing the first NGS-based proficiency testing for clinical laboratories. These and other ongoing efforts by professional societies and organizations reflect the current and expected impact of NGS on the practice of medicine. As a technology, NGS is a convergence of innovations in sequencing chemistries, microfluidics, and optics. Like the polymerase chain reaction, NGS is a transformative technology, and the wealth of data generated poses a tremendous challenge for medicine and a unique opportunity for the field of molecular pathology to play a major role in its successful implementation to improve patient care.

Next-Generation Sequencing for the Analysis of Cancer Specimens

60

John D. Pfeifer

Abstract

Massively parallel sequencing (also known as next-generation sequencing, or NGS), which provides genomic data at low cost and high accuracy, is ideally suited for clinical testing of cancer specimens. NGS results may inform the cancer diagnosis or choice of therapy. The genomes of cancer cells carry somatic (often referred to as acquired) alterations, which fall into four general classes: single nucleotide variants (SNVs), small insertions and deletions (indels), copy number variants (CNVs), and structural variants (SVs). The genetic complexity of cancers underscores the importance of NGS to evaluate the full spectrum of sequence variations in dozens to thousands of genes in a single test. Amplification-based as well as hybrid capture-based methods for NGS testing can be used for the analysis of cancer specimens, and assays that target a panel of genes (from several genes, to several hundred genes), the exome, or the genome have been developed. Although each type of assay carries with it specific test design considerations, all NGS assays share a set of preanalytic, analytic, and postanalytic/reporting issues that must be addressed during test validation and routine clinical use. In addition, the analytic portion of an NGS test consists of three individual components (i.e., the sequencing platform; the wet bench procedures; and the bioinformatics pipeline), which creates some unique quality management issues.

Introduction

Massively parallel sequencing (also known as next-generation sequencing, or NGS), which provides genomic data at low cost and high accuracy, is ideally suited for clinical testing of cancer specimens. NGS is increasingly being used for clinical testing of cancer specimens because NGS can comprehensively evaluate multiple genetic loci when only a limited quantity of DNA is available for testing. The ability to provide comprehensive analysis is important given the increasing number of targeted chemotherapy drugs (which requires analysis of an ever increasing number of genes), while ever smaller tissue specimens are available for testing. The smaller specimens are a result of trends to shift from large excisional biopsies to needle or aspiration biopsies for diagnosis.

The genetic complexity of cancers underscores the important role for NGS in evaluating the full spectrum of sequence variations in dozens to thousands of genes in a single test. The genomes of all cancer cells carry somatic

or acquired DNA alterations, which fall into four general classes, single nucleotide variants (SNVs), small insertions and deletions (indels, which are generally less than a few dozen bases long), copy number variants (CNVs), and structural variants (SVs, such as translocations). Some of the mutations are so-called "driver mutations" because they confer selective clonal growth or survival advantage and are causally involved in oncogenesis. Other mutations are so-called "passenger mutations" since they do not contribute to development or progression of the cancer but are secondary changes with little diagnostic or therapeutic importance, usually due to the genomic instability of many cancers.

Identifying somatic driver mutations in cancer has several direct clinical applications. First, the specific pattern of mutations can be diagnostic in cases in which traditional histopathologic examination is not definitive, as for example in the setting of a tumor of unknown primary origin [1]. Second, somatic mutations can be used to predict how a patient may respond to a drug with respect to toxicity or efficacy. For example, alterations in exon 19 of *EGFR* in patients with non-small-cell lung cancer (NSCLC) are responsive to treatment with gefitinib [2]. Similarly, the majority of patients with NSCLC or lung adenocarcinoma who carry inversions in *ALK* or a translocation involving *ROS1* respond to treatment with crizotinib [3, 4]. Other somatic mutations predict resistance to therapy with tyrosine kinase inhibitors (TKIs), such as *KRAS* mutations in lung cancer [5]. Third, somatic mutations can provide prognostic information on the risk of disease progression or relapse. For example, an internal tandem duplication of *FLT3* is associated with poor prognosis in acute myeloid leukemia (AML), while mutations in nucleophosmin (*NPM1*) are associated with a favorable prognosis in AML [6].

Amplification-based as well as hybrid capture-based NGS methods can be used for the analysis of cancer specimens. Assays that target a panel of genes (from several genes, to several hundred genes), the exome, or the genome have been used clinically for cancer analysis. However, as with all laboratory tests, the clinical utility of the different assay designs is extremely dependent on the clinical setting. In general, since clinical utility has been defined for only a few thousand different mutations in a few hundred genes, sequence analysis of the exome or genome in a clinical setting is currently unjustified. In addition, due to the tissue and tumor heterogeneity of cancer specimens, detection of cancer mutations requires a high depth of coverage that cannot currently be accomplished with exome or genome NGS. Therefore, currently, the most common NGS tests for cancer focus on panels of genes with well documented roles in diagnosis, prognosis, or prediction of response to therapy.

Assay Design Considerations

Several practical and operational considerations of assay design determine the eventual utility of an NGS assay used in the clinical analysis of cancer specimens. The more general aspects of assay design are discussed in Chap. 61. The details that are specific to the analysis of somatic mutations in tissue specimens from cancer patients are discussed in this chapter.

Amplification-Based Methods

Amplification-based NGS methods rely on exponential amplification of the target region utilizing sequence-specific primers. When compared with hybrid capture-based methods, amplification methods have a simpler workflow, with reduced hands-on time and more rapid turnaround time (TAT), and so are more frequently used in clinical settings. Highly multiplexed microfluidic and microdroplet methods, e.g., RainDance Technologies (Billerica, MA) or Fluidigm (South San Francisco, CA), have substantial upfront hardware costs. Several amplification enrichment systems have been optimized for compatibility with benchtop sequencing instruments (e.g., Ion Torrent, Illumina MiSeq), which makes amplification-based technology accessible to any size laboratory for clinical use. However, amplification-based approaches have several limitations. First, there are significant limits on the size of the target region that can be sequenced because of practical issues with the number of PCR reactions that can be multiplexed in a single amplification. Second, only a subset of variant types can be detected; in general SNVs and small indels can be identified, while detection of CNVs and SVs is extremely challenging. Third, as with any amplification-based test, there is the potential for amplification bias, polymerase sequencing errors, contamination, and primer binding artifacts. Fourth, amplification-based NGS requires prior knowledge of the sequences and the nature of the mutations to be targeted; the assay lacks the potential for identifying novel disease-associated mutations outside the targeted regions.

Commercial Amplification-Based Tests

While many clinical NGS labs have internally developed amplification-based NGS tests [7–9], commercially available assays are commonly used in the clinical setting. The AmpliSeq hot spot panel (Life Technologies, Grand Island, NY) and the TruSeq hot spot panel (Illumina, San Diego, CA) are in clinical use.

AmpliSeq assays (Life Technologies) [10] use a proprietary ultra-high multiplex PCR technology to generate thousands of amplicons for massively parallel sequencing. Only approximately 10 ng of input DNA are required and

the assays work well with different types of tumor samples, including archived formalin-fixed, paraffin-embedded (FFPE) tissue samples. The amplicons generated from AmpliSeq kits are ready for sequencing using the Ion PGM system (Life Technologies). The TAT from receiving samples to reporting results can be as short as 3–5 days. While the traditional assays involve only a limited set of loci in a panel of genes (Table 60.1), a new kit (Ion AmpliSeq Exome, Life Technologies) amplifies the exome in 12 primer pools using as little as 50 ng DNA [11]. Figure 60.1 shows the results of a representative assay performed on an Ion Torrent PGM platform with a 316 Chip v2 and using the AmpliSeq™ Cancer Panel v2 (Life Technologies).

TruSeq and related assays (Illumina) [12] also target a limited set of loci in a panel of genes (Table 60.2). The assays require 150–250 ng DNA based on the sample type, and have a TAT of 3–5 days.

Hybrid Capture-Based Methods

NGS using targeted hybridization (hybrid) capture is a sensitive and specific method to detect somatic alterations in cancer samples. With appropriate assay design, hybrid capture enables detection of all four classes of genomic alterations in cancer specimens with very high analytic sensitivity and specificity, a very low limit of detection, and very high reproducibility. Given the genomic heterogeneity that is a fundamental characteristic of cancer, particularly in solid tumors, the efficient and cost-effective targeting of multiple classes of mutations in a large number of genes in a single assay is

Table 60.1 The genes covered by Ion AmpliSeq™ Cancer Hotspot Panel v2

The panel targets mutation hotspots in 48 genes that are almost identical to those of the AmpliSeq™ Cancer Hotspot Panel (Table 60.1). The panel includes 212 amplicons ranging from 170 to 190 bp in length. The total genomic region covered is about 35 kb

required. Hybrid capture methodologies have the flexibility to target a wide range of genes from one gene to the exome. Currently available liquid capture kits (e.g., Ref. 13) have a target size of 1 kb to 24 Mb.

However, hybrid capture NGS tests have several disadvantages. DNA library preparation generally takes 3–5 days (compared with 1 day for amplification-based enrichment library preparation), with a large proportion of this time allocated to probe hybridization (typically 24–48 h incubation time for the hybridization step itself). Therefore, clinical hybrid capture tests have a longer TAT. Although automation can be used to decrease TAT, the equipment is expensive and thus requires a substantial initial capital investment. Hybridization-based NGS clinical tests also frequently suffer from design restrictions, including problems producing high quality sequence data from DNA regions with high GC content, repetitive sequences, and gene family members that share sequence homology (pseudogenes). The bioinformatics and interpretive component of hybrid-capture based testing has emerged as particularly problematic, since the ease with which massive amounts of sequence can be generated on the current generation of platforms can easily overwhelm a laboratory's ability to analyze the data.

Assay Scope

Targeted Gene Panels

Gene panels for acquired mutations in cancer specimens focus on genes that are considered clinically actionable based on evidence for their diagnostic, predictive, and/or prognostic value. The gene panels may be quite narrow (e.g., only a few dozen genes) based on the specific cancer being evaluated, such as colon adenocarcinoma, lung adenocarcinoma, or gastrointestinal stromal tumor [14–16], or much broader (e.g., hundreds of genes) based on recurrently mutated genes across multiple cancer types [17, 18].

Smaller and larger gene panels each have distinct advantages and disadvantages. For clinical testing, limiting the number of targeted genes avoids an excessive number of distracting variants of unknown significance (VUSs), decreases incidental findings, and decreases TAT. Assays with a smaller target region make it cost effective to sequence at greater depth even with multiplexed samples, providing greater analytical sensitivity for detecting mutations with low variant allele frequencies (VAFs) and a lower cost. Another important advantage of small panels that target only loci with well-established clinical relevance is higher rates of reimbursement, a difference that is critical in the clinical setting where testing is funded by insurance payers rather than research grants or philanthropy. In contrast, large gene panels are more likely to include genes relevant to clinical trials or drug development, and so have much more utility in investigational settings. In the end, gene panel design is determined by examining factors such as clinical need, expected sample volume, practicality of running multiple small disease-directed panels vs a single more general cancer based panel, and sources of revenue.

Exomes and Genomes

Exome and genome sequencing often are applied to the study of cancer as a discovery tool in the investigative setting. Exome or genome sequencing is helpful for detection of CNVs and is especially well suited to detection of structural variants (SV), which often involve noncoding DNA breakpoints. However, the use of exome and whole genome in routine clinical practice has several limitations. First, because of the high depth of coverage (about 1,000×) required for sensitive and specific identification of somatic variants in cancer samples due to admixing of benign and malignant cells within the tumor, clonal heterogeneity of the tumor cells, and variation in coverage across different regions of DNA, the cost of exome or genome sequencing is often prohibitive in clinical practice. Second, the utility of sequencing genes without established clinical significance for cancer patient management is an issue. Beyond the genes evaluated by focused panels, there are relatively few loci for which sufficient evidence of clinical significance exists to support interpretation of functional or therapeutic consequences for the variants identified; thus, most variants identified are VUSs and do not meaningfully contribute to patient management. Third, intensive bioinformatics analysis is required to manage the vast amounts of data generated by such large scale sequencing.

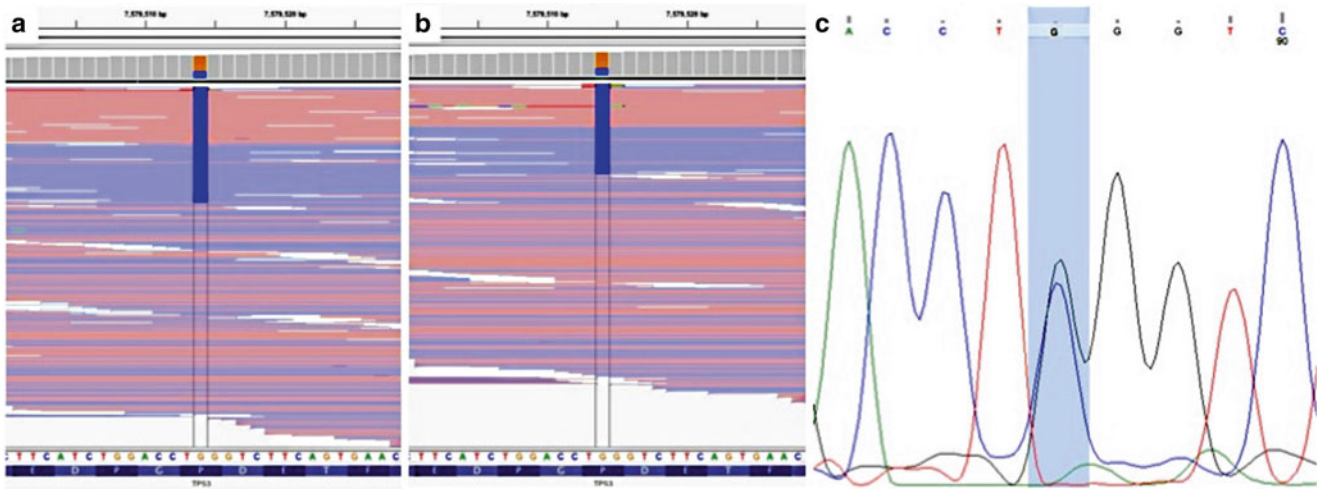

Figure 60.2 Ambiguity of variant allele frequencies (VAFs). Next-generation sequencing (NGS) was performed on two separate tumor samples from one patient; a *TP53* variant was identified in both samples (chr17:7579514G.C). The patient's oropharyngeal squamous cell carcinoma (SCC) contained the variant with a VAF of 0.30 (**a**). The same variant was present in the lung SCC with a VAF of 0.32 (**b**). Sanger sequencing was performed on nonneoplastic tissue from the same patient, which demonstrated that the variant was heterozygous in the germline (**c**), and copy number analysis at this position showed no copy number alterations (not shown). Thus, based on the VAF alone, this variant may have been incorrectly interpreted as a somatic mutation that was shared between the two tumors. Reprinted by permission from Elsevier Inc., C*linical Genomics: A guide to clinical next generation sequencing*. Kulkarni S and Pfeifer J, Eds.

Determination of Somatic Status with or Without Paired Tumor-Normal Tissue Analyses

Determination of Somatic Status Without Paired Normal Tissue

Many factors complicate predictions regarding the germline vs somatic status of a variant, as well as estimates of the percentage of tumor cells that harbor the variant, for sequence changes identified from a cancer sample when a normal tissue sample from the same patient is not available or tested for comparison. Most approaches to this problem rely on the VAF, which is essentially the percentage of sequence reads that have the variant. However, when evaluating the VAF for variants identified from cancer samples, it is important to remember that tumor samples in general, and solid tumor samples in particular, are inherently heterogeneous, consisting not only of the tumor cells but also of associated inflammatory cells, stromal cells, endothelial cells, and normal parenchymal cells (as discussed in more detail below). Since the relative proportion of these various cell types is highly variable between different tumor samples, and even between different areas of the same tumor, the VAF from the cancer specimen is an uncertain guide as to whether a variant is a somatic mutation present in the majority of the tumor cells, only a small subclone of the tumor cells, or even a germline variant. For example, a heterozygous mutation present in a sample that consists almost entirely of tumor cells could have the same VAF (i.e., 0.5, often indicated as 50 %) as a homozygous mutation present in half of the tumor cells, or as a germline variant (Fig. 60.2). Interpretation of VAFs is further complicated by a complex interplay of various classes of mutation affecting the same locus. For example, a SNV in a gene that is amplified in a small subclone of the tumor could produce the same VAF as a heterozygous mutation present in the majority of tumor cells. The use of VAFs as a basis for evaluating the percentage of tumor cells that contain a variant, or to infer the somatic vs germline status for an identified variant, is further complicated by analytic factors inherent to capture and/or amplification techniques that introduce technical sources of bias.

Paired Tumor-Normal Analysis

For NGS analysis of cancer specimens, paired tumor-normal testing can sometimes provide insight into the significance of a VUS obtained from tumor tissue. However, the laboratory decision to perform paired tumor-normal testing, whether ad hoc based on the NGS findings in a particular case or as the routine approach for all cases, depends on a number of factors including the cost, the size of the target region, and the anticipated clinical use of the sequence results. In general, for NGS assays focused on a limited panel of genes designed to identify mutations that are the targets of specific drug therapies, paired tumor-normal testing provides little additional information that impacts patient care. However, for very large gene panels, exome, and genome sequencing, paired tumor-normal testing is an integral part of NGS analysis, essentially in order to filter out germline variants. Unfortunately, current reimbursement paradigms do not support clinical sequencing of non-tumor samples for comparison to tumor samples.

Even before acquired mutations are considered, bioinformatics analysis of exome and genome sequence results of tumor specimens is complicated by the fact that an average person has from 140 to 420 non-silent (non-synonymous SNV, gain or loss of stop codon, frameshift or in-frame indel, or change in splice site) germline variants not present in any significant proportion of other individuals (i.e., they are variants with a minor allele frequency of <0.5 %) [19]. Nonetheless, these variants are not expected to contribute directly to carcinogenesis and thus likely represent benign variation seen in healthy humans [20]. In addition, the number of "novel" germline variants increases dramatically for individuals from ethnicities that are less well genetically characterized, based solely on inadequate sampling of rare benign polymorphisms in those populations. Since benign polymorphisms are generally indistinguishable from tumor-associated mutations in cancer samples if matched normal tissue is not available for comparison, these polymorphisms in the patient's background germline genetic profile cannot be separated from tumor-associated acquired mutations.

With respect to acquired somatic mutations, the number of somatic mutations in a tumor sample is highly variable between cancer types. Some cancers have <1 mutation per megabase (Mb) of coding DNA sequence, with others having >100 mutations per Mb [21–29]. Unlike targeted NGS analysis of relatively limited and well-described hot spot mutations and cancer genes, exome targeting captures 30–75 Mb of sequence (depending on the reagent used for capture) and identifies hundreds of nonsynonymous coding sequence variants from each cancer sample. In so-called "hypermutator phenotype" tumors characterized by unusually high rates of somatic mutation, over 1,000 somatic mutations can be identified [21, 26]. For example, lung squamous cell carcinoma, which has one of the highest described somatic mutation rates, harbors an average of 228 non-silent protein coding sequence mutations, 165 structural rearrangements, and 323 copy number changes per tumor [22]. Inclusion of the noncoding (e.g., intronic or untranslated region) sequence identified by genome sequencing hugely increases the number of variants identified; for example, a median of over 18,000 SNVs alone are found by genome sequencing of lung adenocarcinoma [27].

Comparison of tumor tissue to normal (or more accurately, non-neoplastic) tissue from the same patient is extremely valuable for determining whether an identified variant is a germline variant or a somatic mutation, and for decreasing the overall number of variants that need to be evaluated and interpreted. The simplest bioinformatics approach for paired tumor-normal NGS testing involves subtracting variants identified in the normal sample, producing a set of variants that appears to be enriched in the tumor. The subtraction approach relies on a pure normal sample, verified by tissue histology or some other method, to avoid "subtracting" variants present in even a low level of contaminating tumor cells.

One caveat to removal of germline variants from subsequent analyses is worth note, namely that some germline variants are very relevant in cancer and will be removed by this analytical method. For example, germline variants in *BRCA1* or *BRCA2* drive oncogenesis in families with hereditary breast cancer, and germline variants in *TP53* cause cancer in families with Li–Fraumeni syndrome [30, 31]. However, ideally, standard clinical evaluation should identify those patients at risk for a hereditary cancer syndrome.

Library Complexity

The number of independent DNA template molecules (sometimes referred to as genome equivalents) sequenced in an NGS assay has a profound impact on the sensitivity and specificity of variant detection. While it is possible to perform NGS analysis using only picogram quantities of DNA [32–34], this technical feat is accomplished by simply increasing the number of amplification cycles during library preparation. However, the information content in 1,000 sequence reads derived from one genome is quite different than the information content present in 1,000 sequence reads from 1,000 different genomes. Thus, library complexity and sequence depth (see below) are independent parameters in NGS assay design.

One common way to measure library complexity is through quantitation of the number of unique, on-target reads. Sequence reads with different 5′ and 3′ termini are usually unique and thus arise from DNA from more than one genome (and more than one cell); thus, it is straightforward to estimate the complexity of a DNA library produced by a hybrid capture method since the sequence reads have different 5′ and 3′ termini reflecting the population of DNA fragments captured during the hybridization step. However, it is uncertain whether sequence reads with identical 5′ and 3′ termini have an origin from different genomes (cells) or merely represent PCR amplification bias; thus, direct measurement of the complexity in a DNA library produced by an amplification method is difficult since all the sequence reads from one amplicon will have identical 5′ and 3′ termini regardless of the population of DNA fragments from which they originated.

Accurate calculation (or even estimation) of complexity from morphologic assessment of patient specimens is difficult since all the steps of library preparation involve inefficiencies that interact in complicated ways. Cancer specimens that are highly cellular and contain a high percentage of viable tumor cells typically produce an adequately complex DNA library. Small paucicellular specimens have the potential for generating low complexity DNA libraries likely to

produce biased sequence results. The complicated intratumoral heterogeneity of malignancies (see below) dictates that DNA library complexity should be maximized to achieve optimal NGS sequencing results.

Depth of Coverage

Depth of coverage is defined as the number of aligned reads that contain a given nucleotide position, and sufficient depth of coverage is critical in clinical NGS assays for identification of sequence variants with the required level of sensitivity and specificity. Many factors influence the required depth of coverage. The first variable is the sequence complexity of the target region. Target regions with homology to multiple regions of the genome, a higher number of repetitive sequence elements, pseudogenes, and increased GC content generally have decreased coverage due to technical aspects of the sequencing process [35, 36]. Second, the method used for targeted enrichment can impact coverage depth with amplification methods often providing higher depth (although the complexity of the sequence data may be uncertain, as discussed above). Third, in a multiplexed clinical test where multiple samples are sequenced simultaneously, the size of the target region (e.g., 400 kb for a typical panel of genes, vs 30–75 Mb for an exome, vs over 3 Gb for a genome) will impact the depth of coverage that can be reasonably achieved for each sample because of the defined sequencing capacity of the chip used to generate the sequence reads.

The relationship between depth of coverage and the reproducibility of variant detection from a given sample is straightforward: a higher number of high-quality sequence reads lends confidence to the base called at a particular location, whether the base call from the sequenced sample is the same as the reference base (no variant identified) or is a non-reference base (variant identified), and thus increases assay sensitivity and specificity [35–38]. However, the depth of coverage required to make accurate variant calls also is dependent upon the type of variant being evaluated, and whether the variant is germline or acquired. In general, a lower depth of coverage is acceptable for constitutional testing where germline alterations are more easily identified since they are in either a heterozygous or homozygous state, and all DNA has the same sequence, except for mosaicism. A minimum of 30× coverage with balanced reads (forward and reverse reads equally represented) is usually sufficient for germline testing [39, 40]. However, much higher read depths are necessary to confidently identify somatic variants in tumor specimens due to tissue and tumor heterogeneity (see below); an overall coverage of approximately 1,000× is optimal [7]. For NGS of mitochondrial DNA, an average coverage of >20,000 is required to reliably detect heteroplasmic variants present at 1.5 % [41].

The need for high read depths reflects the complexity involved in somatic variant detection. As discussed below in more detail, tumor biopsy specimens represent a heterogeneous mixture of tissue encompassing malignant cells, as well as supporting stromal cells, inflammatory cells, and uninvolved tissue; malignant cells harboring somatic variation can become diluted out in this admixture. Of additional consideration, intratumoral heterogeneity creates tumor subclones so that only a small proportion of the total tumor cell population may have a given mutation. Thus, the read depth of the assay should be sufficiently high to compensate for this variation.

Preanalytic Issues

Specimen Requirements

The amount of specimen DNA required for clinical NGS testing can be from a variety of patient sample sources including peripheral blood, bone marrow aspirates, buccal swabs, surgical resections, needle biopsies, and fine needle aspirations (FNAs). For solid tumors the most frequently available specimen type is FFPE tumor tissue. Fortunately, FFPE specimens as well as fresh tumor samples are both amenable to NGS analysis by current NGS technologies. However, DNA from FFPE will be a suboptimal substrate for use with emerging approaches that make it possible to determine the sequence of over a thousand bases per individual DNA template molecule, which will improve the analysis of currently difficult regions such as pseudogenes or repetitive sequences.

While it is well established that formaldehyde reacts with DNA and proteins to form covalent crosslinks, engenders oxidation and deamination reactions, and leads to the formation of cyclic based derivatives [42–46], with higher depths of coverage, the rate of sequence artifacts from FFPE samples is quite small compared with paired fresh samples from the same tumor, and is in fact several orders of magnitude below the cutoff for reporting variants in routine clinical practice [47]. Similarly, several studies have demonstrated that, for both amplification and hybrid capture methods, alcohol fixation does not induce sequence artifacts at a clinically significant rate [48, 49]. The lack of a significant rate of NGS sequence artifacts has been shown for both ethanol-fixed specimens (of the type used in Papanicolaou stains) as well as methanol-fixed specimens (of the type used in Romanowsky stains such as Diff-Quik), which allows the increasingly common use of cytology specimens for clinical NGS tests. Since exposure to acid efficiently hydrolyzes phosphate diester links (and also damages nucleotides leading to abasic sites) in both DNA and RNA, acid decalcification renders tissue samples unacceptable for NGS analysis [50]. When decalcification is required, calcium chelating agents such as EDTA should be used since they have no significant impact on nucleic acids.

Histopathologic Review

Prior to DNA extraction from the tumor specimen, the specimen slides corresponding to the tumor used for NGS testing should be reviewed by an anatomic pathologist to ensure the presence of viable (non-necrotic) malignant tissue, and to assess the quality and quantity of the material submitted for testing. The pathologic assessment is an important quality control step since it permits evaluation of possible analytic confounders, including the percentage of nonneoplastic tissue, necrosis, cautery artifact, and so on, and thus helps ensure that the specimen is adequate for the validated assay. More specifically, if a cutoff of 10 % VAF is used for clinical reporting of a variant, then areas with more than 20 % tumor cellularity should be used to ensure that heterozygous variants present in all the tumor cells will likely be detected. Obtaining an estimation of the percentage of tumor cells present in the tissue section relative to total number of cells is useful during interpretation of the sequencing data in regard to VAF. Unfortunately, although a pathologist's review of cancer samples is required to select the regions of tumor with high cellularity and viability, the estimates of percent tumor cells present are unreliable [51, 52].

It is important to recognize that the percentage of nonneoplastic tissue (also known as tissue heterogeneity) is different from intratumoral heterogeneity. Tissue heterogeneity refers to the fact that no tumor specimen is composed of 100 % neoplastic cells. Instead, cancer samples contain a varying proportion of nonneoplastic cells including stromal cells (benign parenchymal cells and fibroblasts), inflammatory cells (primarily neutrophils, lymphocytes, and macrophages), and endothelial cells (of blood vessels and lymphatics). Intratumoral heterogeneity is a term used to refer to the fact that malignant neoplasms usually demonstrate clonal heterogeneity [53, 54]. Consequently, even with a relatively pure tumor sample identified by histopathologic review, the number, type, and frequency of sequence variants detected in that sample may or may not be an accurate reflection of the range and frequency of the variants elsewhere in the tumor.

DNA Extraction

Total DNA yield from a cancer specimen is commonly measured by either spectrophotometry or fluorometry. Metrics including A_{260}/A_{280} and A_{260}/A_{230} are commonly used to estimate nucleic acid purity, and agarose gel electrophoresis can be performed to ensure the presence of high molecular weight genomic DNA. However, the presence of high molecular weight DNA is not necessarily mandatory for NGS, as demonstrated by the fact that both amplification-based and hybrid capture-based methods work well with FFPE samples that contain damaged nucleic acids due to formalin-fixation during routine processing [47]. While sample processing is generally standardized within a laboratory, many variables can significantly impact nucleic acid quality, such as fixation time, storage conditions, and acid decalcification, and in turn can affect subsequent library preparation and sequencing. The use of acid decalcification is especially problematic since acid exposure rapidly destroys nucleic acids [50]; decalcification with a chelating agent (EDTA) is preferred [55].

Analytic Issues

NGS tests require three components, specifically: the sequencing instrument; the laboratory procedures including extraction of nucleic acids and DNA library preparation; and the bioinformatics processes for base calling, reference genome alignment, variant identification, variant annotation, and variant interpretation. The general features of all three of these components as they apply to NGS analysis of cancer specimens are similar to those for constitutional testing, and are covered in Chap. 61. However, some additional issues must be considered in the analysis of tumor samples, specifically in the bioinformatics analysis.

As with all NGS testing, after the sequencing reads are generated from the DNA extracted from a tumor specimen, bioinformatics tools are used to align the reads against a reference genome and identify differences between the tumor DNA sequence and the reference sequence. Given the intrinsic genomic instability of malignancies, and often complicated intratumoral heterogeneity due to the presence of various tumor subclones, maximum clinical utility of NGS testing of cancer specimens can only be achieved using a bioinformatics pipeline designed to detect all four classes of genomic variants (SNVs, indels, CNVs, and SVS) at allele frequencies that are physiologically relevant. The four main classes of variants each require different computational approaches for sensitive and specific identification (assuming the assay is designed to permit their detection) [56], and since various bioinformatics pipelines are known to yield different variant calls for the different classes of variants, and even for specific variants, optimization of the bioinformatics pipeline used for a clinical NGS test is imperative [57].

Single Nucleotide Variations

SNVs occur when a single nucleotide (e.g., A, T, C, or G) is altered in the DNA sequence; note that single base pair insertions and deletions are technically not SNVs but rather indels. SNVs are by far the most common class of sequence variant, and the high density of polymorphic SNVs segregating in the human population (about 1 SNV is present per 800 bases between a single diploid individual and the reference

genome) makes them ideal markers for genetic mapping [58]. Inherited SNVs are generally classified as single nucleotide polymorphisms (SNPs) if they are present at a moderately high frequency in the population (greater than 1 %), although many inherited SNVs exist at lower population allele frequencies yet are nonetheless benign polymorphisms with no known disease association. While SNPs are polymorphisms that have no direct (or clearly established indirect) association with a specific disease, SNVs that are correlated with disease often are referred to as single base pair mutations or point mutations. The biologic impact of SNVs in protein-coding regions depends on whether the change is synonymous (silent) or nonsynonymous (of which the two types are missense mutations and nonsense mutations). In noncoding regions, as well as some coding regions, SNVs may affect RNA processing or gene regulation [59–62]. Nonetheless, selection pressure reduces the overall frequency of single base pair substitutions in coding DNA and in associated regulatory sequences, with the result that the overall SNV rate in protein-coding DNA is much less than that of noncoding DNA. In addition, clinical testing does not usually consider the noncoding regions of the genome, although these regions are being studied and clearly can cause disease.

The platforms and bioinformatics pipelines of NGS are well suited to the detection of SNVs, although the error rates of different platforms must be considered during platform selection and assay design (Fig. 60.3). In fact, the earliest clinical applications of NGS were designed to detect

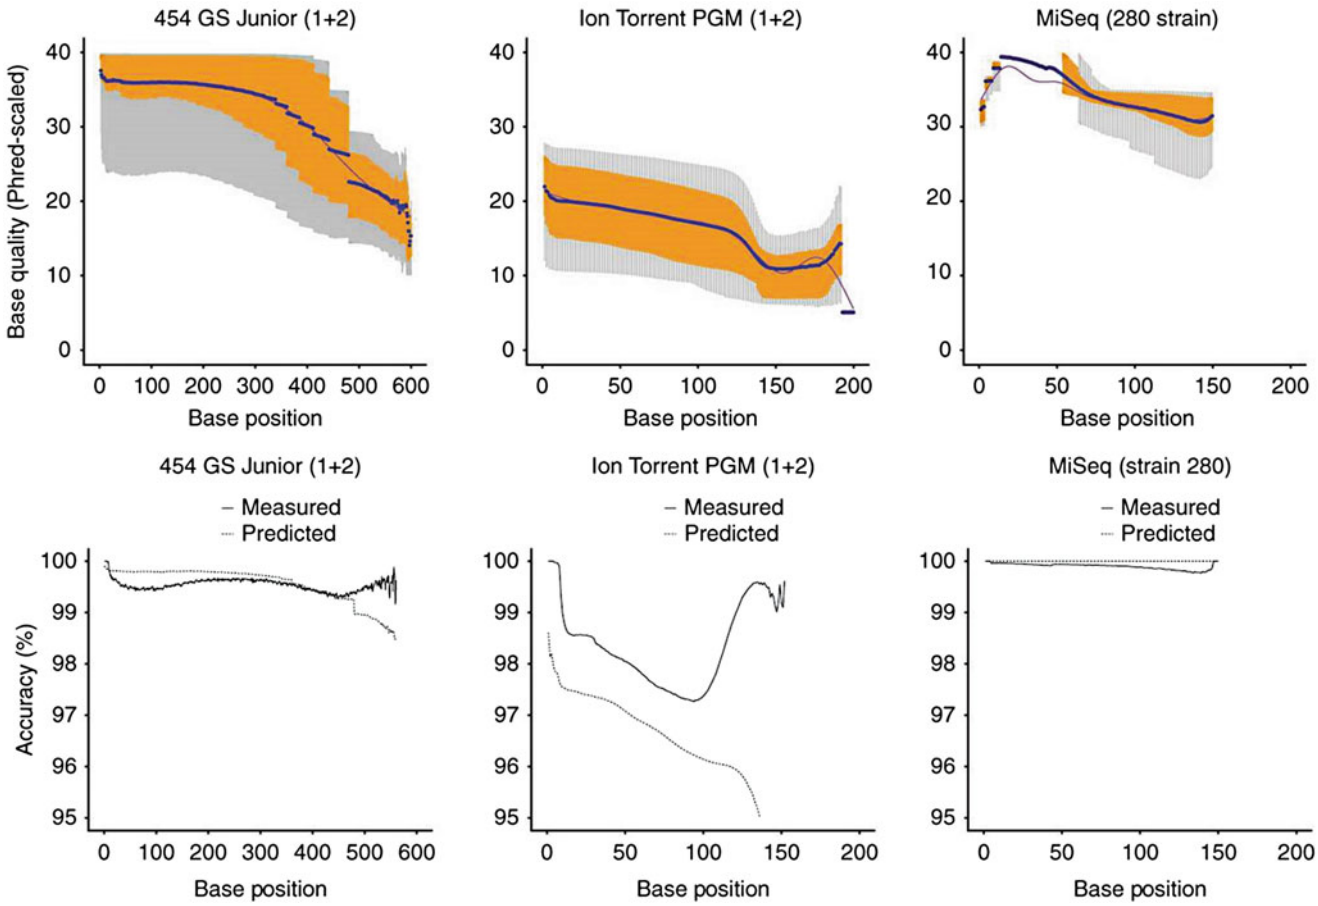

Figure 60.3 Comparison of three major platforms currently used in clinical NGS assays. Since the platforms vary with respect to their chemistry, it is not surprising that they each have different intrinsic error rates which affect the performance for single nucleotide variant (SNV) detection. In one comprehensive study evaluating sequencing platform differences [141], the MiSeq instrument (Illumina) had the lowest substitution error rate (about 0.1 substitutions per 100 bases). The Ion Torrent PGM (Life Technologies) had a substitution error rate over ten-fold greater, which steadily decreased across the read length; however, increased accuracy could be achieved by "clipping" read ends determined to be of low quality [142]. The substitution error rate of the 454GS Junior (454 Life Sciences, A Roche Company, Branford, CT) was intermediate between the MiSeq and Ion Torrent PGM. In terms of indel detection, admittedly only one of many factors that must be considered in selecting an NGS platform, the reversible dye terminator approach of the MiSeq has a lower indel error rate (<0.001 indels per 100 bases sequenced) compared with pH detection of the Ion Torrent PGM (1.5 indels per 100 bases), for reasons discussed in the text [143]. From Loman NJ, Misra RV, Dallman TJ et al. (2012) Performance comparison of benchtop high-throughput sequencing platforms. Nat Biotechnol 30:434-9. SNVs in inherited and acquired diseases, and for this reason the bioinformatics pipelines required for sensitive and specific detection of single base substitutions are among the most advanced in clinical NGS. The expanding catalog of clinically relevant point mutations has been an especially important driver of development of NGS assays [21, 63, 64]. Indeed, to date, NGS tests have been successfully implemented in several clinical laboratories for detecting SNVs [7–9, 14, 16, 17].

From a bioinformatics perspective, many popular NGS analysis programs for SNV detection are designed for constitutional genome analysis where variants occur in 0 % (wild type), 50 % (heterozygous), or 100 % (homozygous) of the reads. These prior probabilities are often built into the algorithms, and consequently, SNVs with VAFs falling too far outside the expected range for homozygous and heterozygous variants are often ignored as false positives. Thus, sensitive and specific bioinformatics approaches for somatically acquired SNVs require either significant revision of the software packages designed for constitutional testing or new algorithms altogether. Some bioinformatics tools are optimized for very sensitive detection of SNVs in NGS data, but these tools require high coverage depth for acceptable performance and rely on spiked in control samples used to calibrate run-dependent error models [37], features that must be accounted for in assay design. The published comparative performance of the various bioinformatics tools for SNV detection provides some guidance to clinical laboratories for design and implementation of NGS assays for somatic mutations [37, 65].

A number of on-line tools can be used to predict the impact of a SNV and evaluate whether a SNV has a documented disease association. However, given the lack of standardized annotation formats, and variability in the level of review that was performed to establish the associations between a specific genotype and a specific phenotype, putative associations must be carefully reviewed in the context of the published medical literature.

Insertions and Deletions

By definition, indels are an insertion and/or deletion of one or more nucleotides into genomic DNA and include events less than 1 kb in length, although most indels are only several bp to several dozen base pair (bp) in length. Of note, many indels are not necessarily the direct result of DNA damage, per se, but instead originate from DNA polymerase errors or incorrect DNA repair following a genomic insult. As a result, indels may be complex (e.g., include both inserted and deleted bases) and often involve areas with repetitive sequences, factors that can make identification difficult. Indels can have widely variable consequences, including altered gene transcription, altered RNA splicing, in frame mutations (synonymous, missense, and nonsense mutations), frameshift mutations (that can be silent, or result in production of a protein with altered structure and function), and change the length of repetitive regions which can lead to the clinical phenomenon known as anticipation (more severe and earlier onset disease with each generation).

Indel detection is very important in clinical NGS of cancer specimens since indels are implicated as the driving mechanism for many oncologic diseases. Additionally, indels are a common mechanism of kinase activation in cancer, a feature exploited clinically by targeted therapy with kinase inhibitors. While the sequencing techniques and bioinformatics tools used for NGS analysis both influence the sensitivity and specificity of indel detection, several specific factors inherent to indels as a mutation class also complicate their detection, including size, DNA sequence context (including the fact that indels commonly occur in repetitive DNA sequences), and variant annotation. The bioinformatics tools optimized for detection of SNVs or other classes of mutation are not optimized to detect indels, and therefore specific tools for indel detection are required.

Since alignment of indel-containing sequence reads is technically challenging, significant improvement in bioinformatics detection of indels can be achieved simply by using algorithms specifically designed for the task. One such specialized approach is called local realignment, which essentially tweaks the local alignment of bases within each mapped read so as to minimize the number of base mismatches [66].

Probabilistic modeling based on mapped sequence reads can be used to identify indels that are up to approximately 15 % the length of an individual sequence read, but not longer. This level of sensitivity is suitable for the detection of many clinically relevant indels like *EGFR* exon 19 activating indels. However, probabilistic methods do not provide an acceptable sensitivity for detection of other insertions such as *FLT3* internal tandem duplications (ITDs) that range from 15 bp to over 300 bp in length [67], the presence of which is used clinically to predict prognosis and guide treatment in patients with cytogenetically normal AML [68].

Split-read analysis approaches to indel detection utilize algorithms that focus on split and soft-clipped reads (sometimes called one-end anchored reads) to identify possible breakpoints in NGS sequence data. The reads can either be analyzed using a pattern-growth algorithm whereby unmapped reads are broken into smaller pieces and realigned separately to identify possible indels, and/or by de novo assembly whereby unmapped reads are reassembled into a contiguous sequence (contig) based on their overlaps with each other [67, 69]. Importantly, evaluation of split and soft-clipped reads allows for the identification of the full size spectrum of indels, and the approach is not subject to the same read length constraints as probabilistic methods [67].

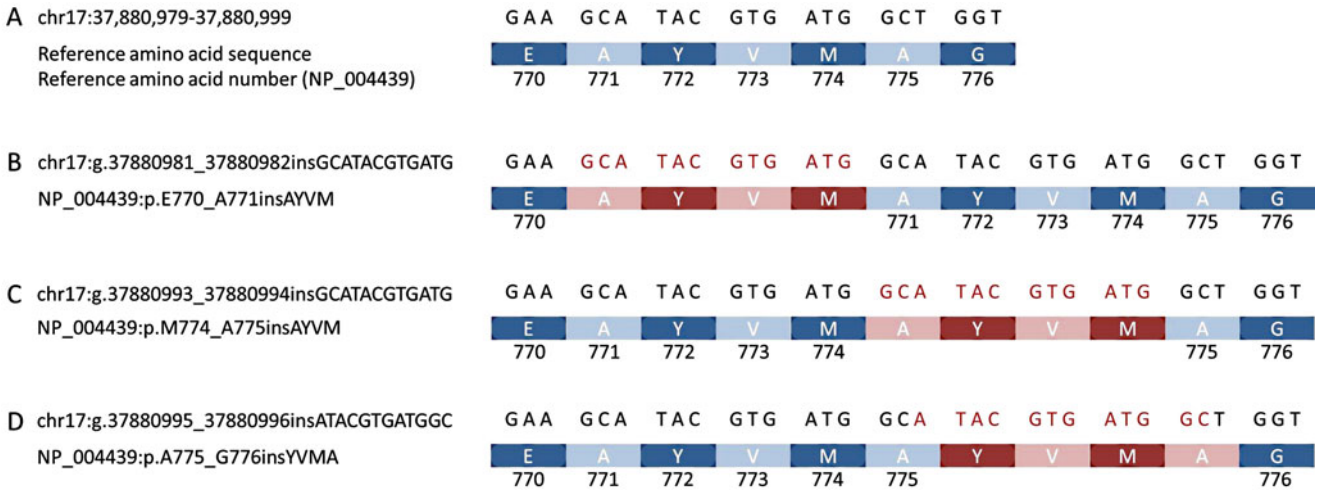

Figure 60.4 Redundant annotations for indels. The most common activating *ERBB2* indel in lung cancer results from duplication of 12 nucleotides in exon 20, resulting in insertion of four amino acids in the protein sequence, but can be annotated in multiple ways. The reference genomic nucleotide sequence and resulting amino acid sequence at the beginning of exon 20, with amino acid numbering according to the NP_00439 isoform of the ERBB2/HER2 protein, are shown (**a**). Three possible annotations for the activating *ERBB2* indel are shown (**b, c,** and **d**; inserted nucleotides and amino acids shown in *red*, reference shown in *blue*). In (**b** and **c**), the inserted nucleotide sequence is the same (GCATACGTGATG), but the site of insertion is different. In (**b**), the insertion is made at the beginning of the reference AYVM sequence, with the genomic annotation chr17:g.37880981_377880982ins12 and protein annotation NP_004439:p.E770_A771insAYVM. In (**c**), the insertion is made after the reference AYVM sequence, shifting the indel annotations to chr17:g.37880993_37880994ins12 and NP_004439:p.M774_A775insAYVM. However, the resulting nucleotide and amino acid sequences are exactly the same in (**b**) and (**c**). However, the same insertion also can be annotated with what seems to be a completely different inserted sequence (**d**). Note that the amino acid before and after the reference YVM is an alanine. However, the reference A771 is encoded by the genomic sequence GCA, whereas the reference A775 is encoded by the genomic sequence GCT. Insertion of the sequence ATACGTGATGGC, splitting the GC and T that normally encode A775 (i.e., genomic annotation chr17:g.37880995_37880996insATACGTGATGGC) keeps an A at amino acid number 775 (though now encoded by GCA instead of the reference GCT). The inserted nucleotides result in insertion of amino acids YVMA between reference amino acid positions 775 and 776 (i.e., protein annotation NP_00439:p.A775_G776insYVMA). The inserted A (just prior to G776) is derived from the last two inserted nucleotides (GC) and the T that was split off from what was originally A775. Although at first glance the various annotations listed in parts (**b**), (**c**), and (**d**) seem different, all result in the same final nucleotide and amino acid sequence. Of note, none of these possible annotations is technically correct based on the Human Genome Variation Society recommendations for mutation nomenclature [144], in which the variant is most appropriately annotated as a duplication (dup): chr17:g.378800982_37880993dup and NP_004439:p.A771_M774dup. Indel Annotation

A major issue with clinical indel detection is annotation (i.e., how the size, composition, and genomic location of the indel is written). As discussed above, indels often occur in repetitive sequences, and thus multiple possible annotations can describe the same resulting sequence (see Fig. 60.4). Left-alignment prior to indel calling can decrease this problem by combining the multiple possible annotations into a single left-aligned annotation [66]. Importantly, left-alignment does not necessarily facilitate comparison of the identified indel to existing databases and literature in which indels are often not annotated in left-aligned format. In fact, left-alignment may preclude correlation of a potentially relevant indel with existing databases during interpretation.

Reference Standards

Since highly optimized indel detection by NGS is relatively new, gold standards for detection and annotation are not yet established. However, the lack of consensus indel calls across various technical approaches and variant annotations make establishing a reference standard difficult. Efforts to develop indel standards are underway, which will markedly increase the ease and clinical utility of clinical NGS testing results [70], but until these efforts are complete, it will be difficult to assess the sensitivity and specificity of clinical NGS assays for indel detection.

Copy Number Variations

CNV refers to structural changes resulting in gain or loss of genomic DNA in a chromosomal region. Individual CNVs may be inherited in the germline, or acquired as somatic mutations as in cancer genomes, such as *MYCN* gene amplification in neuroblastoma. Unlike SNVs, CNVs vary greatly in size and structure, ranging from thousands (by most definitions, CNVs are at least 1 kb long) to millions of nucleotides in length, and often involve complex

DNA rearrangements. While less common than SNVs, CNVs account for the majority of nucleotide differences between any two genomes because of the large size of individual CNVs [71].

NGS provides a comprehensive method for CNV screening; however, identification of CNVs from the short read sequence data generated by current NGS platforms presents significant bioinformatics challenges for both amplification and hybrid capture methods. As discussed in detail in Chap. 59, all current NGS platforms generate relatively short individual read sequences; the individual reads are combined via alignment to a reference genome to identify variants. However, detection of CNVs is conceptually different from identification of SNVs or indels since the individual sequence reads arising from CNVs often do not have sequence changes at the base pair (bp) level. Instead, the reads from within a region of a CNV are simply underrepresented or overrepresented in the collection of individual sequence reads when a deletion or amplification has occurred, respectively. Thus, the bioinformatics approaches to CNV identification rely on detection of an altered number of reads from a particular genetic region, or detection of sequence changes at the margins of the deletion or amplification, or both.

Relative Depth of Coverage

Since a diploid human genome contains two copies of the majority of genomic regions in every cell, a CNV results in a proportional change in the relative DNA content within the region encompassed by the CNV. Assuming deep enough sequencing coverage, the relative change in DNA content will be reflected in the number of reads mapping within the region of the CNV. The relative depth of coverage for a region must be interpreted with respect to an external baseline reference, which is generally accomplished by normalization to the "average" read depth across the same sample [72–74].

SNP Allele Frequency

Analysis of allele frequency at commonly occurring SNVs can be a useful indicator of CNVs or loss of heterozygosity (LOH) in NGS data [75]. Since single SNVs are often not informative for the presence of CNVs or LOH, the analysis usually combines information from multiple SNPs within the CNV region. An amplified CNV region will contain a shift of the allelic ratio away from 50:50 for heterozygous SNVs, with a predominance of the amplified allele nucleotide. For LOH, all SNVs in the region will be homozygous for the retained allele nucleotide, with a loss of any heterozygous SNVs. SNV allele frequency results can provide complementary information to more sensitive methods such as depth of coverage.

Discordant Mate Pair Methods

Mate pair libraries refer to sequence generated from the ends of DNA fragments in the range of 2–5 kb long. Since current NGS platforms only generate sequence reads up to several hundred bp long, only the ends of the DNA fragments are sequenced, generating what are termed paired ends [76, 77]. The paired ends are mapped back to the reference genome using standard alignment algorithms, and the distance between mapped reads is considered proportional to the length of sequence contained in the original fragment. While mate pair mapping can be used to improve variant detection for several classes of mutations, including CNVs, it is most useful for detecting structural variants. Those paired ends that map with an intervening distance significantly greater or less than predicted by the fragment size are referred to as discordant, and the presence of discordant reads indicates the presence of a structural variant.

Split Read Mapping

Direct evidence of a CNV can be obtained from the sequences of DNA fragments that overlap the breakpoints of the CNV. These reads in the presence of a CNV or SV are referred to as split reads, and can be used to anchor the breakpoints of a CNV [78, 79]. Split read mapping allows identification of the precise genomic coordinates of a CNV, to the resolution of single nucleotides. Split read mapping requires sequence reads that are long enough to permit partial read alignment on both sides of the breakpoint, a technical issue that has been largely resolved by the longer read lengths offered by current NGS platforms.

Structural Variants

Identification of structural variants (SVs), including translocations and other chromosomal rearrangements, is critically important in the analysis of cancer specimens for diagnosis, to predict prognosis, and to direct therapy, for both hematologic malignancies and solid tumors. In the clinical laboratory, detection of rearrangements is typically performed by routine cytogenetics or interphase/metaphase fluorescence in-situ hybridization (FISH), but NGS methods also are capable of detecting SVs with high sensitivity and specificity, and offer several advantages over conventional methods such as FISH and cytogenetics. For example, in the case of *MLL* rearrangements characteristic of acute leukemia, where over 100 known fusion partners have been identified, NGS testing has the potential to identify all known and unknown partner genes, while similar testing by fusion FISH probes would be cost prohibitive. Similarly, translocation identification by NGS allows for single base

resolution of the chromosomal breakpoints, which allows for the identification of noncanonical breakpoints that may not respond to chemotherapy. At best, FISH and conventional cytogenetics can only localize breakpoints within 100–300 kb.

Genome sequencing is an unbiased approach for the identification of SVs similar to conventional cytogenetics. In theory, all rearrangements can be detected by genome sequencing as the sequence data cover both introns and exons, but in routine clinical practice genome sequencing is not practical for identification of rearrangements due to the high cost. SVs also can be detected using hybrid capture exome sequencing; however, intronic regions, where rearrangements are known to occur, must be directly targeted, and therefore the use of exome capture reagents in general will not identify SVs and custom capture panels that include intronic probes are required. NGS of RNA (known as RNAseq, which can be performed on the transcriptome or limited to specific targeted regions via hybrid capture-based approaches) can be used to identify SVs [80, 81], but obviously is limited to those settings in which the rearrangement produces a chimeric fusion transcript. Amplification NGS methods require a priori knowledge of the SV architecture and exact breakpoints so that appropriate primers can be used; since this information is rarely known in advance, amplification NGS approaches have very limited utility for SV detection from DNA.

SV detection in NGS methods is challenging but possible. The challenges arise from the mechanisms by which SVs are generated. The breakpoints for interchromosomal and intrachromosomal rearrangements most often are located in noncoding (e.g., intronic or intergenic) DNA sequences, often in highly repetitive regions, and therefore are difficult both to capture and to map to the reference genome. In addition, SV breakpoints often contain superimposed sequence variation ranging from small indels to fragments from several chromosomes [82, 83]. NGS sequence reads spanning complex rearrangements with multiple contributing chromosomes are difficult to map to the reference genome because only small DNA sequences (in general only tens of bases long) map to each of the contributing chromosomes [84].

Bioinformatics Approaches to SV Detection

Numerous software tools are available for SV detection which utilize the orientation, spacing, and depth of mapped NGS sequence reads. Most algorithms rely on discordant mate pairs and split reads, with a few also considering read depth. When implementing NGS for translocation detection, multiple tools should be evaluated to determine which one has optimal performance characteristics for the particular assay under consideration, since, depending on the design of capture probes and specific sequence of the target regions, different translocation detection tools may have large differences in sensitivity or specificity.

As noted above, discordant mate pair reads are paired-end reads that do not map to the reference genome as expected, and split reads are single end reads that map to the genome discontinuously. In the setting of SV detection, paired-end reads that map to different chromosomes, to the same chromosome but in the incorrect orientation, or in the proper orientation but too far apart or too close together can be used to detect genomic rearrangements. Because bioinformatics approaches based on discordant mate pair reads alone are subject to a high false-positive rate, some algorithms for SV detection make use of split reads. Similarly, due to the short read lengths currently available from NGS data, bioinformatics analysis of split reads for the detection of SVs is most reliable when evaluated in concert with paired-end data, since the position of the split read can be determined with higher confidence when its mate can be uniquely mapped to the genome, serving as an anchor. Depending on the choice of mapping software, "soft-clipped" reads may serve to indicate the presence of split reads (soft clips are produced by some alignment software when one member of a mate pair can be uniquely mapped to the genome but its mate cannot; if the mate can be partially aligned, in the correct orientation and with an insert size within the expected range, the unmapped remainder of the sequence is considered to be "soft-clipped") [85]. Soft-clipped reads often can be used to provide single base accuracy for the localization of rearrangements [86, 87], a significant advantage in that such precise localization of gene rearrangement breakpoints facilitates orthogonal validation by PCR.

Orthogonal Validation

As with any laboratory test, clinical NGS tests to detect sequence variants in cancer specimens require confirmation of test results by orthogonal methods during assay development and validation [7–9, 14, 16, 17, 88, 89], as well as to confirm unexpected or puzzling results that arise in routine clinical use. Test validation in general includes three steps, namely establishment of the analytic sensitivity and specificity of the test, definition of the range of detectable mutations and the limits of detection of the assay, and demonstration of detection of variants in cancers which are known to have the mutation. Given that the bioinformatics associated with base calling, reference genome alignment, and variant identification, annotation, and interpretation are such a key component of an NGS test, the bioinformatics methods must be validated as a part of overall test validation.

While each orthogonal validation method has advantages and disadvantages, several issues are common to all methods

in the setting of NGS tests of tumor specimens. First, although the lower limit of sensitivity of optimized conventional approaches is similar to that of routine NGS tests for SNVs, enhanced NGS bioinformatics analysis methods enable detection of variants present at a frequency of < 1 %, a level of sensitivity significantly better than can be achieved by conventional techniques. Second, some of the discrepancies between SNVs detected by NGS assays and an orthogonal validation method may actually represent tissue heterogeneity and/or intratumoral heterogeneity rather than technical errors. Third, orthogonal validation used as confirmatory testing of positive results but not of negative results can raise the issue of discrepant analysis (also known as discordant analysis or review bias) that may poorly estimate test performance [90–92]. This last issue is especially problematic since some current guidelines recommend the use of confirmatory testing for positive results [93–95] without associated testing of negative results (i.e., wild type results).

Conventional orthogonal validation approaches that have been used to confirm SNVs in NGS test results include Sanger sequencing, restriction fragment length polymorphism (RFLP) analysis, allele specific PCR, and SNP arrays. Similar approaches are well suited to confirm the presence of indels identified by NGS. Common technologies used for orthogonal CNV validation are quantitative real-time PCR (qPCR), interphase FISH, and array-based comparative genomic hybridization. The optimal choice depends on the size and scope of CNVs being validated. Classical cytogenetics, metaphase FISH, and interphase FISH are commonly used to confirm the presence of SVs identified by NGS.

Annotation

Use of NGS for clinical testing of cancer specimens is a paradigm shift that has profound implications for variant annotation. Unlike focused testing for genes with well-established clinical correlations, NGS involves analysis of numerous genes for which the spectrum of variation has not been well characterized and for which often only limited evidence is available for a disease association. Essentially, many of the evidence gathering and analysis activities traditionally performed for diagnosis, prognosis, or prediction of response to therapy have migrated from their classical position prior to testing (in the clinic), to a position where they follow the testing (interpretation of test results). This poses challenges to interpretation of whether the variant has a plausible contribution to the cancer phenotype (whether for diagnosis, prognosis, or response to a specific therapy). The annotation of the clinical significance of an identified sequence variant is therefore often a difficult and time-consuming process of gathering and interpreting the relevant scientific and medical evidence. The major factors that complicate annotation of sequence variants include the lack of clinical standards for interpreting primary NGS results, inconsistencies in reporting clinical variants in commonly used file formats, and a lack of systematized communication among clinical (and research) laboratories and the scientific literature.

Fortunately, an increasing number of resources are being created to support the task of interpretation of variants identified by NGS. First, common variants not associated with disease must be filtered out. Large-scale efforts such as HapMap and the 1000 Genomes Project that characterize genetic variation in diverse population groups support assessments of the frequency of human variation; ClinVar, dbSNP, and Variation Viewer support searching and filtering functions related to allele frequencies, and dbSNP provides files of common variants not known to be disease-related. Then, the disease associations of the variant must be considered. Many centralized reference databases, such as those at NCBI, are designed for representing relationships between variants and phenotypes; for example, dbGaP is a catalog of variation–disease associations, ClinVar supports clinical interpretation of variants, and MedGen harmonizes phenotype terminologies and supports computational access to phenotype data.

It is important to recognize that the assessment of pathogenicity reported by many databases is not determined by the database itself, but instead reflects what is submitted. For example sources of data in ClinVar include genetic testing laboratories, semiautomatic data flows from OMIM and GeneReviews, locus-specific databases, research studies, and community projects [96]. The annotation of sequence variations also hinges on standardized classification systems [97–99]; however, for most genes, reliable functional assessments are not possible due to insufficient classification methods. Currently, the clinical significance of pathogenicity is performed using tiered levels ranging from benign to uncertain significance to pathogenic (see reporting section below).

One particularly useful resource under development is the Clinical Genome Resource (ClinGen), an NIH-funded program envisioned to become a centralized resource of clinically annotated genes and variants to improve the understanding of genomic variation. Data are to be collected from numerous clinical and research testing results. Expert curation efforts and development of standards will help standardize clinical assessment of variants in the ClinVar database, develop a consensus process for identifying clinically relevant variants, develop machine learning algorithms to improve accuracy and throughput for variant interpretation, and disseminate and explore integration with electronic health records.

Variants of Unknown Significance

The issues associated with annotation of variants are so important because, even with gene panels, exome, or genome NGS tests optimized for clinically relevant sensitivity and

specificity, the majority of variants identified currently fall into the category of VUSs. By definition, for a VUS, insufficient existing evidence exists to support a definitive annotation regarding the effect of the variant on protein function, cell function, tumor behavior, and/or response to treatment. VUSs are particularly abundant in the sequence of tumor specimens due to the intrinsic genetic instability of most malignancies.

Several general categories of VUSs are defined. A sequence change affecting the coding region of a well-established gene in a particular tumor type, but not following the pattern of somatic mutation typical for that gene, would be a VUS. For example, constitutive activation of ABL1 in myeloid neoplasms typically occurs via translocation with a resulting BCR-ABL fusion protein kinase [100, 101]; however, a novel nonsynonymous SNV in *ABL1* would be a VUS since its effect on ABL1 kinase function cannot be extrapolated from literature about BCR-ABL activity or response to targeted kinase inhibition. Another category of VUSs is previously undescribed variants occurring in DNA sequences that do not encode amino acids, including splice sites and regulatory regions (promoters, enhancers, UTRs), or even more broadly acting regulatory elements like microRNAs or long noncoding RNAs. As examples, variants in the splice acceptor site may result in exon skipping, which may or may not have a significant impact on the protein's function [20], and variants occurring in regulatory regions can have unanticipated and widespread consequences in terms of gene expression or cell function.

A number of different statistical approaches can be applied to predict the likely impact of a nonsynonymous mutation on the function of a gene product. Some widely used prediction algorithms (e.g., SIFT, PROVEAN, PolyPhen) rely on evolutionary conservation of a particular base or amino acid, frequency of a given variant in the normal population, and/or location of a variant within the protein structure to determine whether an identified variant is likely to alter the function of a gene [102–106], although predicting the effect of a mutation on protein function is rarely straightforward [107]. Other approaches cluster somatically mutated genes by the functional pathways in which they are involved, usually in the setting of exome or genome analysis of cancer samples [108–111]; this pathway analysis approach facilitates understanding of shared biological implications of VUSs occurring in otherwise seemingly unrelated genes. Driver mutation analysis is an approach focused on identification of the variants in genes important for tumor growth, survival, or metastasis, as opposed to the passenger variants in genes that merely represent collateral damage in genetically unstable tumor cells [112]. Finally, clonal architecture analysis seeks to glean information about VUSs based on recognition of the rich clonal genetic diversity present in many morphologically homogenous tumors; for example, exome and genome sequencing studies of AML samples both at initial diagnosis and relapse have clearly shown that environmental selective pressures (e.g., the administration of chemotherapy) cause expansion or development of tumor clones with a relatively limited repertoire of escape mutations [113].

All these approaches for assigning functional significance to VUSs in a clinical setting must be viewed with caution. Even rational criteria such as biological plausibility should not stand alone, since identification of a novel variant in a known disease-associated gene, with a predicted functional impact similar to other disease-associated mutations in that gene, or in a pathway with other disease-associated genes, typically does not constitute sufficient evidence of causality. A false-positive assignment of a VUS as pathogenic can have profound clinical consequences including misdiagnosis, inappropriate care (including the delivery of radiation therapy and/or chemotherapy, both of which carry potentially very harmful side effects), and cessation of further testing that may uncover the true genetic features of the tumor.

Postanalytic Issues and Reporting

As discussed in detail in Chap. 59, professional organizations have recommended specific guidelines for reporting constitutional variants; for ease of interpretation, most clinical laboratories classify variants identified in constitutional testing into five categories, as follows: (1) pathogenic, (2) likely pathogenic, (3) uncertain significance, (4) likely benign, and (5) benign [114, 115]. This five-level classification scheme has recently been proposed as the standard for interpretation of variants in inherited disorders through a joint recommendation of the American College of Medical Genetics and Genomics (ACMG) and the Association of Molecular Pathology (AMP) and is expected to be formally adopted following member comment and organizational approval.

In contrast, no consensus guidelines have been published for reporting somatic or acquired variants, although several work groups are currently addressing this issue. Most laboratories currently classify sequence variations with regard to the disease and in relation to the actionability of the given variant with respect to prognosis, diagnosis, or therapeutic selection using the same five categories as for reporting constitutional variants [7]. Since predicted responsiveness to targeted therapy is often the primary reason for NGS testing in the cancer setting, variants expected to be sensitive or resistant to a given therapy should be documented; driver and passenger variants should be reported even in the absence of a direct role in choice of therapy. When a variant is identified that is known to be associated with a familial cancer predisposition syndrome (and when paired tumor-normal analysis is not performed), formal genetic counseling and germline

analysis should be recommended in the report since it can be difficult to ascertain the etiology of a given variant as germline or somatic based on the VAF from NGS analysis of a tumor sample alone.

Quality Management and Other Regulatory Issues

NGS is subject to the same regulatory standards as other clinical molecular tests, and, like other laboratory tests, has a test cycle that includes a preanalytic phase, an analytic phase, and a postanalytic phase. However, the fact that the analytic portion of a NGS test consists of three components (i.e., the sequence platform; the laboratory procedures that are involved in DNA sequence generation; and the bioinformatics associated with base calling, reference genome alignment, variant identification, variant annotation, and variant interpretation) creates some unique quality management issues [88]. Because NGS is a relatively new type of DNA sequence analysis, different laboratories have developed different models for the associated quality control and quality assurance activities to meet appropriate regulatory guidelines and best practice standards, although the methods most useful in routine clinical testing have not been established. The more general aspects of a quality management system are covered in Chap. 62; the focus here is on those aspects unique to NGS testing of tumors.

Preanalytic Issues

The preanalytic phase of testing is traditionally the most difficult aspect of quality management since most of the preanalytic variables that impact laboratory testing are outside traditional laboratory boundaries. Because of the many unique aspects of NGS testing, the situation is even more complex for the analysis of tumor tissue. The first factor is time of specimen fixation, and the specific fixative used. Although, as discussed above, FFPE tissue is an acceptable substrate for NGS testing, the chemical changes in DNA that result from formalin fixation affect the quantity of intact DNA that can be recovered from tissue, and can have very subtle impacts on the actual sequence itself because of deamination reactions that result from formalin exposure; these changes become more significant the longer the period of exposure to formalin. Also, ethanol and methanol fixation (e.g., cytology specimens) create subtle differences in the quantity of nucleic acids that can be recovered.

Specimen size is the second important preanalytic factor. Most amplification-based NGS approaches require a minimum DNA input in the range of 10 ng. While hybrid capture methods have been described that utilize as little as 10 ng of DNA, concerns about library complexity lead most clinical laboratories to require 100–200 ng of DNA as a minimum for hybrid capture NGS testing.

Third, the tissue sample must be appropriate. In the setting of oncology testing, this variable is far more nuanced than the simple requirement that the tissue contains high neoplastic cellularity and viability. Questions occur regarding the most appropriate site to sample in a patient with recurrent disease. Given that clonal heterogeneity is often present within the primary tumor, and that tissue metastases often represent divergent tumor clones [53, 54, 116], the tumor site sampled can have a profound effect on test results, and potentially patient care.

Fourth, in patients who have had an allogeneic bone marrow transplant, it can be difficult to collect tissue with sufficient levels of the patient's tumor cells to allow for the detection and interpretation of variants present at low allele frequencies.

Analytic Issues

Most laboratory tests involve the measurement of continuous variables, and consequently measures of test calibration, analytic variability, and other performance measures required for assay validation usually rely on statistical methods. For example, sophisticated QC approaches based on the Gaussian (normal) distribution have been developed to detect imprecision or systematic bias [117], and Levey-Jennings plots are used to detect variability that cannot be explained by a Gaussian distribution [118, 119]. However, DNA sequencing requires fundamentally different QC approaches to evaluate the integrity of the test results because DNA sequence is a discontinuous, nominal variable [120]. For NGS tests, an estimate of the probability of correctness may be substituted for a quantitative estimate of uncertainty, and several methods have been proposed to address this issue [66, 121–123].

Proficiency Testing

The Clinical Laboratory Improvement Amendments of 1988 (CLIA) regulations mandates proficiency testing (PT) for external quality assessment (EQA) as part of the laboratory accreditation process [124–126], although the precise rules and regulations that govern proficiency testing continue to evolve. Numerous organizations are accredited by CLIA to provide PT programs, but NGS testing of cancer specimens has many analytes for which EQA surveys are not available, and in this setting, laboratories must implement alternative PT assessment procedures. These alternative assessment procedures include split sample analysis with other laboratories, assessment of split samples with an established method

in the laboratory using previously assayed material, blinded exchange of samples with another laboratory, retesting of de-identified patient samples, analysis of DNA from cell lines with previously determined genotypes, or analysis of synthetic DNA of known genotype [127, 128].

Many PT programs are based on an individual analyte, and are appropriately termed analyte-specific or disease-specific PT programs. The utility of disease-specific approaches for DNA analysis has been well documented [129–131]; however, given the number of genes and range of mutations that are routinely evaluated by NGS tests, clinical laboratories cannot follow an analyte-specific PT approach. For this reason, methods-based proficiency testing (MBPT) paradigms have been developed which are centered on the method of analysis rather than the specific analyte being tested [126, 132]. The Centers for Medicare and Medicaid Services (CMS) that oversees the CLIA inspection and accreditation process understands that analyte-specific PT is not possible for the many different mutations that can occur in the many different genes that are analyzed by NGS tests, and therefore supports the concept of MBPT.

MBPT has some distinct advantages for PT of NGS tests. First, MBPT is scalable in that comparisons are possible between laboratories testing for dozens (if not hundreds or thousands) of different genes. MBPT also allows evaluation of proficiency in detection of a wide range of variants, rather than one specific mutation type. Laboratories that participate in MBPT challenges are not penalized for an inability to detect a sequence variant that lies in a region outside the scope of their validated test, or types of sequence variants that are not validated for their NGS test. However, at present, MBPT cannot be used for PT when developed internally by an individual laboratory; MBPT is only acceptable when administered by an external PT provider.

While the emphasis to date has been on comprehensive PT assessments that evaluate all three aspects of an NGS test (the sequence platform, the wet bench procedures involved in DNA sequence data generation, and the bioinformatics associated with variant identification), a novel type of PT termed in silico PT has recently been developed to specifically address the bioinformatics component of NGS tests [126, 128]. In silico PT is a response to the fact that clinical NGS bioinformatics methods are not standardized across laboratories, and thus bioinformatics analysis of NGS sequence reads is a major source of variability between laboratories performing an NGS test on the same nucleic acid sequence. For in silico PT, sequence files from an NGS test are manipulated by computerized algorithms that introduce relevant sequence variants [133]. The resulting in silico data files (also referred to as simulated data files) mimic the complexity of clinical samples and thus are ideal for MBPT for several reasons. First, they challenge every step in the bioinformatics analysis from alignment through variant detection, annotation, and interpretation. Second, simulated data files can include all four major classes of variants, either alone or in combination, for any set of genetic loci. Third, the variant allele frequency can be manipulated to test the sensitivity and specificity of variant detection.

FDA Oversight

In the USA, the US Food and Drug Administration (FDA) regulates the manufacture of equipment, devices, and assay reagent kits used in clinical testing (which in the context of NGS includes the sequencing instruments, the kits used for DNA extraction, library preparation, and specific tests) and the bioinformatics methods to analyze the sequence data [134–136]. The US FDA defines tests that are developed and used within the same clinical laboratory, and that are not provided to other clinical laboratories, as laboratory developed tests (LDTs). In addition, the laboratory that develops an LDT must inform the medical professional who requested the test, in a statement appended to the test report, that, "This test was developed and its performance characteristics determined by {Name of the Laboratory}. It has not been cleared or approved by the US Food and Drug Administration" [137]. Because the number of US FDA cleared or approved NGS platforms, tests, and bioinformatics tools is currently very small, virtually all current clinical NGS assays are LDTs.

In 2010 the US FDA announced its intention to begin oversight of LDTs, and in response professional societies have proposed regulations to help guide FDA into best methods for ensuring appropriate oversight and validation of clinical molecular procedures including NGS tests [138, 139]. As part of the continuing evolution of regulatory oversight of LDTs, the US FDA issued revised guidance in 2013 on the distribution of in vitro diagnostic products labeled for research use only or investigational use only [140]. In this context it is noteworthy that clinical NGS testing is emblematic of the regulatory issues surrounding many LDTs developed for genetic analysis of tumors in that the rapid pace of advancements in understanding the molecular basis of cancer is driving adoption of clinical testing, but the demand and pace of change for clinical testing is far outstripping the pace at which clinical laboratories and vendors can complete the regulatory requirements required for US FDA clearance or approval as an in vitro diagnostic.

Conclusions

The rapid pace of advancements in understanding the genetic basis of cancer is driving adoption of genetic testing of cancer tissue specimens for diagnosis, to provide prognostic information, and to guide therapy. NGS methods have been

adopted for clinical testing because they provide rapid, accurate, and cost effective approaches for sequence analysis of the large genome regions that are increasingly used to stratify patients into different prognostic and treatment response groups. However, since NGS is a new method of sequence analysis that has only recently been introduced into clinical laboratories, sequencing platforms, techniques, assay designs, bioinformatics approaches, and regulatory paradigms are still evolving. In this changing regulatory environment, different laboratories have developed different quality management systems to ensure that NGS tests are performed to the same rigorous standards as more conventional clinical tests that focus on the analysis of nucleic acids, such as DNA sequence analysis by Sanger sequencing, microarray analysis, conventional cytogenetics, and metaphase or interphase FISH.

Clinical Applications of Proteomics

61

Delphine Rolland and Kojo S.J. Elenitoba-Johnson

Abstract

This chapter provides an overview of potential and current clinical applications of proteomics. Although the clinical applications of protein microarrays are discussed in this chapter, we particularly emphasize the potential utilization of mass spectrometry-based approaches for diagnosis, biomarker detection, and quantitation.

Keywords

Protein microarray • Mass spectrometry • Proteomics • Biomarkers

Overview

The term "proteomics" was first used in the mid-1990s to describe large-scale characterization of the entire protein complement of a cell, tissue, or organism. The goal of proteomics is to obtain a more global and integrated view of biology by studying protein expression, localization, interaction, modification, and function. In fact, proteomics has been widely applied in various areas of science, ranging from the deciphering of molecular pathogenesis of diseases and the characterization of novel drug targets, to the discovery of potential diagnostic and prognostic biomarkers. Although the largest application of proteomic analysis remains scientific research, such technologies have already been introduced into clinical laboratories and are poised for broader routine use in the future.

Protein Microarrays

Principle of Protein Microarrays

Technologies well established for DNA/RNA applications have been adapted for protein-based research resulting in the creation of protein microarrays. Currently, protein microarray formats include two major classes, forward-phase arrays and reverse-phase arrays, depending on whether the sample is captured from solution phase or bound to the solid phase (Fig. 61.1).

Forward-phase microarrays are the most frequently used formats allowing the simultaneous analysis of multiple parameters per sample. Specific proteins of interest are selectively trapped from complex protein mixtures (serum, plasma, cell lysate, or cell culture supernatant) by well-defined capture or "bait" molecules (usually antibodies but full-length functional proteins or protein active domains could be used) that are immobilized onto a solid surface. Each spot of the array contains one type of immobilized antibody or bait molecule. Each array is incubated with one sample and the bound analytes are visualized either by direct labeling of the analytes or via labeled secondary antibodies. Standard detection methods include fluorescence, chemiluminescence, and colorimetry. A planar microarray-based

D.G.B. Leonard (ed.), *Molecular Pathology in Clinical Practice*, DOI 10.1007/978-3-319-19674-9_61

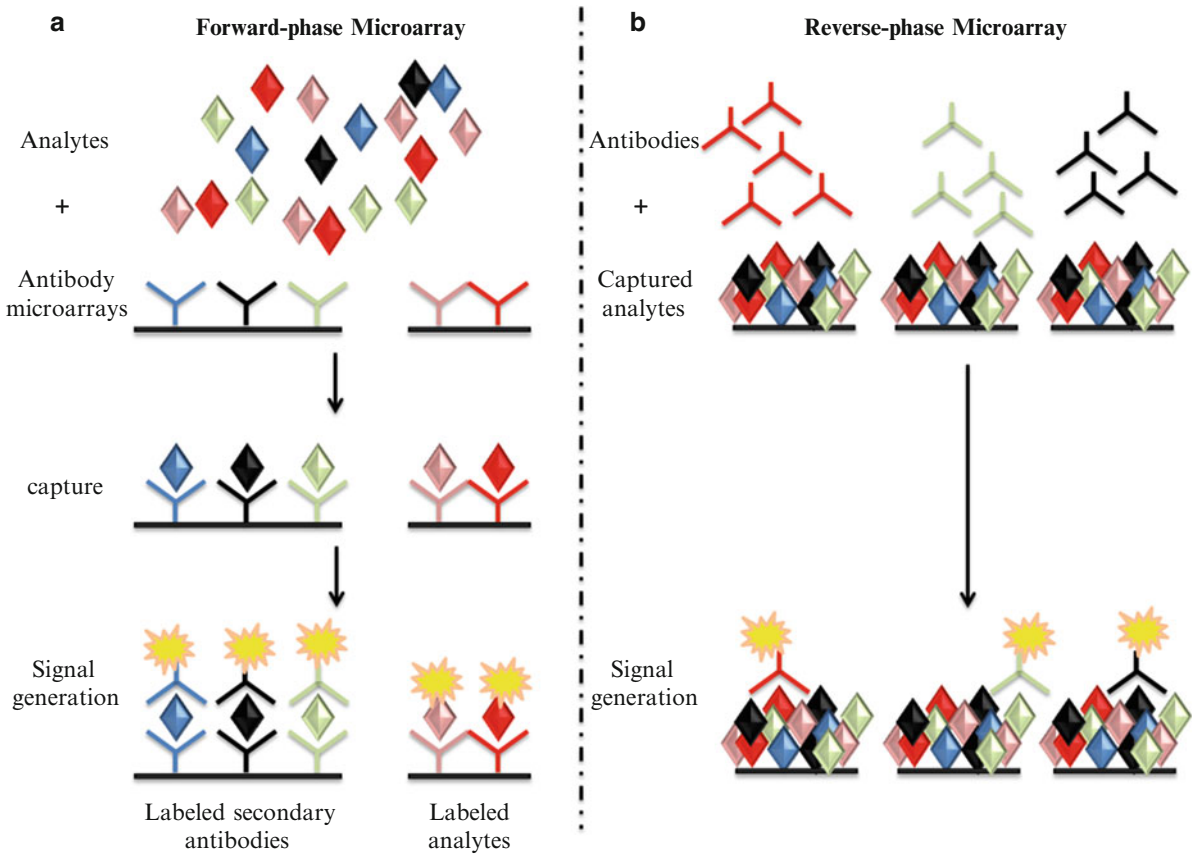

Figure 61.1 Comparison of forward-phase and reverse-phase protein microarrays. (**a**) Forward-phase microarray. Capture antibodies are first immobilized on the slide surface. These immobilized antibodies are used to capture the antigens they recognize from a test sample. (**b**) Reverse-phase microarray. Complex samples are immobilized on the surface and targeted by antibodies overlaid on them

system can generate high-density protein microarrays to screen a large number of analytes in a single experiment. The concept of planar microarray-based systems has been successfully miniaturized and operationalized into a bead-based microarray system where each bead is coupled to a specific bait molecule. This bead-based microarray system provides an interesting alternative since it is more flexible, robust, and advanced with respect to automation to screen thousands of samples within a short time.

For reversed-phase microarrays, a multitude of different samples (tissues or cell lysates) are immobilized as spots in rows on a solid support such that the array contains numerous spots representing the proteome of different patient samples or cell lysates. Then, each microarray is incubated with one highly specific detection molecule or antibody, measuring a single analyte with direct comparison of the analyte across multiple samples. This approach allows sets of proteins to be detected in large collections of tissue or cell samples.

Clinical Applications of Protein Microarrays

To date, many commercial forward-phase microarrays are available to investigate different classes of proteins such as cytokines and chemokines, cancer biomarkers or molecules involved in signaling pathways. Interestingly, several clinical protein microarrays have been cleared by the US Food and Drug Administration (FDA) or CE-marked for use in the European Union. So far, the main applications of these protein microarrays are diagnosis of infectious diseases or immune diseases. For example, the AtheNA Muli-Lyte® Test System (Zeus Scientific, Raritan, NJ, USA) can be used for the diagnosis of the infection by *Borrelia burgdorferi* by multiplex sandwich immunoassay for the quantitative detection of distinct IgG antibody to Vlse-1 and distinct IgM antibody to pepC10. Another example is the Bio-Plex™ 2200 ANA Screen (Bio-Rad Laboratories, Hercules, CA) which detects autoantibodies in serum or plasma as an aid in the diagnosis of systemic rheumatic diseases such as systemic

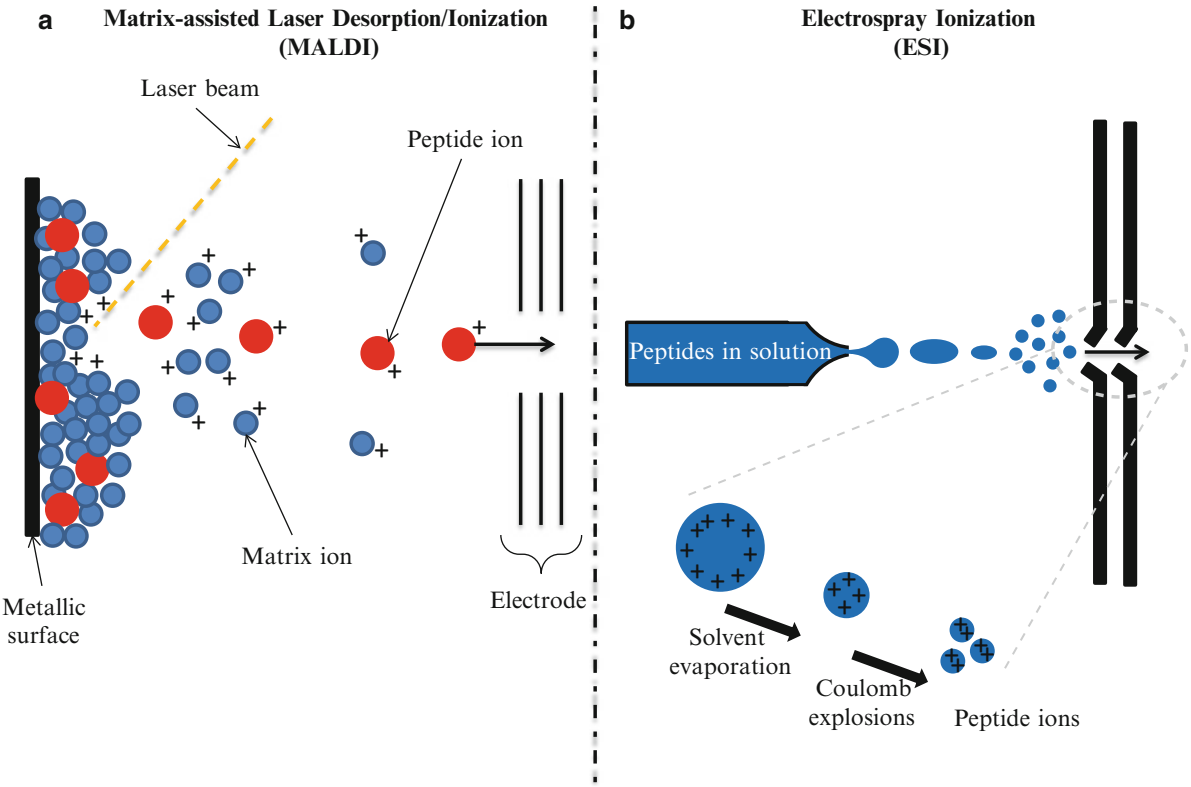

Figure 61.2 Principles of operation of Matrix-Assisted Laser Desorption Ionization (MALDI) and Electrospray Ionization (ESI). (**a**) MALDI. The protein/peptide sample is co-crystallized with a matrix, then the vaporization and ionization of the protein/peptide sample is achieved by a laser pulse-irradiation of the surface. The matrix material heavily absorbs UV laser light, leading to the ablation of the upper layer of the matrix. This process generates ions that are usually accelerated into a mass analyzer for analysis. (**b**) ESI. The liquid containing the analyte is dispersed by electrospray into a fine aerosol. Via Coulomb explosions, large charged droplets are sequentially blown apart to form smaller droplets. Upon reaching a certain size limit, only the discrete peptide sample ions enter the mass analyzer

lupus erythematosus, mixed connective tissue disease, undifferentiated connective tissue disease, Sjogren's syndrome, scleroderma, dermatomyositis, polymyositis, rheumatoid arthritis, CREST syndrome, and Raynaud's disease.

Mass Spectrometry-Based Proteomic Analysis

Introduction to Mass Spectrometry

Instrumentation

Since the first description of a mass spectrometry (MS) experiment in the early 1900s by Thomson [1], MS-based approaches have come a long way from being narrowly applied in analytical chemistry to a key device for clinical testing. The description in the late 1980s of two different soft ionization methods named Matrix-Assisted Laser Desorption/Ionization (MALDI) [2, 3] and ElectroSpray Ionization (ESI) [4] (Fig. 61.2) significantly accelerated MS-based interrogation of large biologically important molecules. The principle of operation of MALDI-based proteomics involves the co-crystallization of a protein/peptide sample on a designated matrix medium (Fig. 61.2a). The vaporization and ionization of the protein/peptide sample is achieved by pulse-irradiation of the surface with a laser. This process generates ions that are accelerated into the mass analyzer for analysis, filtering, and detection. By comparison, the ESI process involves the transfer of ions from solution to gaseous phase at atmospheric pressure (Fig. 61.2b). The application of a very high voltage across a sample solution at very low flow rates in a capillary needle causes ions to accumulate at the narrow tip of the needle where they are then drawn out as the sample solution is pushed out of the needle creating charged droplets that are accelerated in an electric field. Via the Coulomb explosion, large charged droplets are sequentially blown apart to form smaller droplets upon reaching a certain limit leaving only the discrete peptide sample ions to enter the mass analyzer.

After ionization the sample reaches the mass analyzer which separates ions by their mass-to-charge (m/z) ratios. Ion motion in the mass analyzer can be manipulated by electric or magnetic fields to direct ions to a detector which

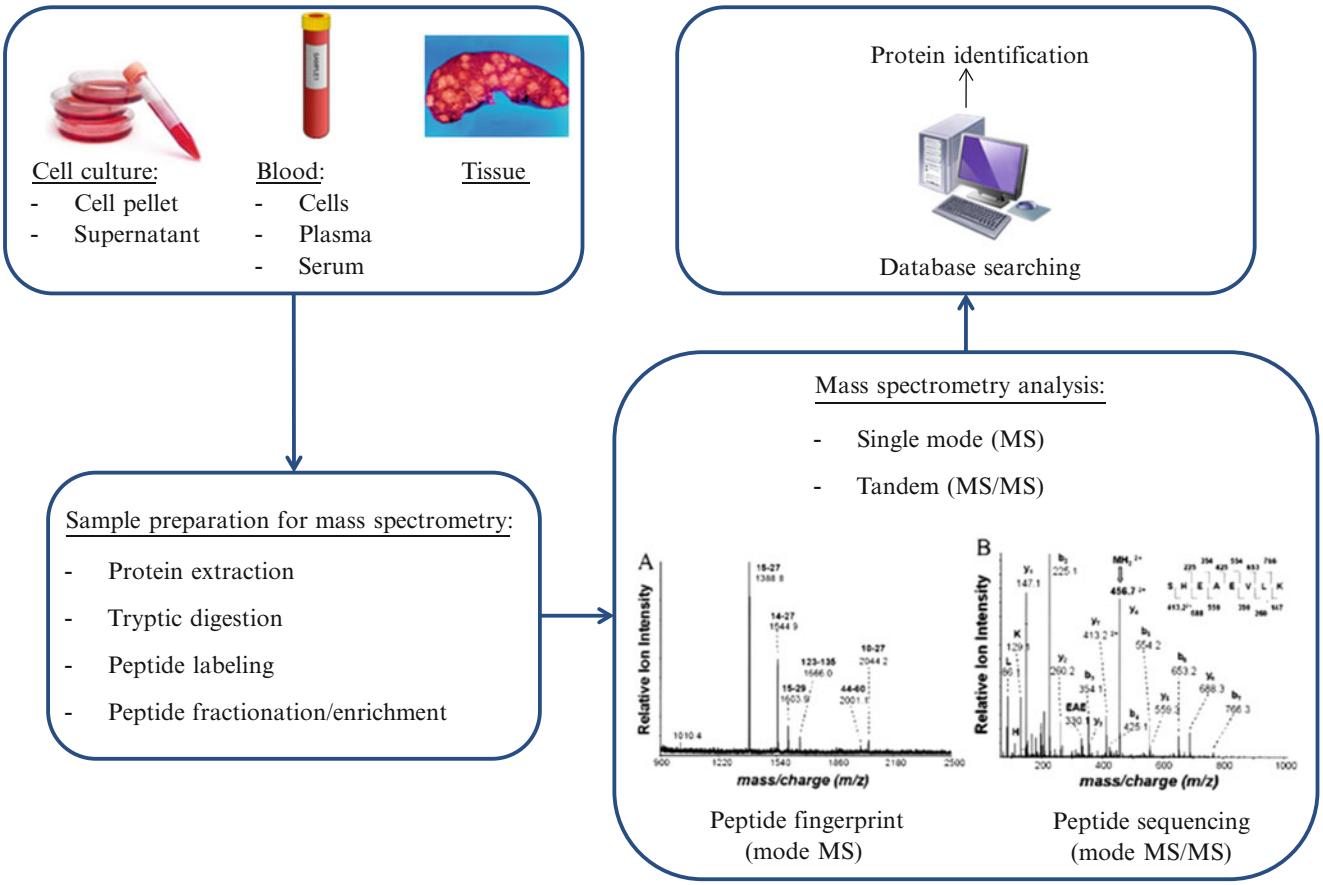

Figure 61.3 Workflow for mass spectrometry proteomics

registers the number of ions at each individual *m*/*z* value. Different types of mass analyzers are available: time-of-flight (TOF), ion trap, and quadrupoles. These mass analyzers differ considerably in sensitivity, resolution, mass accuracy, and the possibility to obtain fragment peptide ions which results in mass spectra with high content of information (MS/MS spectra). The choice of the combination of the ion source with the mass analyzer and the detector depends on the specific application.

Classical Workflow for Mass Spectrometry Proteomics

Mass spectrometry-based proteomic analyses can be divided into top-down or bottom-up processes. In top-down proteomics, intact proteins or polypeptides are directly analyzed by mass spectrometry. On the other hand, bottom-up proteomics entails digestion of complex protein mixtures into peptides using a proteolytic enzyme (typically trypsin). Resulting peptides are separated by liquid chromatography (LC) and analyzed by tandem mass spectrometry (MS/MS). Proteins are identified by matching experimental spectra with those from theoretical spectra of translated genomic databases generated by in silico cleavage using specific enzymes (Fig. 61.3).

Quantitative Mass Spectrometry-Based Proteomics

Quantitative measurement of protein concentrations is one of the key advancements in MS-based proteomics. Global quantitation of protein levels can be achieved by stable isotope labeling of proteins/peptides, use of heavy peptides as standards, and label-free quantitation (Fig. 61.4). Isotope labels can be introduced metabolically (i.e., in vivo), chemically, or enzymatically (i.e., in vitro). Since the metabolic labeling (stable isotope labeling with amino acids in cell culture, [SILAC]) requires maintaining cells in culture for several passages (usually six or seven passages) in the presence of stable isotopes of amino acids (heavy Arg, Lys, Leu, or Ile), its direct application to clinically relevant scenarios is less likely. The in vitro methods for labeling include isotope-coded affinity tagging (ICAT) and isobaric tags for relative and absolute quantitation (iTRAQ). These methods may be adaptable to clinical scenarios since cell viability is not required for labeling. In the original ICAT labeling method, cysteine residues were specifically derivatized with a reagent containing either zero or eight deuterium atoms as well as a biotin group for affinity purification of cysteine-derivatized peptides and subsequent mass spectrometry analysis. The iTRAQ method is another in vitro labeling reagent which targets the

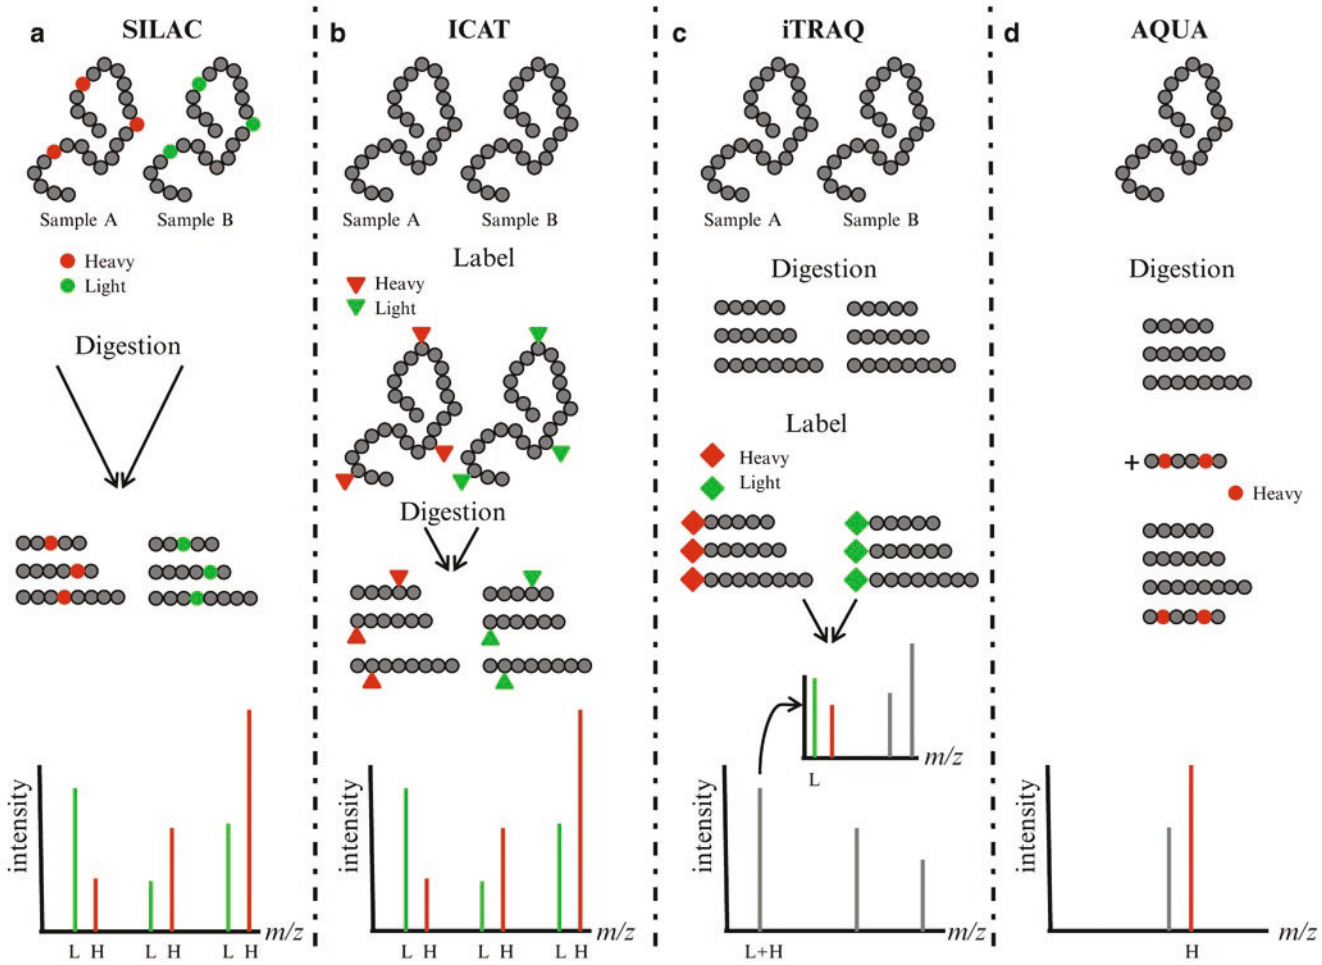

Figure 61.4 Quantitative proteomics. (**a**) In stable isotope labeling with amino acids in cell culture (SILAC), two cell cultures are differentially labeled with heavy amino acids containing stable isotopes (heavy, H) and normal amino acids (light, L). Lysates from labeled cells are digested, mixed, and analyzed by mass spectrometry. Differentially labeled peptides having the same amino acid sequence are detected in MS spectra and the relative abundance of the peptides can be compared. (**b**) In isotope-coded affinity tagging (ICAT), proteins are labeled at cysteine residues with reagent containing either 0 (light, L) or 8 (heavy, H) deuterium atoms. After digestion, labeled peptides are combined and analyzed by mass spectrometry. Peptides with the same amino acid sequence are detected in MS spectra and the relative abundance of the peptides can be compared. (**c**) In isobaric tags for relative and absolute quantitation (iTRAQ), peptides are labeled using isobaric amine-specific tandem tags. The iTRAQ reagent consists of a reporter region with 1 Da difference and a balance region that adjusts the molecular weight of the labeled parent ions. Each tag generates a unique reporter in MS/MS spectra and the relative abundance of peptides can be compared. (**d**) In absolute quantification (AQUA), an isotope-labeled peptide is spiked at a known amount into the sample preparation. The abundance of peptide can be compared with the abundance of the spiked peptide

N-terminus amino acid of peptides with a varying mass. The AQUA (absolute quantification) quantitative approach uses isotope-labeled synthetic peptides as standards spiked at a known amount into a sample preparation. The quantitation is achieved by comparing the mass spectrometric signal of the synthetic peptide to the endogenous peptide in the sample. Label-free quantitation methods are gaining in popularity and are increasingly being employed as an alternative to label-based approaches. These techniques do not use isotopic labeling, but instead directly compare signal intensities across different mass spectrometry runs using either the signal intensity of peptide precursors or the number of fragment spectra identifying peptides of a given protein.

Selected Reaction Monitoring (SRM)

Selected reaction monitoring (SRM), formerly referred to as multiple reaction monitoring mass spectrometry, utilizes two rounds of mass selection by quadrupole mass analyzers to discriminate specific ion peptides within a complex sample based on *m/z* ratios (Fig. 61.5) [5]. Following sample processing with trypsin and separation by nano-LC, ionized peptide precursors of predetermined interest are selected in the first quadrupole (Q1). After Q1 selection, only ions with the predefined *m/z* value are transmitted to the second quadrupole (Q2) where a collision-assisted dissociation causes peptide fragmentation. Detection and quantitation of the

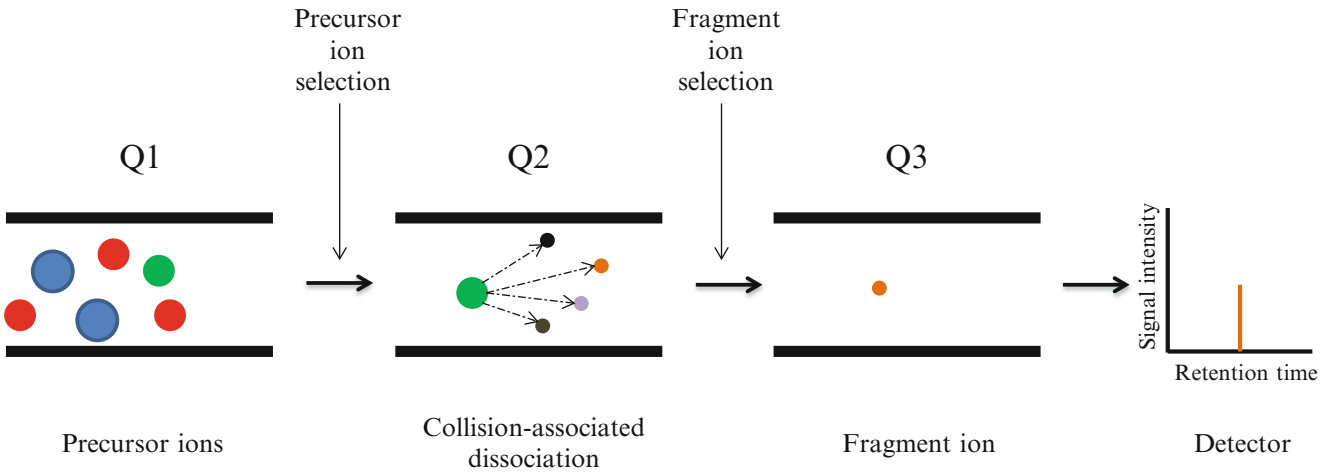

Figure 61.5 Selected Reaction Monitoring (SRM) analysis on triple quadrupole mass spectrometer. Several analytes are co-eluted from the chromatographic system. The ionized peptide precursors with a specific *m/z* are selected in the first quadrupole (Q1). Only ions with the predefined *m/z* value are transmitted to the second quadrupole (Q2) where a collision-assisted dissociation causes peptide fragmentation. Detection and quantitation of the target analyte is achieved following the selective transmission in the third quadrupole (Q3) of a predefined product ion

target analyte is achieved following the selective transmission in the third quadrupole (Q3) of a predefined product ion (a fragment of the precursor peptide). Ultimately, SRM allows the quantitation of a large set of target proteins in complex biological samples.

Protein Posttranslational Modification Study by Mass Spectrometry

Phosphoproteomics

Reversible protein phosphorylations at serine, threonine, and tyrosine residues represent fundamental and highly evolutionarily conserved types of protein posttranslational modifications which control essential cellular processes, including metabolism, growth, cell cycle, motility and differentiation [6, 7]. The Human Genome Project revealed that more than 520 protein kinases and 130 protein phosphatases exert tight and reversible control on protein phosphorylation. Perturbations in protein phosphorylation underlie many human diseases, including diabetes, cardiovascular diseases [8], immune disorders, [9] and cancers [10]. Recently, there has been increased interest in tyrosine kinases (TKs) due to the remarkably successful introduction of specific inhibitors, the TKIs, for the treatment of cancers. Indeed, many TKIs have been approved by the US FDA as routine therapeutic options for certain human cancers [11].

In order to identify aberrant protein phosphorylations via mass spectrometry analysis, an enrichment of the phosphoproteome is required prior to further analysis. This is mostly due to the low phosphorylation stoichiometry of phosphoproteins and the limited dynamic range of mass spectrometers. Several methods are well-described for phosphopeptide or phosphoprotein enrichments such as strong cation exchange chromatography (SCX), immobilized metal affinity chromatography (IMAC), metal oxide affinity chromatography (MOAC) [12], and immunoaffinity purification (IAP) using high affinity anti-phosphotyrosine antibodies [13]. The first three methods are used for global phosphorylation enrichment and will enrich for proteins that are phosphorylated at tyrosine, serine, or threonine residues. With the identification and quantification of phosphorylated peptides extracted from samples, intracellular signaling networks can be generated to highlight pathophysiological mechanisms. The better understanding of biological processes involved in the initiation or maintenance of a deleterious phenotype would be helpful to target specifically activated pathways as therapeutic options.

Glycoproteomics

Glycosylation represents the most common of all known posttranslational modification and, like the majority of cell surface proteins, receptor TKs are also glycoproteins with Asn (N)-linked oligosaccharides (N-glycans). Since glycopeptides often constitute a minor portion of a complex peptide mixture, several procedures have been developed to reduce the sample complexity and enrich glycoprotein content. One way to reduce the complexity is to perform lectin affinity chromatography to enrich for glycopeptides. In 2003, Zhang et al. suggested a new method for the selective isolation of N-glycosyl peptides [14]. This method involves glycoprotein oxidation which converts the *cis*-diol groups of carbohydrates to aldehydes. These aldehydes then can be derivatized with hydrazide groups immobilized on a solid

support to form covalent hydrazone bonds. After proteolytic digestion with trypsin, N-glycopeptides is released by using peptide N-glycosidases (PNGase). The identification and quantification of N-glycopeptides leads to characterization of proteins that are mainly expressed at the plasma membrane and therefore could be useful as potential diagnostic biomarkers.

Clinical Applications of Qualitative Mass Spectrometry Proteomic Analysis

Typing of Amyloidosis

MS-based proteomics has been combined with tissue microdissection for the diagnosis and typing of amyloidosis [15, 16]. With this approach, specific clinical variants of amyloidosis are identified based on correlation with the predominating protein components within the amyloid deposits in the tissue specimens. In this regard, MS-based proteomics has been used to accurately define AL amyloidosis (lambda/kappa light chain), heavy chain amyloidosis, AA amyloidosis, fibrinogen-a-amyloidosis, LECT2 amyloidosis, and other types. The accuracy and sensitivity of this approach continues to drive its potential to supplant Congo-red staining as the primary technique for the identification of amyloid.

MALDI-TOF and Clinical Microbial Identification

Classically, microbiological diagnoses are based on microscopic and biochemical characteristics, growth preference on specific media, metabolic traits and antimicrobial susceptibilities. The first attempt to identify bacteria using mass spectrometry was done more than 30 years ago [17]; however, only recently have MALDI-TOF devices become available for utilization by non-mass spectrometry specialists in a clinical laboratory setting. In practice, the sample can be applied onto the target plate either by deposition of a protein solution when an extraction step has been performed, or by touching the colony of interest with a sterile pipette tip and directly applying a small amount of sample onto the surface of the target plate. Samples are overlaid by a suitable matrix and then analyzed by MALDI-TOF-MS. A characteristic spectrum is recorded and constitutes a specific sample fingerprint, which is unique for a given species. For species-level identification, the size range generally used is 2–20 kDa, which was found to be very stable and with a strong signal-to-noise ratio. The computer software automatically compares the collected spectra with a reference databank containing a wide variety of medically relevant isolates. A retrospective study of 1,116 routine isolates representing the main bacterial groups encountered in the clinical microbiology laboratory showed 95.2 % correct identification by MALDI-TOF [18]. In 2010, Van Veen et al. prospectively analyzed 980 isolates and found an overall concordance between MALDI-TOF and conventional methods of 92 % at the species level and an addition of 6.8 % for specimen identified only at the genus level [19]. The main advantages of MALDI-TOF are the speed of testing, with results available up to 20 h earlier than by conventional testing, and the cost-effectiveness of the method.

Imaging Mass Spectrometry

Imaging mass spectrometry is the use of MALDI-TOF-MS for profiling and imaging proteins directly from thin tissue sections [20]. This application provides specific information on the local molecular composition, relative abundance, and spatial distribution of peptides and proteins in the analyzed section (Fig. 61.6). A tissue section is uniformly coated with a matrix solution by air spraying within which the tissue section becomes physically bound and co-crystallized. The co-crystallized area is then subjected to MALDI ionization using a discrete Cartesian pattern of laser shot spots. The distance between the spots is fixed and depends on the chosen resolution, typically 10–100 μm. From the intensity of a given m/z value monitored in each spectrum, a two-dimensional ion density image is reconstructed using specialized software. When full images are not required, but rather data are needed from discrete targeted areas within the tissue, a histology-directed profiling approach can be employed. Several studies have shown the potential of imaging MS in molecular diagnosis of prostate cancer [21], prediction of the response to neoadjuvant chemotherapy and radiation or HER2 status in breast cancer [22, 23], classification and survival prediction for lung cancer, [24] and determination of molecular tumor margins [25]. However, since imaging mass spectrometry is based on MALDI-TOF-MS, the principal drawbacks of this application are the fact that almost 90 % of the observed signals are below m/z 30,000 and a poor resolution of signal above m/z 50,000.

Clinical Applications of SRM Mass Spectrometry

The prostate-specific antigen (PSA) is a well-established biomarker which has been used in the diagnosis and surveillance of prostate cancer. In 2009, Fortin et al. published a

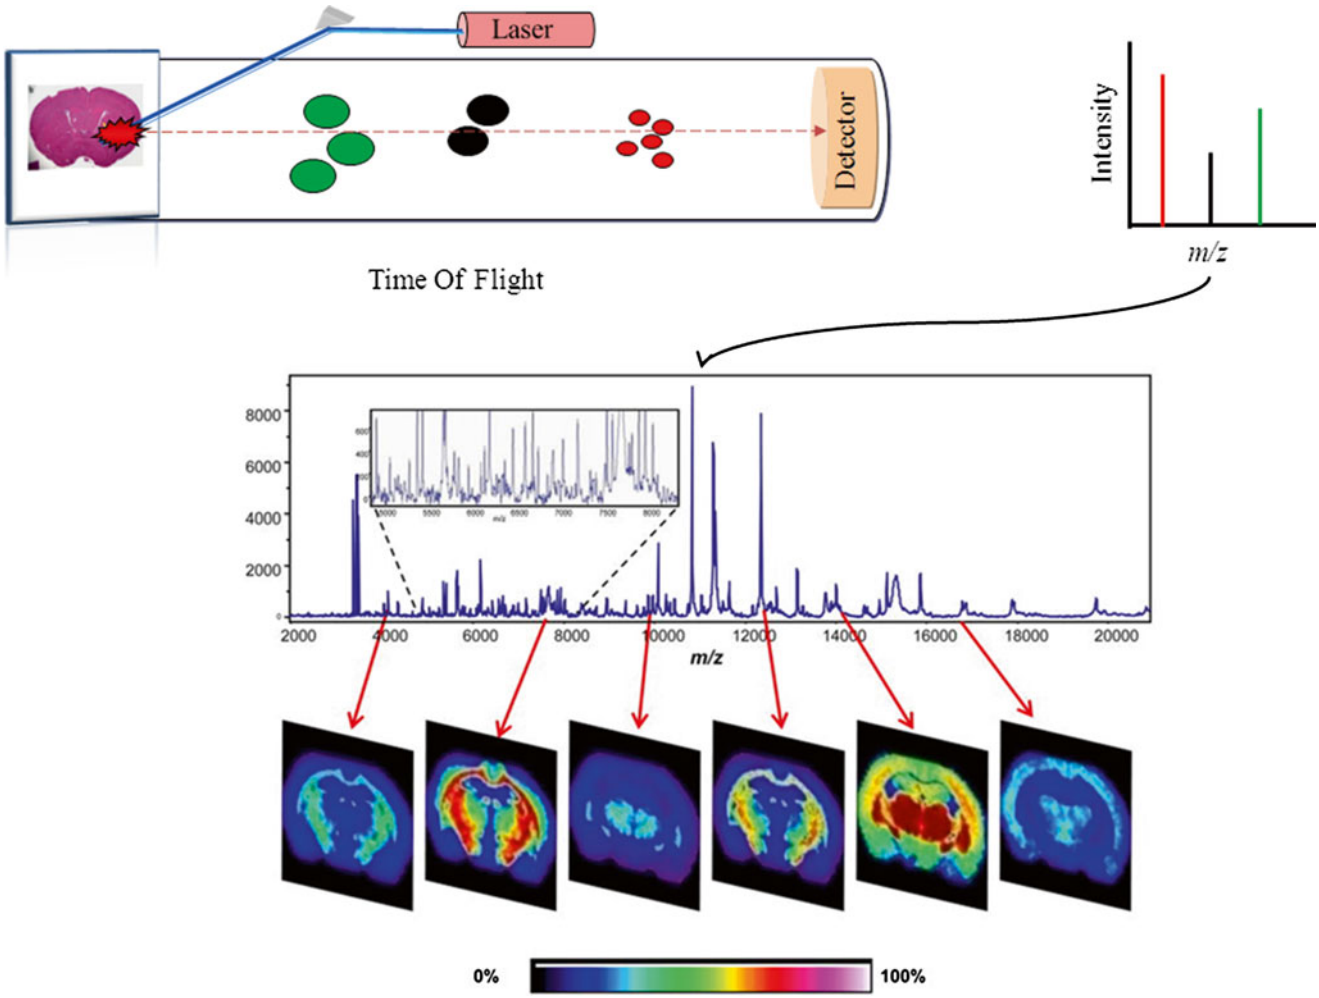

Figure 61.6 Imaging mass spectrometry. Tissue sections are mounted on a metal plate, coated with matrix, and placed in the mass spectrometer (MALDI-TOF). The laser desorbs and ionizes analytes from the tissue and their *m/z* values are determined using a time-of-flight analyzer. By scanning over the tissue and measuring the peak intensities over thousands of spots, mass spectrometric images are generated at specific molecular weight values

sensitive SRM assay to detect PSA in the sera of patients with either benign prostate hyperplasia or prostate cancer [26]. They demonstrated a limit of detection of the PSA peptide LSEPAELTDAVK of 1.5 ng/ml by SRM MS. The PSA levels measured by SRM MS were validated using the VIDAS TPSA ELISA test (bioMérieux) with a reliable correlation between these two technologies ($r^2 = 0.99$). Several other studies established SRM MS as a useful method to detect and quantify different biomarkers such as the C-reactive protein (CRP) [27] and the inter-α trypsin inhibitor heavy chain 4 (ITIH4) [28]. Recently a proof-of-principle study published by Wang et al. demonstrated the potential of SRM MS for clinical application [29]. They were able to design an assay to profile and quantify the high-frequency KRAS missense mutation in colorectal and pancreatic tumors.

Concluding Remarks

Proteomic approaches are increasingly being employed in the clinical laboratory, and include nonneoplastic and neoplastic applications. Routine implementation of proteomic techniques in the clinical laboratory is anticipated to occur in the next few years.

Abstract

Clinical molecular pathology tests identify or measure molecular and genetic markers for an individual patient. These markers confirm a diagnosis, predict prognosis, guide treatment, and monitor response to therapy. The rapid turnaround time, reliability, and high accuracy of molecular pathology tests have reduced the occurrence and cost of health care services, enhanced patient outcome, and improved disease management, making molecular pathology one of the fastest-growing sectors of clinical pathology, with more than 2,500 tests currently available in the National Institutes of Health Genetic Testing Registry (NIH GTR) (Rubinstein et al., Nucleic Acids Res 41(Database issue): D925–D935, 2013). The vast majority of these tests are developed and performed as laboratory developed tests (LTDs), which to date have limited oversight by the US Food and Drug Administration. Regulatory and quality oversight of all clinical testing in the USA is provided by the Clinical Laboratory Improvement Act of 1988 and its implementation through the Centers for Medicare and Medicaid Services. The operation of a clinical molecular pathology laboratory requires integration of medical, scientific, and clinical molecular pathology expertise, resources including facilities, equipment, and personnel, and skills in organization, administration, management, and communication. Quality service is achieved by adherence to clinical laboratory regulations and standards, from specimen collection and processing to reporting of patient results. This chapter reviews fundamental knowledge important for the management and operation of a clinical molecular pathology laboratory.

fastest-growing sectors of clinical pathology, with more than 2,500 tests currently available in the National Institutes of Health Genetic Testing Registry (NIH GTR) [1]. The vast majority of these tests are developed and performed as laboratory developed tests (LTDs), which to date have limited oversight by the US Food and Drug Administration (FDA). Regulatory and quality oversight of all clinical testing in the USA is provided by the Clinical Laboratory Improvement Act of 1988 (CLIA) and its implementation through the Centers for Medicare and Medicaid Services (CMS). The operation of a clinical molecular pathology laboratory requires integration of medical, scientific, and clinical molecular pathology expertise, resources including facilities, equipment, and personnel, and skills in organization, administration, management, and communication. Quality service is achieved by adherence to clinical laboratory regulations and standards, from specimen collection and processing to reporting of patient results. This chapter reviews fundamental knowledge important for the management and operation of a clinical molecular pathology laboratory.

The Role of the Molecular Pathology Laboratory

Molecular pathology laboratories perform tests for different clinical purposes, including genetics, cancer, infectious diseases, identity testing, and human leukocyte antigen (HLA) typing. Although all applications share the use of nucleic acids as the main analyte, the different types of testing require different management considerations (Table 62.1). Considerations relevant for each type of test performed in molecular pathology are reviewed.

Table 62.1 Special considerations in molecular pathology by clinical application

Application	Considerations
Genetics	Ethical issues (presymptomatic and prenatal testing)
	Consequences for family members
	Informed consent requirements
	Requirements for family-related information (ethnicity, pedigree, specimens)
	Time sensitivity (prenatal diagnosis)
	Complex risk-assessment calculations
Oncology	Many types of samples
	Extensive use of paraffin-embedded tissue and fine needle aspirate samples (familiarity with limitations)
	Small biopsy specimens
	Need for diagnostic samples for optimal interpretation of minimal residual disease test results
Infectious diseases	High-volume testing
	Use of automated platforms
	High cost of commercial in vitro diagnostic test kits
	Increased need for quantitative testing with a wide dynamic range and low detection limit
Identity testing	Chain-of-custody documentation for specimens
	Special patient identification requirements
	Complex calculations
	Special accreditation requirements for paternity and forensic testing
	Special qualifications required for laboratory director
HLA testing	Time sensitivity (<24 h turnaround time)
	Complex analyses
	Special accreditation requirements for the laboratory and laboratory director

HLA Human leukocyte antigen

Genetic Disorders

All diseases have a genetic contribution, whether it is a specific genetic disease or an increased likelihood for developing a medical condition. Genetic disorders are primarily caused by mutations present in every cell of an individual. Molecular testing for neoplasia or an infectious disease requires a sample of the tumor or the infected tissue, respectively, while molecular testing for a genetic disease can be performed on most accessible tissue types, the simplest being a blood or buccal cell specimen. In addition, because genetic testing examines germline mutations, it has important implications not only for the individual but also for family members that may have inherited the same mutation. Genetic testing also raises ethical concerns, including informed consent, potential for employment or insurance discrimination based on test results, and beginning-of-life issues with prenatal or preimplantation testing. Genetic test results often are not definitive, requiring complex risk-assessment calculations for interpretation. The American College of Medical Genetics (ACMG) and the American Society of Human Genetics (ASHG) have published guidelines and recommendations for many of the more common single-gene disorders (Table 62.2).

Genetic Testing

Molecular genetic testing is currently used for the following major clinical purposes: diagnostic, carrier, prenatal/preimplantation, presymptomatic, and population screening [2]. Diagnostic testing is performed on affected individuals for establishing or confirming a clinical diagnosis. In general, for diagnostic genetic testing, the patient should have symptoms consistent with the disorder to justify performing the test. Genetic tests may be useful to diagnose an early atypical clinical presentation, or when other diagnostic procedures are more expensive, complex, or will not provide a definite diagnosis. For example, molecular testing for the absence of

the survival motor neuron 1 (*SMN1*) gene for spinal muscular atrophy (SMA) in hypotonic newborns is a simple procedure performed on peripheral blood lymphocytes (PBL), replacing the need for a more painful and complex muscle biopsy. Carrier testing is used to detect recessive mutations in healthy individuals to identify the risk of having an affected child, and can be used for individuals with a family history of a genetic disorder, or for population-based pregnancy screening. Testing of an affected family member can identify the specific mutation present in a family, thus allowing directed testing for other family members and improving the accuracy of the risk assessment for individuals with a negative test result.

Prenatal testing refers to the detection of disease mutations in a fetus, using fetal cells obtained by amniocentesis or chorionic villus sampling (CVS). To overcome some of the problems associated with pregnancy termination for an affected fetus, some laboratories offer preimplantation genetic diagnosis (PGD) in the setting of in vitro fertilization for couples with a family history of a specific genetic disease. PGD is performed on a single blastomere from an early embryo, allowing selection of only unaffected embryos for implantation.

Presymptomatic testing is used primarily for the identification of adult-onset dominant disorders prior to the onset of clinical symptoms, in which the offspring of an affected parent has a 50 % chance of inheriting the disease. This category includes neurological diseases such as Huntington disease and some types of cancer. Presymptomatic testing is the most problematic and challenging in terms of its psychological effect on the individual and hence requires extensive protocols for pre- and post-genetic test counseling. Population screening is also a type of presymptomatic testing and focuses on the most prevalent mutations, often with different sensitivity of mutation detection for different ethnic populations.

Genetic Counseling, Informed Consent, and Ethical Considerations

Genetic testing requires special attention to informed consent issues, the appropriateness of the testing, and the urgency of testing. Many laboratories choose to require documentation of informed consent for the specific genetic test being requested prior to performing the genetic test. In some states, such as New York, documentation by the laboratory of informed consent for genetic testing is required by law (Civil Rights Law §79-l). Non-consensual genetic testing and non-consensual disclosure of genetic test results are only permitted in certain cases, such as the New York Newborn Screening Program. Informed consent can be documented by obtaining a copy of the completed informed consent form signed by the patient and the health care provider who discussed the risks and benefits of testing with the patient, or by confirmation by the physician on the laboratory requisition form that informed consent is on record in his or her medical office. Until informed consent is documented, the laboratory can extract and store the appropriate nucleic acid, but only after confirmation of informed consent can the laboratory perform testing.

The clinical molecular laboratory also should review the clinical and test order information provided on the requisition form to determine whether the test is appropriate for the patient and his or her demographics and clinical history. For example, carrier testing of a minor should be deferred until the minor is an adult, and should prompt a discussion with the referring clinician. Similarly, a request for testing of an asymptomatic individual for a dominant disease requires confirmation of adequate presymptomatic genetic counseling. For prenatal test requests, gestational age should be assessed to assure that the test result is available to allow for termination of the pregnancy, if this is the family's choice. Finally, the laboratory should understand and communicate to health care providers the sensitivities and limitations of the tests performed.

Despite the tremendous advances in understanding of the human genome, the benefit of genetic testing for the patient is not always clear. Testing may be warranted, even if the results are inconclusive or preventive strategies or treatments are not available [3], because of the usefulness of a diagnosis for the patient and their family. The availability of individual genetic information raises critical ethical, legal, and social issues because genetic testing examines the patient's genetic makeup, rather than acquired (somatic) genome abnormalities or infectious agents, with implications for other family members. After intensive lobbying by many advocacy organizations including health professionals and industry leaders, the federal Genetic Information Nondiscrimination Act of 2008, also referred to as GINA, was passed and signed into law on May 21, 2008 [4]. This federal legislation prevents health insurers and employers from using information to determine eligibility, set premiums, or hire and fire employees, and ensures that genetic information is used for the benefit of the patient. The law also encourages individuals to take advantage of genetic screening, counseling, testing, and new therapies that will result from the scientific advances in the field of genetics. All entities that are subject to GINA must, at a minimum, comply with all applicable GINA requirements, and may also need to comply with more protective state laws.

Molecular genetic testing often requires interpretation using complex risk-assessment calculations [5]. Health care professionals must correctly interpret laboratory test results and be able to accurately convey the test results and interpretation to the patient, and the patient's family, as appropriate. Accurate communication of results to patients and families, however, can be complex and time-consuming and therefore may be performed by genetic counselors or physicians trained in medical genetics, rather than physicians without genetics expertise. The benefits of this approach are illustrated by a study in which one-third of physicians misinterpreted a negative genetic test result for familial adenomatous polyposis (FAP) and inappropriately suggested that the patients discontinue recommended aggressive surveillance [6]. Moreover, despite tremendous advances in genetic testing technologies, understanding of genetic test results still tends to be poor in the general public and in individuals undergoing genetic testing to assess disease risk [7–9]. For these reasons, most genetic tests should be ordered through health care professionals trained in genetics to ensure that the benefits and risks of testing have been explained to the patient during the informed consent process [10, 11]. This also ensures that genetic testing is voluntary. Although obtaining consent is primarily the responsibility of the referring clinician, the clinical molecular laboratory should consider requiring documentation of informed consent [2]. New York state law allows the health care professional to attest that consent has been received and kept in the patient medical record prior to testing. Proposed changes by the Centers for Disease Control and Prevention (CDC) to CLIA regulations specific for genetic testing include a requirement for laboratories to document informed consent prior to performing a genetic test [12]. However, since the CDC issued its Notice of Intent to add informed consent documentation to CLIA more than 10 years ago, the number of clinical genetic tests has increased substantially, but the proposed changes have not been finalized.

Confidentiality

Although GINA is a strong and essential first step in the fight against genetic discrimination and misuse of medical information, the sensitivity of and need for special protections for genetic test results is unclear. Some consider that genetic test results need the highest protections of health information, even beyond that provided by the Health Insurance Portability and Accountability Act of 1996 (HIPAA) [13]. The protections include only communicating genetic test results to the referring physician or genetic counselor [2], and even potentially not placing genetic test reports into the health care record of patients to avoid discrimination. Others consider the medical significance of genetic test results warrants these results being available in the health care record and feel that "genetic exceptionalism" is wrong and may prevent appropriate medical care. HIPAA requires that release of any patient information, especially to non-health care entities, must be authorized by the patient and documented. To ensure the confidentiality of genetic test results, some patients choose to personally pay for genetic testing rather than use health insurance, and clinical molecular laboratories should develop processes for handling such payments. The US Department of Health and Human Services (DHHS) has issued guidelines for ensuring the privacy of patients' health information as part of HIPAA [13]. Breach of patients' confidentiality for any type of health care information, not just for genetic information, can result in litigation against the individual and/or the institution.

Cancer

Hematopoietic Neoplasms

Molecular hematopathology refers to molecular testing for leukemias, lymphomas, multiple myeloma, and myelodysplastic conditions to identify somatic DNA alterations [14]. These DNA changes are present only in the affected population of hematopoietic cells and are not a part of the genetic makeup of the individual. The recent development in polymerase chain reaction (PCR) methods, particularly quantitative real-time PCR (qPCR), has provided greater diagnostic sensitivity and specificity for diagnostic testing, as well as for monitoring of disease during and after therapy. Likewise, the ability to perform molecular tests with very small amounts of nucleic acid has enabled the use of a wide range of sample types, including formalin-fixed, paraffin-embedded (FFPE) tissue specimens. For molecular testing, formalin fixation is optimal. In contrast to genetic tests, which need be performed only once for an individual, molecular oncology tests often are performed repeatedly for initial diagnosis and during and after treatment to monitor for residual disease. If testing is not performed at the time of diagnosis, later testing of the diagnostic specimen may be useful to confirm a molecular marker for minimal residual disease (MRD) testing. Molecular hematopathology results, whenever possible, are interpreted in the context of histopathology, flow cytometry, and clinical findings.

Solid Tumors

As the molecular rearrangements and mutations that cause specific solid tumor types are identified, the detection of these mutations is used for diagnosis, prognosis, therapy selection, and MRD assessment [15]. Many of these molecular rearrangements were identified through molecular characterization of specific chromosomal translocations identified by cytogenetic analysis of solid tumors, including bone and soft tissue sarcomas such as alveolar rhabdomyosarcoma, Ewing sarcoma, and synovial sarcoma. The expression of the fusion transcripts for the more common translocations can be detected by reverse transcription-polymerase chain reaction (RT-PCR) testing. The preferred specimen for sarcoma testing is frozen tissue because the optimal analyte is RNA, but in general, the majority of molecular diagnostic tests are performed on FFPE tissue specimens with DNA as the principal analyte. Specific somatic changes in solid tumors also can provide prognostic information. For example, genetic analysis for loss of heterozygosity on chromosomes 1p and 19q in oligodendroglioma tumors correlates with a better outcome [16]. Recently the development of new drugs targeted to specific genetic changes, such as anti-tyrosine kinase inhibitors (TKIs), has enabled the development of new tests such as *EGFR*, *KRAS*, and *BRAF* mutation testing that predict response to the targeted therapies. The tests, coupled to certain therapies, are called companion diagnostic tests and are used for evaluating the patient's tumor molecular profile prior to therapy initiation [17, 18]. The major laboratory issues specific to solid tumor testing today include: (1) the use of FFPE tissue specimens for mutation analysis, as formalin fixation greatly reduced the quality and integrity of DNA; (2) the careful selection of a FFPE tissue block with predominantly tumor cells or the use of macrodissection to reduce the nonmalignant cell population used for testing; and (3) working with small tissue specimens such as needle biopsies and fine needle aspiration specimens (FNAs). As next-generation sequencing (NGS) methods are increasingly used for solid tumor testing, TAT becomes an issue with oncologists needing the test results for selection and initiation of treatment, as well as the interpretation of large amount of data and variants of uncertain significance (VUS).

Infectious Diseases

As molecular techniques have become routine, more and more microorganisms are detected or characterized by molecular testing [16]. Molecular tests are especially suitable for infectious agents that are difficult to culture and for drug-resistance testing to provide more rapid diagnostic results. Molecular methods also are useful for viral quantitation as a part of monitoring response to therapy, such as human immunodeficiency virus type 1 (HIV-1), hepatitis C virus (HCV), and cytomegalovirus (CMV) infections. Because some infectious disease tests are high volume and have been clearly shown to improve patient management through therapy, automated instrumentation has been developed, and commercial test kits, including US FDA-cleared or -approved assays for many pathogen types are available. However, these commercial infectious disease test kits are expensive, and although improved patient outcomes due to early diagnosis and treatment may outweigh laboratory expenses, such savings for all infectious diseases have not been demonstrated.

Identity Testing and HLA Typing

Identity tests use polymorphic DNA markers to establish the identity of an individual or to determine an inheritance pattern [19]. Molecular identity testing is used for medical applications including analysis of bone marrow engraftment following bone marrow transplantation, and maternal cell contamination studies for prenatal genetic testing, as well as for paternity testing and forensic identity testing. Paternity and forensic identity testing, in particular, require additional considerations, including special accreditation (reviewed in

Table 62.1), director qualifications, verification of the identity of the person being tested, chain-of-custody documentation for the specimen, and expertise in complex probability calculations, reporting of results, and legal proceedings. HLA typing is time-sensitive, requires 24-h laboratory staffing, and involves complex analysis of the test results. Laboratories performing HLA typing require special accreditation by the American Society for Histocompatibility and Immunogenetics (ASHI) (Table 62.2).

Regulatory Agencies

All laboratories performing clinical testing must comply with numerous regulations. With the advent of CLIA [20], all laboratories are required to implement minimum quality and personnel standards. Proof of meeting these standards (accreditation), which may be done through voluntary accreditation programs offered by professional organizations, is critical to providing high-quality laboratory services. Clinical molecular laboratories are faced with special challenges due to the complex technical issues and ethical considerations involved in DNA-based testing. Several regulatory agencies are currently developing guidelines and standards for molecular pathology tests (Table 62.2). Some of these regulatory agencies and regulations are discussed below.

CLIA and CLIA'03

All clinical laboratories are regulated by CLIA. The US Congress passed CLIA to establish quality standards for all clinical laboratory testing to ensure the accuracy, reliability, and timeliness of patient test results [21]. CLIA is "test-site neutral," meaning that the same regulations apply to any location performing testing. Every laboratory examining "material derived from the human body for the purpose of providing information for the diagnosis, prevention, or treatment of any disease" is subject to CLIA. Final regulations to implement the law were published in 1992 in the Federal Register [22]. In 2003, new, extensively revised CLIA regulations were published and have been called CLIA'03, also termed the "Final Rules." The changes include major reorganization and consolidation of the regulations by basing requirements on the flow of a patient sample through the laboratory, updating the requirements to accommodate new technologies, and introducing a new quality control concept termed equivocal quality control (EQC), which empowers manufacturers to design instruments with internal quality assessment systems [23]. By this concept, laboratory directors alone, not manufacturers or regulators, must decide to adopt or eschew ECQ in their laboratory.

The CMS, formerly known as the Health Care Financing Administration (HCFA), in conjunction with the CDC, were originally charged with developing and enforcing the CLIA regulations. CMS continues to oversee much of these regulatory activities, including laboratory registration, on-site inspection, training, and accreditation.

CLIA certificates are based on the complexity of the test methods being performed by a clinical laboratory and are divided into three main categories: waived, moderate complexity, and high complexity. The level of complexity is determined by assigning a numerical score for each test or methodology based on numerous criteria including the knowledge, training, and experience required to perform the test, complexity of reagent and material preparation, characteristics of the operational steps, availability of calibrators, controls, and proficiency testing, equipment and test system troubleshooting, and interpretation of results. Under the CLIA'03 regulations, however, all quality control and quality assessment requirements now apply equally to high- and moderate-complexity laboratories, although some of the personnel qualifications remain more stringent for high-complexity laboratories [23]. These criteria are considered to be key elements in performing clinical testing and can be found on the US FDA Web site (http://www.fda.gov/).

Molecular pathology tests are considered high-complexity tests and as such must comply with CLIA requirements. Some of the requirements for high-complexity tests include qualifications of personnel performing and overseeing the testing, procedure manual specifications, method performance verification specifications, proficiency testing, quality assurance, patient test management, and inspection. CLIA, however, does not provide specific guidelines for molecular testing, and, therefore, each clinical molecular laboratory is responsible for the development of a test and quality management program according to CLIA criteria.

Voluntary Accreditation Organizations

CLIA regulations allow CMS to approve nonprofit, professional organizations that have laboratory testing and inspection standards equivalent to or more stringent than the CLIA regulations to inspect clinical laboratories in place of CLIA inspection. The two major organizations providing CLIA inspections are the Joint Commission on Accreditation of Healthcare Organizations (the Joint Commission), which accredits more than 80 % of the US health care organizations, and the Laboratory Accreditation Program of the College of American Pathologists (LAP-CAP). The majority of clinical molecular laboratories are inspected and accredited by LAP-CAP. Other CLIA accrediting organizations

include AABB, American Association for Laboratory Accreditation, American Osteopathic Association, ASHI, and COLA. When a test site meets the accrediting agency's requirements, as assessed by inspection, the laboratory, in essence, is meeting CLIA requirements and receives a CLIA certificate.

The College of American Pathologists

LAP-CAP accredits only clinical laboratories and not entire health care organizations. LAP-CAP does not base its requirements for accreditation on the different CLIA complexity levels of testing; instead it requires that all testing laboratories adhere to the same guidelines. LAP-CAP lists its requirements and guidelines in checklists, each consisting of a series of laboratory guideline questions. All laboratories must follow the Laboratory General checklist as well as the specific laboratory checklists relevant to the testing performed in the clinical laboratory, such as microbiology, blood bank, and other laboratory specialty sections. In addition to general requirements concerning personnel qualifications, quality control, test performance verification, and operation-related guidelines similar to CLIA, the Molecular Pathology checklist also includes test- and application-specific guidelines. The Molecular Pathology checklist also contains specific standards for tests using NGS methods, and addresses both the testing steps to generate the sequence data, the bioinformatics steps used for sequence analysis and variant calling, and the reporting of results. LAP-CAP requires laboratories to have a procedure manual for each test or process that complies with the GP2-3A standards of the Clinical and Laboratory Standards Institute (CLSI; formerly National Committee for Clinical Laboratory Standards, NCCLS) [24]. Clinical laboratories accredited by the CAP, as required by CLIA, also, for each test performed, must participate in a proficiency testing program when available, or perform internal proficiency checks when an external proficiency testing program is not available. Currently CAP inspections are performed every 2 years and are unannounced, with a self-inspection on alternate years.

The New York State Department of Health

The New York State Department of Health (NYSDOH) provides regulatory oversight of all clinical laboratories performing testing of any type on any specimen from a New York resident. The Clinical Laboratory Evaluation Program (CLEP) at Wadsworth Center in Albany, NY, seeks to ensure the accuracy and reliability of results of laboratory tests on specimens obtained within the state through on-site inspections, proficiency testing, and evaluation of the qualifications of personnel of state permit-holding clinical laboratories. NYS Public Health Law Article 5, Title V, requires the licensure of clinical laboratories by establishing minimum qualifications for directors, and by requiring that the performance of all procedures employed by the clinical laboratories meet minimum standards accepted and approved by the NYSDOH. The New York State Clinical Laboratory Technology Practice Act that became effective in 2008 requires that all clinical laboratory technologists and technicians, cytotechnologists, and histological technicians meet specific training requirements and be licensed by the state. However, because of the high complexity of molecular and cytogenetic testing and the lack of adequately trained staff through medical technology training programs, a limited license in molecular pathology or cytogenetics is provided for training under the direction of the laboratory director with qualification for a full license based on training and experience within a molecular laboratory. The clinical laboratory license requirements have been established for laboratories located in or accepting laboratory specimens originating from NYS. CLEP currently issues annual permits to over 1,000 laboratories in NYS. In addition, CLEP provides, on a biennial basis, approximately 3,100 certificates of qualification (CoQs) to individuals to serve as directors and assistant directors of clinical laboratories, which requires either specific training or experience to oversee testing of specific types across the clinical laboratory. A NYSDOH license is issued by testing category, following an on-site inspection. The clinical laboratory must have someone with a CoQ for each category of testing being performed. Finally, NYSDOH requires any test which is not US FDA-approved or -cleared and performed according to the manufacturer's instructions to be approved by the NYSDOH. This test review and approval is frequently required of clinical molecular laboratories because fewer of the tests are US FDA-approved or -cleared. Specific NGS test validation guidelines and requirements have been developed by the NYSDOH. More information about CLEP, NYSDOH regulatory oversight programs, and test approval policies can be found on NYSDOH Web site (http://www.wadsworth.org/).

The US Food and Drug Administration

The US FDA oversees regulation of medical devices under the 1938 Federal Food, Drug, and Cosmetics Act and subsequent amendments. Unless specifically exempted, medical devices must "be properly labeled and packaged, be cleared for marketing by the US FDA, meet their labeling claims, and be manufactured under Good Manufacturing Practices (GMP), which is a mandated quality assurance system."

These rules concerning the design, manufacturing, marketing, and surveillance of medical devices can be found in the Code for Federal Regulations (CFR). The US FDA also oversees some of the functions related to laboratory operations, including classification of tests as required by CLIA and review of clinical laboratory test kits or systems.

The US FDA and Genetic Testing

The recent growth of genetic testing, mostly developed and performed by individual clinical molecular laboratories without US FDA review, has raised public concerns about the quality and clinical usefulness of these tests. The Secretary's Advisory Committee on Genetic Testing (SACGT) was established in 1998 to advise the secretary of the DHHS on medical, scientific, ethical, legal, and social issues raised by the development and use of genetic testing. The SACGT, in conjunction with the Clinical Laboratory Improvement Advisory Committee (CLIAC), recommended that the US FDA provide regulatory oversight of laboratory-developed genetic tests. The vast majority of genetic testing is performed using laboratory developed assays rather than by commercial US FDA-approved or -cleared test kits, raising concerns about the quality and clinical usefulness of these tests. As the first step in developing a review process for LDTs, the US FDA developed a "test review template" for gathering data on the use, performance, interpretation, and reporting of LDTs [25]. Although this template was well received by SACGT, the US FDA was concerned that LTDs were part of medical practice, which is not regulated by the US FDA, and did not develop a review mechanism for LDTs at that time. The successor committee to the SACGT, the Secretary's Advisory Committee on Genetics, Health, and Society (SACGHS), was formed in 2001 and served for 10 years. The SACGHS studied the regulatory oversight of genetic LDTs, and their report provides an overview of the oversight system [26]. Both the Association for Molecular Pathology (AMP) and the CAP have developed proposals for the oversight and strengthening of LDT regulation, after the US FDA announced in 2009 an intention to abandon its regulatory policy of enforcement discretion toward some LDTs. The US FDA has published preliminary guidelines for the oversight of LDTs which will be based on the complexity of the test, with the most high-risk tests requiring US FDA review.

Analyte-Specific Reagents

Although the majority of the US FDA regulations for clinical assays target commercially developed in vitro diagnostic test kits intended for clinical use, the US FDA issued regulations for commercial reagents used in LDTs in 1997 [27, 28]. Although these regulations are not specific for molecular tests, many tests in the clinical molecular laboratory are developed, validated, and performed without the use of US FDA-approved test kits. These tests are distinct from research assays that have unproven clinical utility and cannot be used for patient care. In 1997, the US FDA developed regulations for manufacturers of reagents used in LDTs, as well as the clinical laboratories using such reagents in their LDTs. These reagents, termed "analyte-specific reagents" (ASRs), serve as the key component for LDTs including molecular pathology tests, and include primers or probes that hybridize to specific DNA sequences. The manufacturers of ASRs are prohibited from making statements about the analytic or clinical performance or the recommended use of the reagents, and validation of tests using ASRs is the responsibility of the laboratory. The laboratory must include a disclaimer in the patient report stating, "This test was developed and its performance characteristics determined by (laboratory name). It has not been cleared or approved by the US Food and Drug Administration." The result of the ASR regulations has been an increase in the availability of commercial reagents for molecular pathology tests; however, in the past few years the US FDA has been moving towards in vitro diagnostics (IVDs) and eliminating ASRs whenever possible [29].

Elements of Laboratory Design

Successful laboratory operation requires optimal utilization of space, appropriate equipment, qualified personnel, adequate laboratory information system (LIS) support, and financial management.

Facilities

The power of molecular testing is achieved by the use of PCR as the main diagnostic procedure. A serious problem in the clinical use of PCR is false-positive amplification due to PCR contamination. Because the products of PCR amplification, called an amplicons, can serve as the substrate for the generation of additional PCR products, and because PCR amplification produces a very large number of amplicons, the potential contamination of subsequent amplifications of the same target sequence with amplicons resulting in inaccurate results is immense without the use of proper controls. This kind of contamination has been termed "carryover" to differentiate it from contamination by genomic DNA. This potential for PCR product contamination requires special precautions. Therefore, the single most important step in designing laboratory space for molecular pathology testing is meticulous attention to the physical separation of the pre-PCR and post-PCR work areas to minimize PCR contamination [30].

The pre-PCR area, also referred to as a "clean room" or "pre-amplification area," is used for the pre-PCR steps

of sample receiving and processing, including extraction of nucleic acids and setting up of amplification reactions. The post-PCR area, also considered a "dirty room" or "post-amplification area," is used for PCR amplification and analysis of PCR products. The pre-PCR laboratory ideally contains separate work areas for nucleic acid extractions and PCR setup to minimize cross-contamination of patient nucleic acid samples. Additionally, a containment unit, such as a biosafety cabinet, may be used for setting up PCR reactions. These cabinets usually are equipped with ultraviolet light for reducing DNA contamination of the work area at the end of reaction setup. Some clinical molecular laboratories prefer to further separate the various steps of the pre- and post-PCR areas into separate rooms.

If possible, the air system for the pre-PCR and post-PCR areas should be independent. Otherwise, air filters can be installed in the inflow to the pre-PCR room air system, which can be cleaned routinely. An additional measure to limit PCR contamination is to maintain the pre- PCR and post-PCR rooms at different air pressures. The pre-PCR area is maintained at positive pressure, reducing the entrance of airborne contaminants and PCR products, while the post-PCR room is maintained at negative pressure, reducing contaminants that exit the room. If installation of a pressure system is not possible, then the two work areas can be located at a relative distance from each other.

To comply with universal blood-borne pathogen precautions, nucleic acid extraction from patient specimens can be performed in a closed safety cabinet. Specimens known to contain infectious agents, such as HIV-1 and HCV, can be processed in a separate biological safety hood. If organic solvents such as phenol, chloroform, or xylenes are used, a chemical fume hood should be available in the work area. Within the pre-PCR laboratory, RNA extractions should be physically separated from DNA extraction if the DNA extraction procedure uses RNase, which can degrade RNA. All work areas should be cleaned daily with 10 % bleach solution. In addition to pre-PCR and post-PCR areas, the clinical molecular laboratory also may have a neutral reagent preparation area (unless reagents are separately prepared in both rooms) and a data management room for the processing, review, and reporting of test results, which also may be performed in the post-PCR area.

To maximize use of space, equipment, technical expertise, and trained technologists, all types of molecular pathology testing (genetics, infectious disease, cancer, and identity testing) can be consolidated into a single laboratory. Implementing a core molecular pathology laboratory can reduce labor costs by approximately 30 % [31] as well as reduce equipment costs and space requirements due to duplication of these resources in several laboratories. As more infectious disease testing systems have become available, molecular infectious disease testing is more commonly performed in the microbiology laboratory rather than a molecular laboratory, although this is institution-specific.

PCR Contamination Control

In addition to physical separation of the pre-PCR and post-PCR areas, specific procedures are recommended for use of PCR in the clinical laboratory. To ensure that PCR products are not transferred from the post-PCR to the pre-PCR area, each should contain separate supplies and equipment. Pipettes, instruments, and supplies should not be transferred from the post-PCR to the pre-PCR area. This separation of supplies and equipment also dictates the workflow in the laboratory. PCR samples are first set up in the pre-PCR area and then transferred to the post-PCR area for PCR amplification and post-PCR analysis. Worksheets, once moved to the post-PCR area for post-PCR analysis, can no longer be taken back into the pre-PCR area and must be processed and filed in the post-PCR area or a neutral area.

Reagents and solutions for sample preparation and PCR work should be prepared with type I water, which is defined by specific ion, pH, and contaminant limitation requirements. All reagents, except primers, deoxynucleotide triphosphates (dNTPs), and enzymes, should be purchased as sterile reagents or sterilized to prevent bacterial growth. Reagents, including autoclaved type I water and 10 mM Tris–1 mM EDTA buffer (TE) used to dissolve DNA, should be stored as small aliquots to minimize the number of samplings from the same aliquot. Similarly, oligonucleotides used for PCR amplification should be synthesized and purified in a clean environment. To minimize the number of sample transfers and the chance of sporadic contamination and errors, PCR reagents, including primers, dNTPs and buffers, can be combined into a "premixture master mix" (MM), divided into aliquots that are appropriately labeled, and stored at −20 °C [30]. Before using for clinical testing, a new lot of MM must be tested to ensure that it specifically amplifies the target sequence without producing PCR products in the negative "minus DNA" controls, as is done for new lots of any reagents in the clinical laboratory. A "minus DNA" negative control not containing any specimen DNA is tested last in each run to ensure the lack of DNA or amplicon contamination in the PCR reagents.

Although carryover of amplified sequences contributes to the majority of false positives, cross-contamination can occur between samples, especially from specimens containing a high level of the target sequence such as occurs with infectious disease specimens. Consequently, precautions must be taken not only during the setup of PCR amplification reactions but also in all aspects of sample handling, from sample collection to sample extraction. For good laboratory

practice, gloves should be changed frequently, at least when entering or reentering the pre-PCR area and whenever the technologist notes the gloves to have been contaminated. Technologists should wear protective clothes to prevent operator-borne spread of contaminating DNA products, with separate protective clothes (i.e., laboratory coats) for the pre-PCR and post-PCR areas.

To minimize aerosolization of PCR products, PCR tubes should be pulse-centrifuged before opening. Microcentrifuge tube caps should be opened using both hands, and not flicked open with the thumb of the same hand, to prevent aerosolization. Because cross-contamination of pipettors can lead to false-positive results, and to minimize aerosolization, aerosol barrier tips are used for all pre-PCR steps. MM and other non-sample components should be added to the reaction tubes before the specimen DNA is added; DNA should be added last and each tube capped before the technologist proceeds to the addition of specimen DNA to the next sample. Positive and negative control DNA or RNA should be the last reaction tubes to be set up, after the patient sample reactions are set up and closed.

Another approach to minimize carryover of PCR products is to synthesize all PCR products with deoxyuridine triphosphate (dUTP) in place of deoxythymidine triphosphate (dTTP). Prior to amplification, the PCR reactions are treated with uracil-N-glycosylase (UNG), which will degrade uracil-containing amplicons, allowing amplification only from thymidine-containing target DNA [32]. Some commercial test kits incorporate this process into the kits.

Finally, automation of DNA extraction as well as PCR setup by the use of automated, robotic nucleic acid extractors and liquid handlers has greatly facilitated standardization of testing, reducing PCR contamination, and increasing overall testing accuracy and reliability of results. Real-time PCR technology, in particular, provided additional tools for PCR contamination control by combining PCR amplification with amplicon analysis and thus eliminating aerosolization of PCR products due to manipulation of PCR products [33].

Equipment

The equipment used for clinical molecular testing is rarely manufactured for clinical use. Most equipment is designed for research purposes and adapted for clinical use [30]. Nucleic acid extractions may be performed manually, although for higher volume testing, automated extraction instruments are available with improved reproducibility and reduced technologist time for the clinical laboratory. PCR can be set up manually in biosafety cabinets; for higher-volume testing, robotic liquid handling systems are available. Robotic systems, however, have reagent dead volumes that increase reagent wastage. Thermal cyclers are standard equipment in the molecular pathology laboratory, and the number required depends on the work volume. Post-PCR analysis is highly variable, and is based on the types of PCR product analysis being performed.

Other specialized equipment for post-PCR analysis includes automated sequencers or capillary electrophoresis instruments, chemiluminescent or colorimetric plate readers, and real-time PCR instruments. However, numerous clinical tests have been approved by the US FDA. These assays use commercial kits and specialized equipment for automated extraction and viral load quantitation, usually supplied by the test kit manufacturer [34]. Recently, with the advent of NGS technology, high-throughput sequencing instruments have been developed for simultaneous analysis of thousands of genes to exomes to genomes [35, 36]. Guidelines and checklists for NGS test validation and performance have been developed by both the CAP and NYSDOH [37]. Because of the high level of testing complexity and the concern of PCR contamination, researchers or personnel not trained in clinical molecular testing requirements and processes should not use the clinical molecular equipment.

Automated platforms for molecular tests are becoming available and are more significant for the clinical laboratory as test volumes increase. Automated systems include extraction systems, as well as real-time thermal cyclers that combine PCR amplification and detection. Automated systems are routinely and widely used for viral load testing, such as for HIV-1 and HCV viral load testing. Automated instrumentation can greatly reduce TAT, human error, and technologist time.

Because nonclinical instruments are used for clinical testing, they require rigorous surveillance and prompt technical support by manufacturers who are not always aware of the critical clinical testing issues. In addition, these instruments require ongoing maintenance. Most maintenance procedures are defined by the manufacturer and include temperature checks of the PCR wells for thermal cyclers and calibration of pipettors. In the absence of manufacturer's guidelines, the laboratory should set up its own maintenance program in consultation with the manufacturer.

Laboratory Personnel

Personnel Qualifications

Effective laboratory operation requires well-trained staff and a good management team. CLIA regulations specify that for high-complexity testing, individuals for the positions of director, technical supervisor, and testing staff must have specific qualifications. The director, as named on the CLIA certificate, is required to be a licensed doctor of medicine, osteopathy, or podiatry or have a doctoral degree in one of the biological, chemical, physical, or medical sciences, and

have 2 years of experience supervising a high-complexity laboratory. In NY, laboratories holding or applying for a NYSDOH clinical laboratory permit must also have a director or assistant director holding a CoQ for each testing category. To qualify for a CoQ, an individual must comply with CLIA requirements, in addition to having board certification in the appropriate specialty and working experience, with at least 2 years in current methodology in each category sought and in general laboratory management documented in the form of recommendation letters. The laboratory director is responsible for the overall operation and administration of the laboratory either personally or through oversight of assistant directors. Overall operation and administration of the laboratory includes the development, validation, and implementation of new tests, current procedure manuals, quality control, and training programs for staff, and teaching residents.

The technical supervisor establishes the quality standards of the laboratory by selecting and monitoring methods and instruments and documenting the competency of laboratory personnel, while the general supervisor provides day-to-day supervision of testing, personnel, and reporting of results. The qualifications for these positions range from a licensed doctor to an individual holding a bachelor's degree in science plus specific training or experience or both. The laboratory also may have clinical consultants, who must hold a medical or doctoral degree in a relevant discipline with appropriate experience in molecular testing. The Genetic Testing Good Laboratory Practices Workgroup of CLIAC, created in 1998, reviewed personnel qualifications and recommended including specific genetic experience and board certification for supervisors who oversee genetic testing [25].

Testing personnel who perform high-complexity testing must have an associate's degree in laboratory science or medical laboratory technology, or education and training equivalent to an associate's degree. Laboratory technologists are responsible for all tasks associated with the daily operation of the laboratory, including specimen receiving and processing, testing, identifying problems and troubleshooting, maintaining equipment, and documenting quality control procedures. In addition, they are required to work according to established procedures in adherence with the quality control standards implemented in the laboratory to comply with CLIA, CAP, or other regulations. Because very few molecular tests are approved by the US FDA, molecular pathology technologists perform much of the development of new tests, as well as validation of commercial molecular kits used for clinical molecular testing.

Because of the high level of desired expertise, technologists also need to be encouraged to attend educational courses to obtain the appropriate background in molecular pathology and the skills required for performing these tests. For the same reason, it is also crucial for the senior management of the laboratory to acknowledge the staff, encourage personal growth, and create new mechanisms for promotion. Although some of these recommendations represent the authors' personal views and may present a burden in the stringent financial environment of many health care institutions, the cost of training new technologists is higher than that of creating an environment that promotes job satisfaction and employee retention.

Genetic Counselors

The role of the genetic counselor is to assess the need for genetic testing through obtaining a medical and family history, inform patients about the risks and benefits of specific genetic tests, order the tests, and communicate the results to the patient and their family, as appropriate. Although the genetic counselor is traditionally a part of the clinical medical genetics service, an increasing number of test sites have genetic counselors on their staff as a link between the patient and health care providers with the laboratory.

Resident and Fellow Training in Molecular Pathology

Pathology residency training programs are required to provide molecular pathology training to their residents. Because the molecular biology knowledge and practical molecular experience of pathology residents is highly variable, the AMP Training and Education Committee generated general molecular pathology training goals for pathology resident training programs. These goals include basic knowledge in human genetics and molecular biology which are relevant to all aspects of molecular testing, specific technology information, as well as knowledge of specific molecular pathology tests [38]. Because molecular pathology training time can be brief (1–3 months), training may need to be accomplished through didactic lectures that encompass the tests performed in the laboratory as well as basic concepts in molecular pathology and technology, rather than more extensive practical experience.

Education of molecular pathology fellows requires broader training, resources, and time. The increasing importance of this field for clinical practice and the desire to undergo formal molecular pathology training led to the development of fellowship training programs and professional certification by several professional boards, specifically the American Board of Medical Genetics (ABMG) and the American Board of Pathology (ABP). Official training programs in clinical molecular genetics, established by the ABMG, and in molecular genetic pathology (MGP; jointly established by the ABMG and the ABP) are accredited by the Accreditation Committee on Graduate Medical Education (ACMGE). Official accreditation of either type of training

program requires filing of a program application and review and on-site formal inspection by an ACMGE representative [39]. The goal of these fellowship training programs is to provide structured education for qualified individuals seeking to integrate molecular genetic pathology into their clinical practice experience in all current aspects of the field, including basic science, diagnostic laboratory procedures, laboratory management, and consultation. To be eligible for the board examination, fellows should have a strong background in molecular biology and molecular genetics as well as practical experience, and should be able to use this information for diagnosis and management of genetic disorders for clinical molecular genetics board certification, as well as infectious diseases, malignancies, identity testing, and HLA typing for MGP board certification. Guidelines for competency-based fellowship training in MGP as well as for the development of a new MGP program have been developed by the AMP Training and Education Committee and Directors of MGP Programs [40].

Residents and fellows can contribute significantly to the daily operation of the laboratory, including review of test results under the supervision of the laboratory director, acquisition of clinical information, and communication of test results. In addition, they can assist with the development and implementation of new tests, according to the skill level of the trainee and as time permits. In return, they gain new expertise that may be an advantage when seeking employment.

Staff Training and Accreditation Programs

Appropriate technical staff training is vital to the successful operation of a molecular pathology laboratory [39]. Accreditation programs in medical genetics and molecular pathology ensure that members of the laboratory staff are well trained for performing their assigned roles. Individuals who want to practice clinical molecular pathology have several career pathway options, depending on their initial education.

Individuals who hold a medical or doctoral degree and are interested in directing a molecular pathology laboratory can be certified by the ABMG. ABMG is a member of the American Board of Medical Specialists (ABMS) that provides certification for all medical specialties. Eligibility for certification in clinical molecular genetics by the ABMG requires a doctoral degree (M.D. or Ph.D.) and 2 years of training in an accredited medical genetics program, plus completion of a logbook that documents the trainees' involvement in at least 150 clinical molecular genetic cases, which must be signed by the director of the training program. Certification requires passing a general examination in medical genetics as well as a subspecialty examination in clinical molecular genetics. The examinations are offered every 2 years.

In 1999, the ABMS approved a new MGP subspecialty offered jointly by the ABMG and the ABP. Candidates for this certification must hold a medical degree, have board certification in either medical genetics or pathology (either anatomic or clinical pathology, or both), have a valid license to practice medicine in the USA, and have completed a year of training in an accredited MGP fellowship training program. The first MGP examination was given in 2001, and is now given twice per year. MGP training programs are accredited based on standards developed jointly by the ABP and the ABMG. Diplomates of the ABMG and/or ABMG/ABP are certified for a period of 10 years, after which they are required to participate in a Maintenance of Certification (MOC) program. Participation in MOC begins as soon as certification is granted. The procedures and requirements are described on the ABMG and ABP websites under MOC. MOC is required for all new diplomates to maintain their board certification and individual MOC information is public.

The American Board of Clinical Chemistry (ABCC) has a certification program in molecular diagnosis, offered for the first time in 2000. This certification is offered biannually to individuals who hold doctoral degrees and practice in any one of several clinical laboratory specialties.

Certification in molecular biology is offered to medical and molecular biology technologists by the National Credentialing Agency for Laboratory Personnel, Inc. (NCA). The examination is given biannually and is useful for clinical molecular laboratory staff, particularly the senior technical staff who become certified laboratory specialists in molecular biology. The American Society of Clinical Pathology certifies technical staff as a technologist in molecular pathology, based on qualification for and passing an examination.

Financial Management

Molecular pathology testing is a market with growing gross revenue, which requires an understanding of the influence of finances on the technical aspects of the laboratory. Because many clinical molecular pathology laboratories are part of health care systems, molecular pathology test payment often is subject to limiting managed care contracts and reduced reimbursements, and as such, are often viewed as cost centers. Molecular pathology laboratory management should develop cost-effective business plans that present molecular pathology testing in the context of the clinical programs the testing supports, if the testing is not independently cost-effective, such that hospital administration views the laboratory as a revenue center.

Cost Analysis

In the current restrictive medical economic environment, the decision to perform a specific test must include business (financial) as well as medical considerations. The evaluation process for deciding to implement a new test or deciding to discontinue a current test should include a cost analysis. The amount charged for a test is determined mostly by the costs of performing the test and the value of the test in the market (demand). A cost analysis should account for all expenses associated with performing a given test, both direct and indirect. In a structured approach, a standard template can be developed and used to set a price for any new test, based on the cost for each step of the testing process, plus standard indirect costs.

Cost analysis involves two main types of expenses: direct expenses and indirect expenses [41]. The direct expenses enumerate all costs directly related to the testing, including equipment, reagents, consumables, salary, and benefits. The calculation of reagent costs is based on the known volume of reagent used and the cost per volume, including reagents for controls, dead volumes, and wasted reagents due to expiration or other causes. For manual, low-volume testing, the largest component of direct cost is labor, which can comprise up to 90 % of the total direct test cost. Laboratory labor cost calculations are generally done using the hands-on technologist time needed to perform the test multiplied by an average hourly salary rate plus the appropriate benefit rate. For example, the cost for a PCR-based test should take into consideration the time required for specimen accessioning and storage, DNA extraction, PCR setup, post-PCR analysis (if required), technical interpretation, and entry of results into the LIS, to determine the average hours of technologist time per testing run, which is divided by the number of samples tested at the same time to reach the labor cost per test.

Indirect costs include overhead, such as licensing fees, royalties or licensing fees, supervisory and administrative salaries, equipment maintenance fees, building services (such as electricity, phones, heating, etc.), marketing, and LIS support requirements. These costs are more difficult to determine and are not usually a part of the routine cost analysis for academic laboratories. Accurate determination of laboratory costs is important for assessing profitability.

Billing

Billing for molecular pathology tests follows the same guidelines as billing for other pathology laboratory services, requiring a Current Procedural Terminology (CPT) code for the test performed and an International Classification of Diseases (ICD- 9-CM) diagnostic code to determine the necessity for the test. The ICD-9 code, which is required for payment, should be provided by the requesting physician when a test is ordered, while the pathologist is responsible for using the appropriate CPT codes for billing of test services. Traditional CPT coding of molecular pathology tests, other than most molecular infectious disease tests which have single test-specific CPT codes, have described a molecular procedure rather than a specific method, and billing was based on a combination of several combined CPT codes for the various procedural steps that are performed as part of a molecular test. For tests requiring professional interpretation, the professional component was coded using an interpretation and report CPT code with a modifier code to differentiate the professional billing from the technical component, reported with a "TC." Under the old system, CPT codes were not test specific, could be billed multiple times for a single test as appropriate for the testing method, and created difficulties for payers to understand the test performed and the medical purpose of the test. By describing the work done but not the specific test, the previous molecular procedure-based CPT codes created a non-transparent system. To this end, the American Medical Association (AMA) created a series of new CPT codes for molecular tests that are test specific and the molecular procedure-based codes are no longer in use. A copy of the final rule can be found on the Federal Register Web site [42].

The molecular test CPT billing codes as of 2013 are a two-tiered system. Tier 1 represents more than 95 % of the molecular test volume performed in the USA, while Tier 2 contains nine levels based on test complexity for less commonly performed and more specialized tests. These codes are on the Clinical Laboratory Fee Schedule (CLFS) of CMS, rather than the Physician Fee Schedule (PFS) as requested by the CAP. Self-assignment of codes for tests is not allowed. A new not-otherwise-specified (NOS) code is available for unspecified analytes or emerging tests. The CPT codes will be maintained by a molecular pathology advisory panel (MPAP) advising the AMA CPT Editorial Panel. Code proposals also are reviewed by the Pathology Coding Caucus before submission to the AMA for review and approval. New CPT codes for genomic and multi-gene tests have been approved for use as of January 2015. A complete list of the CPT codes can be found in the *Physician's Current Procedural Manual*, published by the AMA [43]. Pathogen-specific codes for molecular infectious disease tests, such as HIV-1, HCV, and hepatitis B virus (HBV) viral loads, for which all steps of the procedure (extraction, amplification, detection, and reagents) are covered by a single CPT code, have remained the same.

Reimbursement for molecular pathology tests is dictated, to a large extent, by the reimbursement policies of CMS, which historically are used as a guideline for payment by third-party payers such as insurance companies. US FDA

approval is not necessary for billing of molecular pathology tests, but payment now or in the future may be linked to US FDA approval of a test, especially with the new guidelines for US FDA oversight of LDTs.

Patents

Another consideration prior to the implementation of a new test is the patent status of the test. Patents can cover instruments and reagents, but also can cover a specific method of testing for an analyte, any method of testing for an analyte, or a mutation-gene-disease association in general. The most common royalty payments for molecular pathology laboratories are payments for the use of the PCR method and *Taq* polymerase, licensed by Roche Diagnostics, Inc. Many diagnostic tests use PCR. Royalty payments for use of *Taq* polymerase ranged from 9–15 % of the amount billed or reimbursed for a test, and generally are higher for commercial laboratories than for academic laboratories. Although the original patent expired on March 2005, legal arguments in the industry over the use of *Taq* polymerase are still ongoing.

Of special concern are patenting and licensing of patents for mutations in specific genes associated with disease. Examples of such patents include apolipoprotein E genotyping for Alzheimer disease, T- and B-cell receptor gene rearrangement testing, and the hereditary breast cancer genes, *BRCA1* and *BRCA2*. Patenting of genes and gene-disease associations poses a significant risk to the molecular pathology laboratory because many clinically relevant DNA sequences are patented, and the terms of use offered by the holders vary considerably; in some instances, a laboratory will be unable to perform a test because the patent is exclusively licensed to another laboratory [44]. Thus, a laboratory considering implementation of a new molecular test first may conduct searches of existing patents and patent applications to see whether the new test infringes on existing or pending patents. Typically, such searches, if performed, are done by patent attorneys employed by the medical center where the laboratory is located. Internet resources provided by the US Patent and Trademark Office (http://www.uspto.gov) allow laboratories to perform searches directly. If a patent exists that covers any part of the molecular test to be implemented, the laboratory or medical center must negotiate an agreement for clinical testing with the patent holder or licensee, if the patent holder will grant a license. Licensing agreements may include royalty payments that increase the cost of the test, and limitations on the use of the test or the volume of testing the laboratory can perform. For this reason, many molecular pathology leaders argue that patented genetic tests should be broadly licensed at affordable costs to allow any qualified clinical laboratory to perform the tests. Professional societies of pathologists, such as CAP and AMP, have criticized patents on disease genes and exclusive licenses to perform DNA diagnostic tests. In the 2009 lawsuit against Myriad, doctors and pathologists presented arguments that the patents on the *BRCA1* and *BRCA2* genes and the gene-disease association prevented patients from receiving second opinions on their test results and prevented laboratories from performing diagnostic tests on patient samples and interpreting the results. Although initially the US District Court for the Southern District of New York ruled that all the challenged claims were not patentable subject matter, the case was appealed to the US Court of Appeals for the Federal Circuit, which overturned the previous decision in part, ruling that isolated DNA which does not exist alone in nature *can* be patented. As of December 2012 isolated genes remained patentable in the USA; however, on November 30, 2012, the US Supreme Court agreed to hear the case, which eventually led to a unanimous decision of the US Supreme Court that genes are not patentable. In the same decision, the Court decided that complementary DNA (cDNA), which is DNA copied from RNA, is not found in nature and is made by man and therefore is patent-eligible matter. This continues to allow patent enforcements against clinical molecular laboratories, although patent cases have not supported the patent eligibility of cDNA to date.

Laboratory Information Systems

Most molecular pathology laboratories require a computer information system to handle the large volume of data that is both received and reported. Selecting and installing a LIS is a lengthy and labor-intensive process, usually performed by the department or institution rather than by the laboratory. The application software allows users to perform tasks that are specific to the laboratory operations [45]. These tasks include registering patients, accessioning specimens, ordering laboratory tests, reporting test results, and tracking quality control data (Fig. 62.1). In addition, the LIS facilitates use of appropriate templates for reporting of results. The primary function of the LIS is the management of the database of patients and laboratory test results. The most-used system is a relational database management system, which links all the data in tables related to one another by common elements. This kind of structure allows the technologist, for example, to quickly produce a list of only those patient specimens that are going be tested for a particular test. When two or more tables contain the same primary field (patient identifier), information can be retrieved from multiple tables. For example, to monitor engraftment after allogeneic bone marrow transplant, the entire list of test results and dates of testing can be obtained for any specific patient. Because departmental LIS systems have not traditionally been designed to meet the specific information requirements of

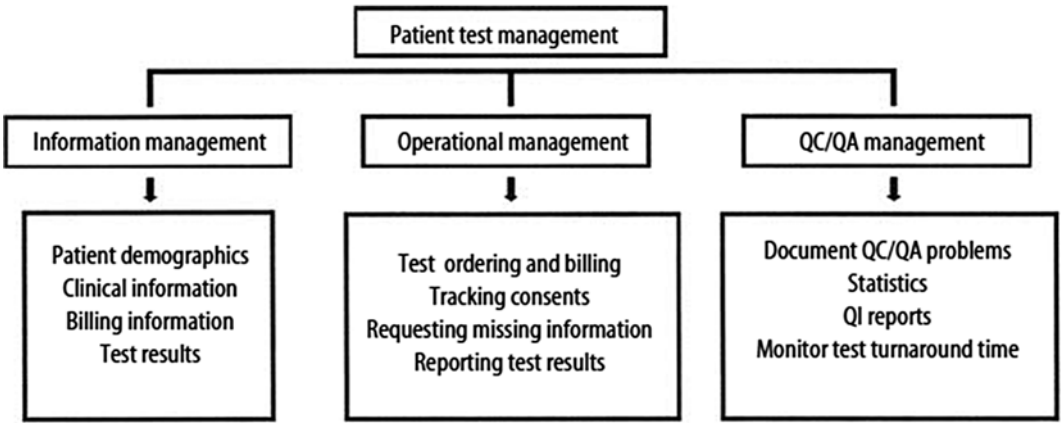

Figure 62.1 Organizational chart for LIS-based molecular pathology testing management

the molecular pathology laboratory, many molecular pathology laboratories also use networked personal computers (PCs) for data management. These PCs are mostly used as tools for running standard applications, such as word processing, spreadsheets, and other specialized applications, such as DNA sequence analysis and genetic risk-assessment applications. Since, however, molecular pathology laboratories have unique data management requirements, a separate patient database may be maintained in the laboratory as an electronic searchable database. Several systems have developed that accommodate the unique workflow and complex data capture needs of the molecular pathology laboratory. These systems, such as Millennium Helix™ (CERNER, Kansas City, MO), have been designed specifically for molecular testing for infectious diseases and molecular genetics by supporting the documentation of mutation results, numeric results associated with short tandem repeat markers, and viral load results. The *Unified Case Manager*™ in Helix, for example, allows the ability to create individual worksheets associated with the case and to view the succession of activities associated with the case. The application also contains bioinformatics coded values from the *Clinical Bioinformatics Ontology*™ (CBO) that enables the use of standard vocabulary for describing molecular and cytogenetic concepts.

To reduce transcription errors and eliminate the labor-intensive work of retyping patient information and test results, the LIS can interface with laboratory instruments for direct transfer of test results for each patient. This has been successfully implemented for specific instruments, such as the COBAS AmpliPrep system (Roche Diagnostics Pleasanton, CA) for HIV-1, HCV, and HBV viral load testing. The results, collated with the patient and specimen identification, are automatically transferred to the LIS, followed by performance and verification by laboratory personnel and report release and transfer to the electronic medical record system for clinical use. For instruments where a direct link is not available the use of a "flat file" of test data can assist in transfer of data from the instrument to the LIS using patient accession numbers.

To improve laboratory operations, many quality control activities can be performed using the LIS, including monitoring of TAT, control results, and statistics. Procedures and other documentation can be maintained and managed by the laboratory computer as well. Security and access control are crucial components of the LIS. Access control (passwords) and patient confidentiality (limiting access to only those who need specific information) are some of the tools required to maintain patient information security. Finally, NGS data pose a special challenge. The large volumes of data produced by NGS platforms, in addition to the requirements for documentation, data storage, interpretation of sequencing variations, as well as appropriate algorithms for reporting of results, require special software and system considerations.

Test Management

Choice of Test Menu

The menu of tests performed by molecular pathology laboratories varies significantly and is determined by three principal factors: clinical requirement and usefulness, laboratory competency, and test costs. Other factors that affect the decision about adding a new test include the prevalence of the disease, the mutation(s) causing the disease, the number of different mutations associated with the disease, availability of ASR or US FDA-approved or -cleared test kits, the complexity of testing, equipment requirements, and existence of patents that apply to the test. Each of these items requires serious consideration and support on behalf of the laboratory and the institution.

The clinical requirement for and usefulness of a test are defined by the significance of the test result for disease diagnosis or prognosis and clinical management. For example, HIV-1 viral load testing is widely used because it provides immediate information regarding the patient response to treatment and prognosis. Likewise, population-based genetic screening for cystic fibrosis (CF), now offered to all individuals and couples of childbearing age, provides immediate information about a couple's risk of having a child affected by CF [46].

"Competency" refers to the availability of knowledgeable and skilled laboratory personnel who can perform, supervise, troubleshoot, and correctly interpret molecular tests. For example, RT-PCR-based tests require knowledge not only of PCR but also of RNA processing in the clinical laboratory.

Test costs are another important factor for selection of tests to offer. Generally, when the cost of a test is low and the volume is high, a test will have a profit margin. A common issue is deciding whether to perform the test or use a reference laboratory for a specific test. This usually requires a break-even analysis to determine the point (threshold) at which there is no profit or loss for performing the test, taking into consideration the cost of the test, the expected revenue, and the expected volume of testing. Rare or urgent tests may be more expensive since tests are run individually rather than as batched analyses, as can be done in a reference laboratory, with combined testing from many sites. However, the need for very rapid test results for critically urgent patient care decisions may require that testing be performed locally rather than by a reference laboratory. In contrast, high-volume tests are likely to be profitable when performed by a laboratory.

The prevalence of the disease or mutation in the population affects the testing volume and therefore the number of laboratories that perform a specific test. The laboratory, however, may choose to test for less-common diseases or mutations if it receives a sufficient specimen volume to make the testing cost-effective. For example, some laboratories offer comprehensive testing for neurological diseases when there is specific clinical expertise at their medical center, or with inclusion of clinical samples referred to the laboratory from other sites in the USA or internationally.

The number of different mutations in one or more genes accounting for a disease is a consideration for testing. In general, the greater the number of mutations in a single gene or the number of different genes that can cause a disease, the more complex and labor-intensive testing becomes. Therefore, for common disorders, such as CF, commercial kits are available that detect at least 25 of the more common mutations in the *CFTR* gene, requiring substantially less time for test development than laboratory-developed methods or complete *CFTR* gene analysis by sequencing.

The complexity of testing and the availability of needed equipment are two important considerations. Tests requiring lengthy procedures, such as Sanger sequencing, or complex analyses (SMA carrier testing, for example) are less likely to be performed by many laboratories, especially if the test volume is low or commercial test kits are not available. The use of ASRs or US FDA-approved IVD test kits, particularly for viral load testing, is preferred by many laboratories because the kit simplifies the laboratory workflow and facilitates testing standardization and quality assurance in the laboratory and across laboratories, even though the IVD test kits are often more expensive than laboratory-developed tests.

Finally, patents that cover the disease mutations, genes, or testing methods or reagents for a test can be a consideration when deciding to implement and perform a test. Patent or license exclusivity may be enforced, licensing or sublicensing fees may be too costly, or other conditions of licensing may not be reasonable for the laboratory, such that the laboratory is not legally allowed or chooses not to implement and perform a test covered by one or more patents. This may be even more significant for complex genetic disease tests that require testing of multiple genes, each of which may be covered by patents, although the US Supreme Court decision that genes are not patent-eligible matter has reduced the patent burden for clinical molecular pathology laboratories.

Choice of Test Methods

Several factors influence the selection of the testing method, including the mutation type, the degree of mutation heterogeneity, the anticipated test volume, the available resources, such as equipment and expertise, and patent issues. The majority of clinical tests target specific mutations or sequences. The greater the number of sequence variations that need to be detected by a test, the more difficult and labor-intensive the test becomes. The most-frequently used method in molecular pathology laboratories is nucleic acid amplification, usually by PCR. Some of the more common factors affecting the choice of methods from nucleic acid extraction through PCR and post-PCR analysis are discussed.

Nucleic acid extraction is a principal part of most molecular tests. Numerous extraction methods are currently available. Some of the issues to consider in choosing an extraction method for DNA or RNA are yield, quality of the nucleic acid required for the subsequent testing steps, storage, processing speed, and costs. Laboratories may use more than one method for DNA or RNA purification. Some of the more common methods currently utilized are desalting methods and silica-gel membrane columns. Columns are particularly convenient for processing of small volumes of

blood for a large number of samples and are available for either DNA or RNA isolation. Many of these extraction methods can be automated, allowing batching of multiple samples in a single run.

The most common method in the molecular pathology laboratory is PCR, which has enabled the implementation of hundreds of clinical molecular tests. The method is particularly suitable for detection of point mutations and other small sequence variations, for detection of chromosomal rearrangements, for detection or quantification of pathogens by amplification, or for sequence analysis. Variations of PCR include RT-PCR for amplification of RNA sequences, multiplex PCR for the simultaneous amplification of two or more sequences, and qPCR for quantification of specific sequences (see Chap. 2).

While PCR amplification is the most commonly used method for nucleic acid amplification in clinical molecular laboratories, many methods are used to analyze the resulting PCR products. The simplest method for analysis of PCR products is gel electrophoresis to visualize and determine the size of the PCR products that have been synthesized with comparison to a sizing standard that has been run on the same gel. A second common method for analysis of PCR products is digestion with a restriction enzyme followed by analysis of the DNA fragments by gel electrophoresis. PCR products can be hybridized to allele-specific oligonucleotide (ASO) probes complementary to either the normal or mutant allele. However, these methods are more labor intensive and expensive and are currently rarely used in clinical molecular laboratories.

Small length changes and genetic rearrangements present in PCR products can be detected by size variations using agarose or acrylamide gel electrophoresis with ethidium bromide staining, or by a fluorescent-dependent detection method using either a plate- or capillary-based automated sequencer. Automated analyzers are especially useful for the simultaneous analysis of numerous PCR products labeled either with a single or multiple fluorophores, or when quantitation of a PCR product is required. Recently, automated microarray based multiplexing molecular platforms have been developed that can be used to assess disease signatures for several clinical applications, including infectious diseases, women's health, cancer, and pharmacogenetics, using a variety of methods for target detection.

In the last decade, a significant portion of PCR testing has been transitioned to real-time PCR, which monitors the generation of the PCR product throughout the amplification process. This approach can be used for either point mutation detection or quantitation, eliminating the need for time-consuming post-PCR analysis and decreasing risk of PCR contamination. This application became the method of choice for many clinical molecular tests, particularly viral load testing as well as genetic tests such as Factor V Leiden and Prothrombin mutation analysis for thrombophilia risk.

When the disease gene is known but the mutations are unknown, mutation-scanning methods are used. The most common scanning methods are single-strand conformation polymorphism (SSCP) and denaturing high pressure liquid chromatography (DHPLC), both of which detect single base pair variations with high sensitivity. Alternatively, Sanger sequencing can be used for direct mutation detection and is currently considered the gold standard for mutation detection. NGS technologies are a powerful strategy sequence analysis of a large number of individuals for multiple genetic targets by bar coding of DNA samples and batching them together in a NGS run. This strategy has significantly decreased the cost of sequencing, providing greater sequence output per run at lower costs with faster TAT.

Clinical Information Requirements

Clinical information is essential for determining the appropriateness of the ordered test and is critical for interpretation of results. Clinical information usually is obtained from the requisition form or an electronic test order system. A complete requisition contains patient demographic information to allow for identification of the patient, the ordering health care provider's name and contact information, the type of sample, the name of the ordered test(s), relevant clinical information, and any other information essential for appropriate interpretation of test results. For some genetic disorders, such as CF, ethnic background is particularly important because disease prevalence can vary significantly with ethnic background, while a pedigree is required for linkage analysis studies and risk assessments. Laboratories should document informed consent for genetic tests (as discussed above in the "Genetic Testing" section), which may be required by state regulation, such as in NY. For cancer or infectious disease testing, indication of the purpose for testing (diagnosis or minimal residual disease assessment) is needed for appropriate interpretation of the test result.

Specimen Requirements

Molecular pathology testing can be performed using many patient sample types. A list of the more common specimen types, applications, handling, and storage requirements is presented in Table 62.3. The most common sample for genetic testing is peripheral blood (PB); buccal cells may be acceptable for some genetic tests. Prenatal testing is performed on cultured or direct amniotic cells and CVS specimens. A maternal sample may be required for prenatal testing to rule out maternal cell contamination of the fetal specimen, usually by identity testing of the fetal and maternal samples, to ensure that the test result reflects the fetal genotype rather

Table 62.3 Specimen types and handling for molecular pathology testing

Specimen type	Test type	Requirements	Shipment	Storage
Blood	Genetics, cancer, identity, HLA typing, virology	EDTA (0.5–10 ml)[a]	RT	4 °C
Bone marrow	Cancer, identity testing	EDTA (0.5–1 ml)	RT	4 °C
Plasma	Infectious diseases	EDTA (2 ml)	Dry ice	−80 °C
Cerebrospinal fluid	Cancer, infectious diseases	None (0.5–2 ml)	Dry ice	−80 °C
Sputum	Cancer, infectious diseases	None (0.5–2 ml)	RT	4 °C
Amniotic fluid (<15 weeks gestation)	Genetics	None (10–15 ml)	RT	4 °C
CVS	Genetics	5–15 mg	RT	4 °C
Cultured amniocytes or CVS	Genetics	2 T25 flasks	RT	4 °C
Buccal cells	Genetics, cancer, identity	2 swabs	RT	4 °C
Fresh tissue	Cancer, identity	50–100 mg	Dry ice	−80 °C
FFPE tissue or cells	Cancer, identity	2–10 5 μm sections	RT	RT
DNA	Genetics, cancer, identity, HLA typing	<1–100 μg	RT	4 °C
RNA	Genetics, cancer	<1–20 μg	Dry ice	−80 °C

CVS chorionic villus sampling, *DNA* deoxyribonucleic acid, *EDTA* ethylene diamine tetraacetic acid, *FFPE* formalin-fixed paraffin-embedded, *HLA* human leukocyte antigen, *RT* room temperature
[a]Sample volume requirements may vary based on application and age of patient

than the maternal genotype. Samples for molecular oncology and infectious disease testing may include PB, bone marrow, tissues, and other body fluid (cerebral spinal fluid, sputum, etc.). FFPE tissue specimens are used predominantly for DNA-based testing, such as gene rearrangement studies for lymphomas and mutation detection in solid tumors, while fresh or frozen tissue generally is used for RNA-based testing, such as the detection of specific fusion transcripts in cancers. Sample requirements and collection and shipment information for molecular tests should be provided by the laboratory to ensure that samples are collected, handled, shipped, and stored appropriately before shipment, during transit, and during storage in the laboratory before sample processing.

Laboratory Operations

Workflow includes the steps of testing from specimen collection to reporting of results. This process can be divided into preanalytic, analytic, and postanalytic phases. The preanalytic phase consists of collecting, transporting, accessioning, and storage of the sample(s) prior to testing, as well as test ordering. The analytic phase is the process of performing the test. The postanalytic phase consists of all steps after the test is performed, including analysis of the test result, generation of the test report, and communication of the results. Although the preanalytic phase is difficult to control since the steps are performed by individuals outside the laboratory, most errors occur in the analytic phase because of the multistep, predominantly manual nature of molecular testing.

Preanalytic Phase

Samples are usually transported to a central receiving area of the laboratory or directly to the molecular pathology laboratory, either by a local hospital transport system or by courier or mail if the samples are sent from remote sites. Upon arrival, samples are accessioned into the LIS and assigned a unique identifier or accession number, allowing the sample to be tracked in the laboratory and hospital database. Information entered during accessioning includes patient demographics, ordered test(s), specimen type, and time and date of specimen collection and receipt by the laboratory. If available, bar-coded labels can be attached to the requisition form and specimen container, and can be used throughout the testing process for tracking of the specimen through the testing process.

The clinical information and specimen type are reviewed for appropriateness of the test requested. Missing clinical information can be obtained by contacting the health care provider or through the electronic medical record system. Genetic test requests are reviewed for ethical considerations.

Some sample types require additional processing prior to nucleic acid extraction. For example, FFPE tissue blocks are sectioned and slides are prepared and reviewed by a pathologist to assess the percentage of tumor cells in the tissue block and sections. CVS tissue is examined by a qualified cytogeneticist to remove contaminating maternal tissue prior to DNA extraction. Similarly, prenatal cultured cells are examined for confluence; low numbers of cells may not produce sufficient DNA for some analyses. For HIV-1 and HCV viral

load tests, for example, the plasma must be separated from the blood cells within 4–6 h of collection and the plasma is stored frozen until processing begins (Table 62.3).

Analytic Phase

For laboratory efficiency and cost-effectiveness, testing is performed on batches of specimens, and the frequency of testing depends on test volume and urgency of clinical need of the test results. The first step in molecular testing is nucleic acid extraction. DNA or RNA can be extracted from the patient specimens using either laboratory-developed methods or commercial nucleic acid extraction kits, and the nucleic acid stored appropriately (see Table 62.3). Most tests use PCR, which is set up in the pre-PCR area of the laboratory. To verify sample identity throughout all the steps of testing and prevent possible mix-up and cross-contamination, a worksheet can be used to indicate sample identifiers and numerical locations in the run, as well as reagent information such as lot numbers and expiration dates. Barcode labels can be used for tracking the specimens through the testing process. The same worksheet can be used later for documentation of test results for patient samples and controls. Patient sample reactions should be set up first, followed by the controls, as discussed in the "PCR Contamination Control" section.

Regardless of the procedure used, certain principles are essential. Specimen and reagent identifications should be checked with every manipulation performed. Expiration dates and identification of reagents should be checked before each use. New lots of reagents must be tested against old lots prior to clinical use. Test results should be documented, either by photographing the gel or by printing out the data from the instrument, unless the results are electronic and are stored in the laboratory database or LIS. Proper labeling and identification of the samples on photographs or data sheets is essential to prevent interpretation errors.

Postanalytic Phase

After tests are performed, the results are analyzed, the test results and interpretation are entered into the laboratory computer manually or by electronic transfer from an instrument, and the results are reported in the LIS and communicated verbally to the health care provider, if appropriate. To reduce errors, results should be interpreted by two independent reviewers, which may include a technologist previously certified to perform a technical interpretation of the specific test through the laboratory's training program, a resident or fellow, or the laboratory director or appropriate designee. Results must comply with the established criteria for result analysis and interpretation as defined in the test procedure manual. Control results are reviewed for accuracy before analysis of patient test results. For PCR-based tests analyzed by electrophoresis, the water/no-template control should not have bands other than primer dimers, and control samples must demonstrate expected results. For quantitative assays, control results must fall within the established cycle threshold (C_T) assay ranges. Patient test results are interpreted as positive or negative, or a quantitative result is obtained by comparison with the assay controls and by comparison to size markers or quantitation standards, as appropriate for the specific test method. Unexpected results are assessed for errors in the analytic process. The identified problems are corrected and testing of all or selected specimens is repeated. Results should be recorded manually or electronically transferred to the assay worksheet by the technologist who performed the assay, signed, dated, and entered in the computer using a report template, if available. Entered reports should then be reviewed and released by a second interpreter. For complex testing, such as HIV-1 genotyping, or test results requiring professional interpretation, the second interpreter should be a qualified professional. For efficient workflow, use of report templates for the most common test results and interpretations, with revisions for specific specimens, facilitates test reporting.

The information required for test reports is defined in the CAP Molecular Pathology checklist and includes patient demographics, test methods, mutation(s) tested, and a clinical interpretation in an easy-to-interpret format. Although the CAP, in compliance with CLIA, does not require supervisory review of all test results, good practice is for all manual assays to be reviewed and approved by the laboratory director or qualified designee before reporting. A final report is generated only after results are verified and electronically signed by the laboratory director or a qualified designee. When laboratory director review is not deemed necessary, such as for tests performed using automated equipment, two separate technologists trained to perform the assay, or the same technologist in duplicate, should review the results after manual entry into the LIS to ensure accurate transcription into the LIS prior to release of the reports. Results most often are communicated by printed report or an electronic information system, but direct discussion of urgent or complex test results may be useful for the clinician. Verbal communication or faxing of test results should be performed in compliance with HIPAA regulations to protect patient confidentiality.

Quality Management Systems

The molecular pathology laboratory must establish, maintain, and document the quality performance of all aspects of laboratory operations and test performance, including quality

control (QC), quality assessment also known as quality assurance (QA), and quality improvement (QI) programs that are adequate and appropriate for the validity of the procedures performed. The next few sections focus on the principal aspects of these programs.

Quality Control Program

The QC program focuses on the analytic validity of the testing process with the purpose of assessing and ensuring the reliability of patient results. According to CLIA, "The laboratory must establish and follow written QC procedures for monitoring and evaluating the quality of the analytic testing process of each method to assure the accuracy and reliability of patient test results and reports" [22]. Specific requirements include adherence to the manufacturer's instructions for instrument operation and test performance, having a current procedure manual, performing and documenting QC test results, maintaining records of all QC activities, and verifying performance specifications. Test sites, especially high-complexity laboratories, may choose to impose more, but not less, stringent QC requirements for the testing process. Molecular pathology tests are largely manual, laboratory-developed, multistep assays, requiring a variety of commercial or laboratory-produced reagents. QC procedures should be designed to detect and reduce errors in the entire testing process. Special attention should be given to the most common types of errors that occur during testing, such as use of expired reagents, improper preparation and storage of reagents and controls, clerical errors, and sample misidentification. Some of the key components of the QC program are discussed below.

Test Validation (Verification of Test Performance Characteristics)

Major differences are defined by CLIA for the implementation of a US FDA-approved or -cleared test compared to the implementation of a LDT. If the test is performed using a US FDA-approved or -cleared IVD test kit, the laboratory needs only to verify the performance characteristics of the test for the population of patients seen at that specific laboratory site. Implementation of a LDT requires collection of more extensive analytic data to establish the performance characteristics of the test. The performance characteristics that need to be evaluated include accuracy, precision, sensitivity, specificity, reportable range, population-specific reference ranges, and any other applicable test characteristics. Laboratories can use the manufacturer's criteria as long as the director determines that these are appropriate for the laboratory's population of patients. To assist in this process, CLIA also recommends that performance characteristics of a new test be compared to a known "gold standard" testing method. This is not always practical, since molecular methods often are developed because of the inadequacy of the currently available test methods. The test method also should be validated for all types of specimens that will be accepted for testing, as well as for interfering substances that may be present in the specimen types.

Establishing the test accuracy requires determining that the test yields appropriate positive, negative, or quantitative results, based on samples with known characteristics as determined by an independent test method. Samples used to determine accuracy can be obtained from several sources, including proficiency surveys or other laboratories performing the test by the same or a different test method. For example, validation results for new RT-PCR procedures for the diagnosis of certain translocations in leukemia can be supported by cytogenetic results for the same specimens.

Establishing the precision of an assay requires demonstrating that the assay results are reproducible. Testing well characterized control specimens and a variety of patient specimens multiple times in separate runs and comparing the results can demonstrate the precision of a test. For quantitative tests, precision is tested over the range of reportable values.

Analytic sensitivity refers to the lowest amount of analyte (nucleic acid) detected or quantified by a test. Analytic sensitivity is determined as the proportion of patient samples that contain the target nucleic acid sequence that tests positive using the test. For qualitative tests, the analytic sensitivity represents the smallest amount of analyte that is reliably detected by the test. For quantitative tests, limit of quantification (LOQ) is used, which is different than the limit of detection (LOD) that simply implies the lower limit of analyte detected by the assay. LOQ is the lowest amount of analyte that can be reliably and accurately quantified. Sensitivity should be determined for quantitative tests such as viral load assays, qualitative assays for pathogen detection, or for MRD monitoring to establish the utility and limitations of the test.

Analytic specificity measures the degree to which the test reacts with nucleic acids other than the intended sequence. It is measured as the proportion of patient samples that do not contain the target nucleic acid that test negative by the test. The analytic specificity of a test can be determined by analyzing a series of positive and negative samples and calculating the detection rate of the true negative samples, as defined by samples that do not contain the target of the test. Distinguishing among closely related pathogens, however, requires a precise design of primers specific for the target microorganism. Nonspecific signals can be produced by nonoptimal amplification conditions or inhibitors, which can be overcome by high-quality DNA extraction procedures and optimization of assay conditions.

The development of a new test usually is driven by new molecular information combined with a clinical need for a better test. Once the laboratory director decides that a new molecular test will be implemented, the methodology for the test, controls, test validation samples, specimen types, costs, and other factors are determined. The method for the assay is chosen based on the type of test information required, clinical utility, current use of the test platform in the laboratory, ease of test performance, and clinically required test characteristics and TAT. Once the test method is chosen, the specific test parameters are designed. Each step of the assay is optimized, including nucleic acid extraction, amplification, detection, and interpretation of results. For laboratories that develop many assays, standard starting conditions and optimization criteria facilitate test implementation. For example, PCR assays can initially use standard reagent concentrations and amplification conditions, followed by fine optimization of the PCR conditions as needed. Once the optimal assay conditions are established, the analytic validation of the assay is performed on clinical specimens and/or controls using those testing conditions.

Initial optimization and performance of the assay must include establishing the controls to be used for testing. Appropriate controls are often commercially available from organizations such as Coriell Institute for Medical Research (Camden, NJ) and the American Type Culture Collection (ATCC; Manassas, VA) as frozen immortalized cell lines or DNA containing the pathogen genome or mutation of interest. Standardized reference panels for viral load testing are available for many viral targets, including HIV-1, HCV, HBV, CMV, and Epstein–Barr virus. In the absence of purchased controls, patient samples tested by a different method or provided by another laboratory may be used.

The last step of the test evaluation requires clinical validation of the new test. Clinical validation determines the probability that a sample from a patient with the disease or disease risk will test positive (clinical sensitivity), and that a sample from a patient without the disease or disease risk will test negative (clinical specificity). A final step of the clinical validation may be to obtain a panel of mixed positive and negative patient samples without the known test results from another laboratory that performs the same test. After the testing, results are compared to the results obtained by the other laboratory and documented. Any discrepancies should be resolved by a different test method or a third laboratory.

Analytic Validity Assessment

The principal focus of current CLIA regulations for test validation is assessment of the analytic validity of the tests. To address this, CAP published recommendations on how to perform analytic and clinical validation studies in a series of checklists also used for laboratory accreditation. NY law (Subsection 58-1.10(g) of Part 58 of Title 10 (Health) of the Official Compilation of Codes, Rules and Regulations) specifically requires that all validation data of new testing are submitted to the state for review and approval prior to clinical use of the test, using guidance documents and checklists in the specific categories of testing. Validation studies must be submitted by NYSDOH prior to use of the test for clinical purposes, but testing can begin once data is submitted and before NYSDOH approval is obtained [47]. Recently, the CLIAC Genetic Testing Good Laboratory Practices Workgroup published a report that provided a series of recommendations for ensuring the quality of genetic testing [48]. The recommendations were made to CLIAC, an advisory entity providing recommendations to the DHHS on approaches required to ensure genetic testing quality since 1997.

Test Procedure Manual

Test procedure manuals are essential for clinical molecular laboratory function and are required by CLIA. The manual should be simple, easy to follow, and functional, but should provide sufficient detail to act as a reference for all aspects of testing for laboratory personnel performing the test and for training purposes. The manual, in a written or electronic format, must be current and available to all laboratory personnel. Manuals for high-complexity tests include written policies for sample collection, equipment performance evaluation, QC program, and standard operating procedures (SOP) for test performance. An example of the contents of a test procedure manual is shown in Table 62.4. The procedures are usually written by laboratory technologists or a supervisor, and then reviewed, edited, and approved by the laboratory director or designee. Any changes to an established procedure manual are documented in writing or electronically and approved by the director. Any laboratory staff members that perform a specific test must review the procedure manual annually, with documentation of the review. All procedure manuals must be reviewed annually by the laboratory director or their designee, as documented in writing.

The necessary elements of a test procedure manual are detailed in the CLIA guidelines, which follow closely the items described in CLSI GP2-A3, Clinical Laboratory Technical Procedure Manuals [24]. An example of a complete laboratory procedure manual is presented in Table 62.5. Manufacturer's product inserts or operation manuals can be used as a component of a test procedure manual, but additional information specific to the testing as performed by the laboratory must be provided.

Controls

Every clinical test requires use of appropriate controls. Controls are used to document reproducibility and to ensure that the test is working properly and results are reliable. Several types of controls are used for molecular tests: positive,

Table 62.4 Contents of a standard test procedure (an example of a PCR-RFLP test)

Item	Content
Background	Theoretical information concerning the disorder and the test
Principle of the assay	Description of how the restriction enzyme detects the specific mutation
Summary of the assay	Characteristics of the restriction-based assay used
Clinical significance	Use of the test for patient care
Strategy for analysis	Overview of the testing steps (i.e., extraction, PCR amplification, digestion, gel electrophoresis)
Specimen collection or acquisition	Description of acceptable specimen type, storage, shipment, and required clinical information
Criteria for rejected samples	Description of unacceptable samples (i.e., specific specimen types, improper labeling, damage)
Equipment and supplies	List of equipment necessary for testing (i.e., PCR machine, gel electrophoresis)
Reagents	List of reagents used for each test step (e.g., PCR, restriction enzyme digestion, gel electrophoresis equipment)
Assay procedure	Description of the testing steps, including general considerations, sample preparation, pre-PCR preparation and setup, thermal cycling, PCR cleanup, PCR product digestion, gel preparation and electrophoresis, gel documentation
Analysis of results	Description of expected results, control results, criteria for gel analysis and interpretation, documentation of results in the LIS and laboratory database, if used
Turnaround time and schedule for retaining specimen	Expected turnaround time for the specific test, specimen and DNA storage, and schedule for retaining the specimen and DNA
References	Literature or commercial-based information
Addenda	E.g., the worksheet for the specific test, the manufacturer's product insert

negative, sensitivity, inhibition, water/no-template, and QC controls. Combinations of these controls are used as appropriate based on the method and purpose of the test. A positive control is defined as a sample that contains the target sequence and produces a positive result when tested. Sources of positive controls include positive patient samples and commercially available cell lines or nucleic acids. A negative control is a sample that does not contain the target sequence and produces a negative result when tested. Sensitivity controls are needed for assays that require a specified level of analytical sensitivity. The sensitivity control is particularly important for MRD tests for cancer and viral load tests to define the lower limit of detection of the specific test. In general, a sensitivity control is included in each run of the test, since the sensitivity of each test run should be documented and not be assumed to be the same as during validation of the test. A no-template control or water control is a control reaction containing all reagents but no template nucleic acid, which tests for contamination of the PCR reagents with sample nucleic acid or amplicons and should not produce any PCR products except for primer dimers. An inhibition control (addition of external target nucleic acid or amplification of another template sequence to check for PCR amplification and absence of PCR inhibitors) is used only when the lack of production of a PCR product is interpreted as a negative result for the test. A QC control is a patient sample that was previously tested and is included for repeat testing on a new run. These samples function to assess the accuracy of the patient specimen results in the current test run, as well as to monitor for interassay variability. A QA sample which is a patient sample tested in two consecutive runs also may be included in each test run. The QA typically monitors for sporadic errors and testing accuracy of individual samples.

The controls should be processed in the same manner as the patient samples during testing; however, their use and storage should be well defined in the test procedure manual to avoid degradation. Controls should be validated for acceptability and approved by the laboratory director or designee before use in clinical testing. Failure of controls to perform as expected should be investigated, with findings and corrective action documented. Some QC results, for example, viral load testing, should be tracked over time and analyzed on standard Levey–Jennings plots. Deviations and adverse trends indicate that something is changing in the analytic system, and requires investigation and corrective action.

Preventive Equipment Maintenance

All instruments used in the clinical molecular laboratory require written standard procedures for normal operation, performance evaluation, and preventive maintenance. Function checks should be performed on a regular schedule to check critical characteristics and detect malfunctions before test results are affected. In the absence of manufacturer's guidelines, the laboratory should establish a mainte-

Table 62.5 Complete molecular pathology laboratory procedure manual: examples of required information, guidelines, and protocols

General information
Staff and contact information
Test information
Requisition forms (genetics, oncology, infectious diseases, identity testing)
Information for clients (shipping, sample type, billing information, consent form, test-specific fax cover-sheets)
Licenses and permits (CLIA certification and CAP accreditation form)
Reagent handling for molecular testing guidelines
Probe and primer documentation
General laboratory operating procedures
Quality control, quality assurance, and quality improvement programs
Specimen-receiving procedure
Prevention of PCR contamination
Logging-of-primers procedure
Autoclaving of solutions procedure
Use of PCR biosafety chambers
Programming of PCR thermal cyclers
Sequencing using a capillary electrophoresis instrument
Equipment-maintenance procedures
Centrifuges, balance, pH meter, and spectrophotometer: checks and cleanup
Water check procedure
Timer check procedure
Thermometer validation
Temperature-check procedure
Maintenance and validation of PCR thermal cyclers
Nucleic acid extraction procedures
Large-scale DNA extraction from blood by desalting method
Small-scale DNA extraction from blood by column
Fresh- and frozen-tissue DNA extraction
Paraffin-embedded-tissue DNA extraction
Prenatal (amniocytes and CVS) DNA extraction
RNA extraction from blood by column
Nucleic acid quantitation
Test-specific procedure manuals
Genetics
Factor V Leiden analysis
Myotonic dystrophy PCR and Southern analysis
Cystic fibrosis mutation analysis
Spinal muscular atrophy direct testing
Spinal muscular atrophy carrier testing (dosage analysis)
Spinal muscular atrophy linkage analysis
Oncology
IGH gene PCR for detection of B-cell clonality
T-cell receptor PCR for detection of T-cell clonality
BCL2 gene PCR for detection of M-bcr and m-bcr breakpoints
PML–RARA RT-PCR for detection of t(15;17) in APL
BCR–ABL RT-PCR for detection of t(9;22) in CML and ALL
RT-PCR for detection of translocations in sarcomas
Identity Testing
Bone marrow engraftment analysis by genotyping of STR markers
Parentage and identity testing
Maternal cell contamination analysis
Infectious Diseases
HIV-1 viral load assay
HCV viral load assay
HBV viral load assay
Microbial molecular identification analysis

ALL acute lymphoblastic leukemia, *APL* acute promyelocytic leukemia, *BCL2* B-cell lymphoma protein 2, *CML* chronic myelogenous leukemia, *HBV* hepatitis B virus, *HCV* hepatitis C virus, *IGH*, immunoglobulin heavy chain, *m-bcr* minor breakpoint cluster *region*, *M-bcr* major breakpoint cluster region, *PML–RARA* promyelocytic leukemia-retinoic acid receptor alpha, *STR* short tandem repeat

nance procedure that appropriately reflects the use of the instrument and assesses its performance characteristics over time. Of particular importance are thermal cyclers, because any change in their performance will have a direct impact on many tests. Thermal cyclers should be routinely monitored for cycle time reproducibility, verification of temperature accuracy, and efficiency of heating and cooling rates. These performance checks are usually incorporated into the instrument's software and are a part of the manufacturer's recommendations for instrument maintenance. Temperature logs for each temperature-dependent piece of equipment, including an acceptable temperature range, are required by CLIA. Temperatures of refrigerators, freezers, and incubators must be documented daily if used for reagent storage. Other instruments, such as water baths, should be documented each day of use. An equipment maintenance and performance evaluation log should be maintained for every laboratory instrument and should be kept for the duration of the clinical use of the instrument. The log should document any maintenance, assessment checks, problems, and any maintenance or repairs performed by the laboratory or manufacturer.

Quality Assessment Program

CLIA requires each laboratory to have an active QA program to assess various aspects of the technical and nontechnical performance of the molecular pathology laboratory. CLIA requires establishment of guidelines and procedures designated not only "to evaluate the ongoing and overall quality of the testing process," but also to evaluate "the effectiveness of its policies and procedures," followed by requirements to "identify and correct problems, assure reliable and prompt reporting of test reports, and assure the adequacy and competence of the staff" [22]. In CLIA'03, "quality assurance" was renamed "quality assessment," recognizing that quality cannot always be assured but it can be evaluated or assessed [23]. The laboratory QA program must monitor and evaluate both the ongoing and the overall quality of the total testing process through error detection, corrective actions and their review, and the integration of improvements in procedures. To meet the CLIA requirements, the clinical molecular laboratory must have a QA program that includes numerous laboratory practices, including personnel training and performance evaluation, proficiency testing, inspections, correlation of molecular results with clinical data, and a QC program. Elements monitored by the QA program, such as TAT, rejected specimens, and various indicators of test quality, do not relate directly to the analytic validity of the testing process and thus are not a part of the QC program. A complete list of these indicators can be found in the LAP-CAP Molecular Pathology checklist. Table 62.6 lists some of the major components for which the LAP-CAP requires ongoing surveillance and documentation.

Table 62.6 Examples of QC and QA topics that require documentation and corrective action

QC and QA of testing
Ongoing evaluation of proficiency test results
Detection and correction of clerical and analytic errors
Recording of failed nucleic acid isolations
Recording of failed hybridization reactions
Monitoring of test turnaround time
Discrepancies between preliminary and final reported results
Discrepancies between the molecular pathology laboratory and other laboratory findings Performance of statistics and appropriate comparative studies on all molecular pathology tests
Logging of unusual, difficult, and instructive cases
Laboratory-developed assay validation
Performing validation to confirm analytic test performance characteristics
Documenting validation studies for establishing assay performance characteristics
Documenting analytic characteristics including accuracy, sensitivity, specificity, and precision
Demonstrating and documenting clinical validity
Procedure manual
Annual review of all policies and procedures by the laboratory director or designee
Review of all new policies, procedures, and changes to existing procedures
Knowledge of testing procedures for the tests performed by each technologist in the laboratory
Information for all DNA probes, PCR primers, and other nucleic acid reagents used for testing
Paternity and forensic identity
Chain-of-custody (proof of identity)
Genetic characteristics (heterogeneity, recombination rates, etc.) of the DNA markers used
Documentation of release of information
Specimen handling
Disposition of unacceptable specimens
Sample condition, inadequate volumes, and evidence of tampering
Reagents
Validation of reagents used for tests
Characteristics of the specific reagents used in each assay
Controls
Failed control results or when results exceed defined tolerance limits
Instruments
Ongoing evaluation of results of instrument maintenance and function (temperatures, instrument characteristics, cleanliness)
Function checks for detection of problems and malfunctions
Repairs and services
Temperature checks for temperature-dependent equipment
Personnel
Continuing medical laboratory education
Safety
Radioactive area surveys and wipe tests
Radioactive waste disposal

Although CLIA requires that clinical laboratories continually evaluate and improve their work in all areas, some requirements are particularly important from an institutional perspective. CLIA mandates that test results obtained from different testing methods performed under the same certificate be compared, documented, and reviewed for the detection of errors that can affect patient care. This means that molecular oncology test results, for example, should be compared with the results obtained by other laboratories, such as the flow cytometry and cytogenetics laboratories, for the same patient.

Training

Personnel performing high-complexity molecular testing must meet established qualifications in education, training, experience, job performance, and competency. Training includes competency in performance of the test methodology, calculations, independent judgment, quality control of the method, and knowledge of the instruments. These training requirements cannot be based simply on academic requirements or experience. The on-site training must be sufficient to ensure that staff members have the skills necessary for performing every step of the analytic process including assay method, preventive maintenance, and quality control measures, as well as recognition of a problem in test performance should it occur.

To this end, a training program ensuring that technologists are properly trained to perform laboratory procedures must be used. As the first step, technologists can be trained by observing a technologist who knows how to perform the procedure and by reading the procedure manual. Then, the technologist should test two to three blind sets of specimens in addition to known controls, with or without observation depending upon the level of experience of the technologist, to ensure that the technologist understands the test and performs it correctly. Monitoring of the training test runs ensures the accuracy of the technologist's performance. Finally, the results of training runs must be documented and approved by the laboratory director or designee.

A part of ongoing training is annual competency evaluation. This allows the laboratory director or designee to review different aspects of the technologist's performance, including technical skills, control of PCR contamination, equipment operation, procedure knowledge, and laboratory safety. The overall performance of each technologist is documented, and corrective or additional training measures are implemented, as needed.

Training also includes continuing education programs, which assist laboratory personnel in attaining new technical skills and knowledge required to keep up with changes in procedures, instruments, and new tests, as well as improve their ability to perform new assays, troubleshoot, and handle new problems.

Proficiency Testing

Proficiency testing plays a key role in assessing the internal quality of work in CLIA-regulated high-complexity testing clinical laboratories. CLIA requires the laboratory to successfully participate in a CMS-approved proficiency testing program for all analytes tested. The CAP provides approved proficiency testing programs in several relevant fields, including genetics, infectious diseases, oncology, and identity testing (Table 62.7). Proficiency testing must be performed at least once per year. In the absence of an external proficiency testing program for a specific test, the laboratory can set up a sample exchange proficiency testing program with another laboratory performing the same test. Proficiency samples must be tested in the same manner as patient samples, by the same technologists performing the clinical testing, using the same interpretation procedures. Laboratories failing two of three consecutive testing events for any test must submit a plan of corrective action with documentation that the test is now performing accurately to the CAP or other proficiency testing agency.

Laboratory Inspection

Molecular pathology laboratories must be inspected by an external inspection team every 2 years for compliance with CLIA regulations. LAP-CAP inspections are performed by a team of inspectors from an institution other than that of the laboratories being inspected, and the inspection team assesses the quality indicators for continued quality performance as listed in the LAP-CAP checklists [49]. The checklists address laboratory procedures including specimen processing and testing, reagents, controls, instrumentation, personnel, physical facilities, and laboratory safety. Inspection also assesses for PCR contamination control, participation and performance in proficiency testing programs, and documentation of the QC and QA program activities (Table 62.6). Failure to comply with specific checklist items is documented as a "Phase I" or "Phase II" deficiency. Most items on the molecular pathology checklist are Phase II, with a serious potential to affect patient care. Phase II deficiencies require immediate attention and correction, documented in writing, to the CAP. Phase I deficiencies are less serious but also require documentation of corrective action. On alternate years, the laboratory is required to perform a self-inspection.

Recently, as part of ongoing efforts to strengthen the laboratory accreditation process, to promote public confidence in the LAP-CAP, and to help assure regulators that CAP-accredited laboratories meet or exceed CLIA requirements, the CAP has made significant changes in its LAP processes, including unannounced inspections rather than scheduled inspections beginning in January 2006. This means that laboratories will not know the exact date of the inspection and the identity of the inspection team members prior to the inspection. Instead, the laboratories will be provided with a 90-day window of the anniversary of their last inspection, 45 days prior to and 45 days after their last inspection, pending CMS approval, in which the inspection will occur. By implementing this process for routine inspections, CAP expects to help ensure that laboratories are in continuous compliance and that they are providing quality patient testing at all times.

Alternatively, laboratories can be inspected directly by CLIA, the Joint Commission, or one of the other accrediting organizations for clinical laboratories under the CLIA program. The CLIA inspection regulations are found in Subpart

Table 62.7 CAP proficiency surveys for molecular pathology testing

Category/name	Survey	Type of testing
Genetics		
MGL	Molecular genetics	Molecular testing for various genetic diseases or genes
PGX	Pharmacogenetics	Molecular testing for various genes
SEC	DNA sequence interpretation	DNA sequence electropherogram analysis and reporting
CY, CYBK, CYM	Cytogenetics	Analysis of online images or prints of metaphase cells
CYCGH	Cytogenomic microarray analysis	Analysis of DNA for constitutional or neoplastic abnormality
Oncology		
MO	Molecular oncology	Molecular analysis of leukemia and lymphomas
BRAF	HNPCC	Molecular analysis of PET for HNPCC
EGFR	Solid tumors-other	Molecular analysis of PET for NSCLC Adenocarcinoma
KIT	Solid tumors-other	Molecular analysis of PET for GIST
KRAS	Solid tumors-other	Molecular analysis of PET metastatic, colorectal carcinoma
MSI	Microsatellite instability	Molecular analysis of PET colorectal carcinoma by DNA amplification of microsatellites
SARC	Sarcoma translocation	Molecular analysis of various sarcoma translocations by RT-PCR
GLI	Glioma	Molecular analysis of PET for glioma by PCR
MHO	Molecular hematologic oncology	Molecular analysis of DNA, cells, and PET, for genotyping myeloid and lymphoid malignancies
MRD	Minimum residual disease	Analysis of BCR/ABL1 and PML/RARA transcripts
CYF, CYH, CYI, CYJ, CYK, CYL	Fluorescence in situ hybridization	Analysis of FISH using amplification and chromosome-specific DNA probes
Identity		
ME	Monitoring engraftment	Monitoring for bone marrow and stem cell engraftment
PAR, PARF	Parentage testing	DNA testing by PCR and RFLP
ML, DL, DML	HLA molecular typing	Molecular typing of class I and class II HLA markers
FID, FIDM	Forensic sciences—nuclear and mitochondrial DNA	Nuclear and mitochondrial DNA analysis for numerous polymorphic loci
DNA, DNAF	Forensic sciences—DNA database	Analysis of polymorphic loci for the DNA database program
Infectious disease		
ID, IDO	Nucleic acid amplification identification	Analysis of infectious pathogens analyzed by advanced amplification methods (NASBA, bDNA, LCR, PCR)
HIV, HV2, HIVG	HIV viral load	Quantitative analysis of HIV by nucleic acid amplification and genotyping, respectively
HBVL, HCVN	Hepatitis B and C viral load	Quantitative analysis of HBV and HCV by nucleic acid amplification and HCV genotyping, respectively
VLS2	CMV, EBV, BK, HHV6, ADV, viral load	Quantitative analysis by nucleic acid amplification
HPV	Human papillomavirus	Qualitative analysis of HPV by nucleic acid testing
HC5, HC6	*C. trachomatis*, herpes, and *N. gonorrhoeae*	Pathogen analysis by nucleic acid probe methods and nucleic acid amplification methods, respectively
NAT	Nucleic acid testing	Qualitative analysis of infectious pathogens designated for blood donor centers
ISH	In situ hybridization	In situ hybridization testing for various viral nucleic acid targets

bDNA branched DNA technology, *FISH* fluorescence in situ hybridization, *HCV* hepatitis C virus, *HLA* human leukocyte antigen, *HPV* human papillomavirus, *LCR* ligase chain reaction, *NASBA* nucleic acid sequence-based amplification, *PCR* polymerase chain reaction, *PET* paraffin-embedded tissue, *RFLP* restriction fragment length polymorphism, *RT-PCR* reverse transcription-polymerase chain reaction

Q of the *Code of Federal Regulations*, which addresses both basic and specific inspection requirements [50]. CLIA inspections under the Joint Commission are conducted by CMS. The CMS policy for laboratory inspections includes announced initial and biennial recertification inspections and unannounced complaint and follow-up inspections. The CMS inspection focuses more on outcomes than on laboratory process. The goals of this outcome-oriented survey are not only to determine the laboratory's regulatory compliance but also to assist laboratories in improving patient care by emphasizing those aspects that have a direct impact on the laboratory's overall test performance.

Accreditation by the Joint Commission meets the conditions required by federal law and regulations. Consequently, laboratories that are accredited by the Joint Commission in lieu of direct federal oversight and that meet the CLIA requirements for laboratories are not subject to routine inspection by state survey agencies to determine their compliance with federal requirements [51]. To be eligible, the Joint Commission must apply standards and criteria that are equal to or more stringent than the requirements established by DHHS. The Joint Commission accreditation process is more stringent than federal certification requirements in that the Joint Commission accredits a health care organization (for example, a hospital) as a whole, not just the laboratory. As such, an organization that loses the Joint Commission accreditation for reasons other than poor laboratory performance also would lose the ability to legally test human specimens under the laboratory's existing certificate of accreditation, if the Joint Commission accreditation is being used to meet the CLIA requirements. The Joint Commission also began conducting unannounced inspections in 2006.

Summary

In this chapter, many of the issues and considerations that are important for the successful management of a molecular pathology laboratory have been discussed. Although these issues are addressed separately, many are interconnected. If even one function is weak, the success of testing is compromised. Molecular pathology is a rapidly growing field of anatomic pathology and laboratory medicine. The most significant challenges facing the management team of a clinical molecular pathology laboratory are continuous acquaintance with rapidly developing new technologies, new approaches for data analysis (bioinformatics), changing regulations, and evolving testing considerations for a variety of clinical applications, as well as understanding basic business concepts in marketing and finance. Keeping pace with these challenges ensures that the clinical molecular pathology laboratory will be an even greater driving force of medical practice in the 21st century and beyond.
